Classification. Given any fixed threshold τ, the goal is to correctly classify each w_u to be either *above* or *below* τ. Naively, to ensure every node is correctly classified, we need to apply a union bound over all the nodes. This will incur a $\mathsf{poly}(d)$ overhead if we use Laplace noise or Gaussian noise as in the standard mechanisms (Lemmas 13 and 14) since the tree can have exponential size. To deal with this issue, we use a *truncated Laplace mechanism* where the Laplace noise is truncated to be bounded (Lemma 16); this ensures that the estimation error is always at most the truncation range and thus can obviate a union bound. However, we still need to pay the privacy loss from compositions. If one node is the ancestor of another, then the input leaves they depend on must overlap, which means simply estimating every node's weight will incur d rounds of composition. To improve this, our classification algorithm will find the transition nodes in the tree: a *transition node* is one whose weight exceeds τ but none of its children has weight above τ. Given the locations of the transition nodes, we can easily classify the other nodes: a node is above τ iff it is the ancestor of (or itself) a transition node. Assuming the previous classification with threshold $\tau' > \tau$ succeeds, none of the nodes' weights should exceed τ' now. Since there are at most τ'/τ transition nodes in a tree, we can use the *sparse vector technique* [22] to find them, and incur fewer rounds of composition.

We remark that the idea of using increasing thresholds and sparse vector techniques has been used in [7, 26, 25].

Pure-DP Lower Bounds

Given Item 1, it suffices to rule out DP algorithms with very strong probabilistic guarantees, i.e., works for thresholds τ_u's that are too small.

Our proof uses the *packing argument* [28]: we construct extremal datasets where any two datasets have a large distance. Then if the output has small error, we can correctly identify the input dataset. On the other hand, by the privacy guarantee, the output distribution for different datasets, though having a large distance, should not be too different, contradicting the fact that they decode to different input datasets.

Not surprisingly, our extremal datasets place the maximal value on a leaf and keep other leaves empty. But the key issue is the decoding step. Indeed, previous packing arguments work with ℓ_∞-error, where the error on *all* output coordinates is small with high probability, thus admitting simple decoding algorithms. We, however, can only guarantee the error on any *fixed* node is small with high probability; we also cannot use a union bound since the output size can be exponential.

The way we circumvent this is by designing a novel probabilistic decoding algorithm where we will correctly decode to the input dataset with probability large enough to derive a contradiction. The decoding algorithm itself performs a random walk on the tree where each step favors the larger estimated weight. Then the success probability of decoding can be lower bounded in terms of the number of correctly classified nodes, which in turn can be lower bounded by its expectation and our probabilistic guarantee suffices.

Additive-Only Lower Bounds

The above packing argument only works for pure-DP setting (or (ε, δ)-DP but with exponentially small δ). Indeed, as shown by our improved approximate-DP algorithm (Theorem 8), the bound can be exponentially small if we allow both approximate-DP and $\alpha > 0$. Therefore we now turn to the only remaining case: approximate-DP and $\alpha = 0$. In this case, by Definition 4, α-mRMSE is an additive-only error.

Our proof starts by slightly modifying the error characterization of linear queries from [24]. This shows that mRMSE for $\boldsymbol{W}$-linear query is characterized by a factorization norm of $\boldsymbol{W}$. Thus proving Theorem 6 boils down to showing a lower bound on this factorization norm of the binary tree matrix. Following previous works on range queries (e.g., [36]), we do so by invoking a dual (maximum-based) characterization of the factorization norm from [35, 33] and give an explicit solution to this dual formulation.

1.3 Relation Between Tree Aggregation and Releasing Thresholds

There is a simple reduction from the tree aggregation problem (Problem 18) to the problem of releasing thresholds. Recall that the problem of releasing thresholds is the same as linear queries with the workload matrix $\boldsymbol{W}^{\mathrm{th}} \in \{0,1\}^{m \times m}$ being the matrix with upper-triangular entries (including the diagonal entries) equal to one.

The reduction works as follows. First, we may index the leaves from $1, \ldots, |\mathsf{leaves}(\mathcal{T})|$ based, say, on their order in the DFS traversal of the tree. It is not hard to see that w_u of any node in the tree corresponds to $(\boldsymbol{W}^{\mathrm{th}}\boldsymbol{x})_b - (\boldsymbol{W}^{\mathrm{th}}\boldsymbol{x})_{a-1} = \sum_{v \in [a,b]} x_v$ for some $a, b \in \{1, \ldots, |\mathsf{leaves}(\mathcal{T})|\}$. Therefore, we may run any DP threshold releasing algorithm (with $m = |\mathsf{leaves}(\mathcal{T})|$) and solve the tree aggregation problem.

The above reduction yields an mRMSE error for the tree aggregation problem that is of the same order as that of releasing thresholds (with $m = |\mathsf{leaves}(\mathcal{T})|$). For the latter, it is known that the tight error is $\Theta_{\varepsilon,\delta}(\log m)$ [29][4]. Assuming that each node at depth less than d has at least two children, $|\mathsf{leaves}(\mathcal{T})| \geq 2^d$ and therefore, the error yielded by this reduction is at least $\Omega_{\varepsilon,\delta}(d)$. In other words, this is not even as good as the straightforward Gaussian mechanism for our problem, which yields an error of $O_{\varepsilon,\delta}(\sqrt{d})$ (and we have shown this to be tight in Theorem 29).

We note that there is another line of research that studies privately learning threshold functions. Recent work has shown that learning threshold functions with (ε, δ)-DP in the PAC model only requires $O_{\alpha,\varepsilon,\delta}\left((\log^* m)^{O(1)}\right)$ samples [32]. Due to the connection

[4] In fact, the lower bound in [29] is even stronger as it holds against the ℓ_2^2-error.

between learning thresholds and releasing threshold functions presented in [8], this gives an algorithm for the latter with an error bound of $O_{\varepsilon,\delta}\left((\log^* m)^{O(1)} \cdot (\log n)^{2.5}\right)$, where n denotes $\|\boldsymbol{x}\|_1$ (i.e., the total count across all leaves in our setting). When combining this bound with the above reduction, one gets a tree aggregation algorithm with error $O_{\varepsilon,\delta}\left((\log^* |\mathsf{leaves}(\mathcal{T})|)^{O(1)} \cdot (\log n)^{2.5}\right)$. Although the term $(\log^* |\mathsf{leaves}(\mathcal{T})|)^{O(1)}$ is very small, this error bound is not directly comparable to the lower and upper bounds achieved in our paper because our bounds are *independent* of n whereas there is a dependency of $(\log n)^{2.5}$ in this releasing threshold-based bound. (Note also that the dependency on n cannot be removed while keeping the dependency on m sublogarithmic, as this would contradict with the aforementioned lower bound of [29].)

Finally, we remark that the reduction does *not* work if we allow the threshold releasing algorithm to incur multiplicative errors. This is because we need to subtract two thresholds to get w_u for each node u in the tree, and subtraction does not preserve multiplicative approximation guarantees.

Paper Organization

We formalize the notation in Section 2. Then in Section 3 we introduce the error measure we will actually use in designing algorithms and proving lower bounds; and relate it to the α-mRMSE measure. The improved approximate-DP algorithm is presented in Section 4 and the corresponding lower bounds are in Section 5. The concluding remarks are in Section 6.

2 Preliminaries

We use $\ln(\cdot)$ and $\log(\cdot)$ to denote the logarithm with base e and 2 respectively. For a positive integer n, let $[n]$ denote the set $\{1, \ldots, n\}$. Let $\mathbb{N}$ denote the set of non-negative integers.

2.1 Norms

We use boldface uppercase (e.g., $\boldsymbol{A}$) to denote matrices and boldface lowercase (e.g., $\boldsymbol{x}$) to denote vectors. We use $\mathbf{0}, \mathbf{1}$ to denote the all-zeros and all-ones vectors / matrices.

For $\boldsymbol{x} \in \mathbb{R}^m$, its *$\ell_p$-norm* is defined as $\|\boldsymbol{x}\|_p := \left(\sum_{i\in[m]} |x_i|^p\right)^{1/p}$ for any $1 \le p < \infty$. Its *ℓ_∞-norm* is defined as $\|\boldsymbol{x}\|_\infty := \max_{i\in[m]} |x_i|$.

2.2 Tools from Differential Privacy

Here we note some useful facts regarding differential privacy [18, 17, 41].

▶ **Fact 9** (Post-Processing). *Let $\mathcal{A}_1$ be an (ε, δ)-DP algorithm and $\mathcal{A}_2$ be a (randomized) post-processing algorithm. Then the algorithm $\mathcal{A}(\boldsymbol{x}) = \mathcal{A}_2(\mathcal{A}_1(\boldsymbol{x}))$ is still an (ε, δ)-DP algorithm.*

▶ **Fact 10** (Group Privacy). *Let $\mathcal{A}$ be an (ε, δ)-DP algorithm and $\boldsymbol{x}, \boldsymbol{x}'$ be two arbitrary inputs. Define $k = \|\boldsymbol{x} - \boldsymbol{x}'\|_1$. Then for any measurable subset S of $\mathcal{A}$'s range, we have*

$$\mathbf{Pr}\left[\mathcal{A}(\boldsymbol{x}) \in S\right] \le e^{k\cdot\varepsilon} \cdot \mathbf{Pr}\left[\mathcal{A}(\boldsymbol{x}') \in S\right] + \delta \cdot \frac{e^{k\cdot\varepsilon} - 1}{e^{\varepsilon} - 1}.$$

▶ **Fact 11** (Basic Composition). *Let $\mathcal{A}_1$ be an $(\varepsilon_1, \delta_1)$-DP algorithm and $\mathcal{A}_2$ be an $(\varepsilon_2, \delta_2)$-DP algorithm. Then $\mathcal{A}(\boldsymbol{x}) = (\mathcal{A}_1(\boldsymbol{x}), \mathcal{A}_2(\mathcal{A}_1(\boldsymbol{x}), \boldsymbol{x}))$ is an $(\varepsilon_1 + \varepsilon_2, \delta_1 + \delta_2)$-DP algorithm.*

▶ **Fact 12** (Parallel Composition). *Let $\mathcal{A}_1$ be an $(\varepsilon_1, \delta_1)$-DP algorithm and $\mathcal{A}_2$ be an $(\varepsilon_2, \delta_2)$-DP algorithm. Assume $\mathcal{A}_1$ and $\mathcal{A}_2$ depend on disjoint subsets of input coordinates. Then the algorithm $\mathcal{A}(\boldsymbol{x}) = (\mathcal{A}_1(\boldsymbol{x}), \mathcal{A}_2(\mathcal{A}_1(\boldsymbol{x}), \boldsymbol{x}))$ is a $(\max\{\varepsilon_1, \varepsilon_2\}, \max\{\delta_1, \delta_2\})$-DP algorithm.*

Two of the most ubiquitous mechanisms in DP are the Laplace and Gaussian mechanisms [16, 17, 23]. We use $\mathsf{Lap}(\sigma)$ to denote the *Laplace distribution* with parameter σ, whose density function is $\frac{1}{2\sigma}\exp\left(-\frac{|x|}{\sigma}\right)$. We use $\mathsf{N}(\mu, \sigma^2)$ to denote the *Gaussian distribution* with mean μ and variance σ^2, whose density function is $\frac{1}{\sigma\sqrt{2\pi}}\exp\left(-\frac{1}{2}\frac{(x-\mu)^2}{\sigma^2}\right)$.

For matrix $\boldsymbol{A}$ and $p \geq 1$, we use $\|\boldsymbol{A}\|_{\infty,p}$ to denote the maximum ℓ_p-norm among all column vectors of $\boldsymbol{A}$. The Laplace and Gaussian mechanisms for linear queries are stated next.

▶ **Lemma 13** (Laplace Mechanism, [16, 34]). *For the $\boldsymbol{W}$-linear query problem, the algorithm that outputs $\boldsymbol{W}\boldsymbol{x} + \boldsymbol{z}$ is ε-DP, where each entry of $\boldsymbol{z}$ is drawn i.i.d. from $\mathsf{Lap}\left(\|\boldsymbol{W}\|_{\infty,1}/\varepsilon\right)$.*

▶ **Lemma 14** (Gaussian Mechanism, [17, 23]). *Assume $\varepsilon, \delta \in (0,1)$. For the $\boldsymbol{W}$-linear query problem, the algorithm that outputs $\boldsymbol{W}\boldsymbol{x} + \boldsymbol{z}$ is (ε, δ)-DP, where each entry of $\boldsymbol{z}$ is drawn i.i.d. from $\mathsf{N}\left(0, 2\ln(1.25/\delta)\|\boldsymbol{W}\|^2_{\infty,2}/\varepsilon^2\right)$.*

Recall that for a tree $\mathcal{T}$, we let $\boldsymbol{W}^{\mathcal{T}} \in \{0,1\}^{\mathsf{nodes}(\mathcal{T})\times\mathsf{leaves}(\mathcal{T})}$ be the indicator matrix whether a leaf is a descendant of (or itself) a node. This represents the tree aggregation problem as $\boldsymbol{W}^{\mathcal{T}}$-linear queries. Observe also that $\left\|\boldsymbol{W}^{\mathcal{T}}\right\|_{\infty,1} = d$ and $\left\|\boldsymbol{W}^{\mathcal{T}}\right\|_{\infty,2} = \sqrt{d}$. Therefore, we can apply Lemma 13 and Lemma 14 (together with tail bounds for Laplace and Gaussian distributions) to obtain the following baselines for tree aggregation.

▶ **Corollary 15** (Baseline Algorithms). *For the tree aggregation problem, there exists an ε-DP (resp., (ε, δ)-DP) algorithm with mRMSE $O(d/\varepsilon)$ (resp., $O(\sqrt{d \cdot \log(1/\delta)}/\varepsilon)$).*

We will also use the Laplace mechanism with a bounded range. For any $R > 0$, we use $\mathsf{TruncLap}(\sigma, R)$ to denote the *truncated Laplace distribution* with parameter σ and range $[-R, R]$, whose density function is proportional to $\exp(-|x|/\sigma)$ for $x \in [-R, R]$ and is 0 if $|x| > R$. Note that $\mathsf{Lap}(\sigma) = \mathsf{TruncLap}(\sigma, +\infty)$.

▶ **Lemma 16** (Truncated Laplace Mechanism, [27]). *The algorithm that, on input $x \in \mathbb{Z}$, outputs $x + z$ is (ε, δ)-DP, where $z \sim \mathsf{TruncLap}\left(\frac{1}{\varepsilon}, \frac{1}{\varepsilon}\ln\left(1 + \frac{e^{\varepsilon}-1}{2\delta}\right)\right)$.*

Our algorithm will also make use of the celebrated *sparse vector technique* [22]. For convenience, we apply it in a black-box way as the following oracle.

▶ **Lemma 17** (Sparse Vector Technique, [22, 23]). *There exists an ε-DP algorithm $\texttt{Sparse}(\boldsymbol{x}, \{f_i\}; \eta, c, \tau, \varepsilon)$ such that:*

- *Input. A dataset $\boldsymbol{x}$, an adaptively chosen stream $\{f_i\}_{i=1,\ldots,d}$ of sensitivity-1 queries, error probability $\eta > 0$, a cutoff point $c \geq 1$, a threshold τ, and a privacy bound $\varepsilon > 0$.*[5]
- *Output. A stream $\{a_i\}_{i=1,\ldots,d} \in \{\bot, \top\}^*$ of on-the-fly answers.*
- *Accuracy. Let i^* be the index of the cth $\top$ in $\{a_i\}_{i\in[d]}$; if there are less than c $\top$'s, let $i^* = d$. Then, for $\Delta = 8c/\varepsilon \cdot \ln(2d/\eta)$, with probability at least $1-\eta$ the following holds for all $i \leq i^*$: If $a_i = \top$, then $f_i(\boldsymbol{x}) \geq \tau - \Delta$; otherwise (i.e., $a_i = \bot$) $f_i(\boldsymbol{x}) < \tau + \Delta$.*

The $\texttt{Sparse()}$ algorithm is in [23, Algorithm 2] with $\delta = 0$, where its privacy is proved in [23, Theorem 3.25]. The accuracy part is also immediate from the algorithm description. For completeness, we give a proof in the full version.

[5] We say a query f is *sensitivity-1* if $\left|f(\boldsymbol{x}) - f(\boldsymbol{x}')\right| \leq 1$ for any two neighboring inputs $\boldsymbol{x}, \boldsymbol{x}'$.

3 Threshold-Based Utility

As mentioned in Section 1.2, we consider a probabilistic utility guarantee with a threshold value supplied at each node in the tree. Then we relate it to the original α-mRMSE notion.

▶ **Problem 18** (Tree Aggregation with Thresholds). *Consider the tree aggregation problem (i.e., Problem 2), wherein additionally, we have a threshold $\tau_u \geq 0$ corresponding to each node $u \in \mathsf{nodes}(\mathcal{T})$ (both internal nodes and leaves). The desired output for the problem is an estimate $\widetilde{\boldsymbol{w}} \in \mathbb{R}^{\mathsf{nodes}(\mathcal{T})}$ of $\boldsymbol{w}$ as before.*

*For parameters $\eta, \alpha \in [0, 1)$, we say that an algorithm for tree aggregation is (α, η)-*accurate *(w.r.t. the given thresholds) if its output vector $\widetilde{\boldsymbol{w}} \in \mathbb{R}^{\mathsf{nodes}(\mathcal{T})}$ satisfies the following:*

$$\text{For all } u \in \mathsf{nodes}(\mathcal{T}) \quad : \quad \mathbf{Pr}\left[|\widetilde{w}_u - w_u| \leq \alpha \cdot \max\{w_u, \tau_u\}\right] \geq 1 - \eta. \tag{1}$$

Unless otherwise specified, for the rest of the paper, we assume that the input to the tree aggregation problem includes a threshold at each node in the tree. Let $\tau_{\mathsf{min}} := \min_{u \in \mathsf{nodes}(\mathcal{T})} \tau_u$ and $\tau_{\mathsf{max}} := \max_{u \in \mathsf{nodes}(\mathcal{T})} \tau_u$. Now, we show that any algorithm with low α-mRMSE also yields a certain utility guarantee in the sense of (1).

▶ **Lemma 19** (Proof in Full Version). *For any $\alpha' > \alpha \geq 0$, $\eta > 0$, any tree aggregation algorithm with α-mRMSE at most $(\alpha' - \alpha)\sqrt{\eta} \cdot \tau_{min}$ is also (α', η)-accurate.*

In contrast to the above bound, our algorithms will satisfy much stronger exponential tail bounds, which will be clear in the next section. To complement Lemma 19, we show that any algorithm that is (α, η)-accurate, as per (1), can be made having small α-mRMSE.

▶ **Lemma 20** (Proof in Full Version). *If there is an $(\varepsilon/2, \delta/2)$-DP algorithm that is (α, η)-accurate for tree aggregation, then there is an (ε, δ)-DP algorithm for tree aggregation with α-mRMSE at most $O\left(\alpha \cdot \tau_{max} + d\sqrt{\eta} \cdot \left(1 + \frac{1}{\varepsilon}\log\left(\frac{1}{\delta}\right)\right)\right)$.*

With the above two lemmas in mind, it essentially suffices for us to consider the accuracy notion in (1), which will be convenient for the rest of the paper.

4 Upper Bounds

In this section, we present a new algorithm for tree aggregation in the approximate-DP setting, achieving a significant improvement over the baseline algorithm (i.e., Corollary 15).

▶ **Theorem 21.** *Let $\alpha > 0$ be a parameter. For any $\varepsilon > 0$ and $\delta \in (0, 1)$, there is an (ε, δ)-DP algorithm for tree aggregation with α-mRMSE at most $O\left(\frac{1}{\alpha^3} \cdot \left(\frac{1}{\varepsilon}\log\left(\frac{2d}{\delta}\right) + 1\right)\right)$.*

By Lemma 20, it suffices to design an efficient algorithm for Problem 18 with small thresholds for every node in the tree. This will be the focus of the section. To this end, we will reduce the estimation problem to a classification problem, and design algorithms for the classification task. We first present the classification algorithm in Section 4.1, then describe the reduction in Section 4.2, and finally put them together in Section 4.3.

4.1 A Classification Problem

For later reduction, the classification task here needs to have a stronger notion of success: the classification for nodes should be correct *simultaneously* with high probability, whereas Problem 18 only requires the estimation of any fixed node to be correct with high probability.

▶ **Problem 22.** *Let $\mathcal{T}$ be a tree of depth d and arity k. Let $\tau \geq 0$ be the (common) threshold for all nodes. Let $M > 0, \eta \in [0, 1/2), \alpha \in [0, 1)$ be parameters.*

The input to the problem is non-negative integer values x_v for each $v \in \mathsf{leaves}(\mathcal{T})$. For each node u, its weight w_u is $w_u = \sum_{v \text{ is a leaf under } u} x_v$.

The desired output is a vector $\boldsymbol{w}' \in \{\bot, \top\}^{\mathsf{nodes}(\mathcal{T})}$ that with probability at least $1 - \eta$ satisfies the following: when the weight of the root of $\mathcal{T}$ is at most M, for each $u \in \mathsf{nodes}(\mathcal{T})$,

- *if $w_u \geq (1 + \alpha) \cdot \tau$, then $w'_u = \top$;*
- *if $w_u < (1 - \alpha) \cdot \tau$, then $w'_u = \bot$;*
- *otherwise (i.e., $(1 - \alpha) \cdot \tau \leq w_u < (1 + \alpha) \cdot \tau$), w'_u can be arbitrary.*

We now present our algorithm for this classification problem and its guarantees.

▶ **Lemma 23.** *There is an (ε, δ)-DP algorithm $\texttt{Classification}(\mathcal{T}; M, \eta, \alpha, \tau, \varepsilon, \delta)$ such that it solves Problem 22 assuming $\tau \geq \sqrt{\frac{2M}{\alpha\varepsilon}} \cdot \max\left\{\sqrt{48 \ln\left(\frac{2d}{\eta}\right)}, \sqrt{6 \ln\left(1 + \frac{e^{\varepsilon/2} - 1}{\delta}\right)}\right\}$.*

Proof. Without loss of generality we assume $\alpha \leq 1/2$. Note that if $M < \tau$, then we can simply set $w'_u \leftarrow \bot$ for all $u \in \mathsf{nodes}(\mathcal{T})$. Therefore we assume without loss of generality $M \geq \tau$ from now on. For any node u, let $\mathsf{depth}(u)$ denote the number of nodes on the path from the root to u. Algorithm 1 contains the formal description.

We first prove the privacy bound. By Lemma 17, Line 7 is $\varepsilon/2$-DP. On the other hand, by Lemma 16 and Fact 12, Lines 11–18 are $(\varepsilon/(2c), \delta/c)$-DP; and since they are executed at most c times, they are $(\varepsilon/2, \delta)$-DP in total. Therefore by Fact 11, Algorithm 1 is (ε, δ)-DP.

Now we turn to the correctness of Algorithm 1. Define i^* to be the index of the cth $\top$ in $a_d, a_{d-1}, \ldots$. If there are less than c $\top$'s, let $i^* \geq 1$ be the index of the last query. Define $\mathcal{E}$ to be the event that the following holds for any $i \geq i^*$:[6] If $a_i = \top$, then $f_i \geq \tau - \Delta$; and if $a_i = \bot$, then $f_i < \tau + \Delta$. By Lemma 17, $\mathbf{Pr}[\mathcal{E}] \geq 1 - \eta$.

We first show, conditioned on $\mathcal{E}$, there are always less than c $\top$'s. Assume towards contradiction that there are c $\top$'s. Then, conditioned on $\mathcal{E}$, for any $a_i = \top$, there exists some $u \in \mathcal{S}_i$ such that $w_u = f_i \geq \tau - \Delta$. Therefore $\widetilde{w}_u \geq w_u - R \geq \tau - \Delta - R$, which implies it will be assigned to $\top$ on Line 14. By design, all these u's satisfying Line 13 form a subset of $\mathcal{T}$ where none of them is an ancestor of another. Therefore the weight of the root is lower bounded by the total weights of these nodes, which is at least $c \cdot (\tau - \Delta)$ but at most M. On the other hand, by the assumption on M and assuming $\Delta < \alpha \cdot \tau$, we also have $c > \frac{M}{\tau - \Delta}$, which gives a contradiction.

Then for the correctness part, it suffices to show for any fixed node $v \in \mathsf{nodes}(\mathcal{T})$, we have $w'_v = \top$ if $w_v \geq (1 + \alpha) \cdot \tau$, and $w'_v = \bot$ if $w_v < (1 - \alpha) \cdot \tau$:

- Case $w_v \geq (1 + \alpha) \cdot \tau$. Assume towards contradiction that $w'_v = \bot$. Let $i_v = \mathsf{depth}(v)$. Then it means when $i = i_v$ on Line 4, $v \in \mathcal{S}_i$. Thus $f_i \geq w_v \geq (1 + \alpha) \cdot \tau$. On the other hand since $w'_v = \bot$, we must proceed to Line 9. Conditioned on $\mathcal{E}$, this implies $f_i < \tau + \Delta$, which is a contradiction assuming $\Delta \leq \alpha \cdot \tau$.
- Case $w_v < (1 - \alpha) \cdot \tau$. Assume towards contradiction that $w'_v = \top$. Let $r \in \mathsf{nodes}(\mathcal{T})$ be the deepest node in the subtree below v that is assigned $\top$. Let $i_r = \mathsf{depth}(r)$. Then it means when $i = i_r$ we execute Line 14 for r. Thus $w_r + R \geq \widetilde{w}_r \geq \tau - \Delta - R$. Meanwhile, we also have $w_r \leq w_v < (1 - \alpha) \cdot \tau$, which is a contradiction assuming $\Delta + 2R \leq \alpha \cdot \tau$.

[6] Note that i goes from d down to 1 in our algorithm.

Algorithm 1 Classification.

Input: $\mathcal{T}$ and parameters $M, \eta, \alpha, \tau, \varepsilon, \delta$ described in Problem 22
Output: $w'_u \in \{\bot, \top\}$ for all $u \in \mathsf{nodes}(\mathcal{T})$

if $M < \tau$ **then** set $w'_u \leftarrow \bot$ for all $u \in \mathsf{nodes}(\mathcal{T})$ and **return** $\boldsymbol{w}'$
Set $c \leftarrow \frac{M}{(1-\alpha)\tau}$ and

$$\Delta \leftarrow \frac{16c}{\varepsilon} \ln\left(\frac{2d}{\eta}\right), \quad R \leftarrow \frac{2c}{\varepsilon} \ln\left(1 + \frac{c \cdot (e^{\varepsilon/(2c)} - 1)}{\delta}\right)$$

Define $\mathcal{S}_i \leftarrow \{u \in \mathsf{nodes}(\mathcal{T}) \mid \mathsf{depth}(u) = i\}$ for each $i \in [d]$
foreach $i = d$ **to** 1 **do**
  if $\mathcal{S}_i = \emptyset$ **then continue**
  Define query $f_i \leftarrow \max_{u \in \mathcal{S}_i} w_u$
  Get $a_i \leftarrow \mathtt{Sparse}(\boldsymbol{x}, f_i; \eta, c, \tau, \varepsilon/2)$ `/* x is the values of leaves(T) */`
  if $a_i = \bot$ **then**
    Set $w'_u \leftarrow \bot$ for all $u \in \mathcal{S}_i$ and update $\mathcal{S}_i \leftarrow \emptyset$
  else `/*` $a_i = \top$ `*/`
    foreach $u \in \mathcal{S}_i$ **do**
      Compute $\widetilde{w}_u \leftarrow w_u + \mathsf{TruncLap}(2c/\varepsilon, R)$
      if $\widetilde{w}_u \geq \tau - \Delta - R$ **then**
        Set $w'_v \leftarrow \top$ and remove v from $\mathcal{S}_{i_v}$ for each u's ancestor v (including u itself) where $i_v = \mathsf{depth}(v)$.
      else `/*` $\widetilde{w}_u < \tau - \Delta - R$ `*/`
        Set $w'_u \leftarrow \bot$ and remove u from $\mathcal{S}_i$
      end
    end
  end
end
return $\boldsymbol{w}'$

Thus it suffices to make sure $\Delta, R \leq \alpha \cdot \tau/3$. Since $M \geq \tau$, we have $c \geq 1$ and $c \cdot \left(e^{\varepsilon/(2c)} - 1\right) \leq e^{\varepsilon/2} - 1$, which gives the assumption in the statement by rearranging terms and noticing $1 - \alpha \geq 1/2$. ◀

Eventually, we will use $\mathtt{Classification}(\mathcal{F}; M, \eta, \alpha, \tau, \varepsilon, \delta)$ algorithm on a forest $\mathcal{F}$ of disjoint trees with the same set of parameters. There we do not need all nodes in $\mathcal{F}$ to be classified correctly. Instead, it suffices to have all nodes in any $\mathcal{T} \in \mathcal{F}$ classified correctly.

▶ **Problem 24.** *Let $\mathcal{F} = \{\mathcal{T}_1, \mathcal{T}_2, \ldots\}$ be a forest of disjoint trees of depth d and arity k. Let $\tau \geq 0$ be the threshold for every node. Let $M > 0, \eta \in [0, 1/2), \alpha \in [0, 1)$ be parameters.*

The input to the problem is non-negative integer values x_v for each leaf v in $\mathcal{F}$. For each node u, its weight w_u is $w_u = \sum_{v \text{ is a leaf under } u} x_v$.

The desired output is a vector $\boldsymbol{w}' \in \{\bot, \top\}^{\mathsf{nodes}(\mathcal{F})}$ that, for any $\mathcal{T} \in \mathcal{F}$ with probability at least $1 - \eta$, satisfies the following: when the root of $\mathcal{T}$ has weight at most M, for each $u \in \mathsf{nodes}(\mathcal{T})$,

- *if $w_u \geq (1 + \alpha) \cdot \tau$, then $w'_u = \top$;*
- *if $w_u < (1 - \alpha) \cdot \tau$, then $w'_u = \bot$;*
- *otherwise (i.e., $(1 - \alpha) \cdot \tau \leq w_u < (1 + \alpha) \cdot \tau$), w'_u can be arbitrary.*

The algorithm for Problem 24 is simply running $\texttt{Classification}(\mathcal{T}; M, \eta, \alpha, \tau, \varepsilon, \delta)$ for each $\mathcal{T} \in \mathcal{F}$. Since the trees are disjoint, the privacy bound follows from Fact 12. Therefore we omit the proof and summarize the following.

▶ **Corollary 25.** *There is an (ε, δ)-DP algorithm $\texttt{Classification}(\mathcal{F}; M, \eta, \alpha, \tau, \varepsilon, \delta)$ such that it solves Problem 24 assuming $\tau \geq \sqrt{\frac{2M}{\alpha\varepsilon}} \cdot \max\left\{\sqrt{48\ln\left(\frac{2d}{\eta}\right)}, \sqrt{6\ln\left(1+\frac{e^{\varepsilon/2}-1}{\delta}\right)}\right\}$.*

4.2 A Reduction from Estimation to Classification

Now we present the reduction algorithm from the estimation problem (i.e., Problem 18) to the classification problem (i.e., Problem 24). The reduction here is given with large flexibility for choosing parameters. Later we will design geometric convergent sequences for simplicity of calculation and derive the final bounds.

▶ **Lemma 26.** *Let $\ell \geq 1$ be an integer. Let M, M_0, and $(M_i, \eta_i, \alpha_i, \tau_i, \varepsilon_i, \delta_i)_{i\in[\ell]}$ be a sequence of parameters. There is an (ε, δ)-DP algorithm $\texttt{Reduction}(\mathcal{T}; \ell, (M_i, \eta_i, \alpha_i, \tau_i, \varepsilon_i, \delta_i)_{i\in[\ell]})$, where $(\varepsilon, \delta) = \left(\sum_{i=1}^{\ell}\varepsilon_i, \sum_{i=1}^{\ell}\delta_i\right)$ such that it solves Problem 18 by carefully combining results from $\texttt{Classification}(\cdot; M_i, \eta_i, \alpha_i, \tau_i, \varepsilon_i, \delta_i)$'s and assuming the weight of the root of $\mathcal{T}$ is at most M and*

$$\tau_i \;\geq\; \sqrt{\tfrac{2M_i}{\alpha_i\varepsilon_i}} \cdot \max\left\{\sqrt{48\ln\left(\tfrac{2d}{\eta_i}\right)}, \sqrt{6\ln\left(1+\tfrac{e^{\varepsilon_i/2}-1}{\delta_i}\right)}\right\} \quad \forall i \in [\ell], \tag{2}$$

$$\eta \;\geq\; \sum_{i=1}^{\ell}\eta_i, \tag{3}$$

$$M_i \;\geq\; (1+\alpha_{i+1})\cdot\tau_{i+1} \quad \forall i = 0, 1, \ldots, \ell-1 \quad \text{and} \quad M_\ell \;\geq\; M, \tag{4}$$

$$(1-\alpha_i)\cdot\tau_i \;\leq\; M_i \;\leq\; (1+\alpha)(1-\alpha_i)\cdot\tau_i \quad \forall i \in [\ell], \tag{5}$$

$$0 \;\leq\; M_0 \;\leq\; \alpha\cdot\tau_{\mathit{min}}. \tag{6}$$

The reduction algorithm is formalized in Algorithm 2 and analyzed in the full version.

Algorithm 2 Reduction.

Input: $\mathcal{T}$ and parameters $\ell, M_0, (M_i, \eta_i, \alpha_i, \tau_i, \varepsilon_i, \delta_i)_{i\in[\ell]}$ described above
Output: $\widetilde{w}_u \in \mathbb{R}$ for all node $u \in \mathsf{nodes}(\mathcal{T})$

Initialize $\mathcal{F}_\ell \leftarrow \{\mathcal{T}\}$
foreach $i = \ell$ **to** 1 **do**
  Initialize $\mathcal{F}_{i-1} \leftarrow \emptyset$
  Compute $\boldsymbol{w}' \leftarrow \texttt{Classification}(\mathcal{F}_i; M_i, \eta_i, \alpha_i, \tau_i, \varepsilon_i, \delta_i)$
  For each node u in $\mathcal{F}_i$, let $\mathcal{T}_u$ be the subtree of u in $\mathcal{F}_i$
  foreach *node u satisfying $w'_u = \top$ and $w'_v = \bot$ for all $v \in \mathsf{nodes}(\mathcal{T}_u)\setminus\{u\}$* **do**
    Set $\widetilde{w}_v \leftarrow M_i$ for each u's ancestor v (including u itself) in $\mathcal{T}$
    Update $\mathcal{F}_{i-1} \leftarrow \mathcal{F}_{i-1} \cup \{\mathcal{T}_1, \mathcal{T}_2, \ldots\}$ where $\mathcal{T}_1, \mathcal{T}_2, \ldots$ are the disjoint trees of $\mathcal{T}_u \setminus \{u\}$
  end
end
Set $\widetilde{w}_v \leftarrow M_0$ for each node v in $\mathcal{F}_0$

4.3 Putting Everything Together

Now we give the algorithm for Problem 18. To this end, we carefully choose parameters and apply Lemma 26, where the required upper bound M is privately estimated with Lemma 16.

▶ **Corollary 27** (Proof in Full Version). *There is an (ε, δ)-DP algorithm* `Estimation`$(\mathcal{T}, \alpha, \varepsilon, \delta, \eta)$ *such that it solves Problem 18 assuming*

$$\tau_{min} \geq \frac{324 \cdot (1+\alpha)^2}{\alpha^4 \cdot \varepsilon} \cdot \max\left\{8 \ln\left(\frac{4d}{\eta}\right), \ln\left(1 + \frac{2 \cdot \left(e^{\varepsilon/4} - 1\right)}{\delta}\right)\right\}.$$

Now we complete the proof of Theorem 21 using Lemma 20 and Corollary 27.

Proof of Theorem 21. We first note that if $\alpha \geq 1$ then the α-mRMSE is trivially zero by outputting the all-zeros vector. Therefore we assume without loss of generality $\alpha \in (0, 1)$.

Let $C > 0$ be a constant to be optimized later. Fix $\eta = d^{-2}$ and $\tau = \frac{C}{\alpha^4} \cdot \left(\frac{1}{\varepsilon} \log\left(\frac{2d}{\delta}\right) + 1\right)$. Let $\varepsilon' = \varepsilon/2$ and $\delta' = \delta/2$. Since $\alpha \in (0, 1)$, $d \geq 1$, and $\delta \in (0, 1]$, we have

$$\tau^* := \frac{324 \cdot (1+\alpha)^2}{\alpha^4 \cdot \varepsilon'} \cdot \max\left\{8 \ln\left(\frac{4d}{\eta}\right), \ln\left(1 + \frac{2 \cdot \left(e^{\varepsilon'/4} - 1\right)}{\delta'}\right)\right\} \leq O\left(\frac{1}{\alpha^4} \cdot \left(\frac{1}{\varepsilon} \log\left(\frac{2d}{\delta}\right) + 1\right)\right).$$

We set C large enough such that $\tau \geq \tau^*$. By Corollary 27, there is an $(\varepsilon', \delta') = (\varepsilon/2, \delta/2)$-DP algorithm for Problem 18 when $\tau_u \equiv \tau$ for all $u \in \mathsf{nodes}(\mathcal{T})$.

The desired α-mRMSE bound now follows from Lemma 20 and the parameters above. ◀

5 Lower Bounds

In this section we prove lower bounds for DP tree aggregation algorithms. In particular, Theorem 28 proves pure-DP lower bounds for all α-mRMSE whenever $\alpha \in [0, 1)$; and Theorem 29 proves approximate-DP lower bounds for additive-only error, i.e., $(\alpha = 0)$-mRMSE.

▶ **Theorem 28** (Pure-DP Lower Bound). *Let $\alpha \in [0, 1)$ be a parameter. For any $\varepsilon > 0$, any ε-DP algorithm for tree aggregation on the complete depth-d binary tree must incur α-mRMSE at least $\Omega\left((1-\alpha)^2 \cdot d/\varepsilon\right)$.*

▶ **Theorem 29** (Approximate-DP Lower Bound for $\alpha = 0$). *For any $\varepsilon > 0$ and any $\delta > 0$ sufficiently small depending on ε, there is a constant $C_{\varepsilon,\delta} > 0$ that any (ε, δ)-DP algorithm for tree aggregation on the complete depth-d binary tree must incur mRMSE at least $C_{\varepsilon,\delta} \cdot \sqrt{d}$.*

Theorem 28 is proved in Section 5.1. The proof of Theorem 29 relies on results from [24] and the factorization norm of the binary tree matrix, which we defer to the full version.

5.1 Pure-DP Lower Bound

To prove Theorem 28, by Lemma 19 it suffices to rule out DP algorithms for Problem 18 with small thresholds. Since Problem 18 is interesting on its own, we will present its lower bound in the approximate-DP setting for full generality.

▶ **Lemma 30.** *Assume $\mathcal{T}$ in Problem 18 is a complete binary tree of depth d. Let $D = 2 \cdot \lceil \tau_{max}/(1-\alpha) \rceil$. If $\mathcal{A}$ is an (ε, δ)-DP algorithm for Problem 18 and suppose $\eta \leq 1/8$ and*

$$\delta \cdot \frac{e^{\varepsilon \cdot D} - 1}{e^{\varepsilon} - 1} \leq \frac{1}{8} \cdot 2^{-(d-1) \cdot \mathcal{H}(4\eta)}, \tag{7}$$

then

$$\tau_{max} = \Omega\left((1-\alpha)\cdot(d-3-(d-1)\cdot\mathcal{H}(4\eta))/\varepsilon\right),$$

where $\mathcal{H}(x) = x\log(1/x) + (1-x)\log(1/(1-x))$ *is the binary entropy function.*

Proof. We define input datasets $\boldsymbol{x}^1, \ldots, \boldsymbol{x}^{2^d}$ where $\boldsymbol{x}^i$ assigns $D/2$ to the ith leaf and 0 to the remaining leaves. Let $\mathcal{P}_i$ be the path from root to the ith leaf. We define a randomized decoding algorithm Dec as follows:

- Dec takes the output $\widetilde{\boldsymbol{w}}$ of $\mathcal{A}$ as input and starts from the root of $\mathcal{T}$.
- Assume Dec is at node $u \in \mathsf{nodes}(\mathcal{T})$.
  - If u is a leaf, then output the index of u among all the leaves.
  - Otherwise let u_0, u_1 be the children of u and we divide into the following cases.
    - If $\widetilde{w}_{u_0} \geq \tau_{\mathsf{max}}$ and $\widetilde{w}_{u_1} \geq \tau_{\mathsf{max}}$, then we move to u_0 or u_1 with equal probability.
    - If $\widetilde{w}_{u_0} < \tau_{\mathsf{max}}$ and $\widetilde{w}_{u_1} < \tau_{\mathsf{max}}$, then we move to u_0 or u_1 with equal probability.
    - Otherwise let $p \in \{0,1\}$ be such that $\widetilde{w}_{u_p} \geq \tau_{\mathsf{max}}$ and $\widetilde{w}_{u_{1-p}} < \tau_{\mathsf{max}}$, then we move to u_p with probability κ and to u_{1-p} with probability $1-\kappa$, where $\kappa = 1-4\eta \in [1/2, 1]$.

Now we fix an index $i \in [2^d]$. Let $\mathcal{P}_i$ be $u_1, \ldots, u_d$. Then for each $j \in [d-1]$, let u_j^0, u_j^1 be the children of u_j and assume without loss of generality $u_j^0 = u_{j+1}$; then we define the following indicators:

- $a_j = \mathbb{I}[(\widetilde{w}_{u_j^0} \geq \tau_{\mathsf{max}} \text{ and } \widetilde{w}_{u_j^1} \geq \tau_{\mathsf{max}}) \text{ or } (\widetilde{w}_{u_j^0} < \tau_{\mathsf{max}} \text{ and } \widetilde{w}_{u_j^1} < \tau_{\mathsf{max}})]$.
- $b_j = \mathbb{I}[\widetilde{w}_{u_j^0} \geq \tau_{\mathsf{max}} \text{ and } \widetilde{w}_{u_j^1} < \tau_{\mathsf{max}}]$.
- $c_j = \mathbb{I}[\widetilde{w}_{u_j^0} < \tau_{\mathsf{max}} \text{ and } \widetilde{w}_{u_j^1} \geq \tau_{\mathsf{max}}]$.

Let $A = \sum_j a_j$, $B = \sum_j b_j$, and $C = \sum_j c_j$. Then it is easy to see $A + B + C = d - 1$ and

$$\mathbf{Pr}\left[\mathsf{Dec}(\mathcal{A}(\boldsymbol{x}^i)) = i\right] = \mathbb{E}\left[2^{-A}\kappa^B(1-\kappa)^C\right] = \kappa^{d-1}\,\mathbb{E}\left[1/(2\kappa)^{d-1-B}(2-2\kappa)^C\right]. \tag{8}$$

Now we further fix the input to be $\boldsymbol{x}^i$ defined above. Then $w_u = D/2$ for $u \in \mathcal{P}_i$ and $w_u = 0$ if otherwise. For $p \in \{0,1\}$, consider the event $\mathcal{E}_j^p$: $\left|\widetilde{w}_{u_j^p} - w_{u_j^p}\right| \leq \alpha \cdot \max\left\{w_{u_j^p}, \tau_{u_j^p}\right\}$. Hence when $\mathcal{E}_j^0$ happens, we have

$$\widetilde{w}_{u_j^0} \geq w_{u_j^0} - \alpha \cdot \max\left\{w_{u_j^0}, \tau_{u_j^0}\right\} \geq D/2 - \alpha \cdot \max\{D/2, \tau_{\mathsf{max}}\} = (1-\alpha)\cdot D/2 \geq \tau_{\mathsf{max}}.$$

Similarly when $\mathcal{E}_j^1$ happens, we have $\widetilde{w}_{u_j^1} \leq w_{u_j^1} + \alpha \cdot \max\left\{w_{u_j^1}, \tau_{u_j^1}\right\} \leq \alpha \cdot \tau_{\mathsf{max}} < \tau_{\mathsf{max}}$. Meanwhile by the definition of Problem 18, we know $\mathbf{Pr}\left[\mathcal{E}_j^p\right] \geq 1 - \eta$. Thus

$$\mathbf{Pr}\left[b_j = 1\right] \geq \mathbf{Pr}\left[\mathcal{E}_j^0 \wedge \mathcal{E}_j^1\right] \geq 1 - 2\eta, \quad \text{and} \quad \mathbf{Pr}\left[c_j = 1\right] \leq \mathbf{Pr}\left[\neg\mathcal{E}_j^0 \wedge \neg\mathcal{E}_j^1\right] \leq \mathbf{Pr}\left[\neg\mathcal{E}_j^0\right] \leq \eta,$$

which implies $\mathbb{E}\left[d - 1 - B\right] \leq 2\eta \cdot (d-1)$ and $\mathbb{E}\left[C\right] \leq \eta \cdot (d-1)$. Note that $d - 1 - B \geq 0$. Define the event $\mathcal{E}$: $d - 1 - B \leq 4\eta \cdot (d-1)$ and $C \leq 4\eta \cdot (d-1)$. Then by Markov's inequality and a union bound, we have $\mathbf{Pr}\left[\mathcal{E}\right] \geq 1 - 1/2 - 1/4 = 1/4$. Plugging into (8), we have

$$\begin{aligned}
\mathbf{Pr}\left[\mathsf{Dec}(\mathcal{A}(\boldsymbol{x}^i)) = i\right] &\geq \kappa^{d-1}/4 \cdot \mathbb{E}\left[1/(2\kappa)^{d-1-B}(2-2\kappa)^C \;\middle|\; \mathcal{E}\right] \\
&\geq \kappa^{d-1}/4 \cdot 1/(2\kappa)^{4\eta\cdot(d-1)} \cdot (2-2\kappa)^{4\eta\cdot(d-1)} && \text{(since } \kappa \in [1/2,1]\text{)} \\
&= \frac{1}{4} \cdot 2^{-(d-1)\cdot\mathcal{H}(4\eta)}. && \text{(setting } \kappa = 1-4\eta \in [1/2,1]\text{)}
\end{aligned}$$

Since $\sum_{i'} \mathbf{Pr}\left[\mathsf{Dec}(\mathcal{A}(\boldsymbol{x}^i)) = i'\right] = 1$, by an averaging argument there exists an i^* such that $\mathbf{Pr}\left[\mathsf{Dec}(\mathcal{A}(\boldsymbol{x}^i)) = i^*\right] \leq 2^{-d}$. Since $\left\|\boldsymbol{x}^i - \boldsymbol{x}^{i^*}\right\|_1 \in \{0, D\}$, by Fact 10 we have

$$\mathbf{Pr}\left[\mathsf{Dec}(\mathcal{A}(\boldsymbol{x}^{i^*})) = i^*\right] \leq \mathbf{Pr}\left[\mathsf{Dec}(\mathcal{A}(\boldsymbol{x}^i)) = i^*\right] \cdot e^{\varepsilon\cdot D} + \delta \cdot \tfrac{e^{\varepsilon\cdot D}-1}{e^\varepsilon - 1} \leq 2^{-d} \cdot e^{\varepsilon\cdot D} + \delta \cdot \tfrac{e^{\varepsilon\cdot D}-1}{e^\varepsilon - 1}.$$

In all, we have

$$\frac{1}{4} \cdot 2^{-(d-1)\cdot\mathcal{H}(4\eta)} \leq \mathbf{Pr}\left[\mathsf{Dec}(\mathcal{A}(\boldsymbol{x}^{i^*})) = i^*\right] \leq 2^{-d} \cdot e^{\varepsilon \cdot D} + \delta \cdot \frac{e^{\varepsilon \cdot D} - 1}{e^{\varepsilon} - 1},$$

which proves the bound after plugging in Assumption (7) and rearranging the terms. ◀

To deal with general η from Problem 18, we simply run independent copies of the algorithm to decrease the error probability.

▶ **Corollary 31** (Proof in Full Version). *Assume $\mathcal{T}$ in Problem 18 is a complete binary tree of depth d. Define $D = 2 \cdot \left\lceil \frac{\tau_{max}}{1-\alpha} \right\rceil$ and $s = \left\lceil \frac{\ln(4/\kappa)}{2\cdot(1/2-\eta)^2} \right\rceil$ for any parameter $\kappa \in (0, 1/2]$. If $\mathcal{A}$ is an (ε, δ)-DP algorithm for Problem 18 and suppose $s \cdot \delta \cdot \frac{e^{s\cdot\varepsilon\cdot D}-1}{e^{s\cdot\varepsilon}-1} \leq \frac{1}{8} \cdot 2^{-(d-1)\cdot\mathcal{H}(\kappa)}$, then*

$$\tau_{max} = \Omega\left(\frac{(1-\alpha)\cdot(1/2-\eta)^2\cdot(d-3-(d-1)\mathcal{H}(\kappa))}{\varepsilon\cdot\ln(4/\kappa)}\right).$$

▶ Remark 32 (General Tree Structures). The proof above works almost identically for binary tree $\mathcal{T}$ that is not necessarily complete, where the bound is simply replacing $d-3$ with $\log(|\mathsf{leaves}(\mathcal{T})|/8)$. To deal with general arity k, we can embed a binary tree $\mathcal{T}'$ into $\mathcal{T}$ where we say $\mathcal{T}$ *embeds* a tree $\mathcal{T}'$ if we can obtain $\mathcal{T}'$ from $\mathcal{T}$ by deleting nodes and edges. Then we can ignore nodes in $\mathsf{nodes}(\mathcal{T}) \setminus \mathsf{nodes}(\mathcal{T}')$ and obtain lower bounds for $\mathcal{T}'$.

Now we are ready to establish Theorem 28 using Lemma 19 and Corollary 31.

Proof of Theorem 28. Let $\mathcal{T}$ be the complete binary tree of depth d. Let C, τ, η be parameters to be optimized later. We consider Problem 18 where $\tau_u \equiv \tau$ for all $u \in \mathsf{nodes}(\mathcal{T})$.

Assume towards contradiction that there is an ε-DP tree aggregation algorithm with α-mRMSE at most $C \cdot (1-\alpha)^2 d/\varepsilon$. Then by Lemma 19, the algorithm is also (α', η)-accurate for Problem 18 if $\alpha' > \alpha$ and $(\alpha' - \alpha)\sqrt{\eta} \cdot \tau \leq C \cdot (1-\alpha)^2 d/\varepsilon$.

Now we set $\eta = 1/4$ and apply Corollary 31 with $\delta = 0, \kappa = 1/4$. This gives a lower bound $\tau = \Omega\left((1-\alpha')\cdot d/\varepsilon\right)$, which means $\frac{C\cdot(1-\alpha)^2\cdot d}{\varepsilon} \geq \Omega\left(\frac{(\alpha'-\alpha)(1-\alpha')\cdot d}{\varepsilon}\right)$. Then we set $\alpha' = (1+\alpha)/2 > \alpha$ and $C = O(1)$ small enough to derive a contradiction. ◀

▶ Remark 33 ($\log(1/\delta)$ Factor in the Approximate-DP Algorithm). As mentioned in Section 1.1, our improved (ε, δ)-DP algorithm (See Theorem 8) has a $\log(1/\delta)$ factor, which is worse than the $\sqrt{\log(1/\delta)}$ factor in the Gaussian mechanism (see Corollary 15). One may wonder if we can further improve the dependency on δ to, say, $\sqrt{\log(1/\delta)}$, without influencing the other parameters. Combining Corollary 31, we show this is in some sense impossible.

Consider the complete binary tree of depth d. Let $\delta = 2^{-\Omega(d)}$. We consider the case where α, η are constants and all the τ_u's are equal to τ. In the approximate-DP setting, we naturally seek bounds better than the ones in the pure-DP setting (recall we can obtain $\tau = O(d/\varepsilon)$ from Corollary 15). Thus we assume $\tau = O(d/\varepsilon)$ in advance.

Then for a suitable choice of $\kappa = \Theta(1)$, the condition in Corollary 31 holds, which gives a lower bound $\tau = \Omega(d/\varepsilon)$ for Problem 18. Then by Lemma 19, this rules out the possibility of improving the dependency on δ in Theorem 8 without worsening the dependency on d.

6 Conclusions

We study the problem of privately estimating counts in hierarchical data, and give several algorithms and lower bounds. We propose a new error measure that takes the multiplicative error into account. The commonly used ℓ_2^2-error measure in evaluating utilities of DP

mechanisms allows some queries to have huge error. On the other hand, the standard measure ℓ_∞-error has a "union bound issue" on particularly long output vector (which is the case in Census and Ads applications).

To mitigate these weaknesses, we propose α-multiplicative root mean squared error (α-mRMSE). Then we examine the standard Laplace mechanism for pure-DP and Gaussian mechanism for approximate-DP, and prove their optimality. Informally, we show Laplace mechanism already achieves optimal bounds in the pure-DP setting for all multiplicative factor α and Gaussian mechanism is optimal in the approximate-DP setting when $\alpha = 0$ (i.e., additive-only error).

For the remaining case where we allow $\alpha > 0$ and an approximate-DP algorithm, we design a new algorithm with exponential improvements over Gaussian mechanism. More precisely, Gaussian mechanism incurs α-mRMSE of $O_{\alpha,\varepsilon,\delta}(\sqrt{d})$ while our algorithm gives improved bounds of $O_{\alpha,\varepsilon,\delta}(\log(d))$ (and $O\left(\frac{1}{\alpha^3} \cdot \left(\frac{1}{\varepsilon}\log\left(\frac{2d}{\delta}\right)+1\right)\right)$ specifically). It remains an interesting question if the dependency on d or α can be improved further. Indeed, current lower bounds do not preclude bounds of the form $O_{\varepsilon,\delta}\left(\frac{1}{\alpha}\cdot\log^*(d)\right)$ or even $O_{\varepsilon,\delta}(1/\alpha)$.

Throughout this work, we assumed that the entries of the input $\boldsymbol{x}$ are non-negative. Another interesting direction is to extend the study to the case where the entries of $\boldsymbol{x}$ can be negative. Here, the multiplicative error would be with respect to the absolute value of the true answer. Our algorithms do not apply here and it is unclear whether allowing a multiplicative error can help reduce the additive error in this setting.

Abstract

Quantum mechanical effects have enabled the construction of cryptographic primitives that are impossible classically. For example, quantum copy-protection allows for a program to be encoded in a quantum state in such a way that the program can be evaluated, but not copied. Many of these cryptographic primitives are two-party protocols, where one party, Bob, has full quantum computational capabilities, and the other party, Alice, is only required to send random BB84 states to Bob. In this work, we show how such protocols can *generically* be converted to ones where Alice is fully classical, assuming that Bob cannot efficiently solve the LWE problem. In particular, this means that all communication between (classical) Alice and (quantum) Bob is classical, yet they can still make use of cryptographic primitives that would be impossible if both parties were classical. We apply this conversion procedure to obtain quantum cryptographic protocols with classical communication for unclonable encryption, copy-protection, computing on encrypted data, and verifiable blind delegated computation.

The key technical ingredient for our result is a protocol for *classically-instructed parallel remote state preparation of BB84 states*. This is a multi-round protocol between (classical) Alice and (quantum polynomial-time) Bob that allows Alice to certify that Bob must have prepared n uniformly random BB84 states (up to a change of basis on his space). While previous approaches could only certify one- or two-qubit states, our protocol allows for the certification of an n-fold tensor product of BB84 states. Furthermore, Alice knows which specific BB84 states Bob has prepared, while Bob himself does not. Hence, the situation at the end of this protocol is (almost) equivalent to one where Alice sent n random BB84 states to Bob. This allows us to replace the step of preparing and sending BB84 states in existing protocols by our remote-state preparation protocol in a generic and modular way.

We also thank Matty Hoban for pointing out a typo in an earlier draft.

1 Introduction

A central distinction between classical and quantum information is that a classical string can always be copied, but a quantum state cannot: the *no-cloning theorem* states that there cannot exist a procedure that produces the state $\rho \otimes \rho$ when given as input an arbitrary quantum state ρ [51]. The first cryptographic protocols that made use of the no-cloning theorem were Wiesner's proposal to use quantum states as unforgeable banknotes [50] and Bennett and Brassard's protocol for information-theoretically secure quantum key-distribution (the BB84 QKD protocol) [6]. These protocols rely on the idea of a *conjugate coding scheme*: classical information can be encoded into a quantum state in (at least) two incompatible bases, most commonly the standard basis $\{|0\rangle, |1\rangle\}$ and the Hadamard basis $\{|+\rangle, |-\rangle\}$, where $|\pm\rangle = \frac{1}{\sqrt{2}}(|0\rangle \pm |1\rangle)$. These four states are commonly referred to as *BB84 states*. If we encode a bit $b \in \{0, 1\}$ as either $|b\rangle$ or $|(-)^b\rangle = \frac{1}{\sqrt{2}}(|0\rangle + (-1)^b|1\rangle)$, then an adversary who does not know which basis we chose for the encoding cannot create a copy of this quantum state. Furthermore, if the adversary tries to measure the state, with probability $1/2$ they will choose the "wrong" measurement basis, which disturbs the state and means that the adversary's tampering can be detected.

There is an important conceptual difference between the BB84 protocol and Wiesner's quantum money scheme. The former addresses the problem of key-distribution, which is a task that can also be achieved classically under computational assumptions using public-key cryptography [18]. In contrast, Wiesner's quantum money scheme achieves a functionality which is entirely impossible classically, even under computational assumptions. Recently there has been renewed interest in this latter kind of application, i.e. to use BB84 states to construct quantum cryptographic primitives that have no classical analogue. Perhaps the most striking example of this is the idea of *quantum copy-protection* [1]. Suppose that a vendor has created a piece of software (viewed as a function that maps some input to some output) and wants to allow a user to run it (i.e. to evaluate the function), while preventing the user from producing additional "pirated" copies of the original software. Clearly, this is impossible classically: any piece of software is specified by a string of symbols, which can easily be copied. Surprisingly, it has been shown that it is possible to encode certain narrow classes of functions in the form of a quantum state in such a way that a user can evaluate the function without being able to copy it [16].

Copy-protection and many related protocols require only limited quantum capabilities from one party, e.g. the *vendor* in the case of copy-protection: they only need to prepare random BB84 states and send them to the other party (e.g. the *user* in copy-protection), who has full quantum computational capabilities. In particular, this requires a quantum channel between the two parties to send the BB84 states. The purpose of this paper is to show that such protocols, where one party's quantum operations are limited to preparing and sending

random BB84 states, can be converted into protocols where that party is *fully classical*. This *dequantises* such protocols in the sense that all communication becomes classical. To achieve this, we need to construct a protocol between a *classical verifier* and a *computationally bounded quantum prover* that achieves the same outcome as if the verifier had prepared and sent random BB84 states to the prover. We call this task *classically-instructed parallel remote state preparation of BB84 states*, or *parallel RSP* for short. Our protocol builds on techniques introduced in [33, 7, 24] that allow the verifier to use post-quantum cryptography to constrain the actions of an untrusted (but computationally bounded) prover and certify the result of a certain computation or the preparation of certain states. In contrast to earlier works on remote state preparation (or *self-testing*) in this setting, which could only certify states comprised of a constant number of qubits, our protocol allows for the certification of an n-fold tensor product of states. We discuss the difference between our approach and previous approaches to RSP (in particular the protocol of [24]) in Section 4. Proving soundness for this parallel RSP protocol is the main technical result of our work. We then use this result to dequantise a number of cryptographic protocols, namely unclonable quantum encryption, quantum copy-protection, quantum computing on encrypted data and blind verification of quantum computation.

2 Main results

We start by first describing the soundness guarantee achieved by our parallel RSP protocol. Intuitively, the goal of our protocol is to guarantee that the prover has prepared a quantum state of the form $H^{\theta_1}|v_1\rangle\langle v_1|H^{\theta_1} \otimes \ldots \otimes H^{\theta_n}|v_n\rangle\langle v_n|H^{\theta_n}$, where $\vec{v}, \vec{\theta} \in \{0,1\}^n$. Additionally, the prover should not have any information about $\vec{v}$ and $\vec{\theta}$ beyond what is contained in its BB84 states, while the verifier should know both $\vec{v}$ and $\vec{\theta}$. Our protocol achieves a guarantee of this kind assuming the quantum-intractability of the *Learning with Errors* (LWE) problem introduced by Regev [43]. Our main result is the following (see the full manuscript for the corresponding formal statement):

▶ **Theorem 1** (Informal). *There exists an interactive protocol between a classical verifier and a computationally bounded quantum prover such that the following holds assuming the quantum-intractability of LWE (with quantum advice). Fix a number n of BB84 states. Consider any efficient prover strategy and let W and P be the verifier's and prover's systems at the end of the protocol, respectively. Then there exists an isometry $V : P \to QP'$ (for $\mathcal{H}_Q \cong (\mathbb{C}^2)^{\otimes n}$ and P' arbitrary) and an additional (subnormalised) state $\alpha_{P'}$ such that for any basis choice $\vec{\theta} \in \{0,1\}^n$, the protocol's final state σ_{WP} conditioned on the prover being accepted satisfies*

$$p_{\text{success}} V \sigma_{WP} V^\dagger \overset{c}{\approx}_{1/\operatorname{poly}(n)} \frac{1}{2^n} \sum_{\vec{v} \in \{0,1\}^n} |v\rangle\langle v|_W \otimes \left(H^{\theta_1}|v_1\rangle\langle v_1|H^{\theta_1} \otimes \ldots \otimes H^{\theta_n}|v_n\rangle\langle v_n|H^{\theta_n}\right) \otimes \alpha_{P'} .$$

Here, p_{success} is the prover's success probability in the protocol and $\overset{c}{\approx}_{1/\operatorname{poly}(n)}$ denotes computational indistinguishability up to inverse polynomial error.

We make two remarks regarding this security guarantee. Firstly, the theorem makes a statement about the joint state of the verifier's system W and the prover's system P after applying an isometry V that *only acts on the prover's space*. This additional isometry is unavoidable: it represents the prover's freedom to use any basis of its choice on its space.

Hence, we cannot guarantee that the prover prepares BB84 states (in the standard basis), only that it prepares BB84 states up to a change of basis. However, crucially this change of basis is *independent of which BB84 state was supposed to be prepared*, i.e., V is independent of $\vec{v}$ and $\vec{\theta}$ (but it can of course depend on the prover's strategy). Put differently, the theorem guarantees that the prover prepares one of 4^n possible states whose relation to each other is the same as the relation between the 4^n BB84 states. This does not affect the utility of the prover's state for applications. In fact, this freedom also exists if the verifier sent n BB84 states to the prover via a quantum channel: the prover could apply an isometry V to these states immediately upon receipt, but the security of any application using the BB84 states is not impacted by this.

Secondly, the theorem holds *for any* basis choice $\vec{\theta}$, but *on average* over the values $\vec{v}$. In other words, in the protocol, the verifier gets to choose the bases at will, but the values will be uniformly random and cannot be chosen by the verifier. Furthermore, the only dependence on $\vec{v}$ and $\vec{\theta}$ in the prover's state is via the BB84 states. This means that the protocol forces the prover to prepare these states "blindly", i.e., the prover does not know which BB84 states were actually prepared. In contrast, the verifier does know, because they chose $\vec{\theta}$ and are in possession of the system W, which contains information about $\vec{v}$. This asymmetry of knowledge about the prover's state is the same as what is achieved by preparing and sending BB84 states through a quantum channel and is crucial for applications.

We also note that a consequence of Theorem 1 is the certification of an n-fold tensor product structure within the prover's system. This can be interpreted as saying that any successful prover must have a quantum memory capable of storing n-qubits. Being able to certify an n-qubit state in the prover's system is the main technical challenge towards proving soundness, as we outline in the next subsection. This notion of a computational proof of quantum space has been formalised in [21], who prove a similar parallel rigidity result to ours, but for a different class of states that does not immediately allow for cryptographic applications.

2.1 Soundness proof for parallel RSP protocol

The full RSP protocol is described as Protocol 3 (though our discussion here is restricted to Protocol 1). Its soundness proof can be found in the full version of the manuscript.

We briefly explain the difference between Protocol 1 and Protocol 3: Protocol 1 is a protocol to *test* the prover, i.e. in this protocol the prover is asked to prepare *and measure* a quantum state, and the verifier runs checks on the prover's answer. The soundness statement for this protocol is a self-testing statement in the sense of [36], which characterises which states and measurements the prover used in the protocol. Although we do not spell this out, it is easy to obtain an explicit self-testing statement from our proof. In contrast, Protocol 3 is a protocol for remote state preparation, so the prover is supposed to prepare, but not yet measure, a particular quantum state. Instead, this quantum state will be used for other applications. This means that we do not want to make a statement about how the prover measured its state, but rather what state remains in its quantum memory. The soundness of Protocol 3 follows from that of Protocol 1 via a statistical argument. In the following, we focus on Protocol 1. We do not explain the protocol and the cryptographic primitives underlying it in detail; instead, we give a very high-level description of the relevant part of the soundness proof of the RSP protocol from [24] and then explain our method for proving a parallel rigidity statement based on that result.

The main cryptographic primitive underlying the RSP protocol is a so-called extended noisy trapdoor claw-free function (ENTCF) family, which can be constructed assuming the quantum hardness of LWE [43, 33]. An ENTCF family is a family of functions indexed by

▶ **Protocol 1. Test round protocol.**

Let $\lambda \in \mathbb{N}$ be the security parameter, $(\mathcal{F}, \mathcal{G})$ an ENTCF family, and $n = \text{poly}(\lambda)$ the number of BB84 states that the verifier wishes to prepare.

1. The verifier selects a uniformly random basis $\theta \xleftarrow{\$} \{0,1\}$, where 0 corresponds to the computational and 1 to the Hadamard basis.
2. The verifier samples keys and trapdoors $(k_1, t_{k_1}; \dots k_n, t_{k_n})$ by computing $(k_i, t_{k_i}) \leftarrow \text{GEN}_{\mathcal{K}_\theta}(1^\lambda)$. The verifier then sends $(k_1, \dots k_n)$ to the prover (but keeps the trapdoors t_{k_i} private).
3. The verifier receives $(y_1, \dots, y_n) \in \mathcal{Y}^{\times n}$ from the prover.
4. The verifier selects a round type $\in$ {preimage round, Hadamard round} uniformly at random and sends the round type to the prover.
   a. For a *preimage round*: The verifier receives $(b_1, x_1; \dots b_n, x_n)$ from the prover, with $b_i \in \{0,1\}$ and $x_i \in \mathcal{X}$. The verifier sets $\texttt{flag} \leftarrow \texttt{fail}_{\texttt{Pre}}$ if $\text{CHK}(k_i, y_i, b_i, x_i) = 0$.
   b. For a *Hadamard round*: The verifier receives $d_1, \dots d_n \in \{0,1\}^w$ from the prover (for some w depending on the security parameter). The verifier sends $q = \theta$ to the prover, and receives answers $v_1, \dots v_n \in \{0,1\}$. The verifier performs the following checks:

Case	Verifier's check
$q = \theta = 0$	Set $\texttt{flag} \leftarrow \texttt{fail}_{\texttt{Had}}$ if $\hat{b}(k_i, y_i) \neq v_i$ for some i.
$q = \theta = 1$	Set $\texttt{flag} \leftarrow \texttt{fail}_{\texttt{Had}}$ if $\hat{u}(k_i, y_i, d_i) \neq v_i$.

Note. We denote the "question" separately by q (even though here we always have $q = \theta$) because when the variant of this protocol in Protocol 2 is used in the context of another cyrptographic task, the verifier can also send questions q which are different from θ.

▶ **Protocol 2. Preparation round protocol.**

Let $\lambda \in \mathbb{N}$ be the security parameter, $(\mathcal{F}, \mathcal{G})$ an ENTCF family, and $n = \text{poly}(\lambda)$ the number of BB84 states that the verifier wishes to prepare.

1. The verifier selects bases $\vec{\theta} \xleftarrow{\$} \{0,1\}^n$, where 0 corresponds to the computational and 1 to the Hadamard basis.
2. The verifier samples keys and trapdoors $(k_1, t_{k_1}; \dots k_n, t_{k_n})$ by computing $(k_i, t_{k_i}) \leftarrow \text{GEN}_{\mathcal{K}_{\theta_i}}(1^\lambda)$. The verifier then sends $(k_1, \dots k_n)$ to the prover (but keeps the trapdoors t_{k_i} private).
3. The verifier receives $y_1, \dots y_n \in \mathcal{Y}$ from the prover.
4. The verifier sends "Hadamard round" to the prover as the round type.
5. The verifier receives $d_1, \dots d_n \in \{0,1\}^w$ from the prover (for some w depending on the security parameter). The verifier computes a string $\vec{v}$ according to

$$v_i = \begin{cases} \hat{b}(k_i, y_i) & \text{if } \theta_i = 0\,, \\ \hat{u}(k_i, y_i, d_i) & \text{if } \theta_i = 1\,. \end{cases}$$

▶ **Protocol 3. Multi-round protocol for preparation of BB84 states.**

Let $\lambda \in \mathbb{N}$ be the security parameter, $(\mathcal{F}, \mathcal{G})$ an ENTCF family, $n = \text{poly}(\lambda)$ the number of BB84 states that the verifier wishes to prepare, $N = M^2$ the maximum number of test rounds (for $M \in \mathbb{N}$), and δ an error tolerance parameter. For $j \in [M]$ we denote by $B_j = \{(j-1)M + 1, \ldots, jM\}$ the j-th "block" of M rounds.

1. The verifier (privately) samples $S \xleftarrow{\$} \{0, \ldots, M-1\}$ (the number of M-round blocks of test rounds that will be performed).
2. The verifier performs SM executions of Protocol 1 with the prover. The verifier aborts if *for any* $j \in [S]$, the fraction of rounds in B_j for which $\texttt{flag} = \texttt{fail}_{\texttt{Pre}}$ or $\texttt{flag} = \texttt{fail}_{\texttt{Had}}$ exceeds δ.
3. The verifier (privately) samples $R \xleftarrow{\$} [M]$ and executes Protocol 1 with the prover $R-1$ times. Then, the verifier executes Protocol 2 with the prover and records the basis choice $\vec{\theta}$ and the string $\vec{v}$ from that execution.

a set of keys $\mathcal{K}_0 \cup \mathcal{K}_1$. $\mathcal{K}_0$ and $\mathcal{K}_1$ are disjoint sets of keys with the property that given a $k \in \mathcal{K}_0 \cup \mathcal{K}_1$, it is computationally intractable to determine which set this key belongs to. See [33, Section 4] for further details on ENTCF families.

In the RSP protocol from [24], for a given *basis choice* $\theta \in \{0, 1\}$ (where "0" corresponds to the computational and "1" to the Hadamard basis), the verifier samples a key $k \in \mathcal{K}_\theta$, alongside some trapdoor information t. The verifier sends k to the prover and keeps t private. The verifier and prover then interact classically; for us, the main point of interest is the last round of the protocol, i.e. the last message from the verifier to the prover and back. Let us denote the protocol's transcript up to the last round by ts. Before the last round, the remaining quantum state of an *honest* prover is the single-qubit state $H^\theta|v\rangle\langle v|H^\theta$ for $v \in \{0, 1\}$. From the transcript and the trapdoor information, the verifier can compute v; in contrast, the prover, who does not know the trapdoor, cannot efficiently compute θ or v. In the last round, the verifier sends θ to the prover, who returns $v' \in \{0, 1\}$; the verifier then checks whether $v' = v$. The honest prover would generate v' by measuring its remaining qubit $H^\theta|v\rangle\langle v|H^\theta$ in the basis θ and therefore always pass the verifier's check.

We can model this last round of the protocol (with a potentially dishonest prover) as follows: at the start, the prover has a state $\sigma^{(\theta,v)}$, which it produced as a result of the previous rounds of the protocol. For an honest prover, $\sigma^{(\theta,v)} = H^\theta|v\rangle\langle v|H^\theta$. Of course, this state can depend on all of ts, but we only make the dependence on θ and v explicit. Upon receiving $\theta \in \{0, 1\}$ the prover measures a binary observable Z (if $\theta = 0$) or X (if $\theta = 1$) and returns the outcome v'. An honest prover would simply use the Pauli observables $Z = \sigma_Z$ and $X = \sigma_X$. The key step in the proof of [24] is to show that, due to the properties of ENTCF families, for any (potentially dishonest) prover that is accepted with high probability, the observables X and Z must anti-commute when acting on the prover's state. Then, Theorem 1 (for $n = 1$) follows from known results [34, 39, 26].

For our parallel RSP protocol we run n independent copies of the protocol from [24] in parallel, except that the basis choice θ_i is the same for each copy.[1] The prover's state before the last round of each copy of the RSP protocol is now denoted by $\sigma^{(\theta,\vec{v})}$, where $\vec{v} \in \{0, 1\}^n$

[1] The advantage of this is that a prover that succeeds with high probability on average over θ must also succeed with high probability for each θ individually. If we were to sample θ independently for each of the parallel copies we could not conclude that a prover succeeds with high probability for any particular choice of $\theta_1, \ldots, \theta_n$ as there are exponentially many such choices.

can be calculated by the verifier from the transcript ts by repeating the same calculation as above for each parallel copy. Generalising from the single-qubit case, given $\theta \in \{0,1\}$ the prover performs a measurement to generate $\vec{v} \in \{0,1\}^n$, which we can describe by binary observables Z_i, X_i (for $\theta = 0, 1$ respectively) that correspond to the observable used to produce the i-th entry of $\vec{v}$. (For an honest prover, $\sigma^{(\theta,\vec{v})} = H^\theta|v_1\rangle\langle v_1|H^\theta \otimes \ldots \otimes H^\theta|v_n\rangle\langle v_n|H^\theta$ and Z_i is a Pauli-Z measurement on the i-th qubit.)

The main challenge in the proof is to establish that the prover must treat all of the parallel copies of the RSP protocol independently, i.e. to show that its (a priori uncharacterised) Hilbert space can be partitioned into n identical subspaces, one for each copy of the protocol. At first sight, it might look as though for this it suffices to show that X_i and Z_j (approximately) commute for all $i \neq j$. However, this is not the case because any such commutation statement can only be shown in a special *state-dependent distance* [47], which does not allow us to combine individual commutation statements into the *global* statement that the Hilbert space factorises into n subspaces. Instead, we need to consider the family $\{Z(\vec{a})X(\vec{b})\}_{\vec{a},\vec{b}\in\{0,1\}^n}$ of 4^n binary observables, where $Z(\vec{a}) = Z_1^{a_1} \cdots Z_n^{a_n}$. We then have to show that $\{Z(\vec{a})X(\vec{b})\}$ form an approximate representation of the Pauli group [26, 48].[2] This means that when acting on the prover's (unknown) state $\sigma^{(\theta)}$ (where $\sigma^{(\theta)}$ is like $\sigma^{(\theta,\vec{v})}$, but averaged over all $\vec{v}$), the operators $\{Z(\vec{a})X(\vec{b})\}$ behave essentially like Pauli operators. Formally, this means showing that on average over $\vec{a}, \vec{b} \in \{0,1\}^n$,

$$\mathrm{Tr}\left[Z(\vec{a})X(\vec{b})Z(\vec{a})X(\vec{b})\sigma^{(\theta)}\right] \approx (-1)^{\vec{a}\cdot\vec{b}}. \tag{2.1}$$

This is the appropriate generalisation of the statement that Z and X anti-commute in the single-qubit case. It is easy to check that Equation (2.1) holds when Z_i and X_i are the Pauli observables.

Our proof of Equation (2.1) has five main steps, which we briefly sketch here with references to the corresponding parts of the formal proof.

(1) Instead of working with the observables X_i, we define "inefficient observables" $\tilde{X}_i = (-1)^{v_i}X_i$, where v_i is the i-th bit of the verifier's string $\vec{v}$. $\tilde{X}_i$ is not an observable that an efficient prover can implement because it depends on v_i, which requires the trapdoor information to be computed efficiently. Intuitively, while X_i describes the prover's answer, $\tilde{X}_i$ describes whether that answer is accepted by the verifier. This has the advantage that the state $\sigma^{(\theta=1)}$ (averaged over $\vec{v}$) of a successful prover is an approximate $+1$-eigenstate of $\tilde{X}_i$, but not of X_i.

(2) We extend the family of states $\{\sigma^{(\theta)}\}_{\theta\in\{0,1\}}$ to a larger family of "counterfactual states" $\{\sigma^{(\vec{\theta})}\}_{\vec{\theta}\in\{0,1\}^n}$, which are defined as the states the prover would have prepared if the verifier had sent keys $k_i \in \mathcal{K}_{\theta_i}$. In Protocol 1 the basis choice is the same for all i, i.e. $\vec{\theta} = \vec{0}$ or $\theta = \vec{1}$, so for other choices of $\vec{\theta}$ these states are never actually prepared. However, they are still well-defined because for any prover in the actual protocol, we can fix that prover's operations (as a quantum circuit acting on a given input) and then consider what state those operations would produce if given keys with an arbitrary basis choice $\vec{\theta}$. The reason these counterfactual states are useful is that we can show that, as a consequence of the properties of ENTCF families, the states $\{\sigma^{(\vec{\theta})}\}_{\vec{\theta}}$ are computationally indistinguishable.

[2] When we say "Pauli group" we always mean the Pauli group modulo complex conjugation, which is also sometimes called the Heisenberg-Weyl group.

(3) We now want to show various commutation and anti-commutation relations for the observables $Z(\vec{a})$ and $\tilde{X}(\vec{b})$. For example, we want to show that Z_i and $\tilde{X}_i$ anti-commute, but Z_i and $\tilde{X}_j$ commute (for $i \neq j$). To show these relations, we make use of the counterfactual states $\sigma^{(\vec{\theta})}$ in the following way: for any particular relation, we can pick a $\vec{\theta}$ that makes showing this relation especially convenient. For example, to show that Z_i and $\tilde{X}_j$ commute, we would choose a $\vec{\theta}$ with $\theta_i = 0$ and $\theta_j = 1$ since the verifier can check the outcomes of "Z-type observables" for $\theta = 0$ and "X-type observables" for $\theta = 1$. Using the properties of ENTCF families, we can argue that the prover's measurements on these counterfactual states still yield outcomes that would pass the verifier's checks for each choice of θ_i. Based on this, we can show the desired relations for a "convenient" choice of counterfactual state $\sigma^{(\vec{\theta})}$. Then, we can relate these statements back to the prover's actual states $\sigma^{(\theta)}$ using the computational indistinguishability of $\{\sigma^{(\vec{\theta})}\}$. This is somewhat delicate because $\tilde{X}_i$ are inefficient.

(4) We can combine the various commutation and anti-commutation statements from the previous step to show that the observables $\{Z(\vec{a})\tilde{X}(\vec{b})\}$ behave like Pauli observables on $\sigma^{(\theta=1)}$, i.e. we show Equation (2.1) but with $\tilde{X}$ instead of X. This step relies on the fact that $\sigma^{(\theta=1)}$ is an approximate $+1$-eigenstate of $\tilde{X}(\vec{b})$ for all $\vec{b}$.

(5) Since we now know that $\{Z(\vec{a})\tilde{X}(\vec{b})\}$ behave essentially like Pauli observables, we can define an explicit isometry $\tilde{V}$ which can be shown to map $\{Z(\vec{a})\tilde{X}(\vec{b})\}$ to the corresponding Pauli observables. This means that we have good control over these inefficient observables, and we know how the inefficient and efficient observables are related. We can use this to define a modified isometry V that maps the efficient observables $\{Z(\vec{a})X(\vec{b})\}$ to the corresponding Pauli observables. This is a stronger version of Equation (2.1) and, combined again with the verifier's checks in the protocol and properties of ENTCF families, can be used to show that the prover must have prepared BB84 states.

We briefly comment on the relation between our soundness proof and that in [36]. At a high level, the soundness proof in [36] also shows a kind of "parallel rigidity" of two executions of a remote state preparation protocol. However, their proof proceeds quite differently from ours: they first show that observables "on the first qubit" anti-commute, which allows them to make a partial statement about the prover's state. This in turn can be used to extend the statement about the prover's observables to two-qubit observables, which is finally used to prove a statement about the prover's two-qubit state. This qubit-by-qubit approach is extremely costly in terms of parameters due to switching back and forth between making partial statements about the observables and state, and cannot reasonably be extended to n qubits. In contrast, we can make a global statement about the prover's 4^n possible observables without first characterising parts of the prover's state. This allows us to prove a parallel rigidity statement for n qubits without an exponential degradation of parameters.

3 Applications

Having introduced our parallel RSP theorem, we can turn to its cryptographic applications. We consider various cryptographic primitives that have previously been defined and constructed in a setting where one party sends random BB84 states to the other. For each primitive, we give a formal definition of the "classical-client version" and show that this definition can be satisfied using our parallel RSP protocol as a building block. Since our parallel RSP protocols relies on the LWE assumption, so do the dequantised protocols we present here. Furthermore, Theorem 1 only guarantees the preparation of BB84 states up to an inverse polynomial error, so as a result, the dequantised protocols only have inverse polynomial security (see Section 5

for a discussion of this point). Some of these primitives have previously been dequantised using an application-specific approach (and similarly relying on computational assumptions) [24, 13, 42, 28, 32]; in contrast, our approach is *generic* and simply uses RSP to replace the sending of BB84 states. We give a short overview of the different applications and refer to the full manuscript for details.

Unclonable quantum encryption. As a first application of our parallel RSP protocol, we consider the notion of *unclonable quantum encryption*. This cryptographic functionality was coined by Gottesman [25] and then formalised by Broadbent and Lord [11]. In a private-key unclonable quantum encryption scheme, a classical message is encrypted into a quantum state (the *quantum ciphertext*) with the following property: given only a single quantum ciphertext, it is impossible to create two states that can later both be decrypted with access to the private key. We consider an unclonable conjugate coding *hybrid encryption* scheme which is inspired by the work of Broadbent and Lord: a plaintext $\vec{m} \in \{0,1\}^n$ is encrypted with a randomly chosen secret key $k = (\vec{s}, \vec{\theta}) \xleftarrow{\$} \{0,1\}^n \times \{0,1\}^n$ and randomness $\vec{v} \xleftarrow{\$} \{0,1\}^n$ into the quantum ciphertext given by $\mathsf{Enc}_k(\vec{m}) = \bigotimes_{i=1}^n H^{\theta_i}|v_i\rangle\langle v_i|H^{\theta_i} \otimes |\vec{v} \oplus \vec{s} \oplus \vec{m}\rangle\langle \vec{v} \oplus \vec{s} \oplus \vec{m}|$. To decrypt using the secret key $k = (\vec{s}, \vec{\theta})$, one applies $H^{\theta_1} \otimes \cdots \otimes H^{\theta_n}$ to the first half of the ciphertext, measures in the computational basis with outcome $\vec{x}$, and then uncomputes the one-time pad in the second half using $\vec{x}$ and $\vec{s}$. The fact that this scheme is unclonable is a consequence of the *monogamy of entanglement* [11, 46].

To dequantise this protocol, we consider a scenario in which a classical client $\mathcal{C}$ wishes to delegate an unclonable ciphertext to a quantum receiver $\mathcal{R}$. As a first step, $\mathcal{C}$ and $\mathcal{R}$ run our parallel RSP protocol to delegate a collection of random BB84 states of the form $H^{\theta_1}|v_1\rangle \otimes \cdots \otimes H^{\theta_n}|v_n\rangle$, where $\vec{v}, \vec{\theta} \in \{0,1\}^n$ are random strings known only to $\mathcal{C}$. Then, $\mathcal{C}$ can choose $\vec{s} \in \{0,1\}^n$ and output the string $\vec{v} \oplus \vec{s} \oplus \vec{m}$ and set $\vec{k} = (\vec{s}, \vec{\theta})$ as the secret key. With this choice of key, the delegated parallel BB84 states are exactly the ciphertext $\mathsf{Enc}_k(\vec{m})$. Because the final output state of the protocol is computationally indistinguishable from a tensor product of BB84 states (known to the client), we can follow a similar proof as in [11] to obtain a classical-client unclonable encryption scheme with inverse-polynomial security.

Quantum copy-protection. In quantum copy-protection (QCP), a vendor wishes to encode a program into a quantum state in a way that enables a recipient to run the program, but not to create functionally equivalent "pirated" copies. The notion of QCP was introduced by Aaronson [1], who gave the first construction for unlearnable and efficiently computable functions in a strong quantum oracle model, which has since been improved to only requiring classical oracles [2]. Recent work [16] has also provided the first construction of QCP for compute-and-compare programs in the quantum random oracle model (QROM) as well as a scheme for multi-bit point functions in the QROM based on unclonable encryption with wrong-key detection (WKD) – a property which enables the decryption procedure to recognise incorrect keys.

Our QCP scheme for multi-bit point functions combines our unclonable hybrid encryption scheme with the generic WKD transformation in the QROM proposed by Coladangelo et al. [16]. The basic idea behind our QCP scheme is as follows. To encode a point function $P_{\vec{y},\vec{m}}$ (which is defined as returning $\vec{m}$ on input $\vec{y}$ and 0^n, otherwise) we simply output $\mathsf{Enc}_{\vec{y}}(\vec{m})$ together with $h(\vec{y})$, where h is a suitable hash function which we model as a truly random function (in the QROM). To evaluate the program on an input $\vec{x} \in \{0,1\}^{2n}$, we first check whether $\vec{x}$ hashes to $h(\vec{y})$ under h. If true, we decrypt as in the aforementioned hybrid encryption scheme and recover $\vec{m}$. Otherwise, we output 0^n.

We then show how to obtain a QCP scheme with a classical client through the use of our parallel RSP protocol for preparing random BB84 states, similar to our aforementioned classical-client unclonable encryption scheme. Our scheme enables a classical client to delegate a correct copy-protected program from the class of multi-bit point functions consisting of uniformly random marked inputs $\vec{y}$ and output strings $\vec{m}$ with inverse-polynomial security.

Quantum computing on encrypted data. Suppose a client wishes to perform some quantum computation, represented as the action of a quantum circuit C on an input state $|x\rangle$, with $x \in \{0,1\}^n$. For simplicity, we will assume the desired output is classical and corresponds to a computational basis measurement of $C|x\rangle$. The client only has limited quantum capability and therefore wishes to delegate the computation to a quantum server while ensuring the privacy of the input $|x\rangle$ and the output resulting from the measurement of $C|x\rangle$. Essentially, the client would like to send the server an encryption of the input and, after performing an interactive protocol, obtain an encryption of the output (which the client can decrypt, but the server cannot)[3]. This primitive is called quantum computing on encrypted data (QCED).

Many protocols for QCED with differing quantum requirements on the client have been developed (see [20] for a survey). Here we will focus on the protocol of Broadbent [8] which achieves QCED with a client that is only required to prepare BB84 states and send them to the server. This makes the protocol well-suited for dequantisation via our parallel RSP protocol. Before explaining this dequantisation, we (informally) define what a QCED protocol *with a classical client* should achieve. As before, the client's input is the string $x \in \{0,1\}^n$ and the goal is to obtain the outcome of measuring $C|x\rangle$ in the computational basis. In contrast to before, this must be achieved using only *classical* interaction with the quantum server. The requirement that the client's input must stay private is captured by the condition that after interacting with the client, it must be computationally intractable for the server to decide which one of two distinct inputs the client used.

Our QCED protocol with a classical client works as follows. The client first performs the parallel RSP protocol with the server, resulting in the preparation of BB84 states (or the client aborting). Provided the protocol succeeded, the client proceeds to run Broadbent's protocol [8] as if the server had received those BB84 states via a quantum channel. The security proof is straightforward. First, we know that after performing RSP the server's state is computationally indistinguishable from a tensor product of BB84 states (known to the client). Furthermore, the interaction in [8] preserves this computational indistinguishability. Hence, the server's state at the end of the protocol is indistinguishable from the state the server would have obtained by executing the protocol with random BB84 states and the security of our protocol follows from [8].

Verifiable delegated blind quantum computation. The final application we consider is verifiable delegated blind quantum computation (VDBQC). VDBQC is an interactive protocol between two parties, in this case denoted as the verifier and the prover. The verifier delegates a computation to the prover and, in addition to ensuring input-output privacy as in QCED, the protocol also ensures that the probability for the verifier to accept an incorrect output is small. In other words, if the prover deviates from the protocol and does not perform the verifier's instructed computation, the verifier should be able to detect this and abort with high probability. As with QCED, a number of such protocols have been developed and we refer the reader to [23] for a survey.

[3] This also allows the client to hide the computation itself from the server by suitably encoding it as part of the input x and taking C to be a *universal circuit*. When the primary goal of the protocol is to hide the computation, it is referred to as a *blind quantum computing protocol* [3, 9].

Here we focus on a protocol by Morimae [38]. This protocol achieves verifiability by combining a protocol for blind quantum computation (or QCED) with the *history state construction*, which is a special encoding of a quantum circuit into a quantum state [31, 30]. In Morimae's protocol, for a given circuit C the verifier uses a QCED protocol to delegate to the prover the preparation of two such history states (one for C and one for the complement of C, where the output qubit is negated). The verifier then requests these states from the prover and proceeds to measure them in the computational or Hadamard basis. This allows the verifier to determine the output of the computation. The history state construction guarantees that malicious behavior on the prover's part would be detected by the verifier's measurement. Additionally, the use of a QCED protocol ensures that the prover is "blind", i.e. does not know which computation the verifier delegated.

To dequantise this protocol, we use our QCED protocol with a classical client to delegate the preparation of the two history states to the quantum prover. We then replace the verifier's measurements on this state by a *measurement protocol* due to Mahadev [33], which allows the classical verifier to delegate these measurements to the prover in a way that forces the prover to report the correct outcomes. We thus obtain a VDBQC protocol with a classical verifier. Crucially, through the use of the classical client QCED protocol and Mahadev's measurement protocol, the prover is "computationally blind", i.e. unable to distinguish which computation the verifier has performed. In contrast, Mahadev's verification protocol [33] does not have this property.[4]

4 Related work

A number recent of works starting with [7, 33] have developed techniques that allow a classical verifier to use post-quantum cryptography to force an untrusted (but computationally bounded) quantum prover to behave in a certain way. Here, we briefly describe these works and explain their relation to our parallel RSP protocol.

In a breakthrough result [33], Mahadev introduced a protocol that allows a classical verifier to delegate a quantum computation to a quantum computer and be able to verify the correctness of the result. The key ingredient for this protocol is a *measurement protocol*, which allows the verifier to securely delegate single-qubit measurements in the standard or Hadamard basis to a quantum prover, assuming that the prover cannot break the LWE assumption. This can then be applied to so-called *prepare-and-measure protocols*: if one has a protocol that involves a quantum prover preparing and sending a quantum state to the verifier and the verifier performing single-qubit measurements on this state, one can use Mahadev's measurement protocol to delegate these quantum measurements to the prover itself. This yields a protocol in which the prover only sends classical measurement outcomes to the verifier, hence making the verifier classical.

This measurement protocol is in many ways similar to what we seek to do in this paper: it removes the need for quantum communication between a fully quantum prover and a verifier with very limited quantum capabilities (only measuring single qubits in the computational or Hadamard basis). The difference to our work is that we are concerned with *prepare-and-send protocols*, in which the verifier sends random BB84 states to the prover instead of receiving them.

[4] In [24], the authors also construct a blind verification protocol based on RSP. However, they approach the problem in a composable framework, which requires them to make an additional assumption on the prover (called the *measurement buffer* in [24]). In contrast, our protocol requires no extra assumptions on the prover. We describe the issue with the measurement buffer assumption in more detail in Section 4.

It turns out that replacing the quantum communication of prepare-and-send protocols requires significantly stronger control over the untrusted prover. At a high level, the reason is the following: for Mahadev's measurement protocol, it suffices to show that *there exists* a quantum state that is consistent with the distribution of measurement outcomes reported by the prover, in the sense that the measurement outcomes for different bases could have been obtained by measurements on (copies of) the same state. In contrast, if we want to replace the step of the verifier sending a physical quantum state to the prover, we need to show that the prover has *actually constructed* a certain quantum state, not just that such a quantum state exists mathematically.[5] We give a more detailed description of what it means to "actually construct" a quantum state in Section 2.1.

The first classical protocol that provably forced a quantum prover to prepare a certain quantum state was the single-qubit RSP protocol of [24] (see also [13] for a related result). This protocol essentially achieves our informal theorem as stated above for a single qubit, i.e. $n = 1$.[6] At first sight, it might seem as though a simple hybrid argument, which replaces each BB84 qubit with a (sequential) instance of [24], suffices to achieve the multi-qubit task. However, the single-qubit RSP protocol of [24] only ensures that each BB84 qubit can be individually replaced by an RSP protocol up to a *global* isometry. Because the prover's state can be entangled in arbitrary ways between intermediate applications of the protocol, it is difficult to justify that all of the individual replacements together form an actual n-qubit BB84 state; as we explain below, the fact that the protocol from [24] is composable does not remedy this situation, either. While some prior work [19] showed that composable *single-qubit* RSP suffices in the context of quantum verification, one would have to show a similar result for each application of interest. Our parallel RSP protocol, in contrast, can be used in a plug-and-play manner for many cryptographic protocols and applications. In addition, our protocol has fewer rounds than a sequential repetition of [24] and also immediately yields a *proof of quantum space* (a certificate that the prover has a certain number of qubits). We give a brief outline of [24] and its soundness proof in Section 2.1.

The main difficulty in going from [24] to our parallel RSP result is enforcing a tensor product structure on the prover's space: we would like to show that, if we execute multiple instances of a single-qubit RSP protocol in parallel, a successful prover must treat each of these copies independently. Mathematically, this means that we need to be able to split the prover's a priori uncharacterised Hilbert space into a *tensor product*, where each tensor factor is supposed to correspond to one instance of the RSP protocol. This is a more demanding version of the classic question of parallel repetition: there, one is interested in showing that any prover's winning probability in the protocol decays in essentially the same way as it would for a prover who executes the instances independently. In contrast, we need to show that the prover really does execute the different instances independently in a physically meaningful sense. We call this stronger requirement *parallel rigidity*.

In [24], the authors show that their protocol has composable security. This may suggest that one can obtain a parallel rigidity statement simply by composing the protocol with itself in sequence or in parallel. However, this is not the case because the composable security

[5] In fact, in [49] it was shown that Mahadev's measurement protocol does ensure that the prover *knows* (in the sense of a proof of knowledge) the state it is measuring, not just that it exists mathematically. The notion of "knowing" a quantum state is quite subtle to define and we forego a detailed description here, but point out that this is weaker than showing that the prover actually constructed the state and (to the best of our knowledge) not sufficient to use Mahadev's protocol for prepare-and-measure scenarios.

[6] The protocol in [24] allows for the qubit to be prepared in one of 10 possible states which includes the 4 BB84 states. Here, we only focus on the 4 BB84 states as this is the case we will deal with in our parallel RSP protocol.

statement in [24] requires an additional assumption called a *measurement buffer*, which effectively acts as a trusted intermediary between the verifier and the prover. A sequential or parallel composition of the protocol in [24] would utilise a different measurement buffer for each instance, thereby forcing the prover to treat the different instances in a (largely) independent way. In particular, this means that one already assumes a tensor product structure with n separate qubits in the prover's space, whereas in our work enforcing this tensor product structure is the key technical challenge. For cryptographic applications, we do not want to place any such assumption on the prover and instead allow the prover to perform arbitrary global operations involving all instances. This is what our parallel RSP protocol achieves. Furthermore, as shown in [4], achieving a composable single-qubit RSP without the measurement buffer is impossible. This means that one cannot hope to achieve parallel RSP by showing a stronger composable version of single-qubit RSP; instead, it is necessary to directly analyse parallel executions of the protocol, as we do in this paper.

The question of parallel rigidity has been studied extensively in the literature on quantum self-testing [17, 14, 39, 40], where one considers a setting of two non-communicating provers. Unfortunately, those techniques are not immediately transferable to the setting we consider here, namely a single computationally bounded prover.

Some progress towards the question of parallel rigidity for single computationally bounded provers was made in [36], which gives a protocol that allows a classical verifier to certify that a quantum prover must have prepared and measured a Bell state, i.e. an entangled 2-qubit quantum state. This has since been applied to device-independent quantum key distribution [35] and oblivious transfer [12], and been extended to work for magic states [37]. The protocol from [36] uses a 2-fold parallel repetition of [24] (with additional steps to allow for the certification of an entangled state, not just product states). As part of their soundness proof, [36] do show a kind of parallel rigidity result for 2 instances of the RSP protocol. However, their method does not generalise to an n-fold parallel repetition without an exponential decay in parameters. Hence, for our n-fold parallel rigidity proof, new techniques are needed. A more detailed comparison between our new parallel rigidity proof and the method in [36] can be found at the end of Section 2.1. We note that in independent concurrent work, [21] also gave an n-fold parallel rigidity proof in the computational setting, but the class of states they deal with is different from random BB84 pairs and they do not consider the dequantisation of cryptographic protocols.

In addition to this line of work focused on rigidity statements, application-specific dequantisations were already considered for private-key quantum money [22, 42], certifiable deletion of quantum encryption [28] and secure software leasing [32]. In all these cases the authors derived the desired security statement from properties of trapdoor claw-free functions, a cryptographic primitive which is also the basis of our RSP protocol. While this is less generic and modular than our approach and requires a new analysis for each application, it does have the advantage that one can obtain *negligible* security, whereas with RSP we obtain inverse polynomial security. We comment more on the possibility of negligible security from RSP-like primitives in Section 5.

5 Discussion

We have shown how a classical verifier can certify a tensor product of BB84 states in the memory of a quantum prover, assuming the quantum-intractability of the LWE problem. Importantly, the prover does not know which BB84 states it has prepared, whereas the verifier does. Hence, the result at the end of the protocol is as if the verifier had sent random

BB84 states to the prover. This allows us to dequantise a number of quantum cryptographic primitives, yielding a generic and modular way of translating these protocols to a setting where only classical communication is used. We have demonstrated the versatility of this approach by applying it to unclonable encryption, quantum copy-protection, computing on encrypted data, and blind verification. Naturally, we expect that other primitives that rely on BB84 states can also be dequantised using our approach. Examples of this include quantum encryption with certified deletion [10, 41] and private key quantum money [50, 42]. We leave these and other applications to future work.

Apart from applying our technique to dequantise additional cryptographic primitives, our work raises a number of further open problems. Firstly, while our RSP primitive is based on the hardness of LWE, we can ask whether it is possible to achieve this functionality from weaker computational assumptions. For instance, would it be possible to perform an RSP-like protocol assuming only the existence of quantum-secure one-way functions? This is of particular interest because recent results have shown that secure two-party computation can be achieved from one-way functions and quantum communication [5, 27]. These results are based on the fact that an oblivious-transfer protocol can be implemented from one-way functions and quantum communication that consists of BB84 states. However, an RSP primitive like ours would allow one to generically dequantise that quantum communication. Hence if RSP (with sufficiently strong parameters) can be obtained from quantum-secure one-way functions, then secure two-party computation can also be obtained from those functions, together with classical communication. In light of earlier work [29, 45] we conjecture that this is impossible. Formalising this intuition could lead to a better understanding of the minimum assumptions required for performing RSP-like protocols.

Secondly, a more technical open problem concerns the parameters of our rigidity theorem, Theorem 1. As stated above, provided the prover accepts, the state the verifier certifies is $1/\operatorname{poly}(n)$-close to a tensor product of n BB84 states (up to an isometry). The $1/\operatorname{poly}(n)$ closeness means that the soundness error of our dequantised protocols also scales as $1/\operatorname{poly}(n)$. It would be desirable to achieve *negligible* soundness error, particularly when considering composable instances of these protocols. This is not possible with the approach taken in this paper as the statistical argument used in deriving our main theorem will necessarily introduce $1/\operatorname{poly}(n)$ factors. However, it might be possible to circumvent an explicit RSP statement: the advantage of the RSP statement in our paper is that one can use it to dequantise existing protocols easily, but these existing protocols typically only use BB84 states because of their no-cloning properties. Therefore, instead of using an RSP protocol to prepare those states, one could instead try to show a "post-quantum cryptographic no-cloning property" directly that could plausibly be used to dequantise these protocols while preserving negligible soundness.

Finally, we mention that our derivation of the parameters in the rigidity theorem is likely not optimal and could be optimised to improve the efficiency of our protocol. The situation here is similar to that of parallel self-testing in the multi-prover setting, with the first works having round complexity that scaled as a high-degree polynomial [44] and more recent works achieving quasilinear scaling [39, 15]. It would be interesting to see whether ideas from these newer works are also applicable in the setting of parallel remote state preparation.

Parameterised and Fine-Grained Subgraph Counting, Modulo 2*

Leslie Ann Goldberg
Department of Computer Science, University of Oxford, UK

Marc Roth
Department of Computer Science, University of Oxford, UK

Abstract

Given a class of graphs $\mathcal{H}$, the problem $\oplus\textsc{Sub}(\mathcal{H})$ is defined as follows. The input is a graph $H \in \mathcal{H}$ together with an arbitrary graph G. The problem is to compute, modulo 2, the number of subgraphs of G that are isomorphic to H. The goal of this research is to determine for which classes $\mathcal{H}$ the problem $\oplus\textsc{Sub}(\mathcal{H})$ is fixed-parameter tractable (FPT), i.e., solvable in time $f(|H|) \cdot |G|^{O(1)}$.

Curticapean, Dell, and Husfeldt (ESA 2021) conjectured that $\oplus\textsc{Sub}(\mathcal{H})$ is FPT if and only if the class of allowed patterns $\mathcal{H}$ is *matching splittable*, which means that for some fixed B, every $H \in \mathcal{H}$ can be turned into a matching (a graph in which every vertex has degree at most 1) by removing at most B vertices.

Assuming the randomised Exponential Time Hypothesis, we prove their conjecture for (I) all hereditary pattern classes $\mathcal{H}$, and (II) all tree pattern classes, i.e., all classes $\mathcal{H}$ such that every $H \in \mathcal{H}$ is a tree. We also establish almost tight fine-grained upper and lower bounds for the case of hereditary patterns (I).

1 Introduction

The last two decades have seen remarkable progress in the classification of subgraph counting problems: Given a small *pattern* graph H and a large *host* graph G, how often does H occur as a subgraph if G? Since it was discovered that subgraph counts from small patterns reveal global properties of complex networks [26, 27], subgraph counting has also found several applications in fields such as biology [2, 30] genetics [32], phylogeny [25], and data mining [33]. Moreover, the theoretical study of subgraph counting and related problems has led to many deep structural insights, establishing both new algorithmic techniques and tight lower bounds under the lenses of fine-grained and parameterised complexity theory [19, 16, 10, 14, 13, 6, 4].

* For the purpose of Open Access, the authors have applied a CC BY public copyright licence to any Author Accepted Manuscript version arising from this submission. All data is provided in full in the results section of this paper.

Without any additional restrictions, the subgraph counting problem is infeasible. The complexity class #W[1] is the parameterised complexity class analogous to NP (see Section 2 for more detail). Under standard assumptions, problems that are #W[1]-hard are not *fixed-parameter tractable* (FPT). The canonical complete problem for #W[1], the problem of counting k-cliques, corresponds to the special case of the subgraph counting problem where H is a clique of size k. This problem cannot be solved in time $f(k) \cdot n^{o(k)}$ for any function f unless the Exponential Time Hypothesis (ETH) fails [8, 9]. Due to this hardness result, the research focus in this area shifted to the question: Under which restrictions on the patterns H and the hosts G is algorithmic progress possible? More precisely, under which restrictions can the problem be solved in time $f(|H|) \cdot |G|^{O(1)}$, for some computable function f? Instances that can be solved within such a run time bound are called *fixed-parameter tractable* (FPT); allowing a potential super-polynomial overhead in the size of the pattern $|H|$ formalises the assumption that H is assumed to be (significantly) smaller than G.

If only the patterns are restricted, then the situation is fully understood. Formally, given a class $\mathcal{H}$ of patterns, the problem #Sub($\mathcal{H}$) asks, given as input a graph $H \in \mathcal{H}$ and an arbitrary graph G, to compute the number of subgraphs of G that are isomorphic to H. Following initial work by Flum and Grohe [19] and by Curticapean [11], Curticapean and Marx [14] proved that, under standard assumptions, #Sub($\mathcal{H}$) is FPT if and only if $\mathcal{H}$ has bounded matching number, that is, if there is a positive integer B such that the size of any matching in any graph in $\mathcal{H}$ is at most B. They also proved that all FPT cases are polynomial-time solvable.

In stark contrast, almost nothing is known for the decision version Sub($\mathcal{H}$). Here, the task is to correctly decide whether there is a copy of $H \in \mathcal{H}$ in G, rather than to count the copies. It is known that Sub($\mathcal{H}$) is FPT whenever $\mathcal{H}$ has bounded treewidth (see e.g. [20, Chapter 13]), and it is conjectured that those are all FPT cases. However, resolving this conjecture belongs to the "most infamous" open problems in parameterised complexity theory [18, Chapter 33.1].

1.1 Counting Modulo 2

To interpolate between the fully understood realm of (exact) counting and the barely understood realm of decision, Curticapean, Dell and Husfeldt proposed the study of counting subgraphs, modulo 2 [12]. Formally, they introduced the problem $\oplus$Sub($\mathcal{H}$), which expects as input a graph $H \in \mathcal{H}$ and an arbitrary graph G, and the goal is to compute *modulo 2* the number of subgraphs of G isomorphic to H.

The study of counting modulo 2 received significant attention from the viewpoint of classical, structural, and fine-grained complexity theory. For example, one way to state Toda's Theorem [31] is PH $\subseteq$ $\mathrm{P}^{\oplus\mathrm{P}}$, implying that counting satisfying assignments of a CNF, modulo 2, is at least as hard as the polynomial hierarchy. Another example is the quest to classify the complexity of counting modulo 2 the homomorphisms to a fixed graph, which was very recently resolved by Bulatov and Kazeminia [7]. There has also been work by Abboud, Feller, and Weimann [1] on the fine-grained complexity of counting modulo 2 the number of triangles in a graph that satisfy certain weight constraints.

In their work [12], Curticapean, Dell and Husfeldt proved that the problem of counting k-matchings modulo 2, that is, the problem $\oplus$Sub($\mathcal{H}$) where $\mathcal{H}$ is the class of all 1-regular graphs, is fixed-parameter tractable, where the parameter k is $|H|$. Since the exact counting version of this problem is #W[1]-hard [11], their result provides an example where counting modulo 2 is *strictly* easier than exact counting (subject to complexity assumptions). The complexity class $\oplus$W[1] can be defined via the complete problem of counting k-cliques

modulo 2. Crucially, $\oplus$W[1]-hard problems are not fixed-parameter tractable, unless the randomised ETH (rETH) fails. Curticapean et al. [12] proved that counting k-paths modulo 2 is $\oplus$W[1]-hard. Since *finding* a k-path in a graph G is fixed-parameter tractable via colour-coding [3], this hardness result provides an example where counting modulo 2 is *strictly* harder than decision (subject to complexity assumptions). Combining those observations, it appears that counting subgraphs modulo 2 may lie strictly in between the complexity of decision and the complexity of exact counting.

A *matching* is a graph whose maximum degree is at most 1. The *matching-split number* of a graph H is the minimum size of a set $S \subseteq V(H)$ such that $H \setminus S$ is a matching. A class of graphs $\mathcal{H}$ is called *matching splittable* if there is a positive integer B such that the matching-split number of any $H \in \mathcal{H}$ is at most B. For example, the class of all matchings is matching splittable while the class of all cycles is not. Curticapean, Dell and Husfeldt extended their FTP algorithm for counting k-matchings modulo 2 to obtain an FPT algorithm for $\oplus\textsc{Sub}(\mathcal{H})$ for any matching-splittable class $\mathcal{H}$. On this basis, they then made the following conjecture.

▶ **Conjecture 1** ([12]). *$\oplus\textsc{Sub}(\mathcal{H})$ is FPT if and only if $\mathcal{H}$ is matching splittable.*

A class $\mathcal{H}$ of graphs is called *hereditary* if it is closed under vertex removal. Intriguingly, if Conjecture 1 is true, then the FPT criterion for counting subgraphs modulo 2 ($\oplus\textsc{Sub}(\mathcal{H})$) would coincide with the polynomial-time criterion for finding subgraphs ($\textsc{Sub}(\mathcal{H})$) for hereditary pattern classes $\mathcal{H}$ as established by Jansen and Marx.

▶ **Theorem 2** ([24]). *Let $\mathcal{H}$ be a hereditary class of graphs and assume* P $\neq$ NP. *Then $\textsc{Sub}(\mathcal{H})$ is solvable in polynomial time if and only if $\mathcal{H}$ is matching splittable.*

Jansen and Marx also conjecture that the condition of $\mathcal{H}$ being hereditary can be removed.

▶ **Conjecture 3** ([24]). *$\textsc{Sub}(\mathcal{H})$ is solvable in polynomial time if and only if $\mathcal{H}$ is matching splittable.*

Conjectures 1 and 3 have the remarkable consequence that $\oplus\textsc{Sub}(\mathcal{H})$ is FPT if and only if $\textsc{Sub}(\mathcal{H})$ is solvable in polynomial time. In the current work we establish this consequence for all hereditary pattern classes.

1.2 Our Contributions

We resolve Conjecture 1 for all hereditary classes $\mathcal{H}$, as well as for every class $\mathcal{H}$ consisting only of trees; note that the upper bounds were shown in [12] and that the lower bounds are the novel part.

▶ **Theorem 4.** *Let $\mathcal{H}$ be a hereditary class of graphs. If $\mathcal{H}$ is matching splittable, then $\oplus\textsc{Sub}(\mathcal{H})$ is fixed-parameter tractable. Otherwise, the problem is $\oplus$W[1]-complete and, assuming rETH, cannot be solved in time $f(|H|) \cdot |G|^{o(|V(H)|/\log|V(H)|)}$ for any function f.*

▶ **Theorem 5.** *Let $\mathcal{T}$ be a recursively enumerable class of trees. If $\mathcal{T}$ is matching splittable, then $\oplus\textsc{Sub}(\mathcal{T})$ is fixed-parameter tractable. Otherwise $\oplus\textsc{Sub}(\mathcal{T})$ is $\oplus$W[1]-complete.*

The requirement that the class of trees $\mathcal{T}$ needs to be recursively enumerable is a standard technicality - the reason for it is that the function f in the running time in the standard definition of an FPT algorithm is required to be computable. It turns out that having $\mathcal{T}$ recursively enumerable is enough for this.

In order to prove our classifications, we adapt the by-now-standard technique for analysing subgraph counting problems established by Curticapean, Dell and Marx [13]. Let $\#\mathsf{Sub}(H \to G)$ denote the number of subgraphs of a graph G that are isomorphic to a

graph H and let $\#\mathsf{Hom}(F \to G)$ denotes the number of homomorphisms (edge-preserving mappings) from a graph F to a graph G. Given a graph H, there is a function a_H from graphs to rationals with finite support such that the following holds for any graph G:

$$\#\mathsf{Sub}(H \to G) = \sum_F a_H(F) \cdot \#\mathsf{Hom}(F \to G)\,, \tag{1}$$

where the sum is over all (isomorphism types of) graphs. Since a_H has finite support, $a_H(F) = 0$ for all but finitely-many graphs F. Thus, equation (1) allows us to express the solution to the *exact* counting problem as a finite linear combination of homomorphism counts. In a nutshell, the framework of [13] states that computing the function $G \mapsto \#\mathsf{Sub}(H \to G)$ is hard to compute if and only if there is a graph F of high treewidth with $a_H(F) \neq 0$. This translates the complexity of (exact) subgraph counting to the purely combinatorial problem of understanding the coefficients a_H. One might hope that this strategy transfers to counting modulo 2 as well. Unfortunately, this is not possible as Equation (1) might not be well-defined if arithmetic is done modulo 2. The reason for this is the fact that the coefficients $a_H(F)$ are of the form $\mu(F,H) \times |\mathsf{Aut}(H)|^{-1}$, where $\mu(F,H)$ is an integer, and $\mathsf{Aut}(H)$ is the automorphism group of the graph H [13]. Thus there is, a priori, no hope to extend the framework to counting modulo 2 for pattern graphs with an even number of automorphisms. In fact, according to Curticapean, Dell and Husfeldt [12], the absence of a comparable framework for counting modulo 2 is one of the main challenges for establishing the hardness part of Conjecture 1, and it is the main reason why the reductions in [12] use more classical, gadget-based reductions.

In this work, we solve the problem of patterns with an even number of automorphisms by considering a colourful intermediate problem. More concretely, we will equip each edge of the pattern H with a distinct colour and show that it will be sufficient to consider only automorphisms that preserve the colours. If H has no isolated vertices, then this is only the trivial automorphism. Formally, the coloured approach will be based on the notion of so-called *fractured* graphs introduced by Peyerimhoff et al. [29].

In what follows (Section 2), we will first introduced all required notions and previous results. In Section 3, we will prove the classification for hereditary pattern classes (Theorem 4). On a technical level, this proof can be considered a warm-up for the significantly harder challenge of establishing the classification for trees (Theorem 5), which we defer to the full version due to the space constraints.

2 Preliminaries

Let $f : A_1 \times A_2 \to B$ be a function. For each $a_1 \in A_1$ we write $f(a_1, \star) : A_2 \to B$ for the function that maps $a_2 \in A_2$ to $f(a_1, a_2)$.

Graphs in this work are undirected and without self loops. A *homomorphism* from a graph H to a graph G is a mapping φ from the vertices $V(H)$ of H to the vertices $V(G)$ of G such that for each edge $e = \{u, v\} \in E(H)$ of H, the image $\varphi(e) = \{\varphi(u), \varphi(v)\}$ is an edge of G. A homomorphism is called an *embedding* if it is injective. We write $\mathsf{Hom}(H \to G)$ and $\mathsf{Emb}(H \to G)$ for the sets of homomorphisms and embeddings, respectively, from H to G. An embedding $\varphi \in \mathsf{Emb}(H \to G)$ is called an *isomorphism* if it is bijective and $\{u, v\} \in E(H) \Leftrightarrow \{\varphi(u), \varphi(v)\} \in E(G)$. We say that H and G are *isomorphic*, denoted by $H \cong G$, if an isomorphism from H to G exists. A *graph invariant* ι is a function from graphs to rationals such that $\iota(H) = \iota(G)$ for each pair of isomorphic graphs H and G.

A *subgraph* of G is a graph G' with $V(G') \subseteq V(G)$ and $E(G') \subseteq E(G)$. We write $\mathsf{Sub}(H \to G)$ for the set of all subgraphs of G that are isomorphic to H. Given a subset of vertices $S \subseteq V(G)$ of a graph G, we write $G[S]$ for the graph induced by S, that is, $G[S]$ has vertices S and edges $\{\{u,v\} \subseteq S \mid \{u,v\} \in E(G)\}$.

We denote by $\mathsf{tw}(G)$ the *treewidth* of the graph G. Since we will rely on treewidth purely in a black-box manner, we omit the technical definition and refer the reader to [15, Chapter 7].

Given any graph invariant ι (such as treewidth) and a class of graphs $\mathcal{G}$, we say that ι is *bounded* in $\mathcal{G}$ if there is a non-negative integer B such that, for all $G \in \mathcal{G}$, $\iota(G) \leq B$. Otherwise we say that ι is *unbounded* in $\mathcal{G}$.

Given a graph $H = (V, E)$, a *splitting set* of H is a subset of vertices S such that every vertex in $H[V \setminus S]$ has degree at most 1. The *matching-split number* of H is the minimum size of a splitting set of H. A class of graphs $\mathcal{H}$ is called *matching splittable* if the matching-split number of $\mathcal{H}$ is bounded.

2.1 Colour-Preserving Homomorphisms and Embeddings

A homomorphism c from a graph G to a graph Q is sometimes called a "Q-colouring" of G. A *Q-coloured* graph is a pair consisting of a graph G and a homomorphism c from G to Q. Note that the identity function id_Q on $V(Q)$ is a Q-colouring of Q. If a homomorphism c from G to Q is vertex surjective, then we call (G, c) a *surjectively* Q-coloured graph.

▶ **Definition 6** (c_{E}). *A Q-colouring c of a graph G induces a (not necessarily proper) edge-colouring $c_E\colon E(G) \to E(Q)$ given by $c_E(\{u,v\}) = \{c(u), c(v)\}$.*

Notation. Given a Q-coloured graph (G, c) and a vertex $u \in V(Q)$, we will use the capitalised letter U to denote the subset of vertices of G that are coloured by c with u, that is, $U := c^{-1}(u) \subseteq V(G)$.

Given two Q-coloured graphs (H, c_H) and (G, c_G), we call a homomorphism φ from H to G *colour-preserving* if for each $v \in V(H)$ we have $c_G(\varphi(v)) = c_H(v)$. We note the special case in which $Q = H$ and c_H is the identity id_Q; then the condition simplifies to $c_G(\varphi(v)) = v$. A colour-preserving embedding of (H, c_H) in (G, c_G) is a vertex injective colour-preserving homomorphism from (H, c_H) to (G, c_G). We write $\mathsf{Hom}((H, c_H) \to (G, c_G))$ and $\mathsf{Emb}((H, c_H) \to (G, c_G))$ for the sets of all colour-preserving homomorphisms and embeddings, respectively, from (H, c_H) to (G, c_G).

Let k be a positive integer, let H be a graph with k edges, and let (G, γ) be a pair consisting of a graph G and a function that maps each edge of G to one of k distinct colours. We refer to γ as a "k-edge colouring" of G. For example, in most of our applications we will fix a graph Q with k edges and a Q-colouring c of G and we will take γ to be the edge-colouring c_E from Definition 6. We write $\mathsf{ColSub}(H \to (G, \gamma))$ for the set of all subgraphs of G that are isomorphic to H and that contain each of the k edge colours precisely once.

2.2 Fractures and Fractured Graphs

In this work, we will crucially rely on and extend the framework of *fractured* graphs as introduced in [29].

▶ **Definition 7** (Fractures). *Let Q be a graph. For each vertex v of Q, let $E_Q(v)$ be the set of edges of Q that are incident to v. A* fracture *of Q is a tuple $\rho = (\rho_v)_{v \in V(Q)}$, where for each vertex v of Q, ρ_v is a partition of $E_Q(v)$.*

Figure 1 Illustration of the construction of a fractured graph from [29]. The left picture shows a vertex v of a graph Q with incident edges $E_Q(v) = \{\bullet, \bullet, \bullet, \bullet, \bullet, \bullet\}$. The right picture shows the splitting of v in the construction of the fractured graph $Q\sharp\sigma$ for a fracture σ satisfying that the partition σ_v contains two blocks $B_1 = \{\bullet, \bullet, \bullet\}$, and $B_2 = \{\bullet, \bullet, \bullet\}$.

Note that a fracture describes how to split (or how to *fracture*) each vertex of a given graph: for each vertex v, create a vertex v^B for each block B in the partition ρ_v; edges originally incident to v are made incident to v^B if and only if they are contained in B. We call the resulting graph the *fractured graph* $H\sharp\rho$; a formal definition is given in Definition 8, a visualisation is given in Figure 1.

▶ **Definition 8** (Fractured Graph $Q\sharp\rho$)**.** *Given a graph Q, we consider the matching M_Q containing one edge for each edge of Q; formally,*

$$V(M_Q) := \bigcup_{e=\{u,v\}\in E(Q)} \{u_e, v_e\} \quad \text{and} \quad E(M_Q) := \{\{u_e, v_e\} \mid e = \{u, v\} \in E(Q)\}.$$

For a fracture ρ of Q, we define the graph $Q\sharp\rho$ to be the quotient graph of M_Q under the equivalence relation on $V(M_Q)$ which identifies two vertices v_e, w_f of M_Q if and only if $v = w$ and e, f are in the same block B of the partition ρ_v of $E_Q(v)$. We write v^B for the vertex of $Q\sharp\rho$ given by the equivalence class of the vertices v_e (for which $e \in B$) of M_Q.

▶ **Definition 9** (Canonical Q-colouring c_ρ)**.** *Let Q be a graph and let ρ be a fracture of Q. The* canonical Q-colouring *of the fractured graph $Q\sharp\rho$ maps v^B to v for each $v \in V(Q)$ and block $B \in \rho_v$, and is denoted by c_ρ.*

Observe that c_ρ is the identity in $V(Q)$ if ρ is the coarsest fracture (that is, each partition ρ_v only contains one block, in which case $Q\sharp\rho = Q$).

2.3 Parameterised and Fine-grained Computation

A *parameterised computational problem* is a pair consisting of a function $P : \Sigma^* \to \{0, 1\}$ and a computable parameterisation $\kappa : \Sigma^* \to \mathbb{N}$. A *fixed-parameter tractable* (FPT) *algorithm* for (P, κ) is an algorithm that computes P and runs, on input $x \in \Sigma^*$, in time $f(\kappa(x)) \cdot |x|^{O(1)}$ for some computable function f. We call (P, κ) *fixed-parameter tractable* (FPT) if an FPT algorithm for (P, κ) exists.

A parameterised Turing-reduction from (P, κ) to (P', κ') is an FPT algorithm for (P, κ) that is equipped with oracle access to P' and for which there is a computable function g such that, on input x, each oracle query y satisfies $\kappa'(y) \leq g(\kappa(x))$. We write $(P, \kappa) \leq_{\mathrm{T}}^{\mathrm{fpt}} (P', \kappa')$ if a parameterised Turing-reduction from (P, κ) to (P', κ') exists. This guarantees that fixed-parameter tractability of (P', κ') implies fixed-parameter tractability of (P, κ). For a more comprehensive introduction, we refer the reader the standard textbooks [15] and [20].

Counting modulo 2 and the rETH

The lower bounds in this work will rely on the hardness of the parameterised complexity class $\oplus\mathsf{W}[1]$, which can be considered a parameterised equivalent of $\oplus\mathsf{P}$. Following [12], we define $\oplus\mathsf{W}[1]$ via the complete problem $\oplus$Clique: Given as input a graph G and a positive integer k, the goal is to compute the number of k-cliques in G modulo 2, i.e., to compute $\oplus\mathsf{Sub}(K_k \to G)$. The problem is parameterised by k. A parameterised problem (P, κ) is called $\oplus\mathsf{W}[1]$-*hard* if $\oplus$Clique $\leq_{\mathrm{T}}^{\mathrm{fpt}} (P, \kappa)$, and it is called $\oplus\mathsf{W}[1]$-*complete* if, additionally, $(P, \kappa) \leq_{\mathrm{T}}^{\mathrm{fpt}} \oplus$Clique.

Modifications of the classical Isolation Lemma (see e.g. [5] and [34]) yield a *randomised* parameterised Turing reduction from finding a k-clique to computing the parity of the number of k-cliques. In combination with existing fine-grained lower bounds for finding a k-clique [8, 9], it can then be shown that $\oplus$Clique cannot be solved in time $f(k) \cdot |G|^{o(k)}$ for any function f, unless the randomised Exponential Time Hypothesis fails:

▶ **Definition 10** (rETH, [23]). *The* randomised Exponential Time Hypothesis *(rETH) asserts that 3-SAT cannot be solved by a randomised algorithm in time* $\exp o(n)$*, where n is the number of variables of the input formula.*

As an immediate consequence, the rETH implies that $\oplus\mathsf{W}[1]$-hard problems are not fixed-parameter tractable.

For the lower bounds in this work, we won't reduce from $\oplus$Clique directly, but instead from the following, more general problem:

▶ **Definition 11** ($\oplus$cp-Hom). *Let $\mathcal{H}$ be a class of graphs. The problem $\oplus$cp-Hom($\mathcal{H}$) has as input a graph $H \in \mathcal{H}$ and a surjectively H-coloured graph (G, c). The goal is to compute $\oplus\mathsf{Hom}((H, \mathsf{id}_H) \to (G, c))$. The problem is parameterised by $|H|$.*

The following lower bound was proved independently in [28, 29] and [12].

▶ **Theorem 12.** *Let $\mathcal{H}$ be a recursively enumerable class of graphs. If the treewidth of $\mathcal{H}$ is unbounded then $\oplus$cp-Hom($\mathcal{H}$) is $\oplus\mathsf{W}[1]$-hard and, assuming the rETH, it cannot be solved in time $f(|H|) \cdot |G|^{o(\mathsf{tw}(H)/\log \mathsf{tw}(H))}$ for any function f.*

Next is the central problem in this work.

▶ **Definition 13** ($\oplus$Sub). *Let $\mathcal{H}$ be a class of graphs. The problem $\oplus$Sub($\mathcal{H}$) has as input a graph $H \in \mathcal{H}$ and a graph G. The goal is to compute $\oplus\mathsf{Sub}(H \to G)$. The problem is parameterised by $|H|$.*

For example, writing $\mathcal{K}$ for the set of all complete graphs, the problem $\oplus$Sub($\mathcal{K}$) is equivalent to $\oplus$Clique.

Complexity Monotonicity and Inclusion-Exclusion

Throughout this work, we will rely on two important tools introduced in [29]. For the sake of being self-contained, we encapsulate them below in individual lemmas.

The first tool is an adaptation of the so-called Complexity Monotonicity principle to the realm of fractured graphs and modular counting (see [29, Sections 4.1 and 6.3] for a detailed treatment and for a proof). Intuitively, the subsequent lemma states that evaluating, modulo 2, a linear combination of colour-prescribed homomorphism counts from fractured graphs, is as hard as evaluating its hardest term with an odd coefficient.

▶ **Lemma 14** ([29]). *There is a deterministic algorithm $\mathbb{A}$ and a computable function f such that the following conditions are satisfied:*

1. *$\mathbb{A}$ expects as input a graph Q and a Q-coloured graph (G, c).*
2. *$\mathbb{A}$ is equipped with oracle access to a function*

$$(G', c') \mapsto \sum_{\rho} a(\rho) \cdot \oplus\mathsf{Hom}((Q\sharp\rho, c_\rho) \to (G', c')) \mod 2\,,$$

   where the sum is over all fractures of Q and a is a function from fractures of Q to integers.
3. *Each oracle query (G', c') is of size at most $f(|Q|) \cdot |G|$.*
4. *$\mathbb{A}$ computes $\oplus\mathsf{Hom}((Q\sharp\rho, c_\rho) \to (G, c))$ for each fracture ρ with $a(\rho) \neq 0 \mod 2$.*
5. *The running time of $\mathbb{A}$ is bounded by $f(|Q|) \cdot |G|^{O(1)}$.*

The second tool is a standard application of the inclusion-exclusion principle (see e.g. [29, Sections 4.2 and 6.3]). It will be used in the final steps of our reductions to remove the colourings.

▶ **Lemma 15** ([29]). *There is a deterministic algorithm $\mathbb{A}$ that satisfies the following conditions:*

1. *$\mathbb{A}$ expects as input a graph H with k edges, a graph G and a k-edge colouring γ of G.*
2. *$\mathbb{A}$ is equipped with oracle access to the function $\oplus\mathsf{Sub}(H \to \star)$, and each oracle query G' satisfies $|G'| \leq |G|$.*
3. *$\mathbb{A}$ computes $\oplus\mathsf{ColSub}(H \to (G, \gamma))$.*
4. *The running time of $\mathbb{A}$ is bounded by $2^{|H|} \cdot |G|^{O(1)}$.*

3 Classification for Hereditary Graph Classes

In this section, we will completely classify the complexity of $\oplus\textsc{Sub}(\mathcal{H})$ for hereditary classes. Let us start by restating the classification theorem.

▶ **Theorem 4.** *Let $\mathcal{H}$ be a hereditary class of graphs. If $\mathcal{H}$ is matching splittable, then $\oplus\textsc{Sub}(\mathcal{H})$ is fixed-parameter tractable. Otherwise, the problem is $\oplus\mathsf{W}[1]$-complete and, assuming rETH, cannot be solved in time $f(|H|) \cdot |G|^{o(|V(H)|/\log|V(H)|)}$ for any function f.*

The proof of Theorem 4 is split in four cases, which stem from a structural property of non matching splittable hereditary graph classes $\mathcal{H}$ due to Jansen and Marx [24]. For the statement, we need to consider the following classes:

- $\mathcal{F}_\omega$ is the class of all complete graphs.
- $\mathcal{F}_\beta$ is the class of all complete bipartite graphs.
- $\mathcal{F}_{P_2}$ is the class of all P_2-packings, that is, disjoint unions of paths with two edges.[1]
- $\mathcal{F}_{K_3}$ is the class of all triangle packings, that is, disjoint unions of the complete graph of size 3.

▶ **Theorem 16** (Theorem 3.5 in [24]). *Let $\mathcal{H}$ be a hereditary class of graphs. If $\mathcal{H}$ is not matching splittable then at least one of the following are true: (1.) $\mathcal{F}_\omega \subseteq \mathcal{H}$, (2.) $\mathcal{F}_\beta \subseteq \mathcal{H}$, (3.) $\mathcal{F}_{P_2} \subseteq \mathcal{H}$, or (4.) $\mathcal{F}_{K_3} \subseteq \mathcal{H}$.*

[1] To avoid confusion, we remark that [24] uses P_3 to denote the path of two edges (and three vertices). In the current work, it will be more convenient to use the number of edges of a path as index.

Thus, it suffices to consider cases 1.–4. to prove Theorem 4. We start with the easy cases of cliques and bicliques; they follow implicitly from previous works [12, 17, 28] and we only include a proof for completeness. Note that a tight bound under rETH is known for those cases:

▶ **Lemma 17.** *Let $\mathcal{H}$ be a hereditary class of graphs. If $\mathcal{F}_\omega \subseteq \mathcal{H}$ or $\mathcal{F}_\beta \subseteq \mathcal{H}$ then $\oplus\text{Sub}(\mathcal{H})$ is $\oplus\mathsf{W}[1]$-hard and, assuming rETH, cannot be solved in time $f(|H|) \cdot |G|^{o(|V(H)|)}$ for any function f.*

Proof. If $\mathcal{F}_\omega \subseteq \mathcal{H}$ then $\oplus\mathsf{W}[1]$-hardness follows immediately from the fact that $\oplus\text{Clique}$ is the canonical $\oplus\mathsf{W}[1]$-complete problem [12]. For the rETH lower bound, we can reduce from the problem of *deciding* the existence of a k-clique via a (randomised) reduction using a version of the Isolation Lemma due to Williams et al. [34, Lemma 2.1]. This reduction does not increase k or the size of the host graph and is thus tight with respect to the well-known lower bound for the clique problem due to Chen et al. [8, 9]: Deciding the existence of a k-clique in an n-vertex graph cannot be done in time $f(k) \cdot n^{o(k)}$ for any function f, unless ETH fails. Our lower bound under rETH follows since the reduction is randomised.

If $\mathcal{F}_\beta \subseteq \mathcal{H}$, then the claim holds by [17, Theorem 5], which established the problem of counting, modulo 2, the induced copies of a k-by-k-biclique in an n-vertex bipartite graph to be $\oplus\mathsf{W}[1]$-hard and not solvable in time $f(k) \cdot n^{o(k)}$ for any function f, unless rETH fails. Since a copy of a biclique (with at least one edge) in a bipartite graph must always be induced, the claim follows. This concludes the proof of Lemma 17. ◀

The more interesting cases are $\mathcal{F}_{P_2} \subseteq \mathcal{H}$ and $\mathcal{F}_{K_3} \subseteq \mathcal{H}$. One reason for this is that, in contrast to cliques and bicliques, the decision version of those instances are fixed-parameter tractable. Hence a reduction from the decision version via e.g. an isolation lemma does not help. In other words, establishing hardness for those cases requires us to rely on the full power of counting modulo 2. More precisely, we will rely on the framework of fractures graphs (see Section 2). Both cases can be considered simpler applications of the machinery used in the later sections, so we will present all steps in great detail. While this might seem unnecessary given the simplicity of the constructions, we hope that it enables the reader to make themselves familiar with the general reduction strategies which will be used throughout the later sections of this work.

3.1 Triangle Packings

The goal of this subsection is to establish hardness of $\oplus\text{Sub}(\mathcal{F}_{K_3})$. To this end, let Δ be an infinite computable class of cubic bipartite expander graphs, and let $\mathcal{Q} = \{L(H) \mid H \in \Delta\}$ where $L(H)$ is constructed as follows: Each $v \in V(H)$ becomes a triangle with vertices v_x, v_y, and v_z corresponding to the three neighbours x, y, and z of v. Finally, for every edge $\{u, v\} \in E(H)$ we identify v_u and u_v. In fact, $L(H)$ is just the *line graph* of H: Every edge of H becomes a vertex in $L(H)$, and two vertices of $L(H)$ are made adjacent if and only if the corresponding edges in H are incident. Since all $H \in \Delta$ are bipartite (and thus triangle-free), we can easily observe the following.[2]

▶ **Observation 18.** *The mapping $v \mapsto (v_x, v_y, v_z)$ is a bijection from vertices of H to triangles in $L(H)$.*

[2] Observation 18 is also an immediate consequence of Whitney's Isomorphism Theorem implying that a triangle of a line graph corresponds to either a claw or to a triangle in its primal graph.

We also consider the fracture of $L(H)$ that splits $L(H)$ back into $|V(H)|$ triangles; consider Figure 2 for an illustration.

▶ **Definition 19** ($\tau(H)$)**.** *Let $H \in \Delta$ and recall that each vertex w of $L(H)$ is obtained by identifying v_u and u_v for some edge $\{u, v\} \in E(H)$. Moreover, w has four incident edges e_x, e_y, e_a, e_b, to v_x, v_y, u_a, u_b, respectively, where x, y, u are the neighbours of v in H and v, a, b are the neighbours of u in H. We define $\tau(H)_w := \{\{e_x, e_y\}, \{e_a, e_b\}\}$, and we proceed similar for all vertices of $L(H)$.*

Next, we use that $\mathsf{tw}(L(H)) = \Omega(\mathsf{tw}(H))$ (see e.g. [22]). Moreover, $\mathsf{tw}(L(H)) \leq |V(L(H))|$ since the treewidth of a graph is always bounded by the number of its vertices. Additionally, $|V(L(H))| = |E(H)|$ by construction. Since the graphs in Δ are cubic, we further have that $|E(H)| = \Theta(|V(H)|)$ for $H \in \Delta$. We combine those bounds with the fact that expander graphs have treewidth linear in the number of vertices (see e.g. [21]); therefore Δ and thus $\mathcal{Q}$ have unbounded treewidth. Putting these facts together, we obtain the following.

▶ **Fact 20.** *$\mathcal{Q}$ has unbounded treewidth and $\mathsf{tw}(L(H)) = \Theta(|V(L(H))|) = \Theta(|V(H)|)$ for $H \in \Delta$.*

We are now able to establish hardness of $\oplus\textsc{Sub}(\mathcal{F}_{K_3})$. The proof will heavily rely on the transformation from edge-coloured subgraphs to homomorphisms established in [29].

▶ **Lemma 21.** *The problem $\oplus\textsc{Sub}(\mathcal{F}_{K_3})$ is $\oplus\mathsf{W}[1]$-hard. Furthermore, on input kK_3 and G, the problem cannot be solved in time $f(k) \cdot |G|^{o(k/\log k)}$ for any function f, unless rETH fails.*

Proof. We reduce from $\oplus\textsc{cp-Hom}(\mathcal{Q})$, which, by Fact 20 and Theorem 12, is $\oplus\mathsf{W}[1]$-hard and for $L(H) \in \mathcal{Q}$, it cannot be solved in time $f(|L(H)|) \cdot |G|^{o(|V(L(H))|/\log |V(L(H))|)}$, unless rETH fails.

Let L and (G, c) be an input instance to $\oplus\textsc{cp-Hom}(\mathcal{Q})$. Recall that Δ is computable – that is, there is an algorithm that takes a graph H and determines whether it is in Δ. Thus, there is an algorithm that takes input $L \in \mathcal{Q}$ and finds a graph $H \in \Delta$ with $L = L(H)$. The run time of this algorithm depends on $|L|$ but clearly not on (G, c). Let $k = |V(H)|$ and note that $|E(L(H))| = 3k$, since, by construction, each vertex v of H becomes a triangle of $L(H)$. We consider the graph G as a $3k$-edge-coloured graph, coloured by c_E. That is, each edge $e = \{x, y\}$ of G is assigned the colour $c_E(e) = \{c(x), c(y)\}$ which is an edge of L (see Figure 2 for an illustration).

Now, for *any* L-coloured graph (G', c') recall that $\mathsf{ColSub}(kK_3 \to (G', c'_E))$ is the set of subgraphs of G' that are isomorphic to kK_3 and that include each edge colour (each edge of L) precisely once. We will see later that $\oplus\mathsf{ColSub}(kK_3 \to (G', c'_E))$ can be computed using our oracle for $\oplus\textsc{Sub}(\mathcal{F}_{K_3})$ using the principle of inclusion and exclusion.

It was shown in [29, Lemma 4.1] that there is a unique function a such that for every L-coloured graph (G', c') we have[3]

$$\#\mathsf{ColSub}(kK_3 \to (G', c'_E)) = \sum_{\rho} a(\rho) \cdot \mathsf{Hom}(L\sharp\rho \to (G', c'))\,. \tag{2}$$

where the sum is over all fractures of L. Additionally, it was shown in [29, Corollary 4.3] that

$$a(\top) = \sum_{\rho \in \mathsf{F}(kK_3, L)} \prod_{w \in V(L)} (-1)^{|\rho_w|-1} \cdot (|\rho_w| - 1)!\,, \tag{3}$$

[3] In the language of [29], Equation (2) is obtained by choosing Φ as the property of being isomorphic to kK_3.

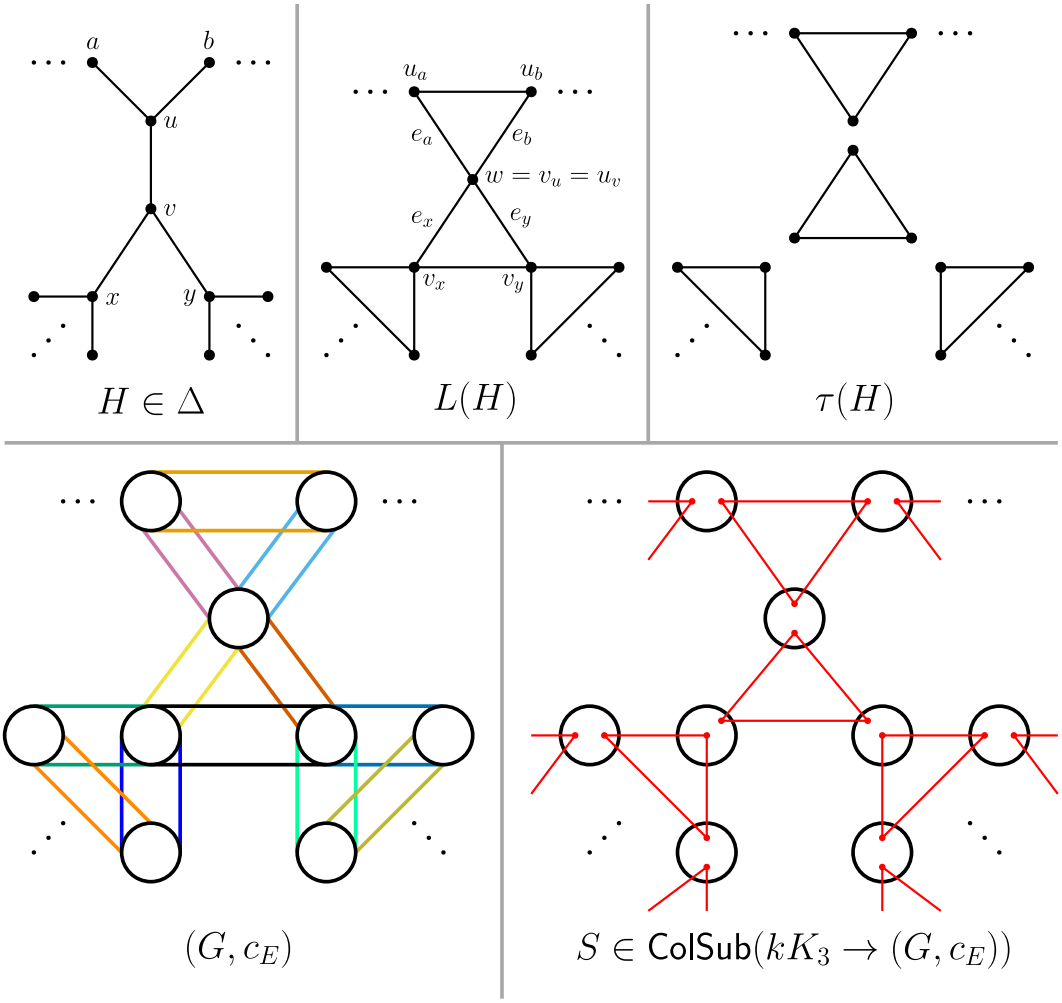

Figure 2 (*Top*:) A cubic bipartite graph $H \in \Delta$, its line graph $L(H)$, and the fractured graph induced by $\tau(H)$. (*Below*:) An $L(H)$-coloured graph (G, c); emphasised in distinct colours is the edge-colouring c_E of G induced by the mapping $\{u, v\} \mapsto \{c(u), c(v)\}$. Additionally we depict an element $S \in \mathsf{ColSub}(kK_3 \to (G, c_E))$, that is, a subgraph of G isomorphic to kK_3 that contains each edge colour of G precisely once.

where $\top$ is the fracture in which each partition consists only of one block (that is, $L\sharp\top = L$), and $\mathsf{F}(kK_3, L)$ is the set of all fractures ρ of L such that $L\sharp\rho \cong kK_3$. However, note that, by Observation 18, there is only way to fracture L into k disjoint triangles, and this fracture is given by $\tau(H)$. Thus, (3) simplifies to

$$a(\top) = \prod_{w \in V(L)} (-1)^{|\tau(H)_w|-1} \cdot (|\tau(H)_w| - 1)!\,, \tag{4}$$

which is odd since each partition of $\tau(H)$ consists of precisely two blocks (so in fact the expression in (4) is $(-1)^{|V(L)|}$).

Note that the algorithm for $\oplus$CP-Hom$(\mathcal{Q})$ is supposed to compute $\oplus\mathsf{Hom}((L, \mathsf{id}_L) \to (G, c))$ which is equal to $\oplus\mathsf{Hom}(L\sharp\top \to (G, c_\top))$. Since $a(\top)$ is odd, we can invoke Lemma 14 to recover this term by evaluating the entire linear combination (2), that is, by evaluating the function $\oplus\mathsf{ColSub}(kK_3 \to \star)$. More concretely, this means that we need to compute

$\oplus\mathsf{ColSub}(kK_3 \to (G', c'_E))$ for some L-coloured graphs (G', c') of size at most $f(|L|) \cdot |G|$ for some computable function f (see 3. in Lemma 14). This can easily be done using Lemma 15 since we have oracle access to the function $\oplus\mathsf{Sub}(kK_3 \to \star)$. We emphasise that, by condition 2. of Lemma 15, each oracle query $\hat{G}$ satisfies $|\hat{G}| \leq |G'|$, where (G', c') is the L-coloured graph for which we wish to compute $\oplus\mathsf{ColSub}(kK_3 \to (G', c'_E))$. Since $|(G', c')| \leq f(|L|) \cdot |G|$, we obtain that $|\hat{G}| \leq f(|L|) \cdot |G|$ as well.

Since, by Fact 20, $k = \Theta(|kK_3|) = \Theta(|V(L)|) = \Theta(\mathsf{tw}(L))$, our reduction yields $\oplus\mathsf{W}[1]$-hardness and transfers the conditional lower bound under rETH as desired. ◀

3.2 P_2-packings

Next we establish hardness for the case of P_2-packings. The strategy will be similar in spirit to the construction for triangle packings; however, rather then identifying a unique fracture for which the technique applies, we will encounter an *odd* number of possible fractures in the current section.

Let Δ be a computable infinite class of 4-regular expander graphs, and let $\mathcal{Q}$ be the class of all subdivisions of graphs in Δ, that is $\mathcal{Q} = \{H^2 \mid H \in \Delta\}$, where H^2 is obtained from H by subdividing each edge once.

We start by establishing an easy but convenient fact on the treewidth of the graphs in $\mathcal{Q}$.

▶ **Lemma 22.** *$\mathcal{Q}$ has unbounded treewidth and $\mathsf{tw}(H^2) = \Theta(|V(H)|)$ for $H \in \Delta$.*

Proof. As in Section 3.1, $\mathsf{tw}(H) = \Theta(|V(H)|)$ for $H \in \Delta$, since expanders have treewidth linear in the number of vertices. Since H is a minor of H^2, and since taking minors cannot increase treewidth (see [15, Exercise 7.7]), we thus have that $\mathsf{tw}(H^2) = \Omega(|V(H)|))$. Finally, we have $\mathsf{tw}(H^2) \leq |V(H^2)|$ since the treewidth is at most the number of vertices, and $|V(H^2)| = O(|V(H)|)$ since H is 4-regular. In combination, we obtain $\mathsf{tw}(H^2) = \Theta(|V(H)|)$ for $H \in \Delta$. Note that this also implies that $\mathcal{Q}$ has unbounded treewidth (as Δ is infinite). ◀

For what follows, given a subdivision H^2 of a graph H, it will be convenient to assume that $V(H^2) = V(H) \cup S_E$, where $S_E = \{s_e \mid e \in E(H\})$ is the set of the subdivision vertices.

▶ **Definition 23** (Odd Fractures)**.** *Let $H \in \Delta$ and let τ be a fracture of H^2. We say that τ is* odd *if the following two conditions are satisfied:*

1. *For each $s \in S_E$ the partition τ_s consists of two singleton blocks.*
2. *For each $v \in V(H)$ the partition τ_v consists of two blocks of size 2.*

Consider Figure 3 for a depiction of an odd fracture.

The following two lemmas are crucial for our construction.

▶ **Lemma 24.** *Let $H \in \Delta$. The number of odd fractures of H^2 is odd.*

Proof. The first condition in Definition 23 leaves only one choice for subdivision vertices. Let us thus consider a vertex $v \in V(H) = V(H^2) \setminus S_E$. Since H is 4-regular, there are 4 incident edges to v. Now note that there are precisely 3 partitions of a 4-element set with two blocks of size 2. Thus the total number of odd fractures of H^2 is $3^{|V(H)|}$, which is odd. ◀

▶ **Lemma 25.** *Let $H \in \Delta$, let $k = 2|V(H)|$ and let τ be a fracture of H^2 such that τ_v consists of at most 2 blocks for each $v \in V(H^2)$. Then $H^2 \sharp \tau \cong kP_2$ if and only if τ is odd.*

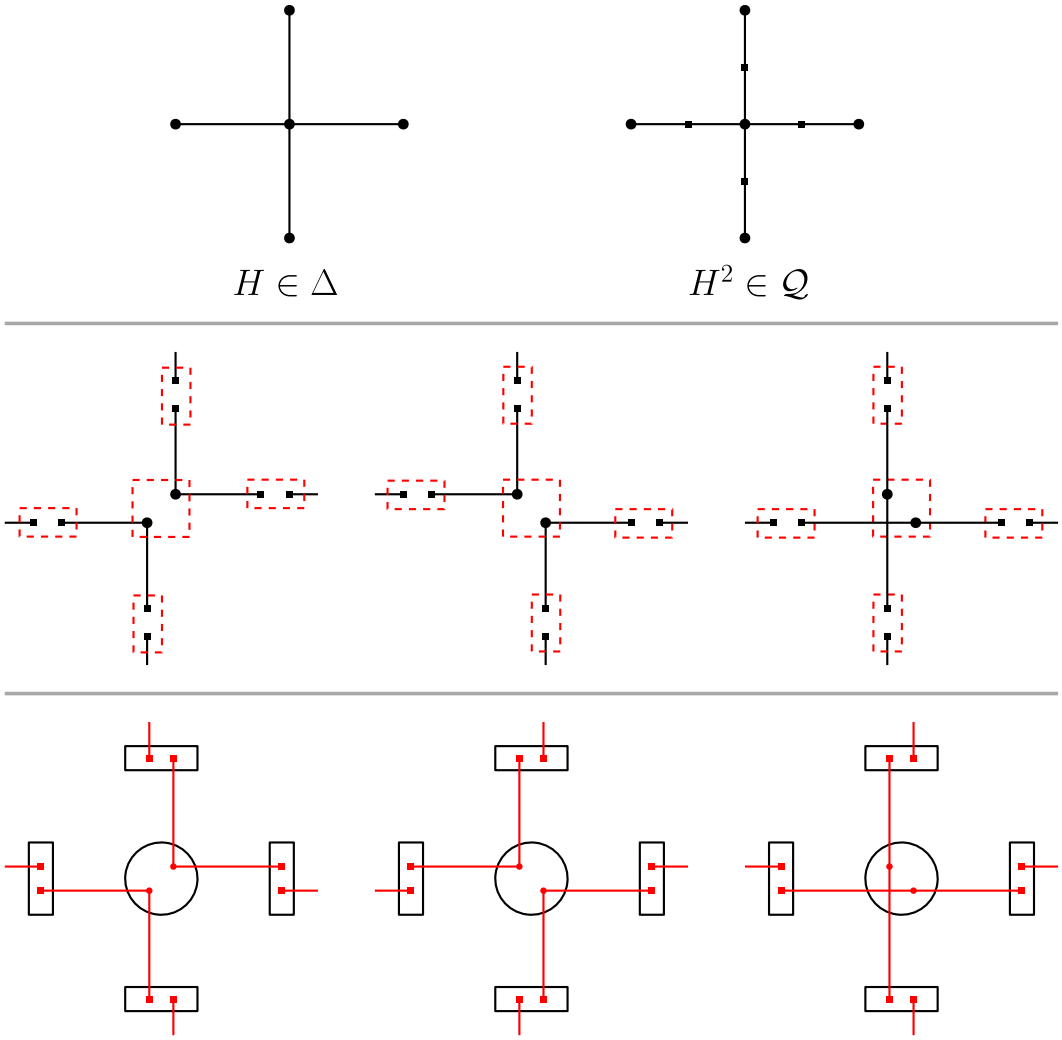

Figure 3 (*Top*:) Subdividing a 4-regular expander in Δ depicted by the neighbourhood of an individual vertex. (*Centre*:) Illustrations of odd fractures (Definition 23). For each non-subdivision vertex, there are only three ways to satisfy 2. in Definition 23. This observation is used in Lemma 24 to show that the number of odd fractures is a power of 3. (*Bottom*:) Elements of $\mathsf{ColSub}(kP_2 \to (G, c_E))$ inducing fractures of H^2 such that each partition has at most two blocks. Lemma 25 shows that those are precisely the odd fractures of H^2.

Proof. First observe that $|E(H^2)| = 2|E(H)| = 4|V(H)| = 2k$. Thus the number of edges of $H^2 \sharp \tau$ is equal to $2k$ (for each fracture τ of H^2), which is also equal to the number of edges of kP_2.

Thus, $H^2 \sharp \tau$ is isomorphic to kP_2 if and only if each connected component of $H^2 \sharp \tau$ is a path of length 2. It follows immediately by Definition 23 that τ being odd implies that $H^2 \sharp \tau$ consists only of disjoint P_2. It thus remains to show the other direction.

Assume for contradiction that there is a subdivision vertex $s \in S_E$ of H^2 such that τ_s consists of only one block (recall that s has degree 2, thus τ_s either consists of two singleton blocks, or of one block of size 2). Let $e = \{u, v\} \in E(H)$ be the edge corresponding to s, that is, s was created by subdividing e. Since $H^2 \sharp \tau$ is a union of P_2, we can infer that τ_v and τ_u contain a singleton block (otherwise we would have created a connected component which is

not isomorphic to P_2). Now recall that both u and v have degree 4, since H is 4-regular. We obtain a contradiction as follows: By assumption of the lemma, we know that τ_v and τ_u can have at most two blocks. Since we have just shown that both contain a singleton block, it follows that both τ_v and τ_u contain one further block of size 3. However, a block of size 3 yields a vertex of degree 3 in the fractured graph $H^2\sharp\tau$, contradicting the fact that $H^2\sharp\tau$ consists only of disjoint P_2.

Thus we have established that, for each $s \in S_E$, the partition τ_s consists of two singleton blocks. Given this fact, the only way for $H^2\sharp\tau$ being a disjoint union of P_2 is that each partition τ_v, for $v \in V(H) = V(H^2) \setminus S_E$, consists of two blocks of size 2. ◀

We are now able to prove our hardness result.

▶ **Lemma 26.** *The problem $\oplus\textsc{Sub}(\mathcal{F}_{P_2})$ is $\oplus\mathsf{W}[1]$-hard. Furthermore, on input kP_2 and G, the problem cannot be solved in time $f(k)\cdot|G|^{o(k/\log k)}$ for any function f, unless rETH fails.*

Proof. We reduce from $\oplus\textsc{cp-Hom}(\mathcal{Q})$, which, by Lemma 22 and Theorem 12, is $\oplus\mathsf{W}[1]$-hard and for $H' \in \mathcal{Q}$, it cannot be solved in time $f(|H'|)\cdot|G|^{o(|V(H')|/\log|V(H')|)}$, unless rETH fails.

Let H' and (G,c) be an input instance to $\oplus\textsc{cp-Hom}(\mathcal{Q})$. There is an algorithm that takes as input a graph $H' \in \mathcal{Q}$ and finds a graph $H \in \Delta$ with $H' = H^2$ – this is basically 2-colouring. The run time of this algorithm depends on $|H'|$ but clearly not on (G,c). Let $k = 2|V(H)|$ and note that $|E(H^2)| = 2|E(H)| = 4|V(H)| = 2k$. We consider the graph G as a $2k$-edge-coloured graph, coloured by c_E. That is, each edge $e = \{x,y\}$ of G is assigned the colour $c_E(e) = \{c(x),c(y)\}$ which is an edge of $H' = H^2$.

Now, for *any* H^2-coloured graph (G',c') recall that $\mathsf{ColSub}(kP_2 \to (G',c'_E))$ is the set of subgraphs of G' that are isomorphic to kP_2 and that include each edge colour (each edge of H^2) precisely once. We will see later that $\oplus\mathsf{ColSub}(kP_2 \to (G',c'_E))$ can be computed using our oracle for $\oplus\textsc{Sub}(\mathcal{F}_{P_2})$ using the principle of inclusion and exclusion.

It was shown in [29, Lemma 4.1] that there is a unique function a such that, for every H^2-coloured graph (G',c'),

$$\#\mathsf{ColSub}(kP_2 \to (G',c'_E)) = \sum_{\rho} a(\rho)\cdot\mathsf{Hom}(H^2\sharp\rho \to (G',c'))\,. \tag{5}$$

where the sum is over all fractures of H^2. As in Section 3.1 from [29, Corollary 4.3] we know that

$$a(\top) = \sum_{\rho\in\mathsf{F}(kP_2,H^2)}\prod_{w\in V(H^2)}(-1)^{|\rho_w|-1}\cdot(|\rho_w|-1)!\,, \tag{6}$$

where $\top$ is the fracture in which each partition consists only of one block and $\mathsf{F}(kP_2,H^2)$ is the set of all fractures ρ of H^2 such that $H^2\sharp\rho \cong kP_2$.

Our next goal is to show that $a(\top) = 1 \mod 2$. First, suppose that a fracture ρ contains a partition ρ_w with at least three blocks. Then $(|\rho_w|-1)! = 0 \mod 2$. Thus such fractures do not contribute to $a(\top)$ if arithmetic is done modulo 2. Next, note that if, for each w, the partition ρ_w contains at most 2 blocks, then

$$\prod_{w\in V(H^2)}(-1)^{|\rho_w|-1}\cdot(|\rho_w|-1)! = 1 \mod 2.$$

Let $\mathsf{Odd}(kP_2, H^2)$ be the set of all fractures ρ of H^2 such that $H^2 \sharp \rho \cong kP_2$ and each partition of ρ consists of at most 2 blocks. Our analysis then yields $a(\top) = |\mathsf{Odd}(kP_2, H^2)| \mod 2$. Finally, Lemma 25 states that $\mathsf{Odd}(kP_2, H^2)$ is precisely the set of odd fractures, and Lemma 24 thus implies that $|\mathsf{Odd}(kP_2, H^2)| = 1 \mod 2$. Consequently, $a(\top) = 1 \mod 2$ as well, and we have achieved the goal.

Next we can proceed similarly to the case of triangle packings. As in that case, the goal is to compute $\oplus\mathsf{Hom}((H^2, \mathsf{id}_{H^2}) \to (G, c)))$ which is equal to $\oplus\mathsf{Hom}((H^2 \sharp \top, c_\top) \to (G, c))$. Since $a(\top)$ is odd, we can invoke Lemma 14 to recover this term by evaluating the entire linear combination (5), that is, if we can evaluate the function $\oplus\mathsf{ColSub}(kP_2 \to \star)$. This can be done by using Lemma 15. Each call to the oracle is of the form $\oplus\mathsf{Sub}(kP_2 \to \hat{G})$ where $|\hat{G}|$ is bounded by $f(k) \cdot |G|$.

Now recall that $k \in \Theta(|V(H)|)$. By Lemma 22, we thus have $k = \Theta(\mathsf{tw}(H^2))$. Hence our reduction yields $\oplus\mathsf{W}[1]$-hardness and transfers the conditional lower bound under rETH as desired. ◀

We can now conclude the treatment of hereditary pattern classes by proving Theorem 4, which we restate for convenience.

▶ **Theorem 4.** *Let $\mathcal{H}$ be a hereditary class of graphs. If $\mathcal{H}$ is matching splittable, then $\oplus\textsc{Sub}(\mathcal{H})$ is fixed-parameter tractable. Otherwise, the problem is $\oplus\mathsf{W}[1]$-complete and, assuming rETH, cannot be solved in time $f(|H|) \cdot |G|^{o(|V(H)|/\log|V(H)|)}$ for any function f.*

Proof. The fixed-parameter tractability result was shown in [12]. For the hardness result, using the fact that $\mathcal{H}$ is not matching splittable and Theorem 16 we obtain four cases.

- If $\mathcal{H}$ contains all cliques or all bicliques, then hardness follows from Lemma 17.
- If $\mathcal{H}$ contains all triangle packings, then hardness follows from Lemma 21.
- If $\mathcal{H}$ contains all P_2-packings, then hardness follows from Lemma 26.

Since the case distinction is exhaustive, the proof is concluded. ◀

Abstract

We show an $(1+\epsilon)$-approximation algorithm for maintaining maximum s-t flow under m edge insertions in $m^{1/2+o(1)}\epsilon^{-1/2}$ amortized update time for directed, unweighted graphs. This constitutes the first sublinear dynamic maximum flow algorithm in general sparse graphs with arbitrarily good approximation guarantee.

Furthermore we give an algorithm that maintains an exact maximum s-t flow under m edge insertions in an n-node graph in $\tilde{O}(n^{5/2})$ total update time. For sufficiently dense graphs, this gives to the first exact incremental algorithm with sub-linear amortized update time for maintaining maximum flows.

1 Introduction

The maximum flow problem and its dual, the minimum cut problem, are one of the cornerstones problems in combinatorial optimization. They are often used as subroutine for solving other prominent graph problems (e.g., Gomory-Hu Trees [11], Sparsest Cut [24]), performing divide-and-conquer on graphs [8] and have found several applications across many areas including computer vision [2], clustering [29] and scientific computing. Designing fast maximum flow algorithms has been an active area of research for decades, with recent advances making tremendous progress towards the quest of designing a near-linear time algorithm [6, 30, 26, 23, 28, 27, 31, 25, 4]. This has culminated in a recent breakthrough result due to Chen, Kyng, Liu, Peng, Probst Gutenberg, and Sachdeva [4], which computes a maximum flow in $m^{1+o(1)}$ time, where m is the number of edges of the input graph.

Recently, we have witnessed a growing interest in designing dynamic algorithms for computing maximum flows in dynamically changing graphs [20, 5, 1, 7, 14, 13, 3, 21]. Despite this, the current fastest algorithms either incur super-constant approximation factors [13, 3] or achieve competitive update times only for sufficiently dense graphs [1]. Moreover, all previous works on dynamic flows are restricted to undirected graphs. From a (conditional) lower bound perspective, for any $\delta > 0$, it is known [7] that no algorithm can exactly maintain maximum flow in $O(m^{1-\delta})$ amortized time per operation, even when restricted to algorithms that support edge insertions, unless the OMv conjecture [16] is false. Nevertheless, the lower bound construction from [7] is on dense graphs, i.e., $m = \Omega(n^2)$, and thus for sparse graphs yields only an $\Omega(m^{1/2})$ lower bound on the update time.

In this paper, we show a simple generic algorithmic framework for maintaining *approximate* maximum flows under edge insertions.

▶ **Theorem 1.** *Let $G = (V, E)$ be an initially empty, directed, unweighted n-vertex graph, s and t be any two vertices, and $\epsilon > 0$, $\mu \in [0, n]$ be two parameters. If there is*

(a) *an incremental algorithm* IncBMF(G, s, t, μ) *for inserting m edges and maintaining s-t maximum flow whose value is bounded by μ in $t_{total}(m, n, \mu)$ total update time and $q(m, n)$ query time, and*

(b) *a static algorithm for computing exact s-t maximum flow in an n-vertex, m'-edge graph in $t_{static}(m', n)$ time, where $m' \leq m$,*

then we can design an incremental algorithm for maintaining a $(1 + \epsilon)$-approximate s-t maximum flow under m edge insertions in

$$\frac{t_{total}(m, n, \mu + 1)}{m} + \frac{t_{static}(m, n)}{\epsilon\mu} + q(m, n)$$

amortized update time and $q(m, n)$ query time.

For maintaining exact maximum flows whose value is bounded by μ, we slightly adapt an incremental version of the Ford-Fulkerson [9] algorithm, which was initially observed by Henzinger [17] and later by Gupta and Khan [14] (cf. Lemma 9). This gives an incremental algorithm with $O(m\mu)$ total update time and $O(1)$ query time. The recent breakthrough result due to Chen, Kyng, Liu, Peng, Probst Gutenberg, and Sachdeva [4] (cf. Theorem 6) gives a static exact maximum flow algorithm that runs in $m^{1+o(1)}$ time. Plugging these bounds in Theorem 1 and choosing $\mu = m^{1/2+o(1)}\epsilon^{-1/2}$ yields the main result of this paper, which we summarize in the theorem below.

▶ **Theorem 2.** *Given an initially empty, directed, unweighted graph $G = (V, E)$, any two vertices s and t in V, and any $\epsilon > 0$, there is an incremental algorithm that maintains a $(1 + \epsilon)$-approximate maximum s-t flow in G under m edge insertions in $m^{1/2+o(1)}\epsilon^{-1/2}$ amortized update time. The algorithm supports queries about the value of the maintained flow in $O(1)$ time.*

When the underlying graph is undirected and unweighted, we additionally show an improved incremental version of an algorithm due to Karger and Levine [22] for maintaining exact maximum flows whose value is bounded by μ. Concretely, our algorithm achieves $\tilde{O}(m + n\mu^{3/2})$ total update time for handling m edge insertions (cf. Lemma 15). Since $\mu \leq n$ always holds in unweighted graphs, we immediately obtain the following result.

▶ **Theorem 3.** *Given an initially empty, undirected, unweighted graph $G = (V, E)$, any two vertices s and t in V, and any $\epsilon > 0$, there is an incremental algorithm that maintains an* exact *maximum s-t flow in G under m edge insertions in $\tilde{O}(n^{5/2})$ total update time. The algorithm supports queries about the value of the maintained flow in $O(1)$ time.*

For sufficiently dense graphs, this gives to the first exact incremental algorithm with sub-linear amortized update time for maintaining maximum flows.

We believe that our approach to dynamic flows may serve as the basis for designing new fully-dynamic maximum flow algorithms with competitive approximation ratio.

Independet Work. A recent independent work by Brand, Liu and Sidford [32] provides an algorithm for incremental approximate maximum flow with $n^{1/2+o(1)}\epsilon^{-1}$ amortized update time on directed graphs. They achieve this result by implementing a dynamic variant of the recent maximum flow algorithm based on the Interior Point Method (IPM) [4]. For comparison, their result extends to capacitated graphs with polynomially bounded capacitites, and achieves a speed up on the running time (albeit only on dense graphs). However, these improvements come at the cost of employing the complicated machinery of IPMs. Our result from Theorem 2 is simpler, matches their running time guarantee on sparse graphs and gives a slightly better dependncy on the accuracy parameter ϵ.

2 Preliminaries

In the following, we settle some basic notation, as well as review definitions and algorithms for computing flows on graphs.

Maximum Flow

Let $G = (V, E)$ be a directed, unweighted graph with n vertices and m edges, let $s \in V$ be a *source* vertex, and let $t \in V$ be a *target* vertex. A *flow* from s to t in G is a function $f : E \to \mathbb{R}^+$ that maps each edge to a non-negative real number; the value $f(e)$ represents the amount of flow sent along e. A flow must satisfy the following properties: (i) for each $e \in E$, we have $f(e) \leq 1$, known as *capacity constraints*, and (ii) for each $v \in V \setminus \{s, t\}$, $\sum_{(u,v)\in E} f(u, v) = \sum_{(v,u)} f(v, u)$, known as *conservation constraints*. The *value* of a flow f is the amount of flow leaving the source s minus the amount flow entering s, i.e., $v(f) = \sum_{(s,u)\in E} f(s, u) - \sum_{(u,s)\in E} f(u, s)$. In the maximum s-t flow problem, the goal is to find a flow f with the largest $v(f)$, called the *maximum s-t flow*. Let $F^* = \max\{v(f) \mid f \text{ is a flow in } G\}$. Note that while F^* is unique, there might be multiple maximum s-t flows attaining F^*.

Residual graph and Augmenting Paths

Given a directed, unweighted graph $G = (V, E)$, and a flow f from s to t in G, we let $G_f = (V, E_f)$ be the *residual graph* of G with respect to f, where E_f contains all edges of E, except that their direction is reversed if $f(e) = 1$. An edge whose direction in G_f is reversed is referred to as a *backward* edge. Otherwise, the edge is a *forward* edge. An augmenting path P from s to t in G is a simple directed path from s to t in G_f. We next review a powerful result relating the residual graphs and optimal flows.

▶ **Lemma 4** ([9]). *If there is no directed path from s to t in the residual graph G_f, then the flow f is a maximum s-t flow.*

Another useful fact is given in the lemma below.

▶ **Lemma 5.** *If there exists a directed path P from s to t in G_f, pushing flow along P in G increases the value of the flow f by at exactly one.*

Exact Maximum Flow in Directed Graphs

Our incremental approximate algorithm heavily relies on the ability to compute a maximum s-t flow quickly. Hence, we use the current fastest result [4] that achieves an exact, almost-linear algorithm for the maximum flow problem on directed graphs.[1]

▶ **Theorem 6** ([4]). *For any directed, unweighted graph $G = (V, E)$ and any two vertices s and t, there is an algorithm that computes an* exact *maximum s-t flow in G in $m^{1+o(1)}$ time.*

Approximate Maximum Flow

To measure the quality of approximate maximum flows, we will use the notion of α-approximations, which indicates that the value of the current flow solution is at least $1/\alpha$ of the optimum value. In other words, a flow f is α-approximate if $F := v(f) \geq \frac{1}{\alpha}F^*$.

3 A framework for Incremental Approximate Maximum Flow

In this section we show a simple generic algorithmic framework for maintaining a $(1+\epsilon)$-approximate maximum s-t flow under edge insertions, i.e., prove Theorem 1. Our construction is based on two important components: (i) incrementally maintaining maximum s-t flows whose value is upper bounded by some parameter μ (one should think of μ being small relative to the size of the network) and (ii) performing periodical rebuilds whenever the maximum s-t flow of the current flow is larger than the parameter μ. The latter is a common approach in dynamic algorithms and was used by Gupta and Peng [15] in their dynamic algorithm for maintaining approximate matchings, and also recently leveraged in the context of *exact* algorithms for the dynamic minimum cut problem [12]. We next further elaborate on the precise requirements of both components and discuss how they lead to our algorithm.

To implement component (i), given a directed, unweighted n-vertex, m-edge graph G, any two vertices s, t, and a parameter $\mu \in [0, n]$, the goal is to construct a data structure denoted by IncBMF(G, s, t, μ), or simply IncBMF, that supports the following operations

- Initialize(G, s, t, μ): Initializes the data structure.
- Insert(u, v): Insert the edge (u, v) to G.
- MaxFlow(s, t): Return the value of the maximum s-t flow in the current graph G if this value is smaller than μ.

Ideally, we would like that IncBMF(G, s, t, μ) supports edge insertions in amortized time proportional to the parameter μ, and queries in constant time. This would alone lead to an efficient incremental maximum flow algorithm whenever the current flow value is bounded by μ.

When the maximum flow is large (i.e., component (ii)), we can make use of the *stability* of maximum flow and periodically invoke a fast static algorithm. Concretely, first note that the value of the maximum s-t flow changes by at most one per insertion. Therefore, if we have a large flow that is close to the maximum one, it will remain close to the maximum flow over a large number of updates. This naturally leads to the following simple but powerful approach: compute a flow at a certain time in the update sequence and do nothing for a certain number of updates as long as the flow is a good approximation to the maximum flow. This idea together with the data structure IncBMF(G, s, t, μ) yields an incremental algorithm for approximating s-t maximum flow, which we formally describe below.

[1] The algorithm extends to graphs with polynomially bound weights, but for the purposes of this paper and simplifying the presentation, we only state the unweighted version of this result

Given a directed, unweighted graph $G = (V, E)$, any two vertices s, t, and two parameters $\epsilon > 0, \mu \in [0, n]$, our data structure maintains:

- a flow estimate F to the maximum s-t flow F^*,
- a counter τ indicating the number of operations since the last rebuild,
- an incremental algorithm IncBMF for maintaining graphs with the maximum flow bounded by some parameter $(\mu + 1)$.

Initially, G is an empty graph, $F \leftarrow 0$, $\tau \leftarrow 0$, and we invoke the operation Initialize of IncBMF with $(G, s, t, \mu + 1)$ as an input. Upon insertion of an edge (u, v) to G, we query IncBMF to determine whether the s-t maximum flow in the current graph is at most μ. If so, we pass the edge insertion to the IncBMF data structure and update F accordingly.

On the other hand, if the current maximum s-t flow is larger than μ (and our algorithm always correctly detects this since IncBMF run with the parameter $(\mu + 1)$ returns the correct answer), we increment τ, which counts the number of insertions since the last reset of τ that fall into this case. If $\tau \geq \epsilon\mu$, we compute an exact maximum flow F^* for the current graph from scratch using a static algorithm, update F using the value of F^* and set $\tau = 0$. We call such a step a *rebuild* step. Observe that since we are in the insertions-only setting, once a maximum flow is larger than μ, it will always remain larger than that value. Finally, to answer a query about the maximum s-t flow, we return F as an estimate. These procedures are summarized in Algorithm 1.

Algorithm 1 Incremental Approximate Maximum Flow (IncApproxMF.)

```
1  Procedure Initialize(G = (V, E), s, t, ϵ, μ)
2      Set E ← 0 and F ← 0
3      Invoke IncBMF.Initialize(G, s, t, μ + 1)
4  Procedure Insert(u, v)
5      E ← E ∪ {(u, v)}
6      if IncBMF.MaxFlow(s, t) ≤ μ then
7          Invoke IncBMF.Insert(u, v)
8          Set F ← IncBMF.MaxFlow(s, t)
9      else
10         Set τ ← τ + 1
11         if τ ≥ ϵμ then
12             Compute an s-t maximum flow in G using a static algorithm
13             Set F to be the value of the flow computed in the previous step
14             Set τ ← 0
15 Procedure MaxFlow(s, t)
16     return F
```

▶ **Theorem 7** (Restatement of Theorem 1). *Let $G = (V, E)$ be an initially empty, directed, unweighted n-vertex graph, s and t be any two vertices, and $\epsilon > 0$, $\mu \in [0, n]$ be two parameters. If there is*

(a) *an incremental algorithm* IncBMF(G, s, t, μ) *for inserting m edges and maintaining s-t maximum flow whose value is bounded by μ in total update time $t_{total}(m, n, \mu)$ and $q(m, n)$ query time, and*

(b) *a static algorithm for computing exact s-t maximum flow in an n-vertex, m'-edge graph in $t_{static}(m', n)$ time, where $m' \leq m$,*

then we can design an incremental algorithm for maintaining a $(1+\epsilon)$-approximate s-t maximum flow under m edge insertions in

$$\frac{t_{total}(m, n, \mu+1)}{m} + \frac{t_{static}(m, n)}{\epsilon\mu} + q(m, n)$$

amortized update time and $q(m, n)$ query time.

Proof. We first prove the correctness of the algorithm. Let G be the current graph and let F be the estimate maintained by the algorithm to the value of the maximum s-t flow F^* in G. We will show that F is an $(1+\epsilon)$-approximation to F^*. To this end, we distinguish the following three cases.

(1) If $F^* \leq \mu$, then by assumption of the theorem, the data structure IncBMFensures that $F = F^*$ and thus our claim trivially holds.

(2) If $F^* = \mu + 1$, the call IncBMF.MaxFlow(s, t) returns the value $\mu + 1$ and, thus, the algorithm reaches the else-case for the first time (here we slightly abuse the notation and denote this as a *rebuild* step).

(3) If $F^* > \mu + 1$, then this is not the first time that the algorithm reaches the else-case and, thus, there was a prior rebuild. Note that F corresponded to the value of some s-t maximum flow at the last prior rebuild. This in turn implies that F must be larger than μ. Let F_0^* be the value of the maximum s-t flow of the graph at that rebuild. Since each edge insertion can increase the value of the maximum flow by at most 1 and we recompute a new maximum flow every $\epsilon\mu$ insertions, we have that $F^* \leq F_0^* + \epsilon\mu$. Since $F_0^* > \mu$ and $F = F_0^* \geq 1$, bringing these together yields:

$$\frac{F^*}{F} \leq \frac{F_0^* + \epsilon\mu}{F} \leq \frac{(1+\epsilon)F_0^*}{F_0^*} \leq 1 + \epsilon,$$

which proves our claimed approximation guarantee.

We next study the running time. Note that our algorithm passes the edge insertions to the incremental algorithm IncBMF (invoked with the parameter $\mu + 1$) only if the value of the maximum flow in the current graph is bounded by μ. Hence, by the theorem assumption, the total update time to handle these insertions is $t_{\text{total}}(m, n, \mu+1) + mq(m, n)$. Amortizing the latter over m insertions gives an amortize cost of $t_{\text{total}}(m, n, \mu+1)/m + q(m, n)$, which in turn gives the first and the third term of our claimed running time guarantee.

It remains to analyze the cost of periodical rebuilds. Note that if the current maximum flow value is larger than μ, our algorithm updates the estimate F every $\epsilon\mu$ operations. By assumption of the theorem, the time to compute an exact maximum flow is $t_{\text{static}}(m', n) \leq t_{\text{static}}(m, n)$ as $m' \leq m$. Charging this time over $\epsilon\mu$ insertions, yields an amortized cost of $t_{\text{static}}(m, n)/(\epsilon\mu)$, which in turn gives the second term our of claimed runtime guarantee and completes the proof of the theorem. ◀

4 Incremental Bounded Maximum Flow

In this section we give two incremental algorithms for exactly maintaining the maximum flow as long as its value is bounded by a predefined parameter μ. The first is an incremental version of the Ford-Fulkerson [9] algorithm, applies to directed graphs, and runs in $O(m\mu)$ total update time, while the second one is an incremental version of an algorithm due to Karger and Levine [22], applies to undirected graphs and runs in $\tilde{O}(m + n\mu^{3/2})$ total update time.

4.1 Directed Graphs

The algorithm we are about to discuss applies to directed, unweighted graphs, was initially observed by Henzinger [17] and later by Gupta and Khan [14], and can be thought of as an incremental version of the celebrated Ford-Fulkserson algorithm [9]. We review it below and slightly adapt it for our purposes.

Henzinger [17] showed how to incrementally maintain maximum s-t flow in $O(F^*)$ amortized update time, where F^* is the value of the maximum flow in the final graph. As there are graphs where $F^* = \Omega(n)$, her running time guarantee is competitive only when F^* is small, e.g., sub-linear on the size of the graph. We next show to slightly adapt her algorithm so that it maintains a maximum flow as long as its value is bounded by a parameter μ.

The key observation behind this algorithm is that the insertions of an (unit-capacitated) edge can only increase the maximum flow value by at most 1. To check whether this value has increased, she uses Lemma 4 as a certificate, i.e., one determines whether the insertion of the (forward) edge in the residual graph G_f creates a directed path from s to t in G_f. A naive way to determine this is to run a graph search algorithm on G_f after each insertion, which requires $\Omega(m)$ for a single update and is thus prohibitively expensive for our purposes. However, one can exploit a data structure due to Italiano [19] for incrementally maintaining single source reachability information from a source s which requires $O(m)$ total update time for handling m insertions. Let us briefly review this data structure before presenting the incremental algorithm.

Incremental Single Source Reachability

In the incremental single source reachability problem, given an (initially empty) directed, unweighted graph $G = (V, E)$ and a distinguished vertex s, the goal is to construct a data structure IncSSR that supports the following operations: (i) Initialize(G, s): initialize the data structure in G with source s, (ii) Insert(u, v): insert the edge (u, v) in G, and (iii) Reach(u): return `True` if u is reachable from s, and `False` otherwise.

Italiano [19] observed that an incremental version of graph search leads to an efficient incremental IncSSR data structure. The main idea is to maintain a reachability tree T from s. Initially, the tree is initialized to $\{s\}$. Upon insertion of an edge (u, v) to G, we need to update T iff $u \in T$ and $v \notin T$. If this is the case, we add (u, v) to T and make the v the child of u. Moreover, the algorithm examines all outgoing neighbors w incident to v, and if $w \notin T$, processes the edge (v, w) recursively using the same procedure. To answer queries, we return `True` if $u \in T$, and `False` otherwise. These procedures are summarized in Algorithm 2.

The correctness of the data structure immediately follows by construction as we always maintain a correct rechability tree T from s for the current graph. For the running time, note that the total time over all insertions is $O(m)$ as each edge is processed at most $O(1)$ times; once when it is inserted into the graph and once when it is added to T.

▶ **Lemma 8** ([19]). *Given an initially empty directed, unweighted graph $G = (V, E)$ and a source vertex s, the incremental algorithm* IncSSR *maintains reachability information from s to every other node in V while supporting insertions in $O(1)$ amortized update time and queries in $O(1)$ in worst-case time.*

The Algorithm

We now have all the necessary tools to present an incremental algorithm maintaining the maximum flow whose value is bounded by μ. Let F^* denote the maximum s-t flow value on the current graph.

Algorithm 2 Incremental Single Source Reachability (IncSSR).

```
1  Procedure Initialize(G = (V, E), s)
2      Set T ← {s} and E ← ∅
3  Procedure Insert(u, v)
4      E ← E ∪ {(u, v)}
5      UpdateTree(u, v)
6  Procedure UpdateTree(u, v)
7      if u ∈ T and v ∉ T then
8          Make v a child of u in T
9          foreach (v, w) ∈ E do
10             UpdateTree(v, w)
11 Procedure Reach(u)
12     if u ∈ T then
13         return True
14     else
15         return False
```

Initially, G and the residual graph G_f are empty graphs, $F^* \leftarrow 0$ and $f(e) \leftarrow 0$ for each $e \in E$. The algorithm proceeds in μ rounds, where a round ends when the value of the current maximum flow increases by one. Each round starts by initializing an incremental single source reachability data structure IncrSSR from the source s (Lemma 8) on the residual graph G_f. Upon an edge insertion (u, v) to G, we pass the directed edge (u, v) to the data structure IncrSSR and test whether t is reachable from s using this data structure. If the latter holds, then we find a simple directed s-t path P in G_f, which in turn serves as an augmenting path for G. We then send one unit of flow along the path P in G and update the current flow and its value accordingly. To answer a query about the maximum flow between s and t, we simply return F^*. These procedures are summarized in Algorithm 3.

The correctness of this algorithm is immediate by Lemma 4, which correctly tells us when to increase the value of the maximum flow, and Lemma 5, which asserts that the sending one unit of flow along an augmenting path increases the value of the flow by exactly one.

For the running time, note that each round requires $O(m)$ total time. As there are exactly μ rounds, we get a total update time of $O(m\mu)$. The query time is $O(1)$ as we simply return the value of current maximum flow.

▶ **Lemma 9.** *Given an initially empty directed, unweighted graph $G = (V, E)$ with n vertices, any two vertices s and t, and a parameter $\mu \in [0, n]$, the algorithm* IncBMF(G, s, t, μ) *exactly maintains, under m edge insertions, the maximum s-t flow in G whose value is bounded by μ in $O(m\mu)$ total update time and $O(1)$ query time.*

4.2 Undirected Graphs

We next give an incremental variant of the deterministic maximum flow algorithm for unweighted, *undirected* graphs due to Karger and Levine [22]. For a threshold parameter μ on the maximum flow value, we obtain a total update time of $\tilde{O}(m + n\mu^{3/2})$ for handling m insertions.

Algorithm 3 Incremental Bounded Maximum Flow (IncBMF).

```
1  Procedure Initialize(G = (V, E), s, t, μ)
2      Set E ← ∅
3      Set f(e) ← 0 for each e ∈ E, G_f ← (V, E) and F* ← 0
4      Invoke IncSSR.Initialize(G_f, s)
5  Procedure Insert(u, v)
6      if F* ≤ μ then
7          Set E ← E ∪ {(u, v)}
8          Invoke IncSSR.Insert(u, v)
9          if IncSSR.Reach(t) then
10             Find a simple directed s-t path P in G_f
11             Augment f along the path P in G and let f' be the resulting flow
12             Set f ← f' and G_f ← G_f'
13             Set F* ← F* + 1
14             Invoke IncSSR.Initialize(G_f, s)
15 Procedure MaxFlow(s, t)
16     return F*
```

The basic idea behind this improvement is to sparsify the residual graph on a flow problem so that the augmenting paths can be found more efficiently than paying $O(m)$ per path, as we did in the incremental version of the Ford-Fulkerson algorithm. Two core components that allow for a faster algorithm are: (i) using spanning forests for edges that do not carry any flow in the residual graph (i.e, edges that remain undirected) and (ii) removing cycles from the current flow after each augmentation step to make sure that the flow does not use too many edges.

We next elaborate more on these two components. First, since we will need a different treatment for directed and undirected edges, setting up some additional notation is useful. For a graph $G = (V, E)$ and a flow f on the edges of G, we let E_f^u denote the "undirected edges" of G, i.e., edges e for which $f(e) = 0$, and let E_f^d denote the "directed edges" of G, i.e., edges e for which $f(e) = 1$. Component (i) involves replacing the edges in E_f^u with a spanning forest T. It is known that T captures the connectivity information among any pair of vertices in E_f^u, and thus whenever searching for an augmenting path, it suffices to do so in the graph induced by edge edges E_f^d and T. Another advantage is that T can have at most $(n-1)$ edges, which is potentially much smaller than the size of E_f^u. One challenge with this approach is that E_f^u evolves over time, i.e., edges might have flow added to it or flow is sent on the reserve direction during an augmentation step. Fortunately, we have efficient data structures to maintain such dynamic updates.

▶ **Lemma 10** ([18]). *Given an undirected graph $G = (V, E)$, there is an algorithm* DynSpanF *to maintain a spanning forest T of G that supports operations edge insertions and deletions (i.e., operations Insert(u, v) and Delete(u, v)) in $O(\log^2 n)$ amortized time per operation.*

Unfortunately the above idea alone is not sufficient. The problem is that we do not have any control on the size of E_f^d. It can be well the case that all edges in the graph become eventually directed, which defeats the purpose of treating undirected edges differently. To get around this, we first introduce the notion of acyclic flows and then review a result that shows that integral acyclic flows use very few edges. This lays the foundations of component (ii).

Algorithm 4 Incremental Bounded Maximum Flow for Undirected Graphs (IncBMFU).

```
1  Procedure Initialize(G = (V, E), s, t, μ)
2      Set f(e) ← 0 for each e ∈ E, E_f^u ← ∅, E_f^d ← ∅ and F* ← 0
3      Invoke DynSpanF.Initialize(G = (V, E_f^u)) to maintain a spanning forest T
4      Invoke IncSSR.Initialize(E_f^d ∪ T, s)
5  Procedure Insert(u, v)
6      if F* ≤ μ then
7          Set E_f^u ← E_f^u ∪ {(u, v)}
8          Invoke DynSpanF.Insert(u, v)
9          if (u, v) ∈ T then
10             Invoke IncSSR.Insert(u, v) and IncSSR.Insert(v, u)
11             if IncSSR.Reach(t) then
12                 Find a simple directed s-t path P in E_f^d ∪ T
13                 Augment f along the path P in G, let f' be the resulting flow and set
                    f ← f'
14                 Set f ← Decycle(f)
                   // delete any edge no longer in E_f^u because flow added
15                 for each e ∈ E_f^u with f(e) > 0 do
16                     Set E_f^u ← E_f^u \ {e} and E_f^d ← E_f^d ∪ {e}
17                     Invoke DynSpanF.Delete(e)
                   // insert an edge to E_f^u because flow removed
18                 for each e ∈ E_f^d with f(e) = 0 do
19                     Set E_f^d ← E_f^d \ {e} and E_f^u ← E_f^u ∪ {e}
20                     Invoke DynSpanF.Insert(e)
21                 Set F* ← F* + 1
22                 Invoke IncSSR.Initialize(E_f^d ∪ T, s)
23 Procedure MaxFlow(s, t)
24     return F*
```

▶ **Definition 11.** *We say that a flow f is* acyclic *if there is no directed cycle on which every edge has positive flow in the direction of the cycle.*

▶ **Lemma 12** ([10]). *Any integral acylic flow f uses at most $O(n\sqrt{v(f)})$ edges.*

Taking cue from the lemma above, our goal would be to ensure that at any time, the current flow we maintain is acyclic. Note that even if a flow is initially acylic, an augmentation step may destroy this property. This suggests that we need a *decycling* step to bring back the flow to the desired state. More importantly, for unweighted, undirected graphs, the *decycling* procedure takes time that is proportional to the number of edges that carry non-zero flow on the current graph.

▶ **Lemma 13** ([22]). *Let G be an unweighted, undirected graph, and let f be a flow of G that is non-zero on exactly x edges. Then there is an algorithm* Decycle(f) *that returns an* acyclic *flow f' with $v(f) = v(f')$ and runs in $O(x)$ time.*

The Algorithm

We now show how the above ideas lead to an incremental algorithm that maintains a maximum flow whose value is bounded by μ. As before, let F^* denote the maximum s-t flow value on the current graph.

Initially, G and the edges sets E_f^u, E_f^d are empty, $F^* \leftarrow 0$ and $f(e) \leftarrow 0$ for each $e \in E$. The algorithm initializes a dynamic spanning forest data structure DynamicSpanF on E_f^u to maintain a spanning forest T (Lemma 10). There are μ rounds, and each round ends when the value of the current maximum flow increases by one. Each round starts by initializing an incremental single source reachability data structure IncrSSR on $E_f^d \cup T$ from the source s (Lemma 8).

Upon an edge insertion (u, v) to G, we first pass this insertion to the data structure DynamicSpanF. If the edge (u, v) ends up being added to T, we then pass this insertion as two edge insertions (u, v) and (v, u) to the data structure IncrSSR and test whether t is reachable from s using this data structure. If the latter holds, then we find a simple directed s-t path in $E_f^d \cup T$, which in turn serves as an augmenting path for G. We then send one unit of flow along the path P in G. To make sure that the flow remains acyclic, we invoke procedure Decycle to remove potential directed cycles and update the current flow to be acyclic. Using the dynamic data structure DynamicSpanF, we delete all edges that no longer belong to E_f^u (because they now carry non-zero flow), and insert all new edges to E_f^u (because flow was removed from them). Finally, we increment the current flow by exactly 1.

To answer a query about the maximum flow between s and t, we simply return F^*. These procedures are summarized in Algorithm 4.

We next argue about the correctness of the algorithm. We start by reviewing the result below which shows that it is safe to restrict our attention to the graph $E_f^d \cup T$ when searching for an augmenting path.

▶ **Lemma 14** ([22]). *Let G_f be the residual graph of an undirected, unweighted graph G with respect to the flow f. Then $E_f^d \cup T$ has an augmenting path if and only if G_f does.*

In light of the lemma above, Lemma 4 and Lemma 5, it suffices to show that our incremental algorithm correctly maintains $E_f^d \cup T$. To this end, observe that this directly follows from (i) the correctness of DynSpanF data structure for maintaining T (Lemma 10) and (ii) by Lines 18-20 in Algorithm 4 which makes sure that the set E_f^d is correctly updated after each augmentation step. This completes the correctness argument.

We prove the running time complexity of the algorithm in the lemma below.

▶ **Lemma 15.** *Given an initially empty undirected, unweighted graph $G = (V, E)$ with n vertices, any two vertices s and t, and a parameter $\mu \in [0, n]$, the algorithm* IncB-MFU(G, s, t, μ) *exactly maintains, under m edge insertions, the maximum s-t flow in G whose value is bounded by μ in $\tilde{O}(m + n\mu^{3/2})$ total update time and $O(1)$ query time.*

Proof. Let us first study the work done to find augmenting paths. Since we decycle flows after each augmentation and the spanning forest T can have at most $2(n-1)$ edges (two edges in reverse direction for each undirected edge), by Lemma 12, each augmentation step is done on a graph with $O(n\sqrt{\mu})$ edges and thus takes $O(n\sqrt{\mu})$ time. Similarly, note that before an augmentation step, the set E_f^d does not change, and we only report to IncSSR data structure the edge insertions that ended up being added to T. There can be at most $2(n-1)$ such edge insertions. Therefore, the total cost of running IncSSR per round is $O(|E_f^d \cup T|) = O(n\sqrt{\mu})$. Since there are μ rounds, the total time is $O(n\mu^{3/2})$.

It remains to account for the dynamic operations handled by DynSpanF data structure. Consider the cost of deletions. An edge is deleted from the data structure whenever we put some non-zero flow on it. Since an augmenting path can have at most n edges, and there are at most μ rounds, this can happen to at most $n\mu$ edges. The latter in turn leads to at most $n\mu$ deletions for a total time of $\tilde{O}(n\mu)$ for handling them (Lemma 10).

We now turn our attention to the cost of insertions. Over the course of the incremental algorithm we pass m edges insertions to DynSpanF, for a total time of $\tilde{O}(m)$ (Lemma 10)). We also also pass insertions to DynSpanF whenever flow has been removed on the edges. However, for flow to be removed from an edge, it must have been first added an on edge, i.e., this edge was passed as a deletion to the data structure. Therefore, we can charge the total cost of these insertions to the total cost of deletions, which we bounded by $\tilde{O}(n\mu)$. This completes the proof of the lemma. ◀

5 Conclusion

In this paper we showed two algorithms for maintaining approximate and exact flows in dynamic graphs undergoing edge insertions. Our dynamic approximation algorithm first showed how to maintain small maximum flows efficiently in the incremental setting, and then employed the well-known technique of periodical rebuilds. For the exact result, we showed that the sparsifiers of residual graphs in the undirected setting can be maintained efficiently under edge insertions.

In general, the dynamic complexity of maximum flows is a largely unexplored area, with many fundamental questions remaining unanswered. For example, do there exist *decremental* algorithms achieving comparable guarantees to the ones we obtained in the incremental setting? Our framework from Theorem 6 readily extends to the graphs undergoing edge deletions only. However, it is not known how to maintain small maximum flows in the decremental setting.

Another fundamental open question is the existence of a fast *fully dynamic* algorithm that approximates maximum flows up to a constant factor. For general undirected graphs, recent research suggests that this question is intimately connected to efficient sparsifiers constructions that (approximately) preserve the cut structure between terminal subset of vertices on graphs. Thus, beyond dynamic graphs, any progress in answering this question would potentially lead to understanding other fundamental problems in graph algorithms.

Abstract

We study low sample complexity mechanisms in participatory budgeting (PB), where each voter votes for a preferred allocation of funds to various projects, subject to project costs and total spending constraints. We analyse the distortion that PB mechanisms introduce relative to the minimum-social-cost outcome in expectation. The Random Dictator mechanism for this problem obtains a distortion of 2. In a special case where every voter votes for exactly one project, [11] obtain a distortion of 4/3. We show that when PB outcomes are determined as any convex combination of the votes of two voters, the distortion is 2. When three uniformly randomly sampled votes are used, we give a PB mechanism that obtains a distortion of at most 1.66, thus breaking the barrier of 2 with the smallest possible sample complexity.

We give a randomized Nash bargaining scheme where two uniformly randomly chosen voters bargain with the disagreement point as the vote of a voter chosen uniformly at random. This mechanism has a distortion of at most 1.66. We provide a lower bound of 1.38 for the distortion of this scheme. Further, we show that PB mechanisms that output a median of the votes of three voters chosen uniformly at random, have a distortion of at most 1.80.

1 Introduction

More than 1500 cities around the globe have begun adopting *Participatory Budgeting* (PB) [22, 13], a process through which residents can vote directly on a city government's use of public funds. Residents might, for example, vote directly on how to allocate a budget of reserved funds between projects like street repairs or library renovations. PB has been shown to promote government transparency, resident engagement, and good governance [23].

[1] In alphabetical order.

We study a PB setup similar to [12] where each vote is an allocation of funds to projects (we call it a "preferred budget") subject to the constraint that the sum of allocations to all projects is equal to one. Projects have a fixed cost, and allocations to any project cannot exceed its cost. However, allocations less than the project's cost are allowed. ([12] consider all project costs equal to one). In this model, therefore, every vote and the outcome of the PB election can be represented as a point on the unit simplex.

We study the *distortion* (Definition 5) that PB mechanisms introduce in expectation relative to the social cost minimizing allocation in the worst case of PB instances, following the lines of [1]. We adopt the ℓ_1 distance as the cost function where a voter with preferred budget a experiences a cost of $d(a, b) = \|a - b\|_1$ from an outcome budget b (Definition 2).

Several preference elicitation methods have been studied for PB [7, 2, 15, 5]. Policymakers must then transform a list of votes into a real-world allocation of funds. Furthermore, even though there may be an "optimal" allocation (under natural notions of social welfare), this allocation may be intractable to compute [19, 21] or difficult to reliably estimate if turnout is low [8]. In some situations, policymakers need to obtain a quick estimate of the budgetary region in which preferences may lie. In these cases, and when running a fully-fledged PB election is costly or difficult, low-sample complexity PB mechanisms are an attractive choice.

Low-sample complexity preference elicitation mechanisms have also been of interest recently in computational social choice [11, 10, 1, 9] – in this work, we give low-sample complexity mechanisms (using the preferred budgets of a small number of sampled voters) for PB, which achieve a distortion of less than 2. Note that 2 is a natural barrier for the distortion in this problem since the *Random Dictator* mechanism achieves a distortion of 2 in our model of PB. The Random Dictator mechanism chooses the outcome as the preferred budget of a uniformly randomly chosen voter. From Theorem 5 of [1], its distortion is at most 2, and from our Lemma 7, it is 2. We further prove that a mechanism that chooses any linear combination of two randomly sampled votes (*Random Diarchy*) also attains a distortion of 2 (Lemma 8). Another low sample-complexity mechanism, *Random Referee* [10], asks a randomly chosen voter ("the referee") to choose one out of two possible outcomes, which are random samples from the preferred budgets of the voters. This mechanism also attains a distortion of at least 2 in our setup (Lemma 9). We give a PB mechanism which samples three voters uniformly at random and attains a distortion of at most 1.66.

1.1 Our Contributions

When the PB mechanism samples three voters uniformly at random, we show that aggregation schemes that choose a median of their preferred budgets achieve a distortion of at most 1.80. We refer to such schemes as the *median schemes* and denote this class of schemes by $\mathcal{M}$.

We then turn to the case where two uniformly randomly chosen voters can come together and "bargain" with a third voter's preferred budget (again chosen uniformly at random) as the "disagreement point." We formulate the bargaining rules for the voters via the well-studied Nash bargaining framework [6]. When these bargaining rules can be further specified by a randomized rule (§4.2), we show that the distortion of the resulting mechanism is at most 1.66 (Theorem 35). We call this mechanism the *randomized Nash bargaining scheme* $\mathfrak{n}_{rand}$.

A key technical tool we use is the analysis of *pessimistic distortion* (PD) (Definition 26) first proposed by [10]. PD is a form of distortion where the comparison is made with a counterfactual which chooses a separate outcome for every small subset of voters (of a fixed size κ), thereby attaining a lower social cost than the true "optimal". In this work, we use $\kappa = 6$. This choice is due to computational constraints. We show that the PD with $\kappa = 6$ is an upper bound on the distortion of our proposed mechanisms with any number of voters n.

We then reduce the problem of computing the PD into a set of linear programs for the median schemes $\mathcal{M}$ and bilinear programs of constant size for the randomized Nash

bargaining scheme $\mathfrak{n}_{rand}$. For this, we use a projection of the preferred budgets of voters into a space (we call it the *incremental allocation space* (§3)) that captures the common preferences of a subset of voters relative to other voters. In the median schemes, funds are allocated to projects ensuring that the final outcome is the median of the preferred budgets of three randomly sampled voters. In the randomized Nash bargaining scheme $\mathfrak{n}_{rand}$, the expected funds allocated to a project satisfy additional proportionality constraints (§4.2), resulting in bilinear programs. Since the proportionality constant is not fixed, this results in another variable in the optimization formulation. The problem has a complex combinatorial structure due to the nuances of Nash bargaining. However, we are able to exploit symmetries of the problem, enabling us to solve it efficiently. Since the bilinear programs are of a constant size (depends on κ, which we set to 6), we can solve these in fixed time.

Same as *Random Dictator* and *Random Referee*, our PB mechanism $\mathfrak{n}_{rand}$ also naturally respects project interactions such as complementarity and substitution as long as the voters are aware of these interactions. This is because the bargaining outcome between two voters is guaranteed to be Pareto optimal for them. We describe this point in detail in §8.

1.2 Related Work

The *sequential deliberation* (SD) mechanism for social choice was proposed in [11] where the two uniformly randomly chosen voters deliberate in each round under the rules of Nash bargaining, and the outcome for every round is the disagreement point for the next round. The SD for one round corresponds to the randomized Nash bargaining scheme $\mathfrak{n}_{rand}$. They analyzed the mechanism in median spaces, which include median graphs and trees, and found an upper bound of the distortion of the mechanism to be 1.208. They also analyze the distortion in the *budget space* (or unit simplex) in a special setting where each voter only approved funds for a single project. In this case, they show that the distortion in the equilibrium of SD is 4/3. This paper extends their work in the case of the unit simplex, such that voters in our model do not have to restrict their vote to one project.

The authors of [16] study a model where voters' opinions evolve via deliberations in small groups over multiple rounds. Opinions in their model correspond to preferred budgets in our model; however, unlike preferred budgets, opinions change as a result of deliberations. They study the distortion in single-winner elections setting and show that it is bounded by $O\left(1+\sqrt{\frac{\log n}{n}}\right)$ when voters deliberate in groups of 3 (n is the number of voters).

The work most closely related to ours is [10]; they study the *random referee* mechanism. We use their technique of analyzing the PD of 6 voters. However, they apply this technique where the underlying decision space is the Euclidean plane and use the underlying geometric structure to perform a grid search. In contrast, we study the PD with Nash bargaining, which leads to a complex structure of outcomes that we capture in linear or bilinear programs.

The authors of [9] analyze low sample-complexity randomized mechanisms for PB. They obtain constant factor guarantees for higher moments of distortion, and the distortion bound they provide is much larger than 2. Several additional results and research directions in PB are described in the survey [4].

1.3 Future Directions

A natural direction for future work is to analyze the distortion for multiple rounds of deliberation in our model, with every round's outcome serving as the next round's disagreement point. Another interesting modelling question is to study the deliberation or bargaining process with more than two agents participating together. Closing the gap of the distortion of $\mathfrak{n}_{rand}$ also remains an interesting open problem.

1.4 Roadmap

We describe the model and preliminaries in §2, introduce a projection operation and give some technical results in §3, characterize the outcome of different schemes in §4. We derive the distortion of the class of median schemes in §5. We derive the distortion under $\mathfrak{n}_{rand}$ in §6. We give empirical results on real-world Participatory Budget (PB) data in §7, and discuss project interactions in §8.

2 Model and Preliminaries

Suppose we have m projects and are required to design a budget. A *budget* denotes the fraction of the total funds that are to be spent on each project. Projects have a maximum possible allocation or "project costs." All votes respect these *project costs*, and consequently, the outcomes of all our mechanisms also respect the project costs.[2] For notational simplicity, we drop the project costs from the model henceforth and operate under the assumption that project costs are 1. All our results trivially follow for general project costs.

▶ **Definition 1.** *Let b_j denote the funds allotted to project j in budget b. We define the* budget simplex *as the set of valid budgets i.e.,* $\mathbb{B} = \{b \in \mathbb{R}^m | \sum_{j=1}^m b_j = 1$ *and* $b_j \geq 0, \forall j \in [m]\}$.

There are n voters, each with a *preferred budget* $v_i \in \mathbb{B}$. A *vote profile* P denotes the list of preferred budgets of all voters, i.e, $P = (v_1, v_2, \ldots, v_n)$. The funds allotted to project j by voter i is $v_{i,j}$. A vote profile defines an *instance of PB*. The outcome of an instance of PB is a budget in $\mathbb{B}$. Voters adopt the ℓ_1 distance as the cost function. (Not to be confused with the project costs, which is a different concept here.)

▶ **Definition 2.** *For $a, b \in \mathbb{B}$, the cost of an outcome b for a voter with preferred budget a is $d(a,b) = \sum_{j=1}^m |a_j - b_j|$. The sum of cost over all budgets, $\sum_{i\in[n]} d(v_i, b)$, is the social-cost of budget b.*

We define the *overlap utility* which is closely related to the *cost*. Note that this notion of overlap utility has been studied in knapsack voting [15, 12].

▶ **Definition 3** (Overlap Utility)**.** $u(a,b) = \sum_{j=1}^m \min(a_j, b_j)$.

▶ **Lemma 4.** *For budgets $a, b \in \mathbb{B}$, $d(a,b) = 2 - 2u(a,b)$.*

A proof is in Appendix A.13 of the extended version [17]. Lemma 4 implies that for a voter, maximizing overlap utility is the same as minimizing the cost. Note that overlap utility is *symmetric*, i.e, $u(a,b) = u(b,a)$.

2.1 Distortion

Here we define *distortion,* which we use as a metric to quantify how good a outcome is in comparison to the optimal solution for minimizing social-cost. We define distortion through the *cost* $d(\cdot,\cdot)$.

▶ **Definition 5.** *The **distortion** of budget b for vote profile P is*

$$\text{Distortion}_P(b) = \frac{\sum_{v\in P} d(v,b)}{\min_{b^*\in\mathbb{B}} \sum_{v\in P} d(v,b^*)}.$$

[2] There is no constraint on the minimum allocation to a project other than that it must be non-negative.

Let $h(P)$ be the output of mechanism h for vote profile P.

▶ **Definition 6.** *The distortion of a class of voting mechanisms $\mathcal{H}$ is:* $\text{Distortion}(\mathcal{H}) = \sup_{n\in\mathbb{Z}^+,\ P\in\mathbb{B}^n,\ h\in\mathcal{H}} \mathbb{E}[\text{Distortion}_P(h(P))]$.

Note that distortion is defined as a supremum over all instances of PB and all mechanisms in class $\mathcal{H}$.[3] The expectation is over the randomness of the mechanism, which also includes the randomness in the selection of voters.

The distortion of a voting mechanism is widely used to evaluate its performance regarding how close its output is to the social cost-minimizing outcome in expectation [1, 20, 3, 14, 10]. The *Random Dictator* [1] voting mechanism has a distortion of 2, as shown in Lemma 7. A proof is given in Appendix A.1 in the extended version [17].

▶ **Lemma 7.** *Any aggregation method constrained to choose its outcome as the preferred budget of a uniformly randomly chosen voter has distortion* 2*.*

Now, consider a mechanism that chooses the outcome via the deliberation between two voters chosen uniformly at random with preferred budgets a and b. Within this class, we consider mechanisms constrained to choose the outcome as a convex combination of budgets a and b.

Now, consider a mechanism constrained to choose the outcome as a linear combination of budgets a and b where a and b denote the preferred budgets of randomly sampled voters. That is, $\alpha(P)a + (1-\alpha(P))b$ for $\alpha(P) \in [0,1]$. Note that $\alpha(P)$ may be optimized over the entire vote profile.[4] We refer to this class of mechanisms as *Random Diarchy* and denote it by $\mathcal{Q}$. Interestingly, the distortion of $\mathcal{Q}$ is 2, the same as that of *Random Dictator*.

▶ **Lemma 8.** *For Random Diarchy* $\inf_{\mathfrak{q}\in\mathcal{Q}} \text{Distortion}(\mathfrak{q}) = 2$.

A proof is given in Appendix A.2 in the extended version [17]. We further show that *Random Referee* scheme described in [11] where one of the two preferred budgets of the bargaining voters is chosen based on the preferred budget of third sampled voter also has a distortion ratio of at least 2 in Lemma 9, proven in Appendix A.3 in the extended version [17]. We denote the class of such mechanisms by $\mathcal{R}$.

▶ **Lemma 9.** *For Random Referee* $\inf_{\mathfrak{q}\in\mathcal{R}} \text{Distortion}(\mathfrak{q}) \geq 2$.

2.2 Model of preference aggregation

Let us define the mechanism formally in steps and we call it **Triadic scheme**.

1. Pick a voter i uniformly at random and set the disagreement point c as the preferred budget of voter i.
2. Now choose two voters a and b uniformly at random with replacement and they bargain with c as the disagreement point.

All our theoretical results in this paper are for the outcome of the triadic scheme. However, as discussed in [11], we can extend this bargaining scheme to multiple rounds by setting the outcome of the previous round as the disagreement point for the next round and sampling the two bargaining voters uniformly at random without replacement. We provide empirical results for this setup for multiple rounds (upto 10 rounds) in § 7.

[3] We will often study the distortion of a single mechanism, i.e., not a class. In that case, $\text{Distortion}(h)$ simply denotes the distortion of the mechanism h.

[4] All such outcomes maximize the sum of the overlap utilities of the deliberating agents.

Our bound on pessimistic distortion assumes that the voters are chosen with replacement as done in [10]. This directly gives us a bound on the distortion when voters are sampled without replacement. It is easy to see that the difference in these bounds is of $O(\frac{1}{n})$. The case where two or more identical voters are sampled out of three defaults to the *Random Dictator* mechanism, which has constant distortion – the probability of this event is of $O(\frac{1}{n})$.

We consider bargaining schemes satisfying one or more of the following constraints, namely a) Pareto efficiency, b) Invariance to Affine Transformation, c) Symmetry, and d) Independence of Irrelevant Alternatives. Bargaining schemes that satisfy all of these constraints are the class of Nash bargaining schemes denoted by $\mathcal{N}$ [6].

▶ **Definition 10.** *An outcome of $\mathcal{N}(a,b,c)$, the **Nash bargaining** between two voters with preferred budgets a and b and the disagreement point c, is a budget z which maximizes the Nash product $(u(a,z)-u(a,c))\times(u(b,z)-u(b,c))$, subject to individual rationality $u(a,z)\geq u(a,c)$ and $u(b,z)\geq u(b,c)$, and in case of a tie between possible outcomes, maximizes $u(c,z)$.*

The fact that $\mathcal{N}$ breaks ties in favor of the disagreement point is crucial for the distortion of triadic scheme with bargaining schemes in $\mathcal{N}$ to be smaller than 2. It is also crucial for the membership of $\mathcal{N}$ in a class of bargaining schemes that maximize the sum of overlap utilities of the bargaining agents and the disagreement point. We now define this class of bargaining schemes.

▶ **Definition 11.** *$\mathcal{M}$ is the class of **median schemes** if any outcome $z\in\mathcal{M}(a,b,c)$ maximises the sum of utilities with budgets a,b and c i.e. $u(z,a)+u(z,b)+u(z,c)$.*

The following important result is proved in Appendix A.11 in the extended version [17].

▶ **Theorem 12.** *Every scheme in $\mathcal{N}$ is also a median scheme i.e. $\mathcal{N}\subseteq\mathcal{M}$*

3 Incremental allocation space

We now give a function that captures the marginal preferences of a subset of voters S regarding the allocation to project j, relative to the preference of the other voters (i.e., $P\setminus S$). This function will be useful as an analytical tool in the paper. Specifically,

▶ **Definition 13.** *Given a vote profile $P=(v_1,v_2,\ldots,v_n)$, and project j, the **incremental project allocation** $X_{j,P}:2^{[n]}\to[0,1]$ maps a subset of budgets S to*

$$X_{j,P}(S)=\max\left(\left(\min_{i\in S}v_{i,j}\right)-\left(\max_{i\in P\setminus S}v_{i,j}\right),0\right).$$

Here max and min over $\emptyset$ are defined as 0 and 1, respectively. $X_{j,P}(S)$ denotes the amount by which the budgets in S *all* agree on *increasing* the allocation to project j above the *maximum* allocation to j by any budget in $P\setminus S$. Summing this quantity over all projects $j\in[m]$ gives us $X_P(S)$, which is defined in the following.

▶ **Definition 14.** *For a vote profile P, the **incremental allocation** $X_P:2^{[n]}\to\mathbb{R}$ is $X_P(S)=\sum_{j=1}^{m}X_{j,P}(S)$ for all $S\subseteq P$.*

We use $X_P(.)$ in §5 since its complexity is dependent only on the number of voters n and not on the number of projects m. This helps us give results valid for arbitrarily large values of m. We illustrate the functions $X_{j,P}(\cdot)$ and $X_P(\cdot)$ in the following example.

▶ **Example 15.** Consider an instance of PB with three projects and a vote profile P with three budgets $a = \langle 1, 0, 0\rangle$, $b = \langle 0, 1, 0\rangle$, and $c = \langle 0.25, 0.25, 0.5\rangle$. [5] Then, $X_{1,P}(a) = 0.75$. This is because the budget a has allocation 1 to project 1, out of which only 0.75 is *incremental* on top of $\max(b_1, c_1)$. Also, $X_{2,P}(a) = X_{3,P}(a) = 0$. As a result, $X_P(a) = 0.75$. Similarly $X_{2,P}(b) = X_P(b) = 0.75$. Also, $X_{3,P}(c) = X_P(c) = 0.5$. Further, $X_P(ac) = 0.25$. This is because the subset $\{a, c\}$ has a minimum allocation of 0.25 to project 1 among themselves. It is also incremental since $b_1 = 0$. Further, we have $X_{1,P}(abc) = X_{2,P}(abc) = X_{3,P}(abc) = X_P(abc) = 0$. This is because the group of all three budgets has no allocation that is common to all. Finally, $X_P(\emptyset) = X_{3,P}(\emptyset) = 0.5$ because no budget allocated funds more than 0.5 to project 3.

We use $\mathcal{P}(P)$ to denote the power set of P. We now give an important corollary regarding the function $X_{j,P}(\cdot)$.

▶ **Corollary 16.** $\sum_{S\in\mathcal{P}(P)} X_{j,P}(S) = 1$, $\forall j \in [m]$.

A proof is given in Appendix A.8 in the extended version [17]. Corollary 16 says that every incremental allocation to project j by budgets in S adds up to 1 when summed over all subsets S (this includes the empty set; $X_{j,P}(\emptyset) > 0$ implies that no voter allocated the full 1 unit budget to project j).

3.1 Projection On Incremental Allocations

We now give a *projection* of $X_{j,P}$ from P to $Q \subseteq P$ to get $X_{j,Q}$. This operation has two applications in this paper. First, it enables us to study the allocations of an outcome z relative to the vote profile P by making projections from $P \cup \{z\}$ to P. Second, it is used to study the outcomes of bargaining with a subset $Q \subseteq P$ of voters with respect to the entire vote profile P via projections from P to Q.

▶ **Lemma 17.** *For any vote profile P and $Q \subseteq P$, the* ***projection from P to Q*** *is $X_{j,Q}(S) = \sum_{\hat{S}\in\mathcal{P}(P\setminus Q)} X_{j,P}(\hat{S} \cup S)$ for all $S \in \mathcal{P}(Q)$, and all $j \in [m]$. Summing over $j \in [m]$, $X_Q(S) = \sum_{\hat{S}\in\mathcal{P}(P\setminus Q)} X_P(\hat{S} \cup S)$.*

A proof is given in Appendix A.9 in the extended version [17]. Lemma 17 captures an important technical fact. To calculate the incremental project allocation function on S over a vote profile $Q \subseteq P$, i.e., $X_Q(S)$, we may sum $X_P(\cdot)$ over all subsets of budgets in P which contain all elements of S but no element of $Q \setminus S$. Note that here $S \subseteq Q \subseteq P$.

We now consider the problem of analyzing an outcome z with the help of the incremental allocation function. Towards this, we define the function $Z_{j,P}(S)$ with respect to an outcome z with the help of the projection operation described in Lemma 17.

▶ **Definition 18.** *For vote profile P and budget z, define $Z_{j,P} : 2^{[n]} \to [0, 1]$ as $Z_{j,P}(S) = X_{j,P\cup\{z\}}(S \cup \{z\})$ $\forall S \subseteq P$.*

Recall from Definition 13 that $X_{j,P}(S)$ denotes the amount by which *all* budgets in S want to increase the allocation to project j over the maximum allocation to j by any budget in $P \setminus S$. The quantity $Z_{j,P}(S)$ denotes the amount by which the outcome budget z "accepts" this preference of S. Naturally, $Z_{j,P}(S) \leq X_{j,P}(S)$.

Analogous to summing $X_{j,P}(S)$ over all $j \in [m]$ to get $X_P(S)$, we can sum $Z_{j,P}(S)$ over all $j \in [m]$ to get $Z_P(S)$.

[5] For brevity, we omit braces and commas in the argument of X.

▶ **Definition 19.** *For vote profile P and budget z, define $Z_P(S) : 2^{[n]} \to [0,1]$ as $Z_P(S) = \sum_{j=1}^{m} Z_{j,P}(S)$ $\forall S \subseteq P$.*

$Z_P(S)$ informally denotes the amount by which outcome budget z "accepts" the preference of S for increasing allocations above the allocations of $P \setminus S$ across all projects. See that $Z_P(S) \leq X_P(S)$.

▶ **Corollary 20.** *For any vote profile P and budget z, $Z_{j,P}(S) \leq X_{j,P}(S)$ for all $j \in [m]$. Summing over $j \in [m]$, $Z_P(S) \leq X_P(S)$.*

Proof. Follows directly from Lemma 17 since $X_{j,P}(S) = Z_{j,P}(S) + X_{j,P\cup\{z\}}(S)$ (we are projecting from $P \cup \{z\}$ to P). ◀

▶ **Corollary 21.** *$\sum_{S\in\mathcal{P}(P)} Z_{j,P}(S) = z_j$ for all vote profiles P and $z \in \mathbb{B}$. Summing over all projects $j \in [m]$, we get $\sum_{S\in\mathcal{P}(P)} Z_P(S) = 1$.*

Proof. We have $z_j = X_{j,\{z\}}(\{z\})$ [Definition 13]. Apply Lemma 17 by doing a projection from $P \cup \{z\}$ to $\{z\}$. ◀

This result captures, in the incremental common budget space, the fact that the total funds allocated by a budget z to projects $j \in [m]$ is 1. The following example illustrates $Z_{j,P}(S)$.

▶ **Example 22.** Consider vote profile $P = \{a, b, c\}$ with two projects. Let the budgets a, b, and c be $\langle 0.2, 0.8\rangle, \langle 0.5, 0.5\rangle$, and $\langle 0.8, 0.2\rangle$ respectively. Let the outcome budget z be $\langle 0.4, 0.6\rangle$. In this case, $X_{2,P}(ab) = 0.3$ and $Z_{2,P}(ab) = 0.3$ since the excess allocation by outcome z to project 2 over the allocation by budget c (i.e., 0.4) is larger than the least excess allocation to project 2 by budgets a and b over allocation in budget c (i.e., $X_{2,P}(ab)$ which is 0.3). In other words, the entire incremental allocation to project 2 by budgets a and b is accepted by outcome z. However, $X_{2,P}(a) = 0.3$ but $Z_{2,P}(a) = 0.1$ since the incremental allocation to project 2 by budget z over budgets b and c is 0.1. Thus only a partial incremental allocation to project 2 by budget a is "accepted" by budget z.

4 Overview of Median and Nash bargaining schemes

Recall the triadic mechanism from § 2.2 and we characterize its outcome. Let the disagreement point be c and the preferred budgets of the agents chosen randomly for the mechanism be a and b. For simplicity of notation, we denote $X_{\{a,b,c\}}(S)$ by $\mathfrak{X}(S)$ for S being any subset of $\{a, b, c\}$[6]. We also denote the outcome budget of the bargaining by z and $Z_{(a,b,c)}(S) = X_{\{a,b,c,z\}}(S\cup\{z\})$ by $\mathcal{Z}(S)$ for $S \subseteq \{a, b, c\}$.

4.1 Overview of class of schemes $\mathcal{M}$ and $\mathcal{N}$

In Figure 1, we illustrate the incremental allocations $\{\mathfrak{X}(S)\}_{S\subseteq\{a,b,c\}}$ with budgets a, b, and c on a Venn diagram. Recall from Definition 19 that $\mathcal{Z}(S)$ denotes what incremental allocation from $\mathfrak{X}(S)$ is "accepted" by outcome z. For the construction of $\mathcal{Z}(\cdot)$, the bargaining agents first select all the allocations "agreed" to by at least two of the three budgets. In Figure 1, this corresponds to the area of the overlaps. Now, we have two cases, i.e. the total allocation to $\mathcal{Z}$ is less than 1 or exceeds 1. We denote the difference between 1 and the total allocation to $\mathcal{Z}$ by Excess.

[6] Note that we do not consider $X_P(\cdot)$ in this section where P is the set of the preferred budgets of all the voters, even those not involved in the bargaining.

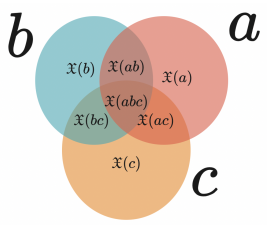

Figure 1 Incremental allocations with two preferred budgets of bargaining agents a and b, and disagreement point c.

Consider the case when the total allocation to $\mathcal{Z}(S)$ is less than 1. Here, the agents need to make further allocations worth Excess. Under the class of median schemes $\mathcal{M}$ [described in §4.3], they may select project allocations from $\mathfrak{X}(a), \mathfrak{X}(b)$, and $\mathfrak{X}(c)$ arbitrarily into the outcome z and thus into $\mathcal{Z}(a), \mathcal{Z}(b)$ and $\mathcal{Z}(c)$. In Figure 1, this corresponds to the area covered by exactly one of the budgets. However, under Nash bargaining schemes $\mathcal{N}$, they select allocations worth $\frac{\text{Excess}}{2}$ from each of $\mathfrak{X}(a)$ and $\mathfrak{X}(b)$.

Now, consider the case when the total allocation to $\mathcal{Z}(S)$ is more than 1. In this case, under median schemes, $\mathcal{M}$, the participating agents select total project allocations worth Excess arbitrarily from $\mathfrak{X}(ab), \mathfrak{X}(bc)$ and $\mathfrak{X}(ca)$ and remove allocations to these projects. In Figure 1, this corresponds to the area of the overlap of exactly two budgets. However, under Nash bargaining schemes $\mathcal{N}$, they select allocations worth $\frac{|\text{Excess}|}{2}$ from each of $\mathfrak{X}(ac)$ and $\mathfrak{X}(bc)$ and remove allocations to these projects from the outcome z.

The following lemma characterizes the overlap of the outcome $z \in \mathcal{N}(a, b, c)$ with the budgets a, b, and c, in terms of the incremental allocation functions $\mathfrak{X}(\cdot)$ and $\mathcal{Z}(\cdot)$.

▶ **Lemma 23.** *For any preferred budgets of bargaining agents a and b, disagreement point c, and outcome z of $\mathcal{N}(a, b, c)$,*

$$\begin{aligned}
\mathcal{Z}(abc) &= \mathfrak{X}(abc), \quad \mathcal{Z}(ab) = \mathfrak{X}(ab),\\
\mathcal{Z}(ac) &= \mathfrak{X}(ac) + \min(\textit{Excess}/2, 0),\\
\mathcal{Z}(bc) &= \mathfrak{X}(bc) + \min(\textit{Excess}/2, 0),\\
\mathcal{Z}(a) &= \mathcal{Z}(b) = \max(0, \textit{Excess}/2),\\
\mathcal{Z}(c) &= \mathcal{Z}(\emptyset) = 0.
\end{aligned}$$

Where, $\textit{Excess} = (1 - \mathfrak{X}(abc) - \mathfrak{X}(ab) - \mathfrak{X}(ac) - \mathfrak{X}(bc))$.

Proof Sketch. In Nash bargaining, no part of z is such that it is not preferred by both a and b. That is, $\mathcal{Z}(c) = \mathcal{Z}(\emptyset) = 0$. Otherwise, we could construct a new outcome z' that reallocated the funds from $\mathcal{Z}(c)$ or $\mathcal{Z}(\emptyset)$ to $\mathcal{Z}(a)$ and $\mathcal{Z}(b)$. This would increase $u(a, z)$ and $u(b, z)$ and thus z would not be Pareto optimal. The parts of z that benefit both a and b must be maximized. That is, $\mathcal{Z}(abc) = \mathfrak{X}(abc)$ and $\mathcal{Z}(ab) = \mathfrak{X}(ab)$. Otherwise, we could construct a new outcome z' that reallocates funds from any other project to the project that benefits both a and b, thus showing that z is not Pareto optimal. The remaining part of the proof is technical and is in Appendix A.12 in the extended version [17]. ◀

We give an explanation of the construction of the Nash bargaining solution z (and correspondingly $\mathcal{Z}$) in three steps.[7]

[7] The steps are only for illustration purposes. There is no chronology or structure required in bargaining processes. We can only characterize the outcome.

Step 1: The voters with preferred budgets a and b mutually decide to allocate funds to projects that benefit both of them. This means, for all projects $j \in [m]$, $z_j = \min(a_j, b_j)$. In terms of $\mathfrak{X}(\cdot)$ and $\mathcal{Z}(\cdot)$, this corresponds to $\mathcal{Z}(abc) = \mathfrak{X}(abc)$ and $\mathcal{Z}(ab) = \mathfrak{X}(ab)$. At this point, $\mathcal{Z}(\cdot)$ is zero for all other subsets of $\{a, b, c\}$.

Step 2: At this point, the total allocation to projects in the bargaining outcome z may be less than 1. The bargaining agents now allocate more funds to the projects $j \in [m]$ for which $z_j < \max(a_j, b_j)$ *and* $z_j < c_j$. Now z_j is set to the "median" of (a_j, b_j, c_j) for *all* projects $j \in [m]$. In terms of $\mathfrak{X}(\cdot)$ and $\mathcal{Z}(\cdot)$, this corresponds to setting $\mathcal{Z}(ac) = \mathfrak{X}(ac)$ and $\mathcal{Z}(bc) = \mathfrak{X}(bc)$.

Step 3: Now, two possibilities arise for the total amount of funds allocated in z so far, i.e., the bargaining agents have either over-spent or under-spent the total funds. These cases are central to the analysis in the paper and will be revisited several times.

Case 1: The total funds currently allocated in z is at most 1, i.e., $\mathcal{Z}(ab) + \mathcal{Z}(bc) + \mathcal{Z}(ac) + \mathcal{Z}(abc) \leq 1$. This is same as:

$$\mathfrak{X}(ab) + \mathfrak{X}(bc) + \mathfrak{X}(ac) + \mathfrak{X}(abc) \leq 1. \tag{1}$$

Recall the definition of Excess in Lemma 23. In this case, since there is a positive Excess, the bargaining agents now allocate more funds to projects with $z_j < \max(a_j, b_j)$. Since in Nash bargaining we assume equal importance of the overlap utilities of both the bargaining agents, they divide the Excess equally. They incrementally fund projects with $z_j < a_j$ and the projects with $z_j < b_j$ with Excess/2 amount each. They ensure that $z_j \leq \max(a_j, b_j)$. The precise manner of doing so is not important to satisfy the axioms of Nash bargaining. In terms of $\mathcal{Z}(\cdot)$, this corresponds to setting $\mathcal{Z}(a) = \mathcal{Z}(b) = \text{Excess}/2$.

Case 2: The total funds currently allocated in z exceeds 1, i.e., $\mathcal{Z}(ab) + \mathcal{Z}(bc) + \mathcal{Z}(ac) + \mathcal{Z}(abc) \geq 1$. This is same as:

$$\mathfrak{X}(ab) + \mathfrak{X}(bc) + \mathfrak{X}(ac) + \mathfrak{X}(abc) \geq 1. \tag{2}$$

If we are in this case, then the bargaining agents have overspent the funds and Excess is negative. They need to remove $-$Excess amount of allocations from z. Recall that at this point, z_j is set to the median of (a_j, b_j, c_j) for *all* projects $j \in [m]$. They remove funds from projects with $(z_j > a_j)$ and the projects with $(z_j > b_j)$ with Excess/2 amount each. They ensure that $z_j \geq \min(a_j, b_j)$. The precise manner of doing so is not important to satisfy the axioms of Nash bargaining. In terms of $\mathcal{Z}(\cdot)$, this corresponds to setting $\mathcal{Z}(ac) = \mathfrak{X}(ac) + \text{Excess}/2$, and $\mathcal{Z}(bc) = \mathfrak{X}(bc) + \text{Excess}/2$.

We now give a randomized way of allocating the Excess funds in **Step 3** while satisfying the axioms of Nash bargaining.

4.2 Randomised Nash bargaining solution $\mathfrak{n}_{\mathsf{rand}}$

Case 1: Denote $s_j^a = \max\{a_j - z_j, 0\}$ for all projects j.[8] To projects with $s_j^a > 0$, allocate incremental funds r_j^a at random such that $\mathbb{E}[r_j^a]$ is proportional to s_j^a. The sum of r_j^a over all $j \in [m]$ is Excess/2 and no incremental allocation r_j^a is more than s_j^a.[9] A similar process is followed for projects j with $z_j < b_j$ by defining $s_j^b = \max\{b_j - z_j, 0\}$ and making incremental allocations r_j^b summing to Excess/2, $\mathbb{E}[r_j^b]$ proportional to s_j^b, and with $r_j^b \leq s_j^b$.

[8] This precisely corresponds to $X_{j,Q}(a)$ in the incremental allocation space.

[9] The randomness of this process is the same as the hypergeometric distribution with (discretized) s_j^a balls corresponding to each project $j \in [m]$ in an urn, and we pick (discretized) Excess/2 balls without replacement to provide incremental allocations.

Case 2: Denote $t_j^a = \max\{z_j - a_j, 0\}$ for all projects $j \in [m]$.[10] From projects with $t_j^a > 0$, remove r_j^a amount of previously allocated funds at random such that $\mathbb{E}[r_j^a]$ is proportional to t_j^a. The sum of r_j^a over all $j \in [m]$ is $-\text{Excess}/2$ and with $r_j^a \leq t_j^a$. A similar process is followed for projects with $z_j > b_j$ by defining $t_j^b = \max\{z_j - b_j, 0\}$ and removing allocations r_j^b from project j summing to $\text{Excess}/2$, $\mathbb{E}[r_j^b]$ proportional to t_j^b, and with $r_j^b \leq t_j^b$.

We now give a characterization of median schemes $\mathcal{M}$ in terms of $\mathcal{Z}$ [recall that $\mathcal{N} \subseteq \mathcal{M}$ from Theorem 12 in §2.2].

4.3 Median schemes $\mathcal{M}$

▶ **Theorem 24.** *For any budgets $a, b, c \in \mathbb{B}$, a budget $z \in \mathbb{B}$ is in $\mathcal{M}(a, b, c)$ if and only if it satisfies the following conditions.*

1. $\mathcal{Z}(abc) = \mathfrak{X}(abc)$ *and* $\mathcal{Z}(\emptyset) = 0$.
2. *In* ***Case 1****:* $\mathcal{Z}(ab) = \mathfrak{X}(ab)$, $\mathcal{Z}(bc) = \mathfrak{X}(bc)$, $\mathcal{Z}(ca) = \mathfrak{X}(ca)$.
3. *In* ***Case 2****:* $\mathcal{Z}(a) = \mathcal{Z}(b) = \mathcal{Z}(c) = 0$.

The proof of this theorem is technical and is given in Appendix A.10 in the extended version [17].

Note that all the conditions on the outcomes of the bargaining schemes in $\mathcal{M}$ are *symmetric* in all three of $\{a, b, c\}$. However, outcomes in $\mathcal{N}$ also satisfy some additional conditions which may not be symmetric in all three of $\{a, b, c\}$.

We now give a lower bound on Distortion($\mathcal{N}$). Since $\mathcal{M}$ contains $\mathcal{N}$, this bound also applies to Distortion($\mathcal{M}$). Moreover, the same bound also holds for the distortion of $\mathfrak{n}_{\text{rand}}$.

▶ **Theorem 25.** Distortion($\mathcal{M}$) $\geq$ Distortion($\mathcal{N}$) > 1.38.
Also, Distortion($\mathfrak{n}_{rand}$) > 1.38.

Proof. The proof is by the following example of a PB instance. Suppose there are $n_A + n_B$ voters and $n_A + 1$ projects for some $n_A, n_B \geq 1$. Let o_i denote the budget where the i-th project receives allocation 1 and all the other projects get allocation 0. Each voter i in group A ($i \in [n_A]$) prefers budget o_i. Each voter i in group B ($i \in [n_A + n_B] \setminus [n_A]$) prefers budget o_{n_A+1}. The analysis of this example is in Appendix A.4 in the extended version [17] where we set $n_A = 2200$; $n_B = 3000$. ◀

We now give upper bounds of the distortion of $\mathcal{M}$.

5 Distortion Of Schemes in $\mathcal{M}$

To find an upper bound of the distortion of triadic scheme with any bargaining scheme, we use a technique introduced in [10], called *pessimistic distortion* (PD). In this technique, we first analyze the distortion for a small group of voters, call it PD, and then show that the distortion over all voters cannot be more than the PD. Specifically, in this paper, we analyze the PD for a group of 6 voters. The idea is that we allow the counterfactual solution to choose a separate "optimal" budget for every 6-tuple of voters, thereby attaining a smaller social cost than a common outcome for all voters. On the other hand, for our mechanism, we consider the expected social cost under one outcome. This is why the distortion calculated is *pessimistic*. Formally:

[10] This precisely corresponds to $X_{j,Q}(bc)$ in the incremental allocation space.

▶ **Definition 26.** *The **pessimistic distortion (PD)** of the class of mechanisms $\mathcal{M}$ with triadic scheme with 6 voters is:*

$$PD(\mathcal{M}) = \sup_{P\in\mathbb{B}^6;\ h\in\mathcal{M}} \frac{\frac{1}{20}\sum_{Q\in\mathcal{C}([6],3)} \frac{1}{3}\sum_{i\in[6]\setminus Q} d(h(Q),P_i)}{\min_{p\in\mathbb{B}} \frac{1}{6}\sum_{i\in[6]} d(p,P_i)}.$$

Here $\mathcal{C}(S,k)$ denotes the set of all k-combinations of set S.[11]

Notice that in the definition of PD, we only consider the cost for the non-bargaining agents (same as in [10]). We illustrate the PD in Figure 2, where the bargaining is over budgets $\{a,b\}$, the disagreement point is c, and the cost is computed only for $\{d,e,f\}$, the budgets not involved in the bargaining. This definition is more pessimistic than considering all agents' costs. Further, since the outcome of $\mathcal{M}$ is *symmetric* in $\{a,b,c\}$, we can use any *combination* Q of three voters to compute the outcome of bargaining without designating one of the budgets as the disagreement point. The next result, proved in Appendix A.14 in

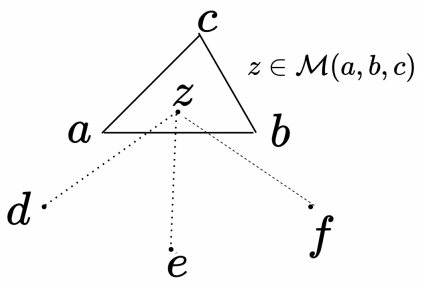

Figure 2 Illustration of PD where a,b,c are sampled for the mechanism $\mathcal{M}$, and $\{d,e,f\}$ are the other budgets for which we measure the cost of outcome z.

the extended version [17], is that the distortion of any bargaining scheme in $\mathcal{M}$ with triadic scheme cannot be more than its PD with triadic scheme with only 6 voters.

▶ **Lemma 27.** $\text{Distortion}(\mathcal{M}) \le PD(\mathcal{M})$.

We now give a representation of the overlap utilities $u(\cdot,\cdot)$ (equivalently the cost $d(\cdot,\cdot)$), in terms of the incremental allocations $X_P(S)$. This representation is of technical importance for proofs.

▶ **Lemma 28.** *For budgets $\{a,b\}$, and a vote profile P that includes $\{a,b\}$, we have $u(a,b) = X_{(ab)}(ab) \overset{(1)}{=} \sum_{\hat{S}\in\mathcal{P}(P\setminus\{a,b\})} X_P(\hat{S}\cup\{a,b\})$.*

Proof. From Definition 3, we have $u(a,b) = \sum_{j=1}^m \min(a_j,b_j)$. From Definition 13 we have $\sum_{j=1}^m \min(a_j,b_j) = \sum_{j=1}^m X_{j,(a,b)}(ab) = X_{(ab)}(ab)$. Now apply Lemma 17 with $Q = S = \{a,b\}$, to obtain equality (1). ◀

[11] For simplicity of notation, we use $\mathfrak{n}(Q)$ in place of $\mathfrak{n}(P_{Q_1},P_{Q_2},P_{Q_3})$ in PD.

Lemma 28 shows that the overlap utility between two budgets a, b is the same as the sum of what a, b, and all subsets of the other budgets in P have in common via the incremental allocation function $X_P(S)$. For example, if $P = (a, b, c, d)$, then $u(a, b) = X_P(ab) + X_P(abc) + X_P(abd) + X_P(abcd)$.

Lemma 28 is useful for the proof of the following important result, which is an upper bound for $PD(\mathcal{M})$.

▶ **Lemma 29.** $PD(\mathcal{M}) \leq 1.80$.

We give a sketch of the proof here. The detailed proof is in Appendix A.15 in the extended version [17].

Proof Sketch. Let p^Q denote a budget obtained on bargaining with budgets in set Q using a bargaining scheme in $\mathcal{M}$. Note that mechanisms in $\mathcal{M}$ are *symmetric* in Q therefore, we do not need to designate a disagreement point in Q for analysis.

$$\begin{aligned} PD(\mathcal{M}) &= \sup_{P\in\mathbb{B}^6;\ h\in\mathcal{M}} \frac{\frac{1}{60}\sum_{Q\in\mathcal{C}([6],3)}\sum_{i\in[6]\setminus Q} d(h(Q),P_i)}{\frac{1}{6}\min_{v\in\mathbb{B}}\sum_{i\in[6]} d(v,P_i)}, \\ &\leq \sup_{P\in\mathbb{B}^6} \frac{\frac{1}{60}\sum_{Q\in\mathcal{C}([6],3)}\sup_{p^Q\in\mathcal{M}(Q)}\sum_{i\in[6]\setminus Q} d(p^Q,P_i)}{\frac{1}{6}\min_{v\in\mathbb{B}}\sum_{i\in[6]} d(v,P_i)}. \end{aligned}$$

Suppose that $PD(\mathcal{M}) > 1.80$. Then the following optimization problem has an optimal objective value strictly greater than 0.

$$\begin{aligned} \text{maximize} \quad & \frac{1}{60}\sum_{Q\in\mathcal{C}([6],3)}\sum_{i\in[6]\setminus Q} d(p^Q,P_i) - 1.80\cdot\frac{1}{6}\sum_{i\in[6]} d(v,P_i), \\ \text{subject to} \quad & P\in\mathbb{B}^6, \\ & p^Q\in\mathcal{M}(Q) \qquad\qquad \forall Q\in\mathcal{C}([6],3), \\ & v\in\mathbb{B}. \end{aligned} \tag{3}$$

To convert this problem into a linear program, we map it to the incremental allocation space of the set of 6 budgets $P = \{P_1, P_2, \ldots, P_6\}$. Denote $X_P(\cdot)$ by $X(\cdot)$ for simplicity of notation in the optimization programs. Similar to Definition 19, we define $V(S) = X_{(P\cup\{v\})}(S\cup\{v\})$ via the "optimal" budget v and $Z^Q(S) = X_{(P\cup\{p^Q\})}(S\cup\{p^Q\})$ using the outcome of our mechanism p^Q, for each $Q\in\mathcal{C}([6],3)$.

By Lemma 4, we write the cost in terms of the overlap utility $d(p^Q,P_i) = 2-2u(p^Q,P_i)$, which, by Lemma 28 and the definition of $Z^Q(S)$, equals $2-2\sum_{S\in\mathcal{P}(P\setminus P_i)} Z^Q(S\cup P_i)$. Similarly, we have $d(v,P_i) = 2-2\sum_{S\in\mathcal{P}(P\setminus P_i)} V(S\cup P_i)$. To make the $p^Q\in\mathcal{M}(Q)$ constraints linear, we use case analysis.

Consider a given $Q = \{q_1,q_2,q_3\}\in C([6],3)$ and a budget $p^Q\in\mathbb{B}$. Let $\mathfrak{X}(S) = X_Q(S)$ and $\mathcal{Z}(S) = X_{(Q\cup\{p^Q\})}(S\cup\{p^Q\})$. Theorem 24 implies that $p^Q\in\mathcal{M}(Q)$ if and only if the following holds:

- **Case 1**: If $\mathfrak{X}(q_1q_2q_3)+\mathfrak{X}(q_1q_2)+\mathfrak{X}(q_1q_3)+\mathfrak{X}(q_2q_3)\geq 1$, $\mathcal{Z}(q_1)=\mathcal{Z}(q_2)=\mathcal{Z}(q_3)=0$.
- **Case 2**: If $\mathfrak{X}(q_1q_2q_3)+\mathfrak{X}(q_1q_2)+\mathfrak{X}(q_1q_3)+\mathfrak{X}(q_2q_3)\leq 1$, $\mathcal{Z}(q_1q_2)=\mathfrak{X}(q_1q_2), \mathcal{Z}(q_1q_3)=\mathfrak{X}(q_1q_3), \mathcal{Z}(q_2q_3)=\mathfrak{X}(q_2q_3)$.

We break each $p^Q\in\mathcal{M}(Q)$ constraint into two cases. Since there are $\binom{6}{3}$ such constraints in the optimization problem, there are $2^{\binom{6}{3}}$ cases overall. We represent each case by a binary string of length 20 where a 0 or 1 at each position denotes whether the triplet Q corresponding to that position is in **Case 1** or **Case 2**.

However, most of these $2^{\binom{6}{3}}$ cases are not unique up to the permutation of preferred budgets, i.e. when the preferred budgets of different voters are permuted, we may move from one case to another. Since these cases have the same objective value, we do not need to solve all the cases. Exploiting further symmetries, we have 2136 unique cases, each of which is formulated as a linear program with precise details in Appendix A.15 in the extended version [17]. We obtain the optimal value for each case to be 0 hence, a contradiction. ◀

Using Lemmas 27 and 29, we get the following key result.

▶ **Theorem 30.** Distortion$(\mathcal{M}) \leq 1.80$.

6 Distortion of $\mathfrak{n}_{\text{rand}}$

Recall the randomized Nash bargaining scheme $\mathfrak{n}_{\text{rand}}$ explained in § 4.2. In this section, we derive an upper bound for it. Towards this, we first define a *hypothetical* bargaining scheme $\tilde{\mathfrak{n}}_{\text{rand}}$. This scheme is hypothetical because it assumes that the bargaining agents use some knowledge about the preferred budgets of the non-bargaining agents to break ties among potential outcomes. We then show in Lemma 32 that the Distortion of $\mathfrak{n}_{\text{rand}}$ is at most as much as that of $\tilde{\mathfrak{n}}_{\text{rand}}$. We then bound the Distortion of $\tilde{\mathfrak{n}}_{\text{rand}}$ by its *expected pessimistic distortion* (EPD), a quantity similar in essence to the PD. We define the EPD in Definition 33. Our main technical contribution in this section is the analysis of the EPD of $\tilde{\mathfrak{n}}_{\text{rand}}$, which we do by expressing it as the solution of a bilinear optimization problem.

6.1 Construction of bargaining solution in $\tilde{\mathfrak{n}}_{\text{rand}}$

Recall Definition 18 of $Z_{j,P}(\cdot)$ for an outcome budget z. Also recall that $Z_{j,P}(\cdot)$ satisfies Corollaries 20 and 21. For $\tilde{\mathfrak{n}}_{\text{rand}}$, we characterize the outcome in the incremental allocation space; denoted by $\tilde{Z}_{j,P}(\cdot)$. Same as $Z_{j,P}(\cdot)$, $\tilde{Z}_{j,P}(\cdot)$ also satisfies Corollaries 20 and 21, i.e.,

$$0 \leq \tilde{Z}_{j,P}(S) \leq X_{j,P}(S) \forall S \in \mathcal{P}(P) \text{ and all } j \in [m]. \tag{4}$$

$$\sum_{j=1}^{m} \tilde{Z}_{j,P}(S) = \tilde{Z}_P(S) \quad \text{and,} \quad \sum_{S \in \mathcal{P}(P)} \tilde{Z}_P(S) = 1. \tag{5}$$

Before describing the construction of $\tilde{\mathfrak{n}}_{\text{rand}}$, we now give the following result on the overlap utility $u(a, z)$ of outcome budget z and any budget $a \in P$ in terms of $Z_P(S)$.

▶ **Lemma 31.** *For a vote profile P, a budget $a \in P$, and any budget z, the overlap utility is $u(a, z) = \sum_{S \in \mathcal{P}(P) | S \ni a} Z_P(S)$.*

Proof. In Lemma 28, use z for b, a for a, and $P \cup \{z\}$ for P. ◀

By Lemma 31, $u(v, \tilde{Z}_P) = \sum_{S \in \mathcal{P}(P) | S \ni a} \tilde{Z}_P(S)$.[12] Similarly, the cost can be given by $d(v, \tilde{Z}_P) = 2 - 2u(v, \tilde{Z}_P)$.

Let c be the disagreement point, and $\{a, b\}$ be the preferred budgets of the agents chosen to bargain. Denote $Q = \{a, b, c\}$. For the construction of $\tilde{Z}_P(\cdot)$, we first do **Step 1** and **Step 2** from § 4. We then have for all $j \in [m]$, $\tilde{Z}_{j,P}(S) = X_{j,P}(S)$ for all $S \in \mathcal{P}(P)$ such that S contains at least 2 elements of Q and $\tilde{Z}_{j,P}(S) = 0$ for all other $S \in \mathcal{P}(P)$. We then encounter either **Case 1** or **Case 2**, as in § 4.

[12] Note the overload in the notation of the overlap utility; it was initially defined for a pair of budgets v and z, here we define it for v and $\tilde{Z}$ where $\tilde{Z}$ captures z.

Case 1: Here we need to allocate more funds to projects. Recall the construction of z for $\mathfrak{n}_{\text{rand}}$ in § 4.2. Recall the random incremental allocations r_j^a and r_j^b used in $\mathfrak{n}_{\text{rand}}$. For the incremental allocations in $\tilde{\mathfrak{n}}_{\text{rand}}$ we construct $\alpha_{j,P}(S) = r_j^a \cdot (X_{j,P}(S)/X_{j,Q}(a))$[13] for all $\{S \mid a \in S; b, c \notin S\}$ for all projects $j \in [m]$. Intuitively, this may be thought of as a proportional selection of projects from every subset of budgets S. Similarly we construct $\beta_{j,P}(S) = r_j^b \cdot (X_{j,P}(S)/X_{j,Q}(b))$ for all $\{S \mid b \in S; a, c \notin S\}$ and all projects $j \in [m]$.

Now, set $\tilde{Z}_{j,P}(S) = \tilde{Z}_{j,P}(S) + \alpha_{j,P}(S) \;\; \forall \{S \mid a \in S; b, c \notin S\}$ and $\tilde{Z}_{j,P}(S) = \tilde{Z}_{j,P}(S) + \beta_{j,P}(S) \;\; \forall \{S \mid b \in S; a, c \notin S\}$ and $\forall\, j \in [m]$.

Case 2: In this case we need to remove allocations from projects. Recall the construction of z for $\mathfrak{n}_{\text{rand}}$ in § 4.2. Recall the removals of allocations r_j^a and r_j^b used in $\mathfrak{n}_{\text{rand}}$. For the removals of allocations in $\tilde{\mathfrak{n}}_{\text{rand}}$, we construct $\alpha_{j,P}(S) = r_j^a \cdot (X_{j,P}(S)/X_{j,Q}(bc))$ for all $\{S \mid b, c \in S, a \notin S\}$ for all $j \in [m]$. Similarly we construct $\beta_{j,P}(S) = r_j^b \cdot (X_{j,P}(S)/X_{j,Q}(ac))$ for all $\{S \mid a, c \in S; b \notin S\}$.

Now, set $\tilde{Z}_{j,P}(S) = \tilde{Z}_{j,P}(S) - \alpha_{j,P}(S) \;\forall \{S \mid b, c \in S; a \notin S\}$, and $\tilde{Z}_{j,P}(S) = \tilde{Z}_{j,P}(S) - \beta_{j,P}(S) \;\forall \{S \mid a, c \in S; b \notin S\} \;\forall\, j \in [m]$.

We can now construct $\tilde{Z}_P(S)$ via $\tilde{Z}_P(S) = \sum_{j=1}^m \tilde{Z}_{j,P}(S)$. With this, we now construct $\tilde{Z}_Q$ as the outcome of the hypothetical bargaining process, via the projection from P to Q That is, $\tilde{Z}_Q(S) = \sum_{\hat{S} \in \mathcal{P}(P \setminus Q)} \tilde{Z}_P(S \cup \hat{S})$ [recall projection in Lemma 17].

See that $\{\tilde{Z}_{j,P}(.)\}_{j \in [m]}$ satisfies Corollaries 20 and 21. Further, $\tilde{Z}_Q(.)$ satisfies all equations of Lemma 23 [proof in Appendix A.16 in the extended version [17]].

6.2 Distortion under $\mathfrak{n}_{\text{rand}}$

We now bound the distortion of the triadic scheme with bargaining scheme $\mathfrak{n}_{\text{rand}}$ by that of the hypothetical scheme $\tilde{\mathfrak{n}}_{\text{rand}}$. A proof is in the Appendix A.18 in the extended version [17].

▶ **Lemma 32.** Distortion($\mathfrak{n}_{rand}$) $\leq$ Distortion($\tilde{\mathfrak{n}}_{rand}$).

We now follow a similar approach as in §5 and define expected pessimistic distortion under bargaining scheme $\tilde{\mathfrak{n}}_{\text{rand}}$ as follows.

▶ **Definition 33.** *The **expected pessimistic distortion** of $\tilde{\mathfrak{n}}_{rand}$ with triadic scheme with 6 voters, EPD($\tilde{\mathfrak{n}}_{rand}$) is*

$$\sup_{P \in \mathbb{B}^6} \frac{\frac{1}{60} \sum_{c \in [6]} \sum_{\substack{\{a,b\} \in \\ \mathcal{C}([6]\setminus\{c\},2)}} \frac{1}{3} \sum_{i \in [6]\setminus\{a,b,c\}} \mathbb{E}[d(\tilde{\mathfrak{n}}_{rand}(a,b,c), P_i)]}{\min_{p \in \mathbb{B}} \frac{1}{6} \sum_{i \in [6]} d(p, P_i)}.$$

▶ **Lemma 34.** Distortion($\tilde{\mathfrak{n}}_{rand}$) $\leq$ *EPD*($\tilde{\mathfrak{n}}_{rand}$).

The proof is similar to Lemma 27 and is in Appendix A.19 in the extended version [17].

▶ **Lemma 35.** *EPD*($\tilde{\mathfrak{n}}_{rand}$) ≤ 1.66.

[13] Note that $\alpha_{j,P}(S) \leq r_j^a$ since $X_{j,P}(S) \leq X_{j,Q}(a)$ [follows from Lemma 17] and $\sum_{j=1}^m \sum_{\substack{S \in \mathcal{P}(P) \\ S \ni a, S \not\ni b,c}} \alpha_{j,P}(S) = \frac{\text{EXCESS}}{2}$ since $\sum_{\substack{S \in \mathcal{P}(P) \\ S \ni a, S \not\ni b,c}} X_{j,P}(S) = X_{j,Q}(S)$ [follows from Lemma 17] and the fact that $\sum_{j=1}^m r_j^a = \text{EXCESS}/2$ [as defined in **Case 1** in §4.2].

The proof is similar to that of Lemma 29 and is presented in Appendix A.20 in the extended version [17]. We present the key ideas of the proof here.

Proof Sketch. Recall the construction of $\tilde{Z}_{j,P}(.) \sim \tilde{\mathfrak{n}}_{\text{rand}}(a,b,c)$ and consider **Case 1**. A similar analysis holds for **Case 2** as well.

We show in Appendix A.20 in the extended version [17] that $\mathbb{E}[\tilde{Z}_P(S)] = \gamma_a^1 X_P(S)$ for all $\{S : S \ni a; S \not\ni b, c\}$ and $\mathbb{E}[\tilde{Z}_P(S)] = \gamma_b^1 X_P(S)$ for all $\{S : S \ni b; S \not\ni a, c\}$ for some variables $0 \le \gamma_a^1, \gamma_b^1 \le 1$. Here, γ_a^1 and γ_b^1 denote what fraction of allocation from the incremental allocation $X_P(S)$ is "accepted" into $\tilde{Z}_P(S)$. In our optimization problem formulation equation (29) in Appendix A.20 in the extended version [17], we use γ_b^1, γ_a^1 as variables of our optimization formulation, together with $X_P(S)$ and therefore we obtain a bilinear program. We solve it with the Gurobi solver [18]. Similar to the proof of Lemma 27, we remove the cases that are not unique to permutations of voters and use further symmetries of the problem to reduce number of bilinear programs from $2^{\binom{6}{3}}$ to 1244. ◀

Using Lemmas 32, 34, and 35, we get the following result.

▶ **Theorem 36.** Distortion$(\mathfrak{n}_{rand}) \le 1.66$.

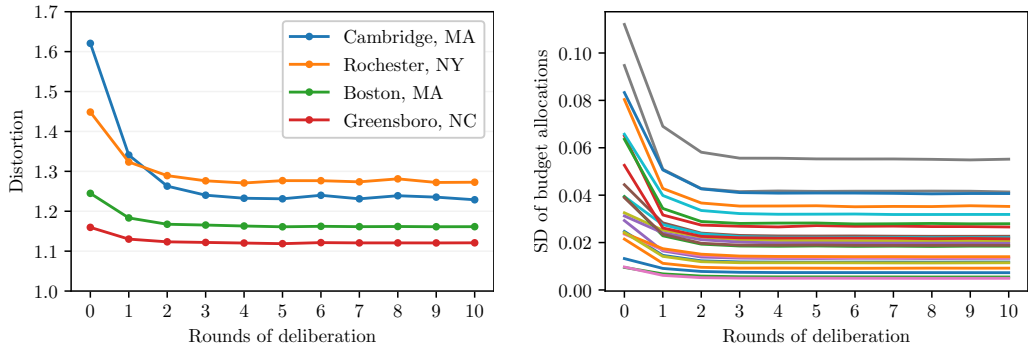
7 Empirical Results

Recall triadic scheme as described in §2.2. We now define a sequential deliberation mechanism that could run bargaining over multiple rounds by setting the disagreement point for each round as the outcome of the previous round as proposed in [11].

1. Pick a voter i uniformly at random. Set the disagreement point for the deliberation c to their preferred budget v_i.
2. Repeat the following process T times,
   a. Pick two voters independently and uniformly at random with replacement. They bargain with c as the disagreement point.
   b. Set the disagreement point c to the outcome of the bargaining.
3. The outcome of the process is c.

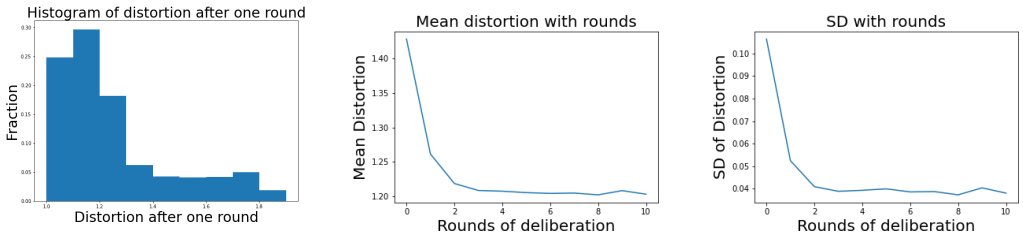
Observe that on setting $T = 1$, we exactly get triadic scheme as §2.2. To evaluate the distortion of sequential deliberation in PB empirically, we ran a simulation from the online participatory budgeting elections in Boston in 2016 ($n = 4,482$), Cambridge in 2015 ($n = 3,273$), Greensboro in 2019 ($n = 512$), and Rochester in 2019 ($n = 1,563$) where the data were obtained from `https://budget.pbstanford.org/`. In these elections, projects had a fixed cost, and voters participated in knapsack voting [15], in which they could choose any number of projects as long as they fitted within the fund limits. Note that in this simulation setup partial project funding is not allowed, unlike the setup in the theoretical model. We further present simulation results in Figures 4a, 4b, 4c on real dataset from a PB (participatory budgeting) process run by a non-profit organisation in Boston in 2016 where they used a fractional allocation setting, more aligned with our theoretical work.

To simulate sequential deliberation, we picked a voter uniformly at random to set their preferred budget as the disagreement point. We then picked another two voters independently and uniformly at random and calculated a Nash bargaining solution between them. We assumed that everyone voted truthfully. We then made the bargaining outcome the new disagreement point and repeated the deliberation process for $T = 10$ rounds. We repeated this entire simulation $10,000$ times for each PB election. The average distortion after each round of deliberation is shown in Figure 3a. The point corresponding to 0 rounds of deliberation is



(a) Average distortion. **(b)** SD of distortion.

Figure 3 (a) The average distortion after each round of sequential deliberation in a simulation using the data from PB elections in four cities. The simulation was run 10,000 times for each city. (b) The standard deviation (SD) of the fund allocation to each project in the simulation of sequential deliberation in the PB election in Cambridge. Each line represents a project.



(a) Histogram of triadic scheme. **(b)** Average distortion. **(c)** SD of distortion.

Figure 4 Distortion results on PB platform in Boston under the fractional allocation setup

the first disagreement point and is selected uniformly at random. Since voters did not have to use all the budget available, we added an "unspent" project and allocated the unspent budget of each voter to this project. We normalized the budget to sum to 1 in each election.

The mean and standard deviation of the distortion after each round of sequential deliberation for the fractional allocation setting as in the PB process in Boston is shown in Figures 4b and 4c, respectively. A histogram plot of the distortion after one round of deliberation is in Figure 4a. As before, we observe a quick convergence within three rounds of sequential deliberation with the point corresponding to zero rounds of deliberation being the first disagreement point.

The results from all the PB elections show that the average distortion is quite low, even after only two rounds of deliberation. It also shows that the distortion converges quickly within three rounds. Further, we measured the stability of the fund allocation to the projects after each round of deliberation. We simulated sequential deliberation on the data from the PB in Cambridge $1,000,000$ times, each time with 10 rounds of deliberation. The fund allocation to each project after each round was recorded. The fund allocation's standard deviation (SD) is shown in Figure 3b. We can see that the SD stabilizes after only three rounds of deliberation.

8 Triadic Scheme With Project Interactions

Mathematically, we model project interactions as follows: if projects in group q are **perfect complements** of each other, then the overlap utility that voters can derive from *each* project in q is the minimum funding of any project in q. For example, consider a proposal of buying some computers for the community. Within this, one project is for buying hardware and another one is for buying software. If the software and hardware projects are funded 0.2 and 0.5, then the community members can only use 0.2 each, and the extra funding of 0.3 for the hardware project is wasted [14].

On the other hand, if the projects in group r are **perfect substitutes**, then the utility that voters can derive from group r is the maximum funding of a project in r. Thus, if two companies are paid 0.2 and 0.5 to do the same work, only 0.5 will be used, and 0.2 is wasted.

We now give a formal model of the set of projects. Let m_c denote the number of groups of *perfect complementary* projects, m_s denote the number of groups of *perfect substitute* projects, and m_r denote the number of *regular* projects. Let $s(q)$ denote the number of projects in group q. For groups of perfect complementary and perfect substitute projects, $s(q) \geq 2$ and for regular projects $s(q) = 1$. The total number of projects is $m = \left(\sum_{q=1}^{m_c+m_s} s(q)\right) + m_r$. For simplicity, project groups are arranged such that groups $1, \ldots, m_c$ are perfect complementary, groups $m_c + 1, \ldots, m_c + m_s$ are perfect substitutes, and $m_c + m_s + 1, \ldots, m_c + m_s + m_r$ are regular projects.

Let $f(b)$ be the *efficiency function* which quantifies how much budget b respects the project interactions. Specifically, $f(b)$ takes a budget $b \in \mathbb{R}^m$ and outputs a vector in $\mathbb{R}^{m_c+m_s+m_r}$, where

$$f(b)_q = \begin{cases} s(q) \cdot \min(\{b_j \mid j \in \text{group } q\}) & \text{if } q \in [1, m_c] \quad \text{(perfect complementary groups)}, \\ \max(\{b_j \mid j \in \text{group } q\}) & \text{if } q \in [m_c + 1, m_c + m_s], \quad \text{(perfect substitute groups)} \\ \{b_j \mid j \in \text{group } q\} & \text{otherwise.} \qquad \text{(regular projects)}. \end{cases}$$

For a group of perfect complementary projects, the corresponding output element is the bottle-neck allocation in the group, multiplied by the number of projects in the group. For a group of perfect substitute projects, the corresponding output element is the largest allocation in that group. For regular projects, the corresponding output elements are the same as the allocation to the project. We now give a modified definition of the overlap utility, accounting for project interactions.

▶ **Definition 37.** *The **overlap utility** of budgets a and b, accounting for project interactions is* $u(a, b) = \sum_{q=1}^{m_c+m_s+m_r} \min(f(a)_q, f(b)_q)$.

In the following definition we formally state the requirements for a budget to be consistent with the project interactions.

▶ **Definition 38.** *A budget b **respects the project interactions** if and only if projects in each perfect complementary group are all funded equally, and at most one project in each perfect substitute group is funded at all.*

The following lemma states that the efficiency function $f(b)$ sums to 1 if and only if the budget b *respects the project interactions.*

[14] This is a stylized model and in general, the scale of the funds required for each project can be very different.

▶ **Lemma 39.** *Budget b respects the project interactions iff the efficiency function $f(b)$ satisfies $\sum_q f(b)_q = 1$. Otherwise, $\sum_q f(b)_q < 1$.*

We now give a result that a Pareto improvement exists over a budget that does not respect the project interactions.

▶ **Lemma 40.** *If $\sum_q f(b)_q < 1$, then for some $k \in [m_c + m_s + m_r]$, there exists a budget b' for which $f(b')_k > f(b)_k$ and $f(b')_q \geq f(b)_q$ for all project groups q.*

The proofs of lemmas 39 and 40 are presented in Appendix A.5 and A.6 in [17].

We now give the main result of this section. We show that if either of the budgets of the bargaining agents respect the project interactions (which will be true for rational agents), then the outcome of any median scheme respects project interactions. Since the class of median schemes contains the class of Nash bargaining schemes (Theorem 12), this result also applied to $\mathcal{N}$ and therefore also to our randomized bargaining scheme $\mathfrak{n}_{\text{rand}}$.

▶ **Theorem 41.** *If budget a or b respects the project interactions, then for any budget $c \in \mathbb{B}$, $\mathcal{M}(a, b, c)$ respects the project interactions.*

Proof. Let z be an outcome from $\mathcal{M}(a, b, c)$. Assume without loss of generality that budget a respects the project interactions, and suppose that outcome z does not. By Lemma 39, $\sum_q f(a)_q = 1$ and $\sum_q f(z)_q < 1$. Thus, there exists some k where $f(a)_k > f(z)_k$. By Lemma 40, there exists a budget z' which respects the project interactions and $f(z')_q \geq f(z)_q$ for all project groups q and $f(z')_k > f(z)_k$. The overlap utility functions satisfy:

$$u(a, z') = \sum_q \min(f(a)_q, f(z')_q) > \sum_q \min(f(a)_q, f(z)_q) = u(a, z),$$
$$u(b, z') = \sum_q \min(f(b)_q, f(z')_q) \geq \sum_q \min(f(b)_q, f(z)_q) = u(b, z).$$
$$u(c, z') = \sum_q \min(f(c)_q, f(z')_q) \geq \sum_q \min(f(c)_q, f(z)_q) = u(c, z).$$

This implies that the sum of overlap utilities of a, b, and C with z' is higher than that with z, a contradiction for an outcome of $\mathcal{M}$. ◀

Theorem 41 implies that if every voter has a preferred budget that respects the project interactions, then the outcome of the sequential deliberation mechanism will also respect the project interactions, no matter how many rounds it runs.

9 Conclusion

We study low sample-complexity mechanisms for PB, which are particularly attractive when the policymakers are interested in obtaining a quick estimate of the voter's preferences or when a full-fledged PB election is difficult or costly to conduct. In our PB setup, the distortion of mechanisms that obtain and use the votes of only one uniformly randomly sampled voter is 2. Extending this result, we show that when two voters are sampled, and a convex combination of their votes is used by the mechanism, the distortion cannot be made smaller than 2. We then show that with 3 samples, there is a significant improvement in the distortion – we give a PB mechanism that obtains a distortion of 1.66. Our mechanism builds on the existing works on Nash bargaining between two voters with a third voter's preferred outcome as the disagreement point. We also give a lower bound of 1.38 for our mechanism.

The Impacts of Dimensionality, Diffusion, and Directedness on Intrinsic Cross-Model Simulation in Tile-Based Self-Assembly

Abstract

Algorithmic self-assembly occurs when components in a disorganized collection autonomously combine to form structures and, by their design and the dynamics of the system, are forced to intrinsically follow the execution of algorithms. Motivated by applications in DNA-nanotechnology, theoretical investigations in algorithmic tile-based self-assembly have blossomed into a mature theory with research strongly leveraging tools from computability theory, complexity theory, information theory, and graph theory to develop a wide range of models and to show that many are computationally universal, while also exposing a wide variety of powers and limitations of each. In addition to computational universality, the abstract Tile-Assembly Model (aTAM) was shown to be intrinsically universal (FOCS 2012), a strong notion of completeness where a single tile set is capable of simulating the full dynamics of all systems within the model; however, this result fundamentally required non-deterministic tile attachments. This was later confirmed necessary when it was shown that the class of directed aTAM systems, those in which all possible sequences of tile attachments eventually result in the same terminal assembly, is not intrinsically universal (FOCS 2016). Furthermore, it was shown that the non-cooperative aTAM, where tiles only need to match on 1 side to bind rather than 2 or more, is not intrinsically universal (SODA 2014) nor computationally universal (STOC 2017). Building on these results to further investigate the impacts of other dynamics, Hader et al. examined several tile-assembly models which varied across (1) the numbers of dimensions used, (2) restrictions imposed on the diffusion of tiles through space, and (3) whether each system is directed, and determined which models exhibited intrinsic universality (SODA 2020). Such results have shed much light on the roles of various aspects of the dynamics of tile-assembly and their effects on the universality of each model. In this paper we extend that previous work to provide direct comparisons of the various models against each other by considering intrinsic simulations between models. Our results show that in some cases, one model is strictly more powerful than another, and in others, pairs of models have mutually exclusive capabilities. This direct comparison of models helps expose the impacts of these three important aspects of self-assembling systems, and further helps to define a hierarchy of tile-assembly models analogous to the hierarchies studied in traditional models of computation.

1 Introduction

Self-assembling systems are those in which a disorganized collection of simple components spontaneously combine to form complex, organized structures through random motion and local interactions. From the pristine, periodic arrangements formed by crystallizing atoms to the robust coordination of dividing cells in developing organisms, such systems are the source of much complexity in nature and a topic of critical importance to many fields of research. Among them is the field of DNA nanotechnology, wherein artificial DNA strands are used as structural units that self-assemble according to the dynamics of DNA base pairing, which has seen immense success over the past several decades in harnessing the power of self-assembly to create microscopic structures with incredible precision [3, 11, 12, 18] and even perform algorithmic tasks at the nano-scale [4, 6, 13, 14, 17, 20, 24, 25]. Because it's difficult and expensive to accurately model the chemistry of DNA, a variety of simplifying models have been proposed to facilitate the design of DNA-based self-assembling systems. Among the more popular and effective ones are tile-assembly (TA) models where components, made of several bound DNA strands exposing small unbound portions with which other components can bind, are abstractly represented as geometric tiles whose labeled sides attach to one another according to predefined affinity rules [5, 16, 22]. The advantage of these models lies not only in their success as design tools, but in their similarity to existing models studied heavily in computer science such as Wang tiles and cellular automata. This similarity isn't a coincidence either; the first TA model proposed, the abstract Tile-Assembly Model (aTAM), was designed, at least in part, to show that the dynamics of DNA-based self-assembly are algorithmically universal [22]. Consequently, DNA nanotechnology shares a unique relationship with the theory of computation, with theorists frequently borrowing ideas from complexity, computability, and information theory to study questions regarding, among many other things, what kinds of structures can be self-assembled, the relative difficulty of assembling different shapes, and how variations in a model's dynamics affect its algorithmic power. This paper is particularly focused on that latter question. As with more conventional

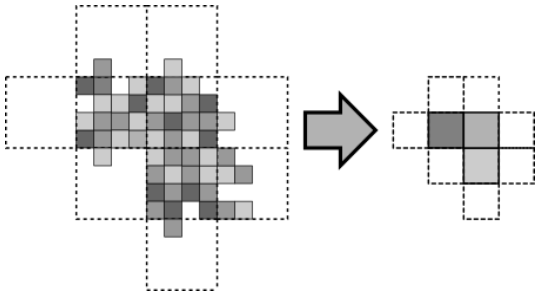

Figure 1 During an intrinsic simulation, the dynamics of individual tile attachments are simulated so that blocks of tiles in the simulating system "look like" individual tiles at scale.

models of computation, we generally study such questions by proving whether one model is capable of simulating all systems of another. We have to be careful about our definition of simulation however, as it's generally straightforward to show that many TA models are capable of universal computation. Consequently, most TA models are capable of "simulating" all others in that they can simulate a Turing machine which can in turn simulate the other model. To learn something useful about the relative power of two TA models therefore, we have to consider the geometry of the tile-assembly dynamics. We do this by adapting a tool from the theory of cellular automata, namely *intrinsic simulation*. For a simulation

to be *intrinsic*, we require that the simulation is not merely symbolic (i.e. how a Turing machine can simulate an aTAM system by storing an internal representation of the tiles as symbols on its tape), but rather geometric wherein blocks of tiles in the simulating system correspond to individual tiles in the simulated system and the order of tile attachments in these blocks follow those in the simulated system up to a fixed scale factor. In other words, such a simulation would appear identical to the system being simulated if we "zoomed out" sufficiently far. This approach is not novel to our results, in fact there is already a relatively mature theory of intrinsic simulations in tile-assembly which has resulted in a "kind of computational complexity theory for self-assembly" [23]. Such efforts have been instrumental in characterizing the relative power of TA models and has lead to a deeper understanding how different dynamics can be used for the same algorithmic purpose.

Our results

In an attempt to extend several previous results regarding intrinsic simulation, here we consider 3 specific variations of the aTAM: *dimensionality*, where both 2D and 3D systems are considered, *diffusion*, where tiles cannot attach in regions which have been surrounded by previously attached tiles, and *directedness*, where tile attachments in a system are required to result in exactly one terminal assembly. It's important to note that these variations aren't arbitrary either. The difference between directed and undirected systems is analogous to the difference between deterministic and probabilistic algorithms and, among other things, plays a role in the study of the complexity of shape assembly [21, 10]. The diffusion restriction on the other hand is often used to make 3D tile-assembly models more "realistic" by limiting tile attachments to those locations in which a tile could reasonably diffuse (i.e. not in a region completely surrounded by other tiles). These variations can be introduced into the aTAM in any combination to yield 8 different models and, considering all ordered pairs of these 8 models gives rise to a table consisting of 64 entries each representing one model's ability or inability to intrinsically simulate the dynamics of another. Generally speaking, results regarding these *cross-model simulations* are complex, involving intricate tile-assembly constructions and counterexamples; consequently, only a handful of these entries have been proved in past literature.

In this paper, we fill a considerable number of missing entries. Table 1 lays out our results along with past results denoted by an asterisk. In it, entries are labeled to indicate whether the model in the row's header can simulate the model in the column's header. There are of course a few entries for which the answer is obvious, which we state as observations with justification rather than full theorems, but many of our results are distinctly non-trivial and some were rather unexpected. For instance, while we initially suspected that the diffusion restricted version of the aTAM (i.e. the Planar aTAM or PaTAM) was, as it's name suggests, a weaker version of the aTAM, we found that both models exhibit dynamics which cannot be simulated by the other. While the table is still missing a few entries, our contributions have brought the number of known entries up to 52 from the 16 which previously existed in published literature (8 of which were technically not explicitly stated, but were trivial observations based on the tile sets and proofs presented in [7]).[1] The rest of our paper is laid out as follows. In Section 2, we provide definitions of the various models and concepts used.

[1] It should also be noted that most of the remaining unknown entries involve simulating directed, diffusion restricted systems. While we do hope to fill these entries in the future, we suspect that their proofs will be quite complicated since simulating diffusion restricted systems is tricky and counterexamples are often harder to find in directed systems.

Table 1 Table of our results, outlining whether the row's model can intrinsically simulate the column's model. PaTAM is the Planar aTAM, 3DaTAM the 3-dimensional aTAM, and SaTAM is the Spatial aTAM (see Section 2.2 for full definitions). *All* refers to the set of all systems in a model and *dir* refers to the subset of directed systems. Cells marked with an asterisk (*) are existing results and those marked with a dagger (†) are trivial observations using tile sets from existing results. All other results are novel.

Then in Section 3 we state our results explicitly and sketch their proofs. That section is perhaps the most important since it is where we intuitively explain our results and describe how they follow from the dynamics of the model. Complete proofs and technical details can be found in a full version of the paper on arXiv [8].

2 Preliminary definitions

Throughout this paper we will use $\mathbb{Z}$, $\mathbb{Z}^+$, and $\mathbb{N}$ to denote the set of integers, positive integers, and non-negative integers respectively. We will also assume $\mathbb{Z}^d$ has the additional structure of a lattice graph so that each point is a vertex and two points are adjacent (i.e. share an edge) exactly when their Euclidean distance is 1.

2.1 Definition of the abstract Tile-Assembly Model

In this section, we define the abstract Tile-Assembly Model in 2 and 3 dimensions. We will use the abbreviation *aTAM* to refer to the 2D model and *3DaTAM* for the 3D model. These definitions are borrowed from [7] and we note that [19] is a good introduction to the model for unfamiliar readers.

Fix $d \in \{2, 3\}$ to be the number of dimensions and Σ to be some alphabet with Σ^* its finite strings. A *glue* $g \in \Sigma^* \times \mathbb{N}$ consists of a finite string *label* and non-negative integer *strength*. A *tile type* is a tuple $t \in (\Sigma^* \times \mathbb{N})^{2d}$, thought of as a unit square or cube with a glue on each side. A *tile set* is a finite set of tile types. We always assume a finite set of tile types, but allow an infinite number of copies of each tile type to occupy locations in the $\mathbb{Z}^d$ lattice, each called a *tile*.

Given a tile set T, a *configuration* is an arrangement (possibly empty) of tiles in the lattice $\mathbb{Z}^d$, i.e. a partial function $\alpha : \mathbb{Z}^d \dashrightarrow T$. Two adjacent tiles in a configuration *interact*, or are *bound* or *attached*, if the glues on their abutting sides are equal (in both label and strength) and have positive strength. Each configuration α induces a *binding graph* B_α whose vertices are those points occupied by tiles, with an edge of weight s between two vertices if the corresponding tiles interact with strength s. An *assembly* is a configuration whose domain (as a graph) is connected and non-empty. The *shape* $S_\alpha \subseteq \mathbb{Z}^d$ of assembly α is the domain of α. For some $\tau \in \mathbb{Z}^+$, an assembly α is *τ-stable* if every cut of B_α has weight at least τ, i.e. a τ-stable assembly cannot be split into two pieces without separating bound tiles whose shared glues have cumulative strength τ. Given two assemblies α, β, we say α is a *subassembly* of β (denoted $\alpha \sqsubseteq \beta$) if $S_\alpha \subseteq S_\beta$ and for all $p \in S_\alpha$, $\alpha(p) = \beta(p)$.

A *tile-assembly system* (TAS) is a triple $\mathcal{T} = (T, \sigma, \tau)$, where T is a tile set, σ is a finite τ-stable assembly called the *seed assembly*, and $\tau \in \mathbb{Z}^+$ is called the *binding threshold*. Given a TAS $\mathcal{T} = (T, \sigma, \tau)$ and two τ-stable assemblies α and β, we say that *α $\mathcal{T}$-produces β in one step* (written $\alpha \to_1^{\mathcal{T}} \beta$) if $\alpha \sqsubseteq \beta$ and $|S_\beta \setminus S_\alpha| = 1$. That is, $\alpha \to_1^{\mathcal{T}} \beta$ if β differs from α by the addition of a single tile. The *$\mathcal{T}$-frontier* is the set $\partial^{\mathcal{T}} \alpha = \bigcup_{\alpha \to_1^{\mathcal{T}} \beta} S_\beta \setminus S_\alpha$ of locations in which a tile could τ-stably attach to α.

We use $\mathcal{A}^T$ to denote the set of all assemblies of tiles in tile set T. Given a TAS $\mathcal{T} = (T, \sigma, \tau)$, a sequence of $k \in \mathbb{Z}^+ \cup \{\infty\}$ assemblies $\alpha_0, \alpha_1, \ldots$ over $\mathcal{A}^T$ is called a *$\mathcal{T}$-assembly sequence* if, for all $1 \leq i < k$, $\alpha_{i-1} \to_1^{\mathcal{T}} \alpha_i$. The *result* of an assembly sequence is the unique limiting assembly of the sequence. For finite assembly sequences, this is the final assembly; whereas for infinite assembly sequences, this is the assembly consisting of all tiles from any assembly in the sequence. We say that *α $\mathcal{T}$-produces β* (denoted $\alpha \to^{\mathcal{T}} \beta$) if there is a $\mathcal{T}$-assembly sequence starting with α whose result is β. We say α is *$\mathcal{T}$-producible* if $\sigma \to^{\mathcal{T}} \alpha$ and write $\mathcal{A}[\mathcal{T}]$ to denote the set of $\mathcal{T}$-producible assemblies. We say α is *$\mathcal{T}$-terminal* if α is τ-stable and there exists no assembly which is $\mathcal{T}$-producible from α. We denote the set of $\mathcal{T}$-producible and $\mathcal{T}$-terminal assemblies by $\mathcal{A}_\square[\mathcal{T}]$.

When $\mathcal{T}$ is clear from context, we may omit $\mathcal{T}$ from the notation above.

Cooperative Attachment

Given a TAS $\mathcal{T} = (T, \sigma, \tau)$, for a tile to attach to an assembly it must match glues whose cumulative strength is at least τ in order to result in a τ-stable assembly. This can happen if, for instance, one of the matched glues has strength at least τ, in which case any other matching glues are superfluous. Alternatively, a tile may still attach without any τ-strength glues though this requires multiple glues to match whose strengths sum to at least τ. We refer to such attachments as *cooperative*.

2.2 Model Variations

In this paper we consider 3 variations of the aTAM. Other than the 3D aTAM, these include *directed* and *diffusion restricted* versions of the models. We say that a TAS $\mathcal{T}$ is *directed* if $|\mathcal{A}_\square[\mathcal{T}]| = 1$, i.e. $\mathcal{T}$ admits only a single producible terminal assembly. When we refer to a *directed model* we simply mean the set of all directed systems in a model. Directed systems are desirable for self-assembly since we often want our tiles to grow into a single target shape.

For diffusion restricted models, we note that in the aTAM it's possible for tiles to attach within a region of space which has been completely surrounded by other tiles. In 2D, we can imagine that the tiles are able to navigate around the assembly through the 3rd dimension, but in 3D such attachments are difficult to justify. Consequently, we also consider models where such attachments are forbidden. In 2D, this restriction could model a self-assembly process on the surface of a droplet of water where surface tension prevents the components from taking advantage of the 3rd dimension. We call the 2D diffusion restricted aTAM the *Planar aTAM* or PaTAM, and we call the 3D diffusion restricted aTAM the *Spatial aTAM* or SaTAM. In these models, and their directed subsets, we refer to regions which have been completely surrounded (in which no tile attachments are allowed to occur) *constrained*. To formally model this restriction, we first note that given a finite d-dimensional assembly α, the graph $\mathbb{Z}^d \setminus S_\alpha$ consists of a finite number of connected components, exactly one of which will be infinite in size. We say that this component graph is the *outside* of α while the finite-sized components are *constrained*. In a diffusion restricted system we only allow tile attachments on the outside of an assembly.

2.3 Intrinsic Simulation

First we provide a high-level definition of the notion of *intrinsic simulation* which should be sufficient for understanding our results. A full technical definition follows afterward. For brevity, in this paper, unless explicitly stated, "simulation" will refer to intrinsic simulation.

High-Level Description of Simulation

Simulation of system $\mathcal{T}$ by system $\mathcal{S}$ occurs at a scale factor m, so that $m \times m$ (or $m \times m \times m$ in 3D) blocks of tiles from $\mathcal{S}$, which we refer to as *macrotiles*, correspond to individual tiles in $\mathcal{T}$. For a given simulation, we define a *macrotile representation function* R which describes this mapping of macrotiles to tiles. Additionally for convenience, using R we define an *assembly representation function* R^* which maps entire assemblies from $\mathcal{S}$ to assemblies in $\mathcal{T}$, essentially evaluating R on each macrotile location for a given assembly in $\mathcal{S}$. Note that we don't require all locations within a macrotile to contain a tile and macrotile blocks containing tiles can still be mapped to empty space under R. When a tile attachment causes the representation of a macrotile location to map to a tile for the first time, we say that the attachment has caused the macrotile to *resolve* and once a macrotile has resolved, any additional tile attachments within the macrotile cannot change its representation under R. While we do allow macrotile locations to map to empty space, for a simulation to be valid there must be restrictions on where tiles are allowed to attach in $\mathcal{S}$. For our notion of simulation to be useful as a metric of comparing the relative capabilities of models, we require that $\mathcal{S}$ only place tiles within the macrotile regions immediately adjacent (not diagonally) to those which have already resolved, and we call such locations *fuzz*. This allows tiles in $\mathcal{S}$ to attach only in macrotiles which could potentially resolve during a valid simulation, since only the locations in $\mathcal{T}$ mapped to by the fuzz locations could possibly receive tiles in $\mathcal{T}$. If a class of systems C can all be simulated by another class of systems C' sharing a single tile set (though each may have a different seed assembly), we say that class C' *intrinsically simulates* C with a *universal tile set*. We can also say that C' is *intrinsically universal* (IU) for C.

Formal Definition of Simulation

Now we provide formal definitions for *intrinsic simulation*. The definitions here are taken from [7] and specifically refer to 3D systems. Similar definitions for 2D intrinsic simulation are given in [9]. For simulation of a 2D system by a 3D system, we use the 3D definitions and assume that all systems in the 2D system are defined in 3D so that assemblies occupy only the $z = 0$ plane.

From this point on, let T be a tile set and let the scale factor be $m \in \mathbb{Z}^+$. An *m-block macrotile* over T is a partial function $\alpha : \mathbb{Z}^3_m \dashrightarrow T$, where $\mathbb{Z}_m = \{0, 1, \ldots, m-1\}$. Let B^T_m be the set of all m-block macrotiles over T. The m-block with no domain is said to be *empty*. For a general assembly $\alpha : \mathbb{Z}^3 \dashrightarrow T$ and $(x', y', z') \in \mathbb{Z}^3$, define $\alpha^m_{(x',y',z')}$ to be the m-block macrotile defined by $\alpha^m_{(x',y',z')}(i_x, i_y, i_z) = \alpha(mx' + i_x, my' + i_y, mz' + i_z)$ for $0 \leq i_x, i_y, i_z < m$. For some tile set S, a partial function $R : B^S_m \dashrightarrow T$ is said to be a *valid m-block macrotile representation* from S to T if for any $\alpha, \beta \in B^S_m$ such that $\alpha \sqsubseteq \beta$ and $\alpha \in \text{dom } R$, then $R(\alpha) = R(\beta)$.

For a given valid m-block macrotile representation function R from tile set S to tile set T, define the *assembly representation function*[2] $R^* : \mathcal{A}^S \to \mathcal{A}^T$ such that $R^*(\alpha') = \alpha$ if and only if $\alpha(x, y, z) = R\left(\alpha'^m_{(x,y,z)}\right)$ for all $(x, y, z) \in \mathbb{Z}^3$. For an assembly $\alpha' \in \mathcal{A}^S$ such that $R^*(\alpha') = \alpha$, α' is said to map *cleanly* to $\alpha \in \mathcal{A}^T$ under R^* if for all non empty blocks $\alpha'^m_{(x,y,z)}$, $(x, y, z) + (u_x, u_y, u_z) \in \text{dom } (\alpha)$ for some $(u_x, u_y, u_z) \in U_3$ such that $u_x^2 + u_y^2 + u_z^2 \leq 1$, or if α' has at most one non-empty m-block $\alpha^m_{0,0}$. In other words, α' may have tiles on macrotile blocks representing empty space in α, but only if that position is adjacent to a tile in α. We call such growth "around the edges" of α' *fuzz* and thus restrict it to be adjacent to only valid macrotiles, but not diagonally adjacent (i.e. we do not permit *diagonal fuzz*).

In the following definitions, let $\mathcal{T} = (T, \sigma_T, \tau_T)$ be a TAS, let $\mathcal{S} = (S, \sigma_S, \tau_S)$ be a TAS, and let R be an m-block representation function $R : B^S_m \to T$.

▶ **Definition 1.** *We say that $\mathcal{S}$ and $\mathcal{T}$ have* equivalent productions *(under R), and we write $\mathcal{S} \Leftrightarrow \mathcal{T}$ if the following conditions hold:*

1. $\{R^*(\alpha') | \alpha' \in \mathcal{A}[\mathcal{S}]\} = \mathcal{A}[\mathcal{T}]$.
2. $\{R^*(\alpha') | \alpha' \in \mathcal{A}_\square[\mathcal{S}]\} = \mathcal{A}_\square[\mathcal{T}]$.
3. *For all $\alpha' \in \mathcal{A}[\mathcal{S}]$, α' maps cleanly to $R^*(\alpha')$.*

▶ **Definition 2.** *We say that $\mathcal{T}$* follows *$\mathcal{S}$ (under R), and we write $\mathcal{T} \dashv_R \mathcal{S}$ if $\alpha' \to^{\mathcal{S}} \beta'$, for some $\alpha', \beta' \in \mathcal{A}[\mathcal{S}]$, implies that $R^*(\alpha') \to^{\mathcal{T}} R^*(\beta')$.*

The next definition essentially specifies that every time $\mathcal{S}$ simulates an assembly $\alpha \in \mathcal{A}[\mathcal{T}]$, there must be at least one valid growth path in $\mathcal{S}$ for each of the possible next steps that $\mathcal{T}$ could make from α which results in an assembly in $\mathcal{S}$ that maps to that next step. While this definition is unfortunately dense, it accommodates subtle situations such as where $\mathcal{S}$ must "commit to" a subset of possible representations in $\mathcal{T}$ before being explicitly mapped, under R, to any one in particular.

▶ **Definition 3.** *We say that $\mathcal{S}$* models *$\mathcal{T}$ (under R), and we write $\mathcal{S} \models_R \mathcal{T}$, if for every $\alpha \in \mathcal{A}[\mathcal{T}]$, there exists $\Pi \subset \mathcal{A}[\mathcal{S}]$ where $\Pi \neq \varnothing$ and $R^*(\alpha') = \alpha$ for all $\alpha' \in \Pi$, such that, for every $\beta \in \mathcal{A}[\mathcal{T}]$ where $\alpha \to^{\mathcal{T}} \beta$, (1) for every $\alpha' \in \Pi$ there exists $\beta' \in \mathcal{A}[\mathcal{S}]$ where $R^*(\beta') = \beta$ and $\alpha' \to^{\mathcal{S}} \beta'$, and (2) for every $\alpha'' \in \mathcal{A}[\mathcal{S}]$ where $\alpha'' \to^{\mathcal{S}} \beta'$, $\beta' \in \mathcal{A}[\mathcal{S}]$, $R^*(\alpha'') = \alpha$, and $R^*(\beta') = \beta$, there exists $\alpha' \in \Pi$ such that $\alpha' \to^{\mathcal{S}} \alpha''$.*

[2] Note that R^* is a total function since every assembly of S represents *some* assembly of T; the functions R and α are partial to allow undefined points to represent empty space.

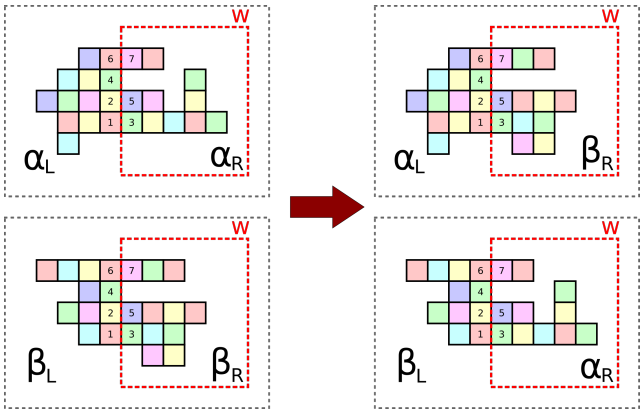

Figure 2 An illustration of the window movie lemma. On the left are two producible assemblies $\alpha = \alpha_L \cup \alpha_R$ and $\beta = \beta_L \cup \beta_R$ made from the same tile set, which are each divided into two subassemblies by the window w. For both assemblies, the window w has the same window movie, i.e. the order in which tiles present glues along the window, depicted by numbers on the tiles describing the relative order in which they attached. Since all growth within the windowed regions depends only on the glues presented along the window, we can splice these assemblies to get $\alpha_L \cup \beta_R$ or $\beta_L \cup \alpha_R$ (illustrated on the right). The window movie lemma then guarantees that both of these assemblies are producible.

▶ **Definition 4.** *We say that* $\mathcal{S}$ intrinsically simulates $\mathcal{T}$ *(under* R*) if* $\mathcal{S} \Leftrightarrow_R \mathcal{T}$ *(equivalent productions),* $\mathcal{T} \dashv_R \mathcal{S}$ *and* $\mathcal{S} \models_R \mathcal{T}$ *(equivalent dynamics).*

2.4 Window Movie Lemma

In [15], the authors proved the Window Movie Lemma, a pumping lemma of sorts for the aTAM (and its variants) which has since seen much use as a powerful tool for proving that certain tile-assembly simulations are impossible. Since it appears in several of our proofs, we first informally describe the lemma, then explicitly state it. A *window* is an edge cut which partitions the lattice graph ($\mathbb{Z}^2$ in 2D or $\mathbb{Z}^3$ in 3D) into two regions. Given some window w and some assembly sequence $\vec{\alpha}$ in a TAS $\mathcal{T}$, a *window movie* M is defined to be the ordered sequence of glues presented along w by tiles in $\mathcal{T}$ during the assembly sequence $\vec{\alpha}$. Informally, if we think of the window w as a thin pane dividing two regions of tile locations and imagine stepping through the assembly sequence $\vec{\alpha}$ one tile attachment at a time, M is constructed by recording the glues which appear on the surface of the pane and their relative order. More formally, a *window movie* is the sequence $M_w^{\vec{\alpha}} = \{(v_i, g_i)\}$ of pairs of grid graph vertices v_i and glues g_i, given by order of appearance of the glues along window w during $\vec{\alpha}$. Furthermore, if k glues appear along w during the same assembly step in $\vec{\alpha}$, then these glues appear contiguously and are listed in lexicographical order of the unit vectors describing their orientation in $M_w^{\vec{\alpha}}$.

Informally, the Window Movie Lemma states that any tile attachments that occur within the region bounded by a window are possible in a region bounded by the same window (up to translation) with an identical window movie. This allows us to splice assembly sequences together and, consequently, pump a sequence of tile attachments so long as we can ensure the existence of identical window movies. Figure 3 illustrates how the Window Movie Lemma can be used to pump growth.

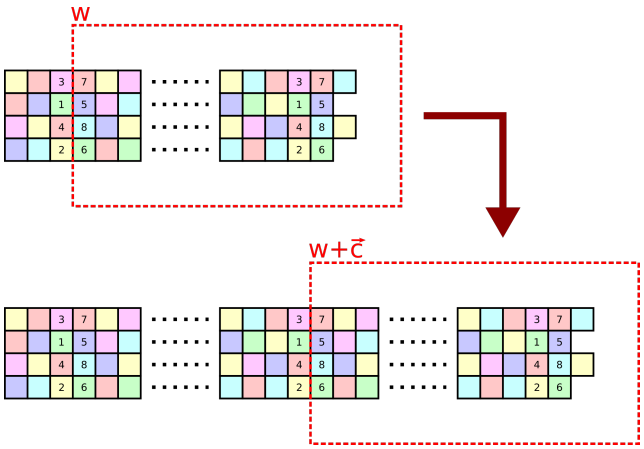

Figure 3 Using the Window Movie Lemma to "pump" assembly sequences. The top assembly depicts a ribbon of tiles growing horizontally to the right and numbers on tiles describe a relative order of attachment. If such a ribbon of tiles grows long enough, then by pigeonhole principle, eventually there must exist two identical vertical slices along its length. Because every tile attachment inside a window w depends only on the tiles and their relative order of attachment along the window, we can thus find an assembly sequence where growth repeats after the second identical vertical slice. This can be performed indefinitely to "pump" the ribbon.

Window Movie Lemma

Let $\vec{\alpha} = \{\alpha_i\}$ and $\vec{\beta} = \{\beta_i\}$ be assembly sequences in TAS $\mathcal{T}$ and let α, β be the result assemblies of each respectively. Let w be a window that partitions α into two configurations α_L and α_R and let $w' = w + \vec{c}$ be a translation of w that partitions β into two configurations β_L and β_R (with α_L and β_L being the configurations containing their respective seed tiles). Furthermore define $M_w^{\vec{\alpha}}$ and $M_w^{\vec{\beta}}$ to be the window movies for $\vec{\alpha}, w$ and $\vec{\beta}, w'$ respectively. Then if $M_w^{\vec{\alpha}} = M_w^{\vec{\beta}}$, the assemblies $\alpha_L \cup \beta'_R$ and $\beta'_L \cup \alpha_R$ (where $\beta'_L = \beta_L - \vec{c}$ and $\beta'_R = \beta_R - \vec{c}$) are also producible.

3 Results

In this section we sketch our results. Detailed proofs can be found in the full version on arXiv [8]. We begin with some trivial observations which allow us to fill in several boxes from Table 1.

▶ **Observation 5.** *If there exists a directed system $\mathcal{T}$ in tile-assembly model M which cannot be simulated by any system in tile-assembly model M', then (1) there exists a system in M which cannot be simulated by any system in M', (2) there exists a system in M which cannot be simulated by any directed system in M', and (3) there exists a directed system in M which cannot be simulated by any directed system in M'.*

▶ **Observation 6.** *There exists systems, both directed and undirected, in the 3D models (3DaTAM and SaTAM) which cannot be simulated by any systems in any of the 2D models (aTAM and PaTAM, both directed and undirected).*

Observation 5 holds because the set of directed systems in a model is a subset of all systems in that model. Consequently, $\mathcal{T}$ is a system in both M and in the directed subset of M. By assumption, $\mathcal{T}$ cannot be simulated by any system in M' and therefore cannot

be simulated by any subset of systems of M', particularly the subset of directed systems. Regarding Observation 6, while we restrict the notion of simulation to use square macrotiles, simulations of systems on triangular lattices have been implemented using roughly hexagonal macrotiles made from square tiles [1], so one might imagine the possibility that by loosening our definition of simulation to use more interesting macrotiles, it could be possible to capture the geometry of 3D square tiles using 2D tiles. In our case however, we note that there can exist no planar embedding of the lattice graph of $\mathbb{Z}^3$ as a consequence of Kuratowski's theorem. Consequently, there can be no way to divide $\mathbb{Z}^2$ into connected regions of macrotile locations which preserves the adjacency of points in $\mathbb{Z}^3$ and therefore simulation could not be possible even if we generalized our notion of macrotiles. This is true for any 3D systems which have producible assemblies whose domains, as graphs, are non-planar as is trivially possible in all 3D models considered.

3.1 Simulations using existing tile sets

In [7], it was shown that there exists IU tile sets for the 3DaTAM, SaTAM, and both models' subsets of directed systems. While the main focus of that result was intrinsic simulation within a model, those IU tile sets can be used to trivially fill in a few boxes of Table 1. First we note that any aTAM system can also be thought of as a 3DaTAM system (or even SaTAM system since tiles occupying only a single plane of 3D space can't constrain a 3D region) with glues only appearing on 4 of the 6 faces of any tile. Second, we note that the IU tile sets for the 3DaTAM and SaTAM differed only by the addition of a few tile types responsible for growing a wall around each face of a macrotile before resolving. This was necessary for intrinsic universality in the SaTAM since without them, the tiles making up a macrotile were sparse enough to necessarily allow a diffusion path for tiles to pass through a resolved macrotile. Consequently, if we don't include those tile types, then the IU tile set can simulate 3DaTAM systems even in the SaTAM since without walls surrounding each macrotile, the diffusion restriction does not interfere with the attachment of any tiles. Finally, by design, this tile set preserves directedness when simulating a directed system. Therefore, using the IU tile set and proofs from [7], the following observations hold.

▶ **Observation 7.** *There exists a universal tile set in both the 3DaTAM and SaTAM which intrinsically simulates all systems in the aTAM, preserving directedness.*

▶ **Observation 8.** *There exists a universal tile set in the SaTAM which intrinsically simulates all systems in the 3DaTAM, preserving directedness.*

3.2 Directed systems cannot simulate undirected systems

▶ **Theorem 9.** *There exist systems in the aTAM, 3DaTAM, PaTAM, and SaTAM, which cannot be simulated by any directed system in any of these models.*

Whereas directed systems only have one terminal assembly, undirected systems can have several. Figure 4 illustrates the tile set and terminal assemblies of a simple undirected system $\mathcal{T}$ which can be a system in the aTAM, 3DaTAM, PaTAM, or SaTAM without modification as it does not use any dynamics unique to any of those models. Because directed systems can only have a single terminal assembly, any directed system attempting to simulate $\mathcal{T}$ would necessarily fail since any assembly representation function R^* could not map one terminal assembly to both terminal assemblies of $\mathcal{T}$.

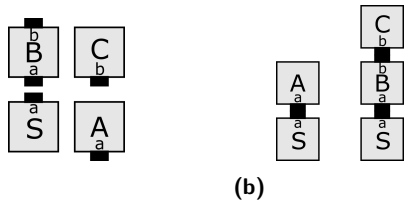

Figure 4 (a) Tile set of an undirected system for the proof of Theorem 9 and (b) Its two terminal assemblies.

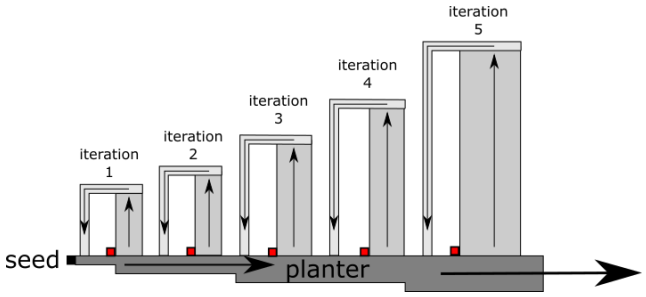

Figure 5 System $\mathcal{T}$ of the proof of Theorem 10. An infinite planter grows to the east from the seed and initiates upward growth of an infinite series of counters, each taller than the last, which initiate single-tile-wide paths that grow to the left then crash downward into the planter. To the left of each counter, at its base, it is possible for a red tile to attach.

3.3 The PaTAM cannot simulate the aTAM

Here we show that there are aTAM systems which cannot be correctly simulated by any PaTAM systems. To show this, we take advantage of the fact that aTAM systems are capable of growth inside of constrained regions while PaTAM systems are not. Specifically, we show that the PaTAM can't simulate the directed aTAM and, by Observation 5, note that this also implies that the PaTAM can't simulate the aTAM.

▶ **Theorem 10.** *There exists a system $\mathcal{T}$ which is a directed aTAM system, and therefore also an aTAM system, which cannot be simulated by any PaTAM system.*

Figure 5 is a schematic diagram of the terminal assembly of $\mathcal{T}$, a directed aTAM system which we claim is impossible to simulate in the PaTAM. Note that $\mathcal{T}$ is more complex than a system in which tiles attach to constrain a region which could have another tile attach within. This is because the definition of intrinsic simulation allows for macrotiles to resolve even when they aren't completely filled with tiles. Consequently, while macrotiles may map to tiles constraining a region, the tiles making up the macrotiles may not constrain a region. Our construction is designed to ensure that at some point, any supposed simulating system must constrain a region before the tiles inside are able to attach. In our directed aTAM system $\mathcal{T}$, this is done by first initiating the growth of a *planter*, a gadget that counts up in binary as it grows eastward, initiating the growth of increasingly tall arms at defined intervals. These arms are essentially binary counter gadgets which each grow upward to a distance, encoded in the glues of the tiles provided by the planter, and initiate the growth of thin arms when they finish. The thin arms are just a single tile wide and begin by growing a fixed distance to the west before growing south to crash into the planter below. By this process, each arm initiated by the planter constrains increasingly large regions of space which each contain a single location between the planter and arms, in which a single tile

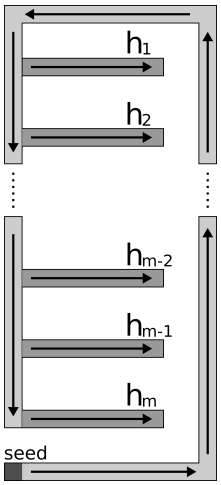

Figure 6 A schematic of system $\mathcal{P}$ for the proof of Theorem 11. Tiles grow in a rectangular shape, periodically spawning arms which can crash into the walls and constrain a region. It is undirected and its size depends non-deterministically on the number of tiles that attach between each corner.

can cooperatively attach (denoted by the red squares in Figure 5). Each of the tiles making up the southward growing portion of the thin arms are of the same tile type, each with identical glues on their north and south faces. While it is possible for different macrotiles to map to the same tile in $\mathcal{T}$, there are only so many combinations of tiles that make up a macrotile. Consequently, regardless of scale factor, if we look far enough down the planter, there will be an arm which grows tall enough that the simulating set must repeat a macrotile representation in two places along the same thin arm. We can then use the Window Movie Lemma to show that this arm "pumps" in our supposed simulating system, before crashing into the planter. It is therefore impossible for any simulating PaTAM system to prevent a region from becoming constrained before the macrotile inside is able to resolve, yielding terminal assemblies which aren't correctly mapped to a terminal assembly in $\mathcal{T}$.

3.4 The aTAM cannot simulate the PaTAM

Given that the PaTAM is just the aTAM with an added restriction on tile attachment, it's not terribly surprising that the PaTAM can't simulate the full dynamics of the aTAM; however, less obvious is the fact that the planarity restriction *also* gives the PaTAM some capabilities not possible in the aTAM, namely the ability to constrain a region and stop growth within. We utilize this ability in our proof of Theorem 11 which is sketched here. Also, by Observation 5, this also holds for the directed aTAM.

▶ **Theorem 11.** *There exists a PaTAM system $\mathcal{P}$ which cannot be simulated by any aTAM system.*

As with the proof for Theorem 10, in the definition of intrinsic simulation, we consider all possible representation functions and scale factors to prove impossibility. Figure 6 is a schematic diagram of PaTAM system $\mathcal{P}$ which is impossible to correctly simulate in the aTAM. Growth of $\mathcal{P}$ begins with tiles attaching in a row growing east. The length of this row is non-deterministic as at any point along the row, it's possible for a corner tile to attach, initiating growth to the north. Consequently, $\mathcal{P}$ is an undirected system so any potential simulating system must be able to simulate all possible assemblies of $\mathcal{P}$. Similarly,

northward and eastward growing rows of tiles attach with some length depending on how many tiles attached before each corner. Finally, a column of tiles begins growing south and, as it does, initiates the growth of several arms eastward, each spaced 4 tiles apart. Both the southward growing column of tiles and the arms continue growth until they are constrained or crash into another part of the assembly. To show that $\mathcal{P}$ cannot be simulated in the aTAM, we assume the existence of a simulating aTAM system $\mathcal{T}$ and prove that it must admit some assembly sequences which don't correspond to those in $\mathcal{P}$. To do this, we consider an assembly sequence in $\mathcal{P}$ where the rectangle of tiles grows to a size, based on the scale factor of the simulation, so that a sufficiently large number of sufficiently long arms are spawned by the south growing column of tiles. We also choose an assembly sequence where the south growing column will eventually collide with the seed tile, constraining the region containing the arms. Because we've chosen the assembly to be sufficiently large, each arm is capable of being "pumped" as per the window movie lemma. We then grow the bottom arm until just after it has collided with the east wall and note that, while $\mathcal{T}$ is an aTAM system and can still grow tiles inside of the constrained region, tiles on the inside and outside will no longer be able to affect each other's growth. There are a few cases to be considered, depending on whether or not the representation function has resolved the last tile of the bottom arm, but essentially we then show that we can continue the growth of the west wall until its macrotiles have resolved to tiles in $\mathcal{P}$ that constrain the rectangle's interior. By a counting argument and our choice of the number of arms, we can then show that one of the other arms must be able to continue growth within the constrained region, and that the assembly sequence in $\mathcal{T}$ maps to one invalid in $\mathcal{P}$.

3.5 The 3DaTAM cannot simulate the SaTAM

The proof of Theorem 12 is similar in principle to the proof of Theorem 11, albeit with a slightly different system which takes advantage of the differences between 2D and 3D. We sketch the proof here.

▶ **Theorem 12.** *There exists an SaTAM system $\mathcal{S}$ which cannot be simulated by any 3DaTAM system.*

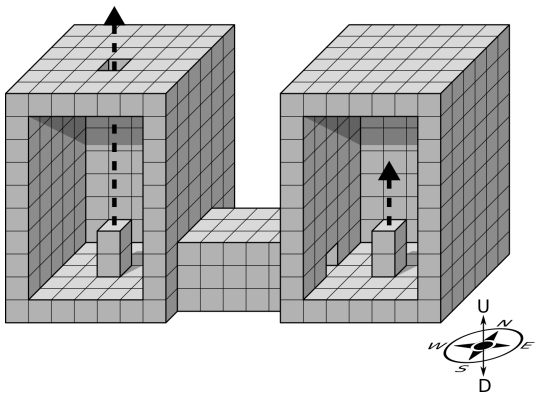

Figure 7 Cut-away view of system $\mathcal{S}$ from the proof of Theorem 12. Two chambers are connected by a thin tunnel. Pillars growing inside the outer west chamber will eventually constrain the region within the chambers, at which point, the pillar growing in the inner east chamber will no longer be able to continue growth.

The system $\mathcal{S}$ for this result, as illustrated in Figure 7, initially grows 2 nearly sealed chambers connected by a thin tunnel which allows for a diffusion path between them. These chambers both have a fixed base size of 9×9, but they can grow to have an arbitrary height in a way similar to the frame of the system used in the proof of Theorem 11. Once fully grown, the ceiling of one chamber contains a single tile wide opening which is the only way for tiles to diffuse into the chambers from outside; we call the chamber with this hole the *outer chamber* and the other one the *inner chamber*. Additionally, from the bottoms of both chambers, pillars can grow upwards to an arbitrary height by the attachment of copies of tiles with identical tile types. The pillar in the inner chamber will eventually crash into the ceiling *or* until the pillar in the outer chamber grows tall enough to plug the opening in its ceiling and constrain the space inside. We show that $\mathcal{S}$ cannot be simulated by any 3DaTAM system by showing that, in any potential simulating system, under the right conditions, although unwanted, it must still possible for the inner chamber pillar to continue growth even after the outer chamber pillar has sealed the chambers. To do this, we note that during some supposed simulation, the only way for the pillar in the inner chamber to "know" that the chambers have been sealed, is for tiles to attach inside of the tunnel. Consequently, because the tunnel is thin with a cross-section made of a hollow 3×3 square, the chambers can only communicate with each other a finite amount of times during a simulation. Specifically, if the scale factor of the simulation is c, then the number of tiles that can be placed in any x-coordinate corresponding to the tunnel is bounded by $5c \times 5c$ which includes any potential tiles growing in the fuzz adjacent to the macrotiles of the tunnel. Therefore, by a simple counting argument, if we initially grew our chambers to have a sufficiently large height, then there must exist some assembly sequence where both pillars grow by any desired number of macrotiles (which we choose to be long enough to allow pumpable growth) and during which no tile is placed in the center of the tunnel. Using the Window Movie Lemma, we then construct an assembly sequence where the outer chamber pumps to constrain the chambers. Because during this assembly sequence, no tiles are placed in the center of the tunnel, there is nothing to stop the inner chamber pillar from also being pumped. Such an assembly sequence must be possible in any 3DaTAM system which supposedly simulates our system $\mathcal{S}$, and since this assembly sequence corresponds to one which is invalid in the SaTAM, such a simulation is impossible.

3.6 The PaTAM can simulate the directed PaTAM

▶ **Theorem 13.** *There exists a universal Planar aTAM tile set S that can simulate any directed PaTAM system.*

Despite the fact that both the PaTAM and directed PaTAM are not intrinsically universal for themselves[7], using tools from [7] and [2] we are able to construct a PaTAM tile set capable of simulating arbitrary directed PaTAM systems. Here we outline the process by which a PaTAM tileset S can simulate any given directed PaTAM system $\mathcal{T}$. The tileset S is universal, meaning that regardless of the directed PaTAM system $\mathcal{T}$, the same tileset will be used at a fixed binding threshold, with only the seed of the simulating system changing to accommodate $\mathcal{T}$.

Given a directed PaTAM system $\mathcal{T}$, we define a simulating system $\mathcal{S}$ using a fixed tile set at binding threshold 2. The seed of $\mathcal{S}$ consists of already-resolved macrotiles in the same configuration as the seed of $\mathcal{T}$. Each macrotile in $\mathcal{S}$ consists of a 9×9 grid of structures we call *component blocks* (CBs) which are each made of many smaller tile-based constructions and which each store an encoding of the system $\mathcal{T}$ along with a bit of extra data in the form

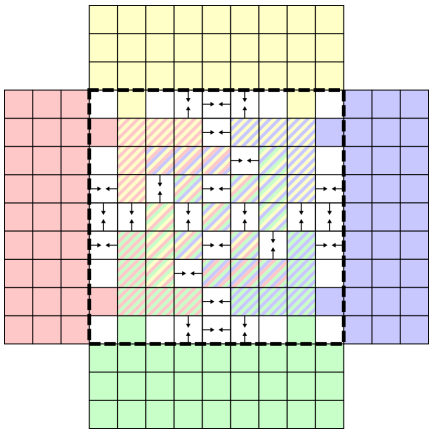

Figure 8 A schematic describing the 9×9 grid of potential component blocks which may appear in a macrotile location. Squares containing two arrows indicate a grid location which may contain a probe region. The surrounding macrotiles are illustrated using colored tiles to represent their relative direction from the current macrotile. Colors of CB locations indicate which surrounding macrotile the CB may have information about.

of specific glues on some of its tiles. The CBs of a macrotile each perform calculations using tiles which emulate Turing machines to determine how they should grow and whether or not the macrotile can resolve given the current information regarding the surrounding macrotiles.

Each CB essentially behaves like an individual tile on the 9×9 grid and we can think of CBs as growing in one of two ways. Either the CB grows using tile attachments from another adjacent CB in a way analogous to a τ-strength tile attachment, or a CB can grow in the gap between two adjacent CBs in certain locations of the grid designated as *probe regions*. This is analogous to a tile attachment that occurs by cooperative binding between two opposing tiles (which we refer to as *across-the-gap* cooperation). These "cooperative attachments" between CBs are used to consolidate information between the CBs. For instance, one CB might contain information encoded about the north adjacent macrotile and one might contain information about the west; in the probe region between them, a new CB can grow which will contain the information about both which it can then use to determine if a tile attachment in $\mathcal{T}$ would be possible in the tile location corresponding to the macrotile. Figure 8 illustrates the layout of a macrotile into CB locations with these probe regions indicated by squares with two opposing arrows.

Probe regions are CB locations in which two adjacent CBs, on opposite sides, can present structures called *probes* which are long, thin structures that grow from the surrounding CBs towards the center of a CB location. Each probe that grows in a probe region, indicates some possible combination of information from surrounding macrotiles and grows in a unique position according to this information. The length of a probe is chosen to be just shy of the center of the CB location, so that when two probes align from opposing sides of the probe region, there will be exactly a single tile wide gap between them. This gap allows a tile to cooperatively attach and grow along the sides of the probes to recover the information from both. Otherwise, if no probes in a probe region align, there will be enough room for the components that make up a CB to squeeze in between the probes from one side of the probe region to another. Figure 9 illustrates two scenarios involving probe regions.

Probe regions were introduced in [2] to solve the problem illustrated in Figure 10. Naively when simulating a tile system, to check for macrotiles which may cooperate across-the-gap, tiles must grow to query both adjacent macrotiles and determine if the attachment is possible.

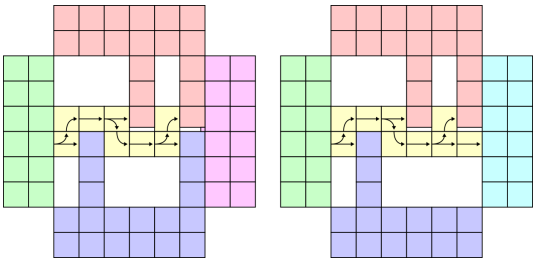

Figure 9 Probe regions between component blocks. The red and blue CBs grow probes to the center of the CB location in the middle while the green CB attempts to grow through the probe region. On the left, two probes happen to align, in which case a path of tiles containing information from the green CB cannot pass and the CB to the east results from the cooperative tile attachment between the probes. On the right, no probes align meaning the path of tiles from the green CB can squeeze between the probes to influence the growth of the CB to the east.

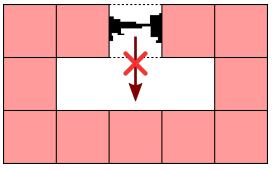

Figure 10 When checking for across-the-gap cooperation during a simulation, tiles can't naively span the entire gap without disconnecting two regions of space.

This however necessarily separates regions of space and in the case of planar systems also constrains one before it has been determined if the attachment can even occur. If it cannot, then tiles will no longer be able to attach in the constrained region and the simulation will likely end up being invalid. Probes avoid this problem by aligning exactly when across-the-gap cooperation is possible while still allowing tile structures to grow through if they don't align.

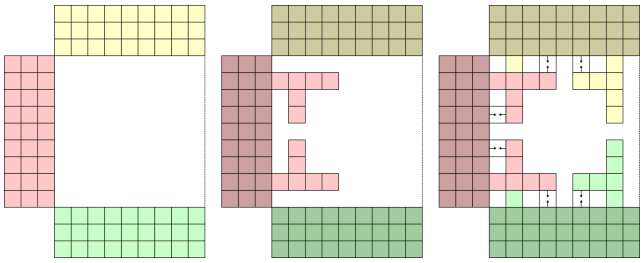

Figure 11 Hands made of component blocks growing from surrounding macrotiles.

Now that we have an idea of how the component blocks and probe regions behave we describe the protocol for resolving a macrotile by highlighting a few important cases. Growth within a macrotile begins when one or more of the surrounding macrotiles resolve and tiles begin to attach within the macrotile. From a surrounding macrotile, the protocol always begins by the growth of two "T"-shaped structures made from CBs called *hands* illustrated in Figure 11. Note that two adjacent surrounding macrotiles may both attempt to grow hands in the same location. This is handled by a single point of competition and the first surrounding macrotile for placing a tile in the closest corner of the shared hand locations is allowed to place theirs. Between the hands and the surrounding macrotiles probes are grown in the regions indicated on the right of Figure 11 which allows a CB to "attach"

cooperatively to combine information from both the hand and nearby macrotile. In some cases this information may be redundant, but with two or more surrounding macrotiles at least one location will always be able to combine information from two macrotiles.

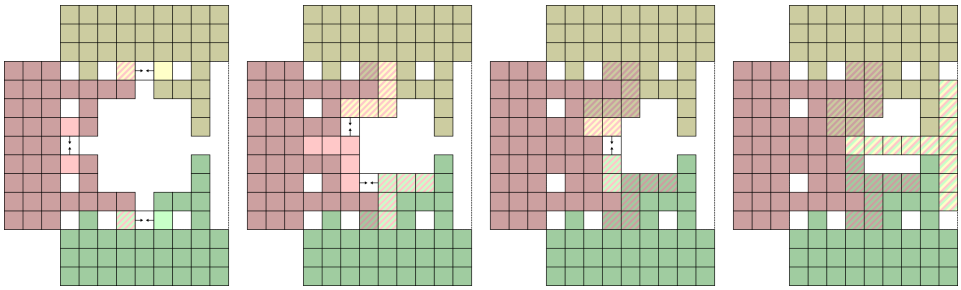

Figure 12 Once the hands have grown, CBs cooperate until information from all sides has been combined into a single CB. Then the macrotile can resolve.

The CBs resulting from cooperation between the hands and surrounding macrotiles then cooperate once again and CBs grow along the hands to form clockwise elbows with additional probe regions between them. CBs then cooperatively attach between these elbows and cooperate again near the center of the tile to eventually combine all of the information from the surrounding macrotiles. Once this occurs, the CB which "attaches" in the center of the tile contains the information from all sides. If the surrounding macrotiles represent tiles in $\mathcal{T}$ capable of placing a tile, additional CBs can grow to the remaining sides to present this information to the remaining sides and repeat the procedure in the adjacent macrotile locations.

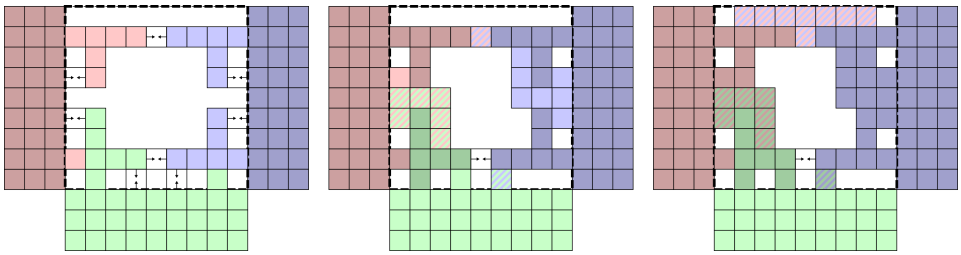

Figure 13 Probe regions between opposing macrotiles can check for across-the-gap cooperation.

In the case that an across-the-gap cooperation is possible in $\mathcal{T}$, the protocol deviates slightly. Illustrated in Figure 13, if across-the-gap cooperation is possible between the east and west macrotiles, their hands will share a probe region with aligned probes. Consequently, a CB can grow in that location and resolve the macrotile. This growth may constrain the region to the south, halting any tile attachments and CB growth in the south side of the macrotile, but this doesn't matter since the macrotile will only need to start the process in adjacent macrotiles that haven't yet resolved. The described protocol is robust to different orders of hand growth and different numbers of surrounding macrotiles, including those that don't end up contributing to macrotile resolution. If at any time a CB has sufficient information to determine how the macrotile should resolve, it begins growth to the center and then surrounding edges of the macrotile. This process will not be interrupted by other CBs since we are simulating a directed system where at most one unique tile can attach in each location.

Parameter Estimation for Gibbs Distributions

David G. Harris
Department of Computer Science, University of Maryland, College Park, MD, USA

Vladimir Kolmogorov
Institute of Science and Technology Austria, Klosterneuburg, Austria

Abstract

A central problem in computational statistics is to convert a procedure for *sampling* combinatorial objects into a procedure for *counting* those objects, and vice versa. We will consider sampling problems which come from *Gibbs distributions*, which are families of probability distributions over a discrete space Ω with probability mass function of the form $\mu_\beta^\Omega(\omega) \propto e^{\beta H(\omega)}$ for β in an interval $[\beta_{\min}, \beta_{\max}]$ and $H(\omega) \in \{0\} \cup [1, n]$.

The *partition function* is the normalization factor $Z(\beta) = \sum_{\omega \in \Omega} e^{\beta H(\omega)}$, and the *log partition ratio* is defined as $q = \frac{\log Z(\beta_{\max})}{Z(\beta_{\min})}$

We develop a number of algorithms to estimate the counts c_x using roughly $\tilde{O}(\frac{q}{\varepsilon^2})$ samples for general Gibbs distributions and $\tilde{O}(\frac{n^2}{\varepsilon^2})$ samples for integer-valued distributions (ignoring some second-order terms and parameters), We show this is optimal up to logarithmic factors. We illustrate with improved algorithms for counting connected subgraphs and perfect matchings in a graph.

1 Introduction

A central problem in computational statistics is to convert a procedure for *sampling* combinatorial objects into a procedure for *counting* those objects, and vice versa. We will consider sampling algorithms for Gibbs distributions. Formally, given a real-valued function $H(\cdot)$ over a finite set Ω, the *Gibbs distribution* is defined as a family of distributions μ_β^Ω over Ω, parameterized by β, of the form

$$\mu_\beta^\Omega(\omega) = \frac{e^{\beta H(\omega)}}{Z(\beta)}$$

These distributions occur in a number of sampling algorithms, as we describe shortly; they also frequently occur in physics, where the parameter $-\beta$ corresponds to the inverse temperature, the function $H(\omega)$ is called the *Hamiltonian* of the system, and the normalizing constant $Z(\beta) = \sum_{\omega \in \Omega} e^{\beta H(\omega)}$ is called the *partition function*.

Suppose we have access to an oracle which return a sample from μ_β^Ω for any chosen query value $\beta \in [\beta_{\min}, \beta_{\max}]$. We will seek to estimate the vector of counts (also known as the *(discrete) density of states (DOS)*), defined as

$$c_x = |H^{-1}(x)|, \qquad x \geq 0$$

In statistical physics, for instance, this essentially gives full information about the system and physically relevant quantities such as entropy, free energy, etc. Another parameter, whose role is less intuitive, is the partition ratio function

$$Q(\beta) = \frac{Z(\beta)}{Z(\beta_{\min})},$$

and in particular the value $Q(\beta_{\max}) = \frac{Z(\beta_{\max})}{Z(\beta_{\min})}$. This can interpreted as a measure of the "diversity" of the distribution as β varies.

As is common in this setting, we assume that (after rescaling if necessary) we are given known parameters n, q with

$$\log Q(\beta_{\max}) \leq q, \qquad H(\Omega) \subseteq \mathcal{F} \stackrel{\text{def}}{=} \{0\} \cup [1, n]$$

In some cases, the domain is integer-valued, i.e. $H(\Omega) \subseteq \mathcal{H} \stackrel{\text{def}}{=} \mathcal{F} \cap \mathbb{Z} = \{0, 1, \ldots, n\}$ for integer n. We call this the *general integer setting*. A special case of the integer setting, which we call the *log-concave setting*, is when the counts $c_0, c_1, c_2, \ldots, c_{n-1}, c_n$ are non-zero and satisfy $c_k/c_{k-1} \geq c_{k+1}/c_k$ for $k = 1, \ldots, n-1$. The general case, where $H(\omega)$ takes values in $\mathcal{F}$, is called the *continuous setting*.[1]

There is an associated probability distribution we call the *gross Gibbs distribution* $\mu_\beta(x)$ over $\mathcal{F}$ given by

$$\mu_\beta(x) = \frac{c_x e^{\beta x}}{Z(\beta)}, \qquad Z(\beta) = \sum_x c_x e^{\beta x}$$

We will only require oracle access to μ_β, for any chosen query value $\beta \in [\beta_{\min}, \beta_{\max}]$; this is provided automatically given access to μ_β^Ω. We let γ denote the target failure probability and ε the target accuracy of our algorithms, i.e. with probability at least $1-\gamma$, the algorithms should return estimates within a factor of $[e^{-\varepsilon}, e^{\varepsilon}]$ of the correct value. Throughout, "sample complexity" refers to the number of calls to the oracle; for brevity, we also define the *cost* of a sampling algorithm to be its *expected sample complexity*.

To avoid degenerate cases, we assume $n, q \geq 2$ and $\varepsilon, \gamma \in (0, \frac{1}{2})$ throughout. If upper bounds n and/or q are not available directly, they can often be estimated by simple algorithms (up to constant factors), or can be guessed by exponential back-off strategies.

1.1 Algorithmic sampling-to-counting

To make our problem setting more concrete, consider the following scenario: we have a combinatorial system, where the objects have a "weight", and we have an algorithm to sample objects from the corresponding Gibbs distribution for any parameter β. This may be an exact sampler, or it may be an approximate sampler such as a Markov chain whose stationary distribution is the Gibbs distribution. The runtime (e.g. the mixing time of the Markov chain) may depend on β. As a few prominent examples:

[1] The log-concave algorithms still work if some of the counts c_i are equal to zero; in this case, the non-zero counts must form a discrete interval $\{i_0, i_0+1, \ldots, i_1-1, i_1\}$ and the required bound must hold for $k = i_0+1, \ldots, i_1-1$.

1. Connected subgraphs of a given graph; the weight of a subgraph is its cardinality [10].
2. Matchings of a given graph; the weight of a matching, again, is its cardinality [15, 13].
3. Independent sets in bounded-degree graphs; the weight is the size of the independent set [7, 13].
4. Assignments to a given k-SAT instance; the weight is the number of unsatisfied clauses [8].
5. Vertex cuts for the ferromagnetic Ising model; the weight is the imbalance of the cut [5].

We may wish to know the number of objects of a given weight class, e.g. connected subgraphs of a given size. This can be viewed in terms of estimating the counts c_i. In a number of these applications, such as connected subgraphs and matchings, the count sequence is further known to be log-concave.

Our estimation algorithms can be combined with these prior sampling algorithms to yield improved algorithmic results, essentially for free. As some examples, we will show the following:

▶ **Theorem 1.** *Let $G = (V, E)$ be a connected graph, and for each $i = 0, \dots, |E| - |V| + 1$ let c_i be the number of connected subgraphs with $|E| - i$ edges. There is an fully-polynomial randomized approximation scheme (FPRAS) to estimate all values c_i in time complexity $\tilde{O}(|E|^3|V|/\varepsilon^2)$.*

▶ **Theorem 2.** *Let $G = (V, E)$ be a graph of maximum degree D and for each $i = 0, \dots, |V|$ let c_i be the number of independent sets of size i. For any constant $\xi > 0$ there is an FPRAS with runtime $\tilde{O}(|V|^2/\varepsilon^2)$ to simultaneously estimate all values $c_0, \dots, c_t$ for $t = (\alpha_c - \xi)|V|$, where α_c is the computational hardness threshold shown in [7].*

▶ **Theorem 3.** *Let $G = (V, E)$ be a graph with $|V| = 2v$ and for each $i = 0, \dots, v$ let c_i be the number of matchings in G with i edges. Suppose $c_v > 0$ and $c_{v-1}/c_v \le f$ for a known parameter f. There is an FPRAS for all c_i running in time $\tilde{O}(|E||V|^3 f/\varepsilon^2)$. In particular, if G has minimum degree at least $|V|/2$, the time complexity is $\tilde{O}(|V|^7/\varepsilon^2)$.*

Theorem 1 improves by a factor of $|E|$ over the algorithm in [11]. Similarly, Theorem 3 improves by a factor of $|V|$ compared to the FPRAS for counting matchings in [15]. Theorem 2 matches the runtime of an FPRAS for a *single* value i_k given in [13].

There are two minor technical issues we should clarify here. First, to obtain a randomized estimation algorithm, we must also bound the computational complexity of our procedures in addition to the number of oracle calls. In all the algorithms we develop, the computational complexity is a small logarithmic factor times the query complexity. The computational complexity of the oracle is typically much larger than this overhead. Thus, our sampling procedures translate directly into efficient randomized algorithms, whose runtime is the expected sample complexity multiplied by the oracle's computational complexity. We will not comment on computational issues henceforth.

Second, we may only have access to some approximate oracle $\tilde{\mu}_\beta$ that is close to μ_β in terms of total variation distance (e.g. by running an MCMC sampler). By a standard coupling argument (see e.g. [19, Remark 5.9]), our results remain valid if exact oracles are replaced with sufficiently close approximate oracles.

1.2 Our contributions

Before we can formally describe our algorithm for count estimation, we need to clear up two technical issues. The first is that counts can only be recovered up to scaling, so some (arbitrary) normalization must be chosen. For sake of consistency with other algorithms, we use the parameter $\pi(x)$ defined as:

$$\pi(x) \stackrel{\text{def}}{=} \mu_{\beta_{\min}}(x) = \frac{c_x e^{\beta_{\min} x}}{Z(\beta_{\min})}$$

The second, much trickier, issue is that if a count c_x is relatively small, then it is inherently hard to estimate accurately. To explain this, suppose that $\max_{\beta\in[\beta_{\min},\beta_{\max}]} \mu_\beta(x) = \mu_*$. In this case, $\Omega(1/\mu_*)$ samples are clearly needed to distinguish between $c_x = 0$ and $c_x > 0$; with fewer samples, we will never draw x from the oracle. Moreover, $\Omega(\frac{1}{\mu_* \varepsilon^2})$ samples are needed to estimate c_x to relative error ε. Since we can vary β, the complexity of estimating c_x must depend on the *best case* $\mu_\beta(x)$, over all allowed values of β. This gives rise to the parameter $\Delta(x)$ defined as

$$\Delta(x) \stackrel{\text{def}}{=} \max_{\beta\in[\beta_{\min},\beta_{\max}]} \mu_\beta(x)$$

With these two provisos, let us define the problem $P^{\delta,\varepsilon}_{\texttt{count}}$ for parameters $\delta, \varepsilon \in (0,1)$ as follows. We seek to obtain a pair of vectors $(\hat{\pi}, u)$, to satisfy two properties:

- **(i)** for all $x \in \mathcal{F}$ with $c_x \neq 0$, there holds $|\hat{\pi}(x) - \pi(x)| \leq u(x) \leq \varepsilon\pi(x)(1 + \delta/\Delta(x))$.
- **(ii)** for all $x \in \mathcal{F}$ with $c_x = 0$, there holds $\hat{\pi}(x) = 0$, and $u(x)$ can be set to an arbitrary value.

In other words, $[\hat{\pi}(x) - u(x), \hat{\pi}(x) + u(x)]$ should be a confidence interval for $\pi(x)$. In particular, if $\Delta(x) \geq \delta$, then $P^{\delta,\varepsilon}_{\texttt{count}}$ provides a $(1 \pm O(\varepsilon))$ relative approximation to $\pi(x)$. When $\Delta(x) \ll \delta$, then it still provides meaningful approximation guarantees which are critical in some of our other algorithms.

We develop three main algorithmic results:

▶ **Theorem 4.** *$P^{\delta,\varepsilon}_{\texttt{count}}$ can be solved with the following complexities:*

- *In the continuous setting, with cost $O\Big(\frac{q\log n + \sqrt{q\log n}/\delta}{\varepsilon^2}\log\frac{q}{\delta\gamma}\Big)$.*
- *In the general integer setting, with cost $O\Big(\frac{n^2+n/\delta}{\varepsilon^2}\log^2\frac{nq}{\gamma}\Big)$.*
- *In the log-concave setting, with cost $O\Big(\frac{\min\{(q+n)\log n, n^2\}+1/\delta}{\varepsilon^2}\log\frac{nq}{\gamma}\Big)$.*

where recall that cost refers to the expected number of queries to the oracle.

Our full results are somewhat more precise, see Theorems 13, 20 and 21 for more details.

We also show lower bounds for $P^{\delta,\varepsilon}_{\texttt{count}}$; we summarize these results here as follows:

▶ **Theorem 5.** *Let $n \geq n_0, q \geq q_0, \varepsilon < \varepsilon_0, \delta < \delta_0, \gamma < 1/4$ for certain absolute constants $n_0, q_0, \varepsilon_0, \delta_0$. There are problem instances μ which satisfy the given bounds n and q such that:*

- **(a)** *$P^{\delta,\varepsilon}_{\texttt{count}}$ requires cost $\Omega(\frac{(q+\sqrt{q}/\delta)\log\frac{1}{\gamma}}{\varepsilon^2})$.*
- **(b)** *$P^{\delta,\varepsilon}_{\texttt{count}}$ requires cost $\Omega(\frac{\min\{q+\sqrt{q}/\delta, n^2+n/\delta\}\log\frac{1}{\gamma}}{\varepsilon^2})$, and μ is integer-valued.*
- **(c)** *$P^{\delta,\varepsilon}_{\texttt{count}}$ requires cost $\Omega(\frac{(1/\delta+\min\{q,n^2\})\log\frac{1}{\gamma}}{\varepsilon^2})$, and μ is log-concave.*

These first two results match Theorem 4 up to logarithmic factors in n and q. The result for the log-concave setting has an additive discrepancy $\tilde{O}(\frac{n}{\varepsilon^2})$ in the regime when $1/\delta + q = o(n)$. (Throughout, we use the notation $\tilde{O}(x) = x\,\mathrm{polylog}(x)$.) See Theorem 36 for a more precise and general statement of these bounds. We emphasize that these lower bounds only apply to estimation algorithms which make use of the Gibbs oracle in a black-box way.

Some count-estimation algorithms have been considered for specific problems, e.g. in [14] for counting matchings or in [7] for counting independent sets. These procedures depended on specific properties of the Gibbs distribution, e.g. log-concavity. In addition, the algorithm in [14] was roughly worse by a factor of n compared to Theorem 4. By swapping in our new algorithm for $P_{\texttt{count}}^{\delta,\varepsilon}$, we will immediately obtain simpler, and more efficient, algorithms for these problems.

The general problem $P_{\texttt{count}}$ has not been theoretically analyzed, to our knowledge. In practice, the *Wang-Landau (WL)* algorithm [20] is a popular heuristic to estimate counts in physical applications. This uses a completely different methodology from our algorithm, based on a random walk on $\mathcal{F}$ with a running count estimate $\hat{c}$. As discussed in [18], there are more than 1500 papers on the WL algorithm as well as variants such as the $1/t$-WL algorithm [3]. These algorithms are not well understood; some variants are guaranteed to converge asymptotically [9], but bounds on convergence rate or accuracy seem to be lacking. For a representative example, see for example [17], which describes a Gibbs distribution model of protein folding, and uses the WL algorithm to determine relevant properties.

Estimating partition ratio

As a key building block, we develop new subroutines to estimate partition ratios. Formally, let us define the problem $P_{\texttt{ratio}}^{\texttt{all}}$ to compute a data structure $\mathcal{D}$ with an associated *deterministic* function $\hat{Q}(\alpha|\mathcal{D})$ satisfying the property

$$|\log \hat{Q}(\alpha|\mathcal{D}) - \log Q(\alpha)| \leq \varepsilon \qquad \text{for all } \alpha \in (\beta_{\min}, \beta_{\max}]$$

We say in this case that $\mathcal{D}$ is ε-*close*. We emphasize that, although generating $\mathcal{D}$ will require sampling from the Gibbs distribution, using it will not. Our main result here will be the following:

▶ **Theorem 6.** *$P_{\texttt{ratio}}^{\texttt{all}}$ can be solved with the following complexities:*

- *In the continuous setting, with cost $O\big(\frac{q \log n}{\varepsilon^2} \log \frac{1}{\gamma}\big)$.*
- *In the general integer setting, with cost $O\big(\frac{n^2 \log n}{\varepsilon^2} \log \frac{1}{\gamma} + n \log q\big)$.*
- *In the log-concave integer setting, with cost $O\big(\frac{n^2}{\varepsilon^2} \log \frac{1}{\gamma} + n \log q\big)$.*

A number of algorithms have been developed for *pointwise* estimation of $Q(\beta_{\max})$, with steadily improving sample complexities [4, 19, 12]. We denote this problem by $P_{\texttt{ratio}}^{\texttt{point}}$. The best prior algorithm for $P_{\texttt{ratio}}^{\texttt{point}}$ in the continuous setting [16] had cost $O\big(\frac{q \log n}{\varepsilon^2} \log \frac{1}{\gamma}\big)$ (matching our algorithm for $P_{\texttt{ratio}}^{\texttt{all}}$). No specialized algorithms were known for the integer setting. We also show matching lower bounds:

▶ **Theorem 7.** *Let $n \geq n_0, q \geq q_0, \varepsilon < \varepsilon_0, \delta < \delta_0, \gamma < 1/4$ for certain absolute constants $n_0, q_0, \varepsilon_0, \delta_0$. There are problem instances μ which satisfy the given bounds n and q such that:*

(a) *$P_{\texttt{ratio}}^{\texttt{point}}$ requires cost $\Omega(\frac{q \log \frac{1}{\gamma}}{\varepsilon^2})$.*

(b) *$P_{\texttt{ratio}}^{\texttt{point}}$ requires cost $\Omega(\frac{\min\{q, n^2\} \log \frac{1}{\gamma}}{\varepsilon^2})$. and μ is log-concave*

Thus, Theorem 6 is optimal up to logarithmic factors; this essentially settles the complexity of $P_{\texttt{ratio}}$ as functions of n and q.

The first algorithm of Theorem 6, for the continuous setting, is similar to the pointwise algorithm in [16]; we defer it the to the full version of the paper.

1.3 Overview

We will develop two, quite distinct, types of algorithms: the first uses "cooling schedules" similar to [12, 16], and the second is based on a new type of "covering schedule" for the integer setting. In Section 6, we use these algorithms for approximate counting of matching and connected subgraphs. In Section 7, we show the lower bounds for the problems $P_{\texttt{ratio}}$ and $P_{\texttt{count}}$.

We remark that when $q \leq n^2$ in the integer setting, general continuous algorithms may be more efficient than the specialized integer algorithms for some tasks. These will be used for our algorithms to count independent sets and connected subgraphs, for instance.

Before the technical details, let us provide a high-level roadmap. For simplicity, we assume that tasks need to be solved with constant success probability.

The continuous setting

We can use a variant on an algorithm of [16] to solve $P^{\texttt{all}}_{\texttt{ratio}}$. Assuming this problem can be solved, let us examine the problem $P^{\delta,\varepsilon}_{\texttt{count}}$. As a starting point, consider the identity

$$\pi(x) = e^{-(\beta-\beta_{\min})x} \cdot \mu_\beta(x) \cdot Q(\beta) \qquad \text{for all } x \in \mathcal{F}, \beta \in [\beta_{\min}, \beta_{\max}]. \tag{1}$$

For any value β, we can estimate $Q(\beta)$ using our algorithm for $P^{\texttt{all}}_{\texttt{ratio}}$, and we can estimate $\mu_\beta(x)$ by drawing $\Theta(\frac{1}{\mu_\beta(x)\varepsilon^2})$ samples from μ_β. We then make use of the following important result: if $\mu_\beta([0,x])$ and $\mu_\beta([x,n])$ are both bounded below by constants, then $\mu_\beta(x) \geq \Omega(\Delta(x))$.

Therefore, we do the following: (i) use binary search to find value β with $\mu_\beta([0,x]) \approx \mu_\beta([x,n])$; and (ii) estimate $\mu_\beta(x)$ using $O(\frac{1}{\delta\varepsilon^2})$ samples; (iii) use Eq. (1) to determine $\pi(x)$. From standard concentration bounds, this satisfies the conditions of $P^{\delta,\varepsilon}_{\texttt{count}}$; for example, if $\Delta(x) \geq \delta$, then $\mu_\beta(x)$, and hence $\pi(x)$, is estimated within relative error ε.

To estimate all the counts, we find cut-points $y_1, \ldots, y_t$, where each interval $[y_i, y_{i+1}]$ has a corresponding value β_i with $\mu_{\beta_i}([y_i, n]) \geq \Omega(1)$ and $\mu_{\beta_i}([0, y_{i+1}]) \geq \Omega(1)$. Any $x \in [y_{i+1}, y_i]$ then has $\mu_{\beta_i}(x) \geq \Omega(\Delta(x))$, so we can use samples from μ_{β_i} to estimate c_x simultaneously for all $x \in [y_i, y_{i+1}]$. We show that only $t = O(\sqrt{q \log n})$ distinct intervals are needed, leading to a cost of $O(\frac{\sqrt{q \log n}}{\delta\varepsilon^2})$ plus the cost of solving $P^{\texttt{all}}_{\texttt{ratio}}$. The formal analysis appears in Section 3.

The integer setting

To solve $P^{\delta,\varepsilon}_{\texttt{count}}$, we develop a new data structure we call a *covering schedule*. This consists of a sequence $\beta_{\min} = \beta_0, \beta_1, \ldots, \beta_t = \beta_{\max}$ and corresponding values $k_1, \ldots, k_t$ so that $\mu_{\beta_i}(k_i)$ and $\mu_{\beta_i}(k_{i+1})$ are large for all i. (The definition is adjusted slightly for the endpoints $i = 0$ and $i = t$). Define $w_i = \min\{\mu_{\beta_i}(k_i), \mu_{\beta_i}(k_{i+1})\}$ ("weight" of i). If we take $\Omega(1/w_i)$ samples from μ_{β_i}, we can accurately estimate the quantities $\mu_{\beta_i}(k_i), \mu_{\beta_i}(k_{i+1})$, in turn allowing us to estimate

$$\frac{Q(\beta_i)}{Q(\beta_{i-1})} = e^{(\beta_i - \beta_{i-1})k_i} \frac{\mu_{\beta_{i-1}}(k_i)}{\mu_{\beta_i}(k_i)}$$

By telescoping products, this in turn allows us to estimate every value $Q(\beta_i)$.

Next, for each index $x \in \mathcal{H}$, we use binary search to find α with $\mu_\alpha([0,x]) \approx \mu_\alpha([x,n])$ and then estimate $\mu_\alpha(x)$ by taking $O(\frac{1}{\delta\varepsilon^2})$ samples. If α lies in interval $[\beta_i, \beta_{i+1}]$ of the covering schedule, we can use the estimates for $Q(\beta_i)$ and $Q(\beta_{i+1})$ to estimate $Q(\alpha)$ and hence $\pi(x)$. Since we do this for each $x \in \mathcal{H}$, the overall cost of this second phase is roughly $O(\frac{n}{\delta\varepsilon^2})$.

There is a more efficient algorithm for $P^{\delta,\varepsilon}_{\texttt{count}}$ for log-concave counts. In this case, for a fixed β and $x \in [\sigma^-, \sigma^+]$ we have $\mu_\beta(x) \geq \min\{\mu_\beta(\sigma^-), \mu_\beta(\sigma^+)\}$. Thus, a single value β_i in a covering schedule "covers" the interval $[k_i, k_{i+1}]$. We can solve $P^{\delta,\varepsilon}_{\texttt{count}}$ with $O(\frac{1}{\delta\varepsilon^2} + \sum_i \frac{1}{w_i\varepsilon^2})$ samples, by drawing $\Theta(\frac{1}{w_i\varepsilon^2})$ samples at β_i and $\Theta(\frac{1}{\delta\varepsilon^2})$ samples at $\beta_{\min}$ and $\beta_{\max}$.

After solving $P^{\delta,\varepsilon}_{\texttt{count}}$, we can then solve $P^{\texttt{all}}_{\texttt{ratio}}$ essentially for free, by estimating $\hat{Q}(\alpha \mid \mathcal{D}) = \sum_i e^{(\alpha-\beta_{\min})i}\hat{\pi}(i)$. So $P^{\texttt{all}}_{\texttt{ratio}}$ in the integer setting reduces to a special case of $P_{\texttt{count}}$. (Interestingly, the continuous-case algorithm works very differently – there, $P^{\texttt{all}}_{\texttt{ratio}}$ is a subroutine used to solve $P_{\texttt{count}}$.)

Obtaining a covering schedule

The general $P_{\texttt{count}}$ algorithm described above uses $O(\sum_i \frac{n}{w_i\varepsilon^2})$ samples to estimate the values $Q(\beta_i)$, and similarly the log-concave algorithm uses $O(\frac{1}{\delta\varepsilon^2} + \sum_i \frac{1}{w_i\varepsilon^2})$ samples. We thus refer to the quantity $\sum_i \frac{1}{w_i}$ as the *inverse weight* of the schedule. In the most technically involved part of the paper, we produce a covering schedule with inverse weight $O(n \log n)$ (or $O(n)$ in the log-concave setting). Here we just sketch some key ideas.

First, we construct a "preschedule" where each interval can choose two different indices σ_i^-, σ_i^+ instead of a single index k_i, with the indices interleaving as $\sigma_i^- \leq \sigma_{i+1}^- \leq \sigma_i^+ \leq \sigma_{i+1}^+$. The algorithm repeatedly fill gaps: if some half-integer $\ell + 1/2$ is not currently covered, then we can select a value β with $\mu_\beta([0,\ell]) \approx \mu_\beta([\ell+1, n])$. For this β, there is a value $\sigma^+ \in [\ell+1, n]$ with $\mu_\beta(\sigma^+) \cdot (\sigma^+ - \ell) \geq \Omega(\frac{1}{\log n})$, and similarly a value $\sigma^- \in [0, k]$ with $\mu_\beta(\sigma^-) \cdot (\ell - \sigma^- + 1) \geq \Omega(\frac{1}{\log n})$. The interval $[\sigma^-, \sigma^+]$ then fills the gap and also has weight $w \geq \Omega(\frac{1}{(\sigma^+ - \sigma^-)\log n})$.

At the end of the process, we throw away redundant intervals so each x is covered by at most two intervals, and "uncross" them into a schedule with $k_i \in \{\sigma^+_{i-1}, \sigma^-_i\}$. Since $\frac{1}{w_i} \leq O((\sigma_i^+ - \sigma_i^-)\log n)$ for each i, this gives an $O(n \log n)$ bound of the inverse weight of the schedule.

2 Preliminaries

Define $z(\beta) = \log Z(\beta)$ and $z(\beta_1, \beta_2) = \log \frac{Z(\beta_2)}{Z(\beta_1)} = \log \frac{Q(\beta_2)}{Q(\beta_1)}$; note that $z(\beta_{\min}, \beta_{\max}) \leq q$ by definition. We write $z'(\beta)$ for the derivative of function z.

Define the Chernoff separation functions $F_+(x,t) = \left(\frac{e^\delta}{(1+\delta)^{1+\delta}}\right)^x$ and $F_-(x,t) = \left(\frac{e^{-\delta}}{(1-\delta)^{1-\delta}}\right)^x$, where $\delta = t/x$. These are well-known upper bounds on the probability that a binomial random variable with mean x is larger than $x+t$ or smaller than $x-t$, respectively. We also define $F(x,t) = F_+(x,t) + F_-(x,t)$.

For a random variable X, we write $\mathbb{V}(X)$ for the variance of X, and $\mathbb{S}[X] = \frac{\mathbb{E}[X^2]}{(\mathbb{E}[X])^2} - 1 = \frac{\mathbb{V}(X)}{(\mathbb{E}[X])^2}$ for the relative variance of X.

We write $\mu_\beta(x,y), \mu_\beta[x,y)$ instead of $\mu_\beta((x,y)), \mu_\beta([x,y))$, etc. for readability.

2.1 The `Balance` subroutine

Given a target χ, we sometimes need to find a value β with $\mu_\beta[0,\chi] \approx 1/2 \approx \mu_\beta[\chi, n]$. That is, χ is the "balancing point" in the distribution μ_β. Formally, for values $\beta_{\texttt{left}} \leq \beta_{\texttt{right}}$, let us denote by $\Lambda_\tau(\beta_{\texttt{left}}, \beta_{\texttt{right}}, \chi)$ the set of values $\beta \in [\beta_{\texttt{left}}, \beta_{\texttt{right}}]$ which satisfy the following two properties:

- Either $\beta = \beta_{\texttt{left}}$ or $\mu_\beta[0,\chi) \geq \tau$
- Either $\beta = \beta_{\texttt{right}}$ or $\mu_\beta[\chi, n] \geq \tau$

To find this, we use a subroutine `Balance`. To summarize briefly, since $\mu_\beta[0,\chi]$ is a monotonic function of β and can be estimated by sampling, the value β is found via a noisy binary search. Our main result is the following:

▶ **Theorem 8.** *Suppose that τ is an arbitrary constant and $\beta_{\min} \le \beta_{\texttt{left}} < \beta_{\texttt{right}} \le \beta_{\max}$. Then $\beta \leftarrow \texttt{Balance}(\beta_{\texttt{left}}, \beta_{\texttt{right}}, \chi, \gamma, \tau)$ has cost $O(\log \frac{nq}{\gamma})$. With probability at least $1-\gamma$, there holds $\beta \in \Lambda_\tau(\beta_{\texttt{left}}, \beta_{\texttt{right}}, \chi)$ (we say in this case that the call is* good*).*

The details appear in the full paper. The following observation explains the motivation for the definition.

▶ **Proposition 9.** *If $\beta \in \Lambda_\tau(\beta_{\min}, \beta_{\max}, x)$, then $\mu_\beta(x) \ge \tau\Delta(x)$.*

Proof. Consider $\alpha \in [\beta_{\min}, \beta_{\max}]$ with $\mu_\alpha(x) = \Delta(x)$. The result is clear if $\alpha = \beta$. Suppose that $\alpha < \beta$; the case $\alpha > \beta$ is completely analogous. So $\beta > \beta_{\min} = \beta_{\texttt{left}}$, and since $\beta \in \Lambda_\tau(\beta_{\min}, \beta_{\max}, x)$, this implies that $\mu_\beta[0,x] \ge \tau$. We then have:

$$\begin{aligned}\mu_\alpha(x) &= \frac{c_x e^{\alpha x}}{\sum_y c_y e^{\alpha y}} \le \frac{c_x}{\sum_{y\le x} c_y e^{\alpha(y-x)}} \le \frac{c_x}{\sum_{y\le x} c_y e^{\beta(y-x)}} \\ &= \frac{c_x e^{\beta x}}{\sum_{y\le x} c_y e^{\beta y}} = \frac{\mu_\beta(x)}{\mu_\beta[0,x]} \le \frac{\mu_\beta(x)}{\tau}.\end{aligned}$$

◀

2.2 Statistical sampling

We can obtain an unbiased estimator of the probability vector μ_β by computing empirical frequencies $\hat\mu_\beta$ from N independent samples from μ_β; we denote this process as $\hat\mu_\beta \leftarrow \texttt{Sample}(\beta; N)$. We record the following standard concentration bound, which we will use repeatedly:

▶ **Lemma 10.** *For $\varepsilon, \gamma \in (0, \frac12), p_\circ \in (0,1]$, suppose we draw random variable $\hat p \sim \frac1N Binom(N,p)$ where $N \ge \frac{3e^\varepsilon \log(4/\gamma)}{(1-e^{-\varepsilon})^2 p_\circ}$. Then, with probability at least $1-\gamma$, the following two bounds both hold:*

$$|\hat p - p| \le \varepsilon(p + p_\circ), \qquad \text{and} \tag{2}$$

$$\hat p \in \begin{cases} [e^{-\varepsilon}p, e^{\varepsilon}p] & \text{if } p \ge e^{-\varepsilon}p_\circ \\ [0, p_\circ) & \text{if } p < e^{-\varepsilon}p_\circ \end{cases} \tag{3}$$

In particular, if Eq. (3) holds and $\min\{p,\hat p\} \ge p_\circ$, then $|\log\hat p - \log p| \le \varepsilon$.

Proof. See full paper. ◀

Many of our algorithms are based on calling $\hat\mu_\beta \leftarrow \texttt{Sample}(\beta; N)$ and making decisions depending on the values $\hat\mu_\beta(I)$ for certain sets $I \subseteq \mathcal{F}$; they succeed when the estimates $\hat\mu_\beta(I)$ are close to $\mu_\beta(I)$. We say the execution of `Sample` *well-estimates* I if Eqs. (2),(3) hold for $p = \mu_\beta(I)$ and $\hat p = \hat\mu_\beta(I)$; otherwise it *mis-estimates* I. Likewise we say `Sample` well-estimates k if it well-estimates the singleton set $I = \{k\}$. Since this comes up so frequently, we write

$$\hat\mu_\beta \leftarrow \texttt{Sample}(\beta; \varepsilon, \gamma, p_\circ)$$

as shorthand for $\hat\mu_\beta \leftarrow \texttt{Sample}(\beta; \lceil \frac{3e^\varepsilon \log(4/\gamma)}{(1-e^{-\varepsilon})^2 p_\circ} \rceil)$. Note that this has cost $O(\frac{\log(1/\gamma)}{\varepsilon^2 p_\circ})$, and each set I is well-estimated with probability at least $1-\gamma$.

As we have touched upon, our algorithms for $P^{\delta,\varepsilon}_{\texttt{count}}$ estimate each value $\pi(x)$ by sampling $\hat\mu_\alpha(x)$ for a well-chosen value α. We use similar formulas to produce the estimates $\hat\pi(x), u(x)$ in all these cases. We record the following general result:

▶ **Lemma 11.** *Suppose that for $x \in \mathcal{F}$, we are given $\alpha \in [\beta_{\min}, \beta_{\max}]$ and non-negative parameters $\hat{Q}(\alpha), \hat{\mu}_\alpha(x), p_\circ$ (all of which may depend upon x), satisfying the following bounds:*
(A1) $|\log \hat{Q}(\alpha) - \log Q(\alpha)| \le 0.1\varepsilon$.
(A2) $p_\circ \le \mu_\alpha(x)(1 + \delta/\Delta(x))$
(A3) $|\hat{\mu}_\alpha(x) - \mu_\alpha(x)| \le 0.1\varepsilon(\mu_\alpha(x) + p_\circ)$.

Then the estimated values

$$\hat{\pi}(x) = \hat{Q}(\alpha)e^{(\beta_{\min}-\alpha)x}\hat{\mu}_\alpha(x), \qquad u(x) = 0.4\hat{Q}(\alpha)e^{(\beta_{\min}-\alpha)x}\varepsilon(\hat{\mu}_\alpha(x) + p_\circ)$$

satisfy the criteria for the problem $P^{\delta,\varepsilon}_{\texttt{count}}$.

Proof. See full paper. ◀

Since this formula comes up so often, we write

$\texttt{EstimatePi}(x, \alpha, p_\circ)$

as shorthand for setting $\hat{\pi}(x), u(x)$ according to the formula in Lemma 11. The values $\hat{Q}(\alpha)$ and $\hat{\mu}_\alpha(x)$ should be clear from the context.

In a number of places, we need to estimate certain telescoping products. Direct Monte Carlo sampling does not give strong tail bounds, so we use a standard method based on median amplification. See the full paper for a description and proof.

▶ **Theorem 12.** *Suppose we can sample non-negative random variables $X_1, \dots, X_N$. The subroutine $\texttt{EstimateProducts}(X, \tau, \varepsilon, \gamma)$ takes input $\varepsilon, \gamma \in (0, 1)$ and $\tau > 0$, and returns a vector of estimates $(\hat{X}^{\texttt{prod}}_1, \dots, \hat{X}^{\texttt{prod}}_N)$. It uses $O(N(1 + \tau/\varepsilon^2)\log\frac{1}{\gamma})$ total samples of the X variables. If $\tau \ge \sum_{i=1}^N \mathbb{S}[X_i]$, then with probability at least $1 - \gamma$, it holds that $\frac{\hat{X}^{\texttt{prod}}_i}{\prod_{j=1}^i \mathbb{E}[X_j]} \in [e^{-\varepsilon}, e^{\varepsilon}]$ for all $i = 1, \dots, N$.*

In this case, it is also convenient to define $\hat{X}^{\texttt{prod}}_0 = 1 = \prod_{j=1}^0 \mathbb{E}[X_j]$.

3 Solving $P^{\delta,\varepsilon}_{\texttt{count}}$ in the continuous setting

In this section, we develop Algorithm 1 for $P^{\delta,\varepsilon}_{\texttt{count}}$. Here, we use a general algorithm to solve $P^{\texttt{all}}_{\texttt{ratio}}$ in the continuous setting with cost $O\big(\frac{q \log n}{\varepsilon^2} \log \frac{1}{\gamma}\big)$.

Algorithm 1 Solving $P^{\delta,\varepsilon}_{\texttt{count}}$ for error parameter γ.

call $\mathcal{D} \leftarrow \texttt{PratioAll}(\varepsilon/10, \gamma/4)$.
initialize $x_0 \leftarrow n, \alpha_0 \leftarrow \beta_{\max}$
for $t = 1$ **to** $T = 10\min\{q, \sqrt{q \log n}\}$ **do**
  set $\alpha_t \leftarrow \texttt{Balance}(\beta_{\min}, \alpha_{t-1}, x_{t-1}, \frac{\gamma}{100T}, 1/4)$
  set $\hat{\mu}_{\alpha_t} \leftarrow \texttt{Sample}(\alpha_t; \frac{10^8 \log \frac{50T}{\delta\gamma}}{\delta\varepsilon^2})$
  if $\alpha_t > \beta_{\min}$ **then**
    set x_t to be the minimum value with $\hat{\mu}_{\alpha_t}[0, x_t] \ge 1/100$
    foreach $y \in (x_t, x_{t-1}]$ **do** $\texttt{EstimatePi}(y, \alpha_t, \delta/200)$ with $\hat{Q}(\alpha_t) = \hat{Q}(\alpha_t \mid \mathcal{D})$
  else if $\alpha_t = \beta_{\min}$ **then**
    foreach $y \in [0, x_{t-1}]$ **do** $\texttt{EstimatePi}(y, \alpha_t, \delta/200)$ with $\hat{Q}(\alpha_t) = \hat{Q}(\alpha_t \mid \mathcal{D})$
    return

▶ **Theorem 13.** *Algorithm 1 solves* $P^{\delta,\varepsilon}_{\texttt{count}}$ *with cost*

$$O\Big(\frac{\min\{q, \sqrt{q \log n}\} \log \frac{q}{\delta\gamma}}{\delta\varepsilon^2} + \frac{q \log n \log \frac{1}{\gamma}}{\varepsilon^2}\Big).$$

The complexity bound follows immediately from specification of suborutines. We next analyze the success probability; this will require a number of intermediate calculations.

▶ **Proposition 14.** *With probability at least* $1 - \gamma/10$*, the following conditions hold for all iterations* t*:*

(i) $\alpha_t \in \Lambda_{1/4}(\beta_{\min}, \alpha_{t-1}, x_{t-1})$ *and* $x_t < x_{t-1}$ *and and* $\mu_{\alpha_t}[0, x_t) \le \frac{1}{70}$

(ii) $\alpha_t = \beta_{\min}$ *or* $\mu_{\alpha_t}[0, x_t] \ge \frac{1}{200}$.

Proof. See full paper. ◀

For the remainder of the analysis, we suppose that the bounds of Proposition 14 hold.

▶ **Proposition 15.** *For all iterations* t*, we have* $\alpha_{t+1} < \alpha_t$ *strictly and* $\mu_{\alpha_{t+1}}[x_t, n] \ge 1/4$*. Furthermore, if* $\alpha_{t+1} \ne \beta_{\min}$*, then* $z(\alpha_{t+1}, \alpha_t) \ge 2 + \frac{x_{t+1}}{x_{t-1} - x_{t+1}}$.

Proof. See full paper. ◀

▶ **Lemma 16.** *The loop at line 3 terminates before iteration* T*.*

Proof. Suppose not; by Proposition 14, we have $x_1 > x_2 > \cdots > x_{T-1} > \beta_{\min}$ strictly. Since each x_i comes from $\mathcal{F}$, we must have $x_1 \le n$ and $x_{T-2} \ge 1$. Let $g = T - 4$; note that due to bounds on n, q. we have $g \ge T/2 > 0$. For each $\ell = 1, \dots, g$, consider the non-negative value $a_\ell = \log(\frac{x_{\ell-1}}{x_{\ell+1}})$. We note the following bound:

$$\begin{aligned}\sum_{\ell=1}^{g} a_\ell &= \log\frac{x_1}{x_3} + \log\frac{x_2}{x_4} + \log\frac{x_3}{x_5} + \cdots + \log\frac{x_{g-2}}{x_g} + \log\frac{x_{g-1}}{x_{g+1}} \\ &= \log x_1 + \log x_2 - \log x_g - \log x_{g+1} \qquad \text{by telescoping sums} \\ &\le \log n + \log n - 0 - 0 = 2\log n\end{aligned}$$

By using Proposition 15 for each iteration $1, \dots, g$, we can compute:

$$q \ge z(\beta_{\max}, \beta_{\min}) \ge \sum_{i=1}^{g} z(\alpha_{i+1}, \alpha_i) \ge \sum_{i=1}^{g} 2 + \frac{x_{i+1}}{x_{i-1} - x_{i+1}} = 2g + \sum_{\ell=1}^{g} \frac{1}{e^{a_\ell} - 1}. \tag{4}$$

By Jensen's inequality applied to the concave function $y \mapsto \frac{1}{e^y - 1}$, we have

$$\sum_{\ell=1}^{g} \frac{1}{e^{a_\ell} - 1} \ge \frac{g}{\exp(\frac{1}{g}\sum_{\ell=1}^{g} a_\ell) - 1} \ge \frac{g}{\exp(\frac{2\log n}{g}) - 1}. \tag{5}$$

If $q > 2\log n$, then Eq. (4) shows $g \le q/2$. If $q \ge 2\log n$, then $\exp(\frac{2\log n}{g}) - 1 \le \frac{4e\log n}{g}$, and then Eq. (5) implies $q \ge \frac{g}{(4e\log n)/g} \ge g^2/20$, i.e. $g \le \sqrt{20q\log n}$. Either way, we have $g \ge \min\{\sqrt{20q\log n}, q/2\}$. Since $g \ge T/2$, this is a contradiction to the definition of T. ◀

▶ **Proposition 17.** *With probability at least* $1 - \gamma/10$*, the preconditions of Lemma 11 for* `EstimatePi` *(with* $p_\circ = \delta/200$*) hold for all* $y \in \mathcal{F}$*.*

Proof. See full paper. ◀

Overall, the total failure probability is at most $\gamma/10$ (from Proposition 14) plus $\gamma/10$ (from Proposition 17). This concludes the proof of Theorem 13. It also shows the first part of Theorem 4.

4 Solving $P_{\texttt{count}}$ and $P^{\texttt{all}}_{\texttt{ratio}}$ for integer-valued Gibbs distributions

The algorithms in the integer setting hinge on a data structure called the *covering schedule*. Formally, we define a covering schedule to be a sequence of the form

$$(\beta_0, w_0, k_1, \beta_1, w_1, k_2, \dots, \beta_{t-1}, w_{t-1}, k_t, \beta_t, w_t)$$

which satisfies the following additional constraints:

(i) $\beta_{\min} = \beta_0 < \dots < \beta_t = \beta_{\max}$;
(ii) $k_1 < k_2 < \dots < k_t$
(iii) $w_i \in [0,1]$ for $i = 0, \dots, t$.

Note that $t \le n+1$. We say that $\mathcal{I}$ is *proper* if for all $i = 1, \dots, t$ it satisfies

$$\mu_{\beta_{i-1}}(k_i) \ge w_{i-1} \text{ and } \mu_{\beta_i}(k_i) \ge w_i.$$

We define

$$\texttt{InvWeight}(\mathcal{I}) = \sum_{i=0}^{t} \frac{1}{w_i}.$$

Our algorithm to solve $P_{\texttt{count}}$ will have four stages. As a high-level summary, it proceeds as follows:

1. Construct a suitable covering schedule $\mathcal{I} = (\beta_0, w_0, k_1, \dots, k_t, \beta_t, w_t)$.
2. Estimate the values $Q(\beta_i)$ for $i = 0, \dots, t$.
3. Use these estimates $\hat{Q}(\beta_i)$ to estimate the counts c_i
4. Use the estimated counts $\hat{c}_i$ to estimate the entire function $Q(\beta)$

The first stage is quite involved, so we defer it to Section 5 where we show the following result:

▶ **Theorem 18.** *There is a procedure* $\texttt{FindCoveringSchedule}(\gamma)$ *which produces a covering schedule* $\mathcal{I}$*, which is proper with probability at least* $1-\gamma$*. In the general integer setting, the procedure has cost* $O(n \log^3 n + n \log n \log \frac{1}{\gamma} + n \log q)$ *and has* $\texttt{InvWeight}(\mathcal{I}) \le O(n \log n)$*. In the log-concave setting, the procedure has cost* $O(n \log^2 n + n \log \frac{1}{\gamma} + n \log q)$ *and has* $\texttt{InvWeight}(\mathcal{I}) \le O(n)$*.*

The second stage is summarized in the following result:

▶ **Theorem 19.** *There is an algorithm* $\texttt{PratioCoveringSchedule}(\mathcal{I}, \varepsilon, \gamma)$ *which takes as input a covering schedule* $\mathcal{I} = (\beta_0, w_0, k_1, \dots, k_t, \beta_t, w_t)$ *and produces estimates* $\hat{Q}(\beta_0), \dots, \hat{Q}(\beta_t)$*. The overall algorithm cost is* $O\Big(\frac{\min\{nW, q \log n\} \log \frac{1}{\gamma}}{\varepsilon^2}\Big)$ *where* $W = \texttt{InvWeight}(\mathcal{I})$*. If* $\mathcal{I}$ *is proper, then with probability at least* $1-\gamma$ *it satisfies* $|\log \hat{Q}(\beta_i) - Q(\beta_i)| \le \varepsilon$ *for all* i*. (When this latter condition holds, we say that the call to* $\texttt{PratioCoveringSchedule}$ *is* good*).*

Proof. To get the cost $O\big(\frac{q \log n}{\varepsilon^2} \log \frac{1}{\gamma}\big)$, we simply run the algorithm $\mathcal{D} \leftarrow \texttt{PratioAll}(\varepsilon, \gamma)$ for the continuous setting as in Theorem 6, and output $\hat{Q}(\beta_i \mid \mathcal{D})$ for all i. To get the other cost bound (in terms of W), we use the following algorithm:

Algorithm 2 Estimating values $Q(\beta_i)$ via `EstimateProducts`.

1 **for** $\boldsymbol{i = 1, \ldots t}$ form random variables $X_i \sim \text{Bernoulli}(\mu_{\beta_{i-1}}(k_i))$ and $Y_i \sim \text{Bernoulli}(\mu_{\beta_i}(k_i))$
2 set $\hat{X}^{\texttt{prod}} \leftarrow \texttt{EstimateProducts}(X, W, \varepsilon/2, \gamma/4)$
3 set $\hat{Y}^{\texttt{prod}} \leftarrow \texttt{EstimateProducts}(Y, W, \varepsilon/2, \gamma/4)$
4 for $i = 0, \ldots, t$ set $\hat{Q}(\beta_i) = \exp\left(\sum_{j=1}^{i}(\beta_j - \beta_{j-1})k_j\right) \cdot \hat{X}_i^{\texttt{prod}} / \hat{Y}_i^{\texttt{prod}}$

Here, assuming that $\mathcal{I}$ is proper, we have $\mathbb{S}[X_i] = \frac{1}{\mu_{\beta_{i-1}}(k_i)-1} \leq \frac{1}{w_{i-1}}$ for each i, so $\sum_i \mathbb{S}[X_i] \leq W$. Likewise $\sum_i \mathbb{S}[Y_i] \leq W$. So with probability at least $1 - \gamma/2$ the estimates $\hat{X}_i^{\texttt{prod}}, \hat{Y}_i^{\texttt{prod}}$ are all within $e^{\pm\varepsilon/2}$ of $\prod_{j=1}^{i}\mathbb{E}[X_j], \prod_{j=1}^{i}\mathbb{E}[Y_j]$ respectively. Observe that

$$\frac{\mathbb{E}[\prod_{j=1}^{i} X_j]}{\mathbb{E}[\prod_{j=1}^{i} Y_j]} = \prod_{j=1}^{i-1} \frac{\mu_{\beta_{j-1}}(k_j)}{\mu_{\beta_j}(k_j)} = \prod_j e^{(\beta_{j-1}-\beta_j)k_j} \frac{Z(\beta_j)}{Z(\beta_{j-1})} = \frac{Z(\beta_i)}{Z(\beta_0)} \cdot \exp\Big(\sum_{j=1}^{i}(\beta_{j-1} - \beta_j)k_j\Big)$$

so in that case, the values $\hat{Q}(\beta_i)$ are also within $e^{\pm\varepsilon}$ of $Z(\beta_i)/Z(\beta_0) = Q(\beta_i)$ as required. ◀

4.1 Solving $P^{\delta,\varepsilon}_{\texttt{count}}$

We now move on to the third stage, of using the covering schedule to solve $P_{\texttt{count}}$. There are two quite distinct algorithms here: one for generic integer-valued distributions, and a specialized algorithm for log-concave distributions. We begin with the following algorithm for general integer distributions:

Algorithm 3 Solving problem $P^{\delta,\varepsilon}_{\texttt{count}}$.

1 set $\mathcal{I} = (\beta_0, w_0, k_1, \ldots, k_t, \beta_t, w_t) \leftarrow \texttt{FindCoveringSchedule}(\gamma/10)$
2 set $(\hat{Q}(\beta_0), \ldots, \hat{Q}(\beta_t)) \leftarrow \texttt{PratioCoveringSchedule}(\mathcal{I}, \varepsilon/100, \gamma/10)$
3 **for** $i = 0, \ldots, t$ **do** let $\hat{\mu}_{\beta_i} \leftarrow \texttt{Sample}(\beta_i; \varepsilon/100, \frac{\gamma}{10(n+1)^2}, w_i)$
4 **for** $j \in \mathcal{H}$ **do**
5 set $\alpha \leftarrow \texttt{Balance}(\beta_{\min}, \beta_{\max}, j, \frac{\gamma}{10(n+1)^2}, 1/4)$
6 find index $i < t$ with $\alpha \in [\beta_i, \beta_{i+1}]$
7 let $\hat{\mu}_\alpha \leftarrow \texttt{Sample}(\alpha; \varepsilon/100, \frac{\gamma}{10(n+1)^2}, \delta/4)$
8 **if** $\boldsymbol{\hat{\mu}_\alpha(k_{i+1}) \geq \delta}$ **then** $\texttt{EstimatePi}(j, \alpha, \delta/4)$ where $\hat{Q}(\alpha) = \frac{\hat{\mu}_{\beta_i}(k_{i+1})}{\hat{\mu}_\alpha(k_{i+1})} e^{(\alpha-\beta_i)k_{i+1}} \hat{Q}(\beta_i)$
9 **else if** $\boldsymbol{j \geq k_{i+1}}$ **then** $\texttt{EstimatePi}(j, \beta_{i+1}, w_{i+1}/8)$ where $\hat{Q}(\beta_{i+1})$ is set at line 2.
10 **else if** $\boldsymbol{j < k_{i+1}}$ **then** $\texttt{EstimatePi}(j, \beta_i, w_i/8)$ where $\hat{Q}(\beta_i)$ is set at line 2.

▶ **Theorem 20.** *Algorithm 3 solves $P^{\delta,\varepsilon}_{\texttt{count}}$ with cost $O\Big(\frac{(n/\delta)\log\frac{n}{\gamma} + n^2 \log n \log\frac{1}{\gamma}}{\varepsilon^2} + n \log q\Big)$.*

Proof. See full paper. ◀

This gives the second part of Theorem 4. As we have mentioned, there is an alternative algorithm to estimate counts in the log-concave setting:

Algorithm 4 Solving $P^{\delta,\varepsilon}_{\texttt{count}}$ in the log-concave setting.

set $\mathcal{I} = (\beta_0, w_0, k_1, \dots, k_t, \beta_t, w_t) \leftarrow \texttt{FindCoveringSchedule}(\gamma/10)$
set $(\hat{Q}(\beta_0), \dots, \hat{Q}(\beta_t)) \leftarrow \texttt{PratioCoveringSchedule}(\mathcal{I}, 0.1\varepsilon, \gamma/6)$
update $\delta \leftarrow \min\{\delta, 1/n, 1/\texttt{InvWeight}(\mathcal{I})\}$.
for $i = 1, \dots t-1$ **do**
  let $\hat{\mu}_{\beta_i} \leftarrow \texttt{Sample}(\beta_i; 0.01\varepsilon, \frac{\gamma}{6(n+1)}, w_i)$
  foreach $j \in \{k_i + 1, k_i + 2, \dots, k_{i+1}\}$ **do** $\texttt{EstimatePi}(j, \beta_i, \delta/4)$
let $\hat{\mu}_{\beta_{\min}} \leftarrow \texttt{Sample}(\beta_{\min}; 0.01\varepsilon, \frac{\gamma}{6(n+1)}, w'_0)$ for $w'_0 = \min\{w_0, \delta/2\}$
foreach $j \in \{0, 1, \dots, k_1\}$ **do** $\texttt{EstimatePi}(j, \beta_{\min}, w'_0)$.
let $\hat{\mu}_{\beta_{\max}} \leftarrow \texttt{Sample}(\beta_{\max}; 0.01\varepsilon, \frac{\gamma}{6(n+1)}, w'_t)$ for $w'_t = \min\{w_t, \delta/2\}$)
foreach $j \in \{k_t + 1, k_t + 2, \dots, n\}$ **do** $\texttt{EstimatePi}(j, \beta_{\max}, w'_t)$.

▶ **Theorem 21.** *In the log-concave setting, Algorithm 4 solves $P^{\delta,\varepsilon}_{\texttt{count}}$ with cost*

$$O\Big(n \log^2 n + n \log q + \frac{\min\{n^2, q \log n\} \log \frac{1}{\gamma} + (n + 1/\delta) \log \frac{n}{\gamma}}{\varepsilon^2}\Big)$$

Proof. See full paper. ◀

Again, with some simplification of parameters, this gives the third part of Theorem 4.

4.2 Solving $P^{\texttt{all}}_{\texttt{ratio}}$

Finally, having estimated the counts, we can proceed to use these estimates to fill in the entire function $Q(\beta)$. This is a black-box reduction from $P_{\texttt{count}}$ to $P^{\texttt{all}}_{\texttt{ratio}}$.

▶ **Theorem 22.** *Given a solution $(\hat{\pi}, u)$ for $P^{1/n, 0.1\varepsilon}_{\texttt{count}}$ in the integer setting, we can solve $P^{\texttt{all}}_{\texttt{ratio}}$ with probability one and no additional queries to the oracle.*

Proof. The data structure $\mathcal{D}$ is the vector $\hat{\pi}$, and for a query value α we set $\hat{Q}(\alpha \mid \mathcal{D}) = \sum_{i \in \mathcal{H}} \hat{\pi}(i) e^{(\alpha - \beta_{\min})i}$. See full paper for proof details. ◀

Our $P^{\delta,\varepsilon}_{\texttt{count}}$ algorithms thus solve $P^{\texttt{all}}_{\texttt{ratio}}$ with cost $O\big(\frac{n^2 \log n \log \frac{1}{\gamma}}{\varepsilon^2} + n \log q\big)$ in the general integer setting, and $O\big(\frac{n^2 \log \frac{1}{\gamma}}{\varepsilon^2} + n \log q\big)$ in the log-concave setting. This shows the two bounds of Theorem 6.

5 Constructing a covering schedule

In the full paper, we show that any non-negative log-concave sequence $a_1, \dots, a_m$ satisfying $a_k \le \frac{1}{k}$ for each $k \in [m]$ satisfies $a_1 + \dots + a_m \le e$. Without the log-concavity assumption we would have $a_1 + \dots + a_m \le \sum_{k=1}^m \frac{1}{k} \le 1 + \log m$ (by a well-known inequality for the harmonic series). Motivated by these facts, we define the following parameter in this section:

$$\rho \stackrel{\text{def}}{=} \begin{cases} 1 + \log(n+1) & \text{in the general integer setting} \\ e & \text{in the log-concave setting} \end{cases}$$

We will show the following more precise bound on the weight of the schedule.

▶ **Theorem 23.** *In the integer setting, the procedure* `FindCoveringSchedule`(γ) *produces a covering schedule* $\mathcal{I}$ *with* `InvWeight`$(\mathcal{I}) \le a(n+1)\rho$ *and* $\mathbb{P}[\mathcal{I}$ *is proper*$] \ge 1-\gamma$*, where* $a > 4$ *is an arbitrary constant. It has cost* $O(n\rho(\log^2 n + \log\frac{1}{\gamma}) + n\log q)$.

This immediately implies Theorem 18. In order to build the covering schedule, we first build an object with relaxed constraints called a *preschedule*, discussed in Sections 5.1. In Section 5.2, we convert this into a schedule.

5.1 Constructing a preschedule

Let us fix constants $\tau \in (0, \frac{1}{2})$, $\lambda \in (0,1)$, and set $\phi = \tau\lambda^3/\rho$. Let us introduce basic terminology and definitions.

An $\mathcal{H}$-interval is a discrete set of points $\{\sigma^-, \sigma^-+1, \dots, \sigma^+-1, \sigma^+\}$, for integers $0 \le \sigma^- \le \sigma^+ \le n$. We also write this more compactly as $\sigma = [\sigma^-, \sigma^+]$. We define $\mathtt{span}(\sigma) = \sigma^+ - \sigma^- + 1$, i.e. the cardinality of σ when viewed as a subset of $\mathcal{H}$.

A *segment* is a tuple $\theta = (\beta, \sigma)$ where $\beta \in [\beta_{\min}, \beta_{\max}]$, and σ is an $\mathcal{H}$-segment. We say θ is ϕ-*proper* (or just proper if ϕ is understood) if it satisfies the following two properties:

- Either $\beta = \beta_{\min}$ or $\mu_\beta(\sigma^-) \ge \phi/\mathtt{span}(\sigma)$
- Either $\beta = \beta_{\max}$ or $\mu_\beta(\sigma^+) \ge \phi/\mathtt{span}(\sigma)$

A *preschedule* is a sequence of distinct segments $\mathcal{J} = ((\beta_0, \sigma_0), \dots, (\beta_t, \sigma_t))$ satisfying the following properties:

(`I0`) $\sigma^-_{i+1} \le \sigma^+_i$ for $i = 0, \dots, t-1$.
(`I1`) $\beta_{\min} = \beta_0 \le \dots \le \beta_t = \beta_{\max}$.
(`I2`) $0 = \sigma^-_0 \le \dots \le \sigma^-_t \le n$ and $0 \le \sigma^+_0 \le \dots \le \sigma^+_t = n$

We say that $\mathcal{I}$ is ϕ-*proper* if all segments θ_i are ϕ-proper.

The main idea of the algorithm is to maintain a sequence of proper segments satisfying properties (`I1`) and (`I2`), and grow it until it satisfies (`I0`). This uses an additional subroutine $\sigma \leftarrow \mathtt{FindInterval}(\beta, \sigma_{\mathtt{left}}, \sigma_{\mathtt{right}})$, where $\beta \in [\beta_{\min}, \beta_{\max}]$, and $\sigma_{\mathtt{left}}, \sigma_{\mathtt{right}}$ are two discrete intervals in $\mathcal{H}$ and the returned interval $\sigma = [\sigma^-, \sigma^+]$ has $\sigma^- \in \sigma_{\mathtt{left}}, \sigma^+ \in \sigma_{\mathtt{right}}$. Deferring for the moment the definition of `FindInterval`, the details are provided below.

Algorithm 5 Computing an initial preschedule.

call $\sigma_{\min} \leftarrow \mathtt{FindInterval}(\beta_{\min}, \{0\}, \mathcal{H})$ and $\sigma_{\max} \leftarrow \mathtt{FindInterval}(\beta_{\max}, \mathcal{H}, \{n\})$
initialize $\mathcal{J}$ to contain the two segments $(\beta_{\min}, \sigma_{\min}), (\beta_{\max}, \sigma_{\max})$
while $\mathcal{J}$ *does not satisfy* (`I0`) **do**
  pick arbitrary consecutive segments $\theta_{\mathtt{left}} = (\beta_{\mathtt{left}}, \sigma_{\mathtt{left}})$ and $\theta_{\mathtt{right}} = (\beta_{\mathtt{right}}, \sigma_{\mathtt{right}})$ in $\mathcal{J}$ with $\sigma^+_{\mathtt{left}} < \sigma^-_{\mathtt{right}}$.
  let $M = \left\lfloor \frac{\sigma^+_{\mathtt{left}} + \sigma^-_{\mathtt{right}}}{2} \right\rfloor + \frac{1}{2}$
  call $\beta \leftarrow \mathtt{Balance}(\beta_{\mathtt{left}}, \beta_{\mathtt{right}}, M, \frac{1}{4n}, \tau)$
  call

$$\sigma \leftarrow \begin{cases} \mathtt{FindInterval}(\beta, [\sigma^-_{\mathtt{left}}, M-\frac{1}{2}], [M+\frac{1}{2}, \sigma^+_{\mathtt{right}}]) & \text{if } \beta_{\mathtt{left}} < \beta < \beta_{\mathtt{right}} \\ \mathtt{FindInterval}(\beta, \{\sigma^-_{\mathtt{left}}\}, [M+\frac{1}{2}, \sigma^+_{\mathtt{right}}]) & \text{if } \beta = \beta_{\mathtt{left}} \\ \mathtt{FindInterval}(\beta, [\sigma^-_{\mathtt{left}}, M-\frac{1}{2}], \{\sigma^+_{\mathtt{right}}\}) & \text{if } \beta = \beta_{\mathtt{right}} \end{cases}$$

  insert (β, σ) into $\mathcal{J}$ between $\theta_{\mathtt{left}}$ and $\theta_{\mathtt{right}}$
return $\mathcal{J}$

Now let us say that a segment (β, σ, w) is *extremal* if it satisfies the following conditions:

$$\mu_\beta(k) \leq \frac{1}{\lambda} \cdot \frac{\texttt{span}(\sigma)}{\texttt{span}(\sigma) + (\sigma^- - k)} \cdot \mu_\beta(\sigma^-) \qquad \forall k \in \{0, \dots, \sigma^- - 1\} \tag{6a}$$

$$\mu_\beta(k) \leq \frac{1}{\lambda} \cdot \frac{\texttt{span}(\sigma)}{\texttt{span}(\sigma) + (k - \sigma^+)} \cdot \mu_\beta(\sigma^+) \qquad \forall k \in \{\sigma^+ + 1, \dots, n\} \tag{6b}$$

There are two additional invariants we hope to maintain in Algorithm 5:
(I3) Each segment θ of $\mathcal{J}$ is ϕ-proper.
(I4) Each segment θ of $\mathcal{J}$ is extremal.

We say the call $\sigma \leftarrow \texttt{FindInterval}(\beta, \sigma_{\texttt{left}}, \sigma_{\texttt{right}})$ is *good* if the segment $\theta = (\beta, \sigma)$ satisfies (I3) and (I4), and we say the call at line 7 is *valid* if $\beta \in \Lambda_\tau(\beta_{\texttt{left}}, \beta_{\texttt{right}}, M)$ and both $\theta_{\texttt{left}}$ and $\theta_{\texttt{right}}$ satisfy (I3), (I4). The calls at line 1 are always valid. The following result summarizes `FindInterval`.

▶ **Theorem 24.** $\texttt{FindInterval}(\beta, \sigma_{\texttt{left}}, \sigma_{\texttt{right}})$ *has cost* $O\big(\rho(\sigma^+_{\texttt{right}} - \sigma^-_{\texttt{left}} + 1) \log n\big)$. *If the call is valid, then the call is good with probability at least* $1 - \frac{1}{4(n+2)}$.

We defer the proof, which is quite technical, the full paper. Putting it aside for the moment, we have the following results:

▶ **Proposition 25.** *Algorithm 5 outputs a preschedule, and it is ϕ-proper with probability at least* $1/2$.

Proof. If all calls to `Balance` and `FindInterval` are good, then $\mathcal{J}$ maintains properties (I3) and (I4), and in particular it is ϕ-proper. The loop in lines 3 – 8 is executed at most n times, since each time it covers a new half-integer value M. So the algorithm calls `FindInterval` at most $n+2$ times and `Balance` at most n times. Since `Balance` or `FindInterval` fail with probability at most $\frac{1}{4n}$ and $\frac{1}{4(n+2)}$ respectively, properties (I3) and (I4) are maintained with probability at least $1/2$. ◀

▶ **Proposition 26.** *Algorithm 5 has cost* $O(n \log q + n\rho \log^2 n)$.

Proof. See full paper. ◀

5.2 Converting the preschedule into a covering schedule

There are two steps to convert the preschedule into a covering schedule. First, we throw away redundant intervals. Second, we "uncross" the adjacent intervals. While we are doing this, we also check if the resulting schedule is proper; if not, we will discard it and generate a new preschedule from scratch.

▶ **Proposition 27.** *Given a preschedule $\mathcal{J}$, there is a procedure* $\texttt{MinimizePreschedule}(\mathcal{J})$, *which has zero sample complexity, to generate a preschedule* $\mathcal{J}' = ((\beta_0, \sigma_0), \dots, (\beta_t, \sigma_t))$ *satisfying the following three properties:*
(J1) $\sigma_i^+ < \sigma_{i+2}^-$ *for* $i = 0, \dots, t-2$.
(J2) $\beta_0 < \beta_1 < \cdots < \beta_t$ *strictly.*
(J3) *For any $k \in \mathcal{H}$, there are at most two segments $\theta_i = (\beta_i, \sigma_i) \in \mathcal{J}'$ with $k \in \sigma_i$.*
Furthermore, if $\mathcal{J}$ is ϕ-proper, then so is $\mathcal{J}'$ with probability one.

Proof. Start with $\mathcal{J}$ and repeatedly apply two operations: (i) discard a segment $i \in \{1, \dots, t-1\}$ if $\sigma_{i+1}^- \leq \sigma_{i-1}^+$ or (ii) merge adjacent segments with $\beta_i = \beta_{i+1}$, namely, replace the two segments $(\beta_i, \sigma_i), (\beta_{i+1}, \sigma_{i+1})$ with a single segment $(\beta_i, [\sigma_i^-, \sigma_{i+1}^+])$. The operations are performed in any order until no further changes are possible; let $\mathcal{J}'$ be the result of this process. ◀

We next describe the procedure to uncross a preschedule. Here $\nu > 0$ is some arbitrary constant.

Algorithm 6 `UncrossSchedule`$(\mathcal{J}, \gamma)$ for preschedule $\mathcal{J} = ((\beta_0, \sigma_0), \dots, (\beta_t, \sigma_t))$.

for $i = 0, \dots, t$ **do** let $\hat{\mu}_{\beta_i} \leftarrow \texttt{Sample}(\beta_i; \frac{\nu}{2}, \frac{\gamma}{4(t+1)}, e^{-\nu/2} w_i)$ where $w_i = \phi / \texttt{span}(\sigma_i)$
for $i = 1, \dots, t$ **do**
  if $\exists\, k \in \{\sigma_{i-1}^+, \sigma_i^-\}$ *s.t.* $\hat{\mu}_{\beta_{i-1}}(k) \geq e^{-\nu/2} w_{i-1}$ *and* $\hat{\mu}_{\beta_i}(k) \geq e^{-\nu/2} w_i$ **then**
    set $k_i = k$ for arbitrary such k
  else return $\perp$
return *covering schedule* $\mathcal{I} = (\beta_0, e^{-\nu} w_0, k_1, \beta_1, e^{-\nu} w_1, k_2, \dots, k_t, \beta_t, e^{-\nu} w_t)$

▶ **Theorem 28.** *Suppose that preschedule $\mathcal{J}$ satisfies properties* `(J1)`, `(J2)`, `(J3)`. *Then:*
(a) *The output is either $\perp$ or a covering schedule $\mathcal{I}$ with* $\texttt{InvWeight}(\mathcal{I}) \leq \frac{2e^{\nu}(n+1)}{\phi}$.
(b) *It outputs an improper covering schedule with probability at most γ, irrespective of $\mathcal{J}$.*
(c) *If $\mathcal{J}$ is ϕ-proper, then it outputs a proper covering schedule with probability at least $1 - \gamma$.*
(d) *The cost is $O(n\rho \log \frac{n}{\gamma})$.*

Proof. See full paper. ◀

We can finish by combining all the preschedule processing algorithms, as follows:

Algorithm 7 Algorithm `FindCoveringSchedule`(γ).

while `true` **do**
  call Algorithm 5 with appropriate constants ν, λ, τ to compute preschedule $\mathcal{J}$
  call $\mathcal{J}' \leftarrow \texttt{MinimizePreschedule}(\mathcal{J})$
  call $\mathcal{I} \leftarrow \texttt{UncrossSchedule}(\mathcal{J}', \gamma/4)$
  if $\mathcal{I} \neq \perp$ **then return** $\mathcal{I}$

By Proposition 25 and Theorem 28, each iteration of Algorithm 7 terminates with probability at least $\frac{1}{2}(1 - \gamma/4) \geq 3/8$, so there are $O(1)$ expected iterations. Each call to `UncrossSchedule` has cost $O(n\rho \log \frac{n}{\gamma})$. By Proposition 26, each call to Algorithm 5 has cost $O(n \log q + n\rho \log n)$.

By Theorem 28(a), $\texttt{InvWeight}(\mathcal{I}) \leq 2\rho(n+1) \cdot \frac{e^{\nu}}{\tau\lambda^3}$. The term $\frac{e^{\nu}}{\tau\lambda^3}$ gets arbitrarily close to 2 for constants ν, λ, τ sufficiently close to $0, 1, \frac{1}{2}$ respectively.

Finally, by Proposition 28, each iteration of Algorithm 7 returns a non-proper covering schedule with probability at most $\gamma/4$ (irrespective of the choice of $\mathcal{J}$). Thus, the total probability of returning a non-proper covering schedule over all iterations is at most $\sum_{i=0}^{\infty} (3/8)^i \gamma/4 = 2\gamma/5 \leq \gamma$ as desired.

This shows Theorem 23.

6 Combinatorial applications

Consider a combinatorial setting with c_i objects of weights $i = 0, \dots, n$, and we can sample from a Gibbs distribution at rate β (for certain values of β). If we know at least one of the counts, then estimates for $\pi(x)$ directly translate into estimate of c_i. Our usual strategy here will be to solve $P^{\delta,\varepsilon}_{\texttt{count}}$ for $\delta = O(\min_x \Delta(x))$, for chosen boundary parameters $\beta_{\min}, \beta_{\max}$; in this case, it can easily be seen that the resulting estimated counts $\hat{c}_i = c_0 \hat{\pi}(i)/\hat{\pi}(0)$ are accurate within $e^{\pm\varepsilon}$ relative error.

In many of these combinatorial applications, the counts are known to be log-concave; in this case, there are natural choices for algorithm parameters which lead to particularly clean bounds. When counts are not log-concave, more involved properties of the Gibbs distribution (e.g. it approaches a normal distribution) must be used.

▶ **Theorem 29.** *Suppose the counts are log-concave and non-zero. If* $\beta_{\min} \le \log \frac{c_0}{c_1}$ *and* $\beta_{\max} \ge \log \frac{c_{n-1}}{c_n}$*, then* $\Delta(k) \ge \frac{1}{n+1}$ *for all* $k = 0, \dots, n$*, and* $\log Q(\beta_{\max}) \le q := 3n\Gamma$ *where* $\Gamma := \max\{\beta_{\max}, \log \frac{c_1}{c_0}, 1\}$*. In particular, for* $\delta = \frac{1}{n+1}$*, we can solve* $P^{\delta,\varepsilon}_{\texttt{count}}$ *with cost*

$$O\Big(\min\Big\{\frac{n\Gamma \log n \log \frac{1}{\gamma}}{\varepsilon^2}, \frac{n^2 \log \frac{1}{\gamma}}{\varepsilon^2} + n \log \Gamma\Big\}\Big)$$

Proof. See full paper. ◀

Theorem 3 follows directly from Theorem 29 combined with an MCMC sampler for matchings appearing [15]. (See full paper for details).

6.1 Counting connected subgraphs

Consider a connected graph $G = (V, E)$. In [11], Guo & Jerrum described an algorithm to sample a connected subgraph $G' = (V, E')$ with probability proportional to $\prod_{f \in E'}(1 - p(f)) \prod_{f \in E - E'} p(f)$, for any weighting function $p : E \to [0, 1]$. If we set $p(f) = \frac{1}{1+e^\beta}$ for all edges f, then their algorithm samples from the Gibbs distribution with c_i being the number of connected subgraphs of G with $|E| - i$ edges. Guo & He [10] subsequently improved the algorithm runtime; we summarize their result as follows:

▶ **Theorem 30** ([10], Corollary 10)**.** *There is an algorithm to sample from the Gibbs distribution with counts* c_i *for any value of* $\beta > 0$*; the expected runtime is* $O(|E| + |E||V|e^\beta)$*.*

Proof of Theorem 1. The sequence c_i counts the number of independent sets in the co-graphic matroid, where $n = |E| - |V| + 1$. By the result of [1], this sequence c_i is log-concave; also $c_0 = 1$ so it suffices to estimates counts up to any scaling. The ratios c_{n-1}/c_n and c_1/c_0 are both at most $|E|$, since to enumerate a connected graph with $|V|$ edges we may select a spanning tree and any other edge in the graph, and to enumerate a graph with $|E| - 1$ edges we simply select an edge of G to delete.

So we can apply Theorem 29, setting $\beta_{\max} = \log |E| \ge \log \frac{c_{n-1}}{c_n}, \beta_{\min} = -\log |E| \le \log \frac{c_0}{c_1}$ and $\Gamma = \log |E|$. The definition of an FPRAS traditionally sets $\gamma = O(1)$, and here $n = |E|$. So the algorithm uses $O(\frac{|E| \log^2 |E|}{\varepsilon^2})$ samples in expectation. With these parameters, each call to the sampling oracle of Theorem 30 has runtime $O(|E|^2|V|)$. The total runtime is then $O(\frac{|E|^3|V| \log^2 |E|}{\varepsilon^2})$. ◀

The work [11] sketches an FPRAS for this problem as well; the precise complexity is unspecified and appears to be much larger than Theorem 1. We also note that Anari et al. [2] provide a general FPRAS for counting the number of independent sets in arbitrary matroids, which would include the number of connected subgraphs. This uses a very different sampling method, which is not based on the Gibbs distribution. They do not provide concrete complexity estimates for their algorithm.

6.2 Counting independent sets in bounded-degree graphs

For a graph $G = (V, E)$ of maximum degree D, let I_k denote the collection of independent sets of size k for $k = 0, \dots, |V|$. A key problem in statistical physics is to sample efficiently from I_k. Here, there is critical hardness threshold defined by $\lambda_c = \frac{(D-1)^{D-1}}{(D-2)^D} \approx e/D$, such

that, for $\beta > \lambda_c$, it is intractable to sample from the Gibbs distribution at rate λ; on the other, for $\beta < \lambda_c$, there is a polynomial-time sampler for the Gibbs distribution. We quote the following result of [6].

▶ **Theorem 31** ([6]). *Let $D \geq 3$ and $\xi > 0$ be any fixed constants. There is an algorithm to approximately sample from the Gibbs distribution at $\beta \in [0, \lambda_c - \xi]$, up to total variation distance ρ, with runtime $O(n \log n \log(n/\rho))$.*

The related problem of estimating the values i_k was considered in [7]. Based on this sampling result, they identified a related computational threshold for estimating the counts $c_k = |I_k|$. Namely, they define the threshold value $\alpha_c = \frac{\lambda_c}{1+(D+1)\lambda_c}$ and then show that, for $k > \alpha_c|V|$, it is intractable to estimate c_k or to sample approximately uniformly from I_k; on the other hand, for constant $D \geq 3$ and $\xi > 0$ and $k < (\alpha_c - \xi)|V|$, then describe an algorithm to estimate c_k in polynomial time. A follow-up work [13] provided tighter estimates for the Gibbs distribution and improved algorithms; specifically, it showed how to estimate a given count c_i for $i < (\alpha - \xi)|V|$ with runtime $\tilde{O}(n^2/\varepsilon^2)$.

A key analytical technique of [13] was to show that the Gibbs distribution for independent sets closely approximated to a normal distribution, i.e. it obeyed a type of Central Limit Theorem. Using Theorem 3.1 of [13], we have the following crude estimate:

▶ **Lemma 32** ([13]). *Let $D \geq 3$ and $\xi > 0$ be any fixed constants. There is a constant $\xi' > 0$ such that, for any $k \leq (\alpha_c - \xi)|V|$, there is some value $\beta \in [0, \lambda_c - \xi']$ with $\mu_\beta(k) \geq \Omega(1/\sqrt{|V|})$.*

By using Lemma 32, we immediately get the following result:

▶ **Theorem 33.** *Let $D \geq 3$ and $\xi > 0$ be any fixed constants. There is an algorithm to estimate all counts $c_0, \dots c_{\lfloor(\alpha_c - \xi)|V|\rfloor}$ with runtime $\tilde{O}(\frac{n^2 \log(1/\gamma)}{\varepsilon^2})$.*

Proof. We set $\beta_{\min} = 0, \beta_{\max} = \lambda_c - \xi', n = |V|$. Note that the Gibbs distribution is *not* necessarily log-concave. Since $c_0 = 1$ and clearly $c_i \leq 2^n$ for all i, we have $Q(\beta_{\max})/Q(\beta_{\min}) \leq (2^n e^{\beta_{\max} n})/1$; in particular, since $\beta_{\max} = O(1)$ (for fixed D), we have $Q(\beta_{\max})/Q(\beta_{\min}) \leq e^{O(n)}$ and we can take $q = \Theta(n)$. By Lemma 32, we have $\Delta(k) \geq \Omega(1/\sqrt{n})$ for these parameters. Thus, it suffices to solve $P^{\delta, 0.1\varepsilon}_{\texttt{count}}$ for $\delta = \Omega(1/\sqrt{n})$.

For this purpose, we will actually use the continuous-setting algorithm – it is more efficient than the general integer-setting algorithm. By Theorem 13, this algorithm has cost

$$O\Big(\frac{\min\{q, \sqrt{q \log n}\} \log \frac{q}{\delta\gamma}}{\delta\varepsilon^2} + \frac{q \log n \log \frac{1}{\gamma}}{\varepsilon^2}\Big) = O\Big(\frac{n \log^{3/2} n + n \log n \log \frac{1}{\gamma}}{\varepsilon^2}\Big).$$

Accordingly, we need to run the approximate sampler of Theorem 31 with $\rho = \text{poly}(n, 1/\varepsilon, \log \frac{1}{\gamma})$ leading to a computational complexity of $O(n \log n \log(\frac{n \log 1/\gamma}{\varepsilon}))$. With some simplification of parameters, the overall runtime becomes

$$O\Big(\frac{n^2 \log^{5/2} n \log(n/\varepsilon) + n^2 \log^2 n \log \frac{1}{\gamma} \log(\frac{n \log 1/\gamma}{\varepsilon})}{\varepsilon^2}\Big) = \tilde{O}\Big(\frac{n^2 \log \frac{1}{\gamma}}{\varepsilon^2}\Big). \qquad \blacktriangleleft$$

We note that the algorithm in [13] has this same runtime, but only estimates a *single* count c_i; our algorithm simultaneously produces estimates for all values c_i up to the threshold value $i < (\alpha_c - \xi)|V|$ with the same runtime. It also does not depend on the precise distributional properties of the Gibbs distribution; it only requires the much cruder estimate in Lemma 32.

7 Lower bounds on sample complexity

Following [16], our strategy is to construct a target instance $c^{(0)}$ surrounded by an envelope of d alternate instances $c^{(1)}, \dots, c^{(d)}$, such that solving $P^{\texttt{point}}_{\texttt{ratio}}$ or $P_{\texttt{count}}$ on an unknown instance $c^{(r)}$ distinguishes between the cases $r = 0$ and $r > 0$. On the other hand, an "indistinguishability lemma" gives a lower bound on the sample complexity of any such procedure to distinguish the distributions.

Define $\mu^{(r)}_\beta$ to be the Gibbs distribution with parameter β for instance $c^{(r)}$, and $Z^{(r)}(\beta)$ to be its partition function, and $z^{(r)} = \log Z^{(r)}$, and $\Delta^{(r)}(x) = \max_{\beta \in [\beta_{\min}, \beta_{\max}]} \mu^{(r)}_\beta(x)$. We will require that the instances are *balanced*, namely, that they satisfy the property $\prod_{r=1}^d c^{(r)}_x = (c^{(0)}_x)^d$ for all $x \in \mathcal{F}$. We also define parameters

$$U(\beta) = \prod_{r=1}^{d} \frac{Z^{(r)}(\beta)}{Z^{(0)}(\beta)}, \qquad \Psi = \max_{\beta \in [\beta_{\min}, \beta_{\max}]} \log U(\beta).$$

▶ **Lemma 34** ([16]). *Let $\mathfrak{A}$ be an algorithm which generates queries $\beta_1, \dots, \beta_T \in [\beta_{\min}, \beta_{\max}]$ and receives values $x_1, \dots, x_T$, where each x_i is drawn from μ_{β_i}. At some point the procedure stops and outputs TRUE or FALSE. The queries β_i and the stopping time T may be adaptive and may be randomized.*

Suppose that $\mathfrak{A}$ outputs TRUE on input $c^{(0)}$ with probability at least $1 - \gamma$ and outputs FALSE on inputs $c^{(1)}, \dots, c^{(d)}$ with probability at least $1 - \gamma$, for some parameter $\gamma < 1/4$.

If the instances are balanced, then the cost of $\mathfrak{A}$ on instance $c^{(0)}$ is $\Omega(\frac{d \log(1/\gamma)}{\Psi})$.

To get more general lower bounds for count estimation, we consider a problem variant called $\check{P}^{\delta,\varepsilon}_{\texttt{count}}$, namely, to compute a vector $\hat{c} \in (\mathbb{R}_{>0} \cup \{?\})^{\mathcal{F}}$ satisfying the following two properties:

- **(i)** for all pairs x, y with $\hat{c}_x, \hat{c}_y \neq ?$, there holds $|\log \frac{\hat{c}_x}{\hat{c}_y} - \log \frac{c_x}{c_y}| \leq \varepsilon$
- **(ii)** for all x with $\Delta(x) \geq \delta$ there holds $\hat{c}_x \neq ?$.

Given a solution $(\hat{\pi}, u)$ to $P^{\delta, 0.1\varepsilon}_{\texttt{count}}$, we can solve $\check{P}^{\delta,\varepsilon}_{\texttt{count}}$ with zero sample complexity and probability one (see full paper for details). Problem $\check{P}^{\delta,\varepsilon}_{\texttt{count}}$ is easier than $P^{\delta,\varepsilon}_{\texttt{count}}$ (up to constant factors in parameters), in two ways: first, it does not require any specific normalization of the counts, only pairwise consistency. Second, it only provides approximation guarantees for c_x if $\Delta(x) \geq \delta$, while $P^{\delta,\varepsilon}_{\texttt{count}}$ provides meaningful bounds over a wide range of scales.

▶ **Corollary 35.**

- **(a)** *Suppose that $|z^{(0)}(\beta_{\min}, \beta_{\max}) - z^{(r)}(\beta_{\min}, \beta_{\max})| > 2\varepsilon$ for all $r = 1, \dots, d$. Then any algorithm for $P^{\texttt{point}}_{\texttt{ratio}}$ must have cost $\Omega(\frac{d \log(1/\gamma)}{\Psi})$ on instance $c^{(0)}$.*
- **(b)** *Suppose that for each $r = 1, \dots, d$ there are x, y with $\Delta^{(0)}(x), \Delta^{(0)}(y) \geq \delta$, and $|\log(c^{(0)}_x / c^{(0)}_y) - \log(c^{(r)}_x / c^{(r)}_y)| > 2\varepsilon$. (We refer to the values x, y as the* witnesses *for r.) Then any algorithm for $\check{P}^{\delta,\varepsilon}_{\texttt{count}}$ must have cost $\Omega(\frac{d \log(1/\gamma)}{\Psi})$ on instance $c^{(0)}$.*

Proof. We show how to convert these algorithms into procedures distinguishing $c^{(0)}$ from $c^{(1)}, \dots, c^{(d)}$:

- **(a)** Given a solution $\hat{Q}(\beta_{\max})$ to $P^{\texttt{point}}_{\texttt{ratio}}$, output TRUE if $|\log \hat{Q}(\beta_{\max}) - z^{(0)}(\beta_{\min}, \beta_{\max})| \leq \varepsilon$, else output FALSE.
- **(b)** Given a solution $\hat{c}$ to $\check{P}^{\delta,\varepsilon}_{\texttt{count}}$, output TRUE if $\hat{c} \neq ?$ for all x with $\Delta^{(0)}(x) \geq \delta$, and every pair x, y with $\Delta(x), \Delta(y) \geq \delta$ satisfy $|\log(\hat{c}_x / \hat{c}_y) - \log(c^{(0)}_x / c^{(0)}_y)| \leq \varepsilon$, else output FALSE. ◀

By applying Corollary 35 to carefully constructed instances, we will show the following:

▶ **Theorem 36.** *Let $n \geq n_0, q \geq q_0, \varepsilon < \varepsilon_0, \delta < \delta_0, \gamma < 1/4$ for certain absolute constants $n_0, q_0, \varepsilon_0, \delta_0$. There are problem instances μ which satisfy the given bounds n and q such that:*

(a) $\check{P}^{\delta,\varepsilon}_{\texttt{count}}$ *requires cost* $\Omega(\frac{\min\{q+\sqrt{q}/\delta, n^2+n/\delta\}\log\frac{1}{\gamma}}{\varepsilon^2})$*, and μ is integer-valued.*

(b) $\check{P}^{\delta,\varepsilon}_{\texttt{count}}$ *requires cost* $\Omega(\frac{(1/\delta+\min\{q,n^2\})\log\frac{1}{\gamma}}{\varepsilon^2})$*, and μ is log-concave.*

(c) $P^{\texttt{point}}_{\texttt{ratio}}$ *requires cost* $\Omega(\frac{\min\{q,n^2\}\log\frac{1}{\gamma}}{\varepsilon^2})$*, and μ is log-concave.*

(d) $\check{P}^{\delta,\varepsilon}_{\texttt{count}}$ *requires cost* $\Omega(\frac{(q+\sqrt{q}/\delta)\log\frac{1}{\gamma}}{\varepsilon^2})$.

(e) $P^{\texttt{point}}_{\texttt{ratio}}$ *requires cost* $\Omega(\frac{q\log\frac{1}{\gamma}}{\varepsilon^2})$.

The lower bounds on $\check{P}^{\delta,\varepsilon}_{\texttt{count}}$ immediately imply lower bounds on $P^{\delta,\varepsilon}_{\texttt{count}}$, in particular, they give Theorems 5 and 7. Result (e) was already shown in [16], but we include it here since it is a corollary of other results.

The proofs and constructions appear in the full paper.

On Finding Constrained Independent Sets in Cycles

Ishay Haviv
School of Computer Science, The Academic College of Tel Aviv-Yaffo, Israel

Abstract

A subset of $[n] = \{1, 2, \ldots, n\}$ is called stable if it forms an independent set in the cycle on the vertex set $[n]$. In 1978, Schrijver proved via a topological argument that for all integers n and k with $n \geq 2k$, the family of stable k-subsets of $[n]$ cannot be covered by $n - 2k + 1$ intersecting families. We study two total search problems whose totality relies on this result.

In the first problem, denoted by SCHRIJVER(n, k, m), we are given an access to a coloring of the stable k-subsets of $[n]$ with $m = m(n, k)$ colors, where $m \leq n - 2k + 1$, and the goal is to find a pair of disjoint subsets that are assigned the same color. While for $m = n - 2k + 1$ the problem is known to be PPA-complete, we prove that for $m < d \cdot \lfloor \frac{n}{2k+d-2} \rfloor$, with d being any fixed constant, the problem admits an efficient algorithm. For $m = \lfloor n/2 \rfloor - 2k + 1$, we prove that the problem is efficiently reducible to the KNESER problem. Motivated by the relation between the problems, we investigate the family of *unstable* k-subsets of $[n]$, which might be of independent interest.

In the second problem, called Unfair Independent Set in Cycle, we are given ℓ subsets $V_1, \ldots, V_\ell$ of $[n]$, where $\ell \leq n - 2k + 1$ and $|V_i| \geq 2$ for all $i \in [\ell]$, and the goal is to find a stable k-subset S of $[n]$ satisfying the constraints $|S \cap V_i| \leq |V_i|/2$ for $i \in [\ell]$. We prove that the problem is PPA-complete and that its restriction to instances with $n = 3k$ is at least as hard as the Cycle plus Triangles problem, for which no efficient algorithm is known. On the contrary, we prove that there exists a constant c for which the restriction of the problem to instances with $n \geq c \cdot k$ can be solved in polynomial time.

1 Introduction

For integers n and k with $n \geq 2k$, the Kneser graph $K(n, k)$ is the graph whose vertices are all the k-subsets of $[n] = \{1, 2 \ldots, n\}$, where two such sets are adjacent in the graph if they are disjoint. The graph $K(n, k)$ admits a proper vertex coloring with $n - 2k + 2$ colors. This indeed follows by assigning the color i, for each $i \in [n - 2k + 1]$, to all the vertices whose minimal element is i, and the color $n - 2k + 2$ to the remaining vertices, those contained in $[n] \setminus [n - 2k + 1]$. In 1978, Lovász [22] proved, settling a conjecture of Kneser [20], that fewer colors do not suffice, that is, the chromatic number of the graph satisfies $\chi(K(n, k)) = n - 2k + 2$. Soon later, Schrijver [28] strengthened Lovász's result by proving that the subgraph $S(n, k)$ of $K(n, k)$ induced by the stable k-subsets of $[n]$, i.e., the vertices of $K(n, k)$ that form independent sets in the cycle on the vertex set $[n]$, has the same chromatic number. It was further shown in [28] that the graph $S(n, k)$ is vertex-critical, in the sense that any removal of a vertex from the graph decreases its chromatic number.

It is interesting to mention that despite the combinatorial nature of Kneser's conjecture [20], Lovász's proof [22] relies on the Borsuk–Ulam theorem [6], a fundamental result in the area of algebraic topology. Several alternative proofs and extensions were provided in the literature over the years (see, e.g., [24, 25]). Although they are substantially different from each other, they all essentially rely on topological tools.

The computational search problem associated with Kneser graphs, denoted by KNESER, was proposed by Deng, Feng, and Kulkarni [7] and is defined as follows. Its input consists of integers n and k with $n \geq 2k$ and an access to a coloring of the vertices of $K(n,k)$ with $n-2k+1$ colors. The goal is to find a monochromatic edge in the graph, i.e., two disjoint k-subsets of $[n]$ that are assigned the same color by the given coloring. Since the number of colors used by the input coloring is strictly smaller than the chromatic number of $K(n,k)$ [22], it follows that this search problem is total, in the sense that every input is guaranteed to have a solution. Note that the input coloring may be given as an oracle access that provides the color of any queried vertex, and that an algorithm for the problem is considered efficient if its running time is polynomial in n. In other variants of the problem, the input coloring is given by some succinct representation, e.g., a Boolean circuit or an efficient Turing machine. The computational search problem SCHRIJVER is defined similarly, where the input represents a coloring of the vertices of $S(n,k)$ with $n-2k+1$ colors, and the goal is to find a monochromatic edge, whose existence is guaranteed by the aforementioned result of Schrijver [28].

The computational complexity of the SCHRIJVER problem was determined in [15], where it was shown to be complete in the complexity class PPA. This complexity class, introduced in 1994 by Papadimitriou [26], is known to capture the complexity of several additional total search problems whose totality is based on the Borsuk–Ulam theorem, e.g., Consensus Halving, Bisecting Sandwiches, and Splitting Necklaces [12]. Note that this line of PPA-completeness results is motivated not only from the computational complexity perspective, but also from a mathematical point of view, as one may find those results as an indication for the necessity of topological arguments in the existence proof of the solutions of these problems. As for the KNESER problem, it is an open question whether it is also PPA-hard, as was suggested by Deng et al. [7]. We remark that its complexity is related to that of the Agreeable Set problem from the area of resource allocation (see [23, 16]). The KNESER and SCHRIJVER problems were also investigated in the framework of parameterized algorithms [16, 17], where it was shown that they admit randomized fixed-parameter algorithms with respect to the parameter k, namely, algorithms whose running time is $n^{O(1)} \cdot k^{O(k)}$ on input colorings of $K(n,k)$ and $S(n,k)$.

Before turning to our results, let us mention another computational search problem, referred to as the CYCLE-PLUS-TRIANGLES problem. Its input consists of an integer k and a graph on $3k$ vertices, whose edge set is the disjoint union of a Hamilton cycle and k pairwise vertex-disjoint triangles. The goal is to find an independent set of size k in the graph. The existence of a solution for every input of the problem follows from a result of Fleischner and Stiebitz [13], which settled in the early nineties a conjecture of Du, Hsu, and Hwang [9] as well as its strengthening by Erdös [10]. Their proof in fact shows that every such graph is 3-choosable, and thus 3-colorable, so in particular, it contains an independent set of size k. Here, however, the existence of a solution for every input of the problem is known to follow from several different arguments. While the proof of [13] relies on the polynomial method in combinatorics (see also [3]), an elementary proof was given slightly later by Sachs [27], and another proof, based on the chromatic number of $S(n,k)$, was provided quite recently by Aharoni et al. [1]. Yet, none of these proofs is constructive, in the sense that they do not

suggest an efficient algorithm for the Cycle-Plus-Triangles problem. The question of whether the problem admits an efficient algorithm was asked by several authors and is still open (see, e.g., [14, 1, 4]). Interestingly, the approach of [1] implies that the problem is not harder than the restriction of the Schrijver problem to colorings of $S(n,k)$ with $n = 3k$.

1.1 Our Contribution

In this paper, we introduce two total search problems concerned with finding stable sets under certain constraints. The totality of the problems relies on the chromatic number of the graph $S(n,k)$ [28]. We study these problems from algorithmic and computational perspectives. In what follows, we describe the two problems and our results on each of them.

1.1.1 The Generalized Schrijver Problem

We start by considering a generalized version of the Schrijver problem, which allows the number of colors used by the input coloring to be any prescribed number. Let Schrijver(n,k,m) denote the problem which asks to find a monochromatic edge in $S(n,k)$ for an input coloring that uses $m = m(n,k)$ colors. Note that every input of the problem is guaranteed to have a solution whenever $m \leq n - 2k + 1$, and that for $m = n - 2k + 1$, the problem coincides with the standard Schrijver problem.

The Schrijver(n,k,m) problem obviously becomes easier as the number of colors m decreases. For example, it is not difficult to see that for $m = \lfloor n/k \rfloor - 1$, the problem can be solved efficiently, in time polynomial in n. Indeed, the clique number of the graph $S(n,k)$ is $\lfloor n/k \rfloor$, which is strictly larger than m, so by querying the input coloring for the colors of the vertices of a clique of maximum size, one can find two adjacent vertices with the same color. Our first result extends this observation and essentially shows that the Schrijver(n,k,m) problem can be solved efficiently for any number of colors m satisfying $m = O(n/k)$.

▶ **Theorem 1.** *For every integer $d \geq 2$, there exists an algorithm for the* Schrijver(n,k,m) *problem with $m < d \cdot \lfloor \frac{n}{2k+d-2} \rfloor$ whose running time is $n^{O(d)}$.*

Our next result relates the generalized Schrijver(n,k,m) problem to the Kneser problem.

▶ **Theorem 2.** *Schrijver$(n,k,\lfloor n/2 \rfloor - 2k + 1)$ is polynomial-time reducible to Kneser.*

The simple proof of Theorem 2 involves a proper coloring of the subgraph of $K(n,k)$ induced by the *unstable* k-subsets of $[n]$, i.e., the vertices of $K(n,k)$ that do not form vertices of $S(n,k)$. This graph, which we denote by $U(n,k)$, can be properly colored using $\lceil n/2 \rceil$ colors. Indeed, every unstable k-subset of $[n]$ includes an odd element, hence by assigning to each vertex of $U(n,k)$ some odd element that belongs to its set, we obtain a proper coloring of the graph with the desired number of colors. Since $U(n,k)$ is a subgraph of $K(n,k)$, it follows that for all admissible values of n and k, we have $\chi(U(n,k)) \leq \min(n-2k+2, \lceil n/2 \rceil)$.

Motivated by the reduction given by Theorem 2, we further explore the graph $U(n,k)$, whose study may be of independent interest. We prove that the above upper bound on the chromatic number is essentially tight (up to an additive 1 in certain cases; see Corollary 19 and the discussion that follows it). The proof is topological and applies the Borsuk–Ulam theorem. We further determine the independence number of the graph $U(n,k)$ (see Theorem 20), using a structural result of Hilton and Milner [18] on the largest non-trivial intersecting families of k-subsets of $[n]$.

The motivation for Theorem 2 comes from the fact that the SCHRIJVER problem is known to be PPA-hard, whereas no hardness result is known for the KNESER problem. It would be interesting to figure out whether or not the SCHRIJVER(n, k, m) problem with $m = \lfloor n/2 \rfloor - 2k + 1$ admits an efficient algorithm. While this challenge is left open, the following result shows that the problem is not harder than the restriction of the standard SCHRIJVER problem to colorings of $S(n, k)$ with $n = 4k$.

▶ **Theorem 3.** *If there exists a polynomial-time algorithm for the restriction of the SCHRIJVER problem to colorings of $S(n, k)$ with $n = 4k$, then there exists a polynomial-time algorithm for the SCHRIJVER(n, k, m) problem where $m = \lfloor n/2 \rfloor - 2k + 1$.*

We finally observe that the restriction of SCHRIJVER(n, k, m) with $m = \lfloor n/2 \rfloor - 2k + 1$ to instances satisfying $n = \Omega(k^4)$ admits an efficient randomized algorithm. This essentially follows from the fixed-parameter algorithm presented in [17] (see Section 3 for details).

1.1.2 The Unfair Independent Set in Cycle Problem

The second problem studied in this paper is the Unfair Independent Set in Cycle problem, denoted by UNFAIR-IS-CYCLE and defined as follows. Its input consists of two integers n and k with $n \geq 2k$ and ℓ subsets $V_1, \ldots, V_\ell$ of $[n]$, where $\ell \leq n - 2k + 1$ and $|V_i| \geq 2$ for all $i \in [\ell]$. The goal is to find a stable k-subset S of $[n]$ that satisfies the constraints $|S \cap V_i| \leq |V_i|/2$ for $i \in [\ell]$. The name of the problem essentially borrows the terminology of [1], where a set is said to fairly represent a set V_i if it includes at least roughly half of its elements, hence the desired stable set in the UNFAIR-IS-CYCLE problem is required to *unfairly* represent each of the given sets V_i. It is not difficult to show, using the chromatic number of $S(n, k)$, that every input of the UNFAIR-IS-CYCLE problem has a solution (see Lemma 13). Note that the requirement that the input sets satisfy $|V_i| \geq 2$ for all $i \in [\ell]$ is discussed in Section 2.4.

It is natural to compare the definition of the UNFAIR-IS-CYCLE problem to that of the Fair Independent Set in Cycle problem, denoted by FAIR-IS-CYCLE and studied in [15] (see Definition 11). While the goal in the former is to find a stable subset of $[n]$ with a prescribed size k that includes *no more* than half of the elements of each V_i, the goal in the latter is, roughly speaking, to find a stable subset of $[n]$, of an arbitrary size, that includes *at least* half of the elements of each V_i. The specification of the size k in the inputs of UNFAIR-IS-CYCLE makes the problem non-trivial and allows us to study it for various settings of the quantities n and k.

The following result shows that the complexity of the UNFAIR-IS-CYCLE problem is perfectly captured by the class PPA. This is established using the SCHRIJVER and FAIR-IS-CYCLE problems which are PPA-complete [15].

▶ **Theorem 4.** *The UNFAIR-IS-CYCLE problem is* PPA*-complete.*

We next consider some restrictions of the UNFAIR-IS-CYCLE problem to instances in which the integer n is somewhat larger than $2k$. On the one hand, the restriction of the problem to instances with $n = 3k$ is at least as hard as the CYCLE-PLUS-TRIANGLES problem, for which no efficient algorithm is known (see Proposition 15). On the other hand, we prove that on instances whose ratio between n and k is above some absolute constant, the problem can be solved in polynomial time.

▶ **Theorem 5.** *There exists a constant $c > 0$, such that there exists a polynomial-time algorithm for the restriction of the UNFAIR-IS-CYCLE problem to instances with $n \geq c \cdot k$.*

The proof of Theorem 5 is based on a probabilistic argument with alterations, which is derandomized into a deterministic algorithm using the method of conditional expectations (see, e.g., [5, Chapters 3 and 16.1]). The approach is inspired by a probabilistic argument of Kiselev and Kupavskii [19], who proved that for $n \geq (2 + o(1)) \cdot k^2$, every proper coloring of the Kneser graph $K(n, k)$ with $n - 2k + 2$ colors has a trivial color class (all of whose members share a common element).

1.2 Outline

The rest of the paper is organized as follows. In Section 2, we collect some definitions and results that will be used throughout the paper. In Section 3, we study the generalized Schrijver problem and prove Theorems 1, 2, and 3. In Section 4, we study the Unfair-IS-Cycle problem and prove Theorems 4 and 5. Finally, in Section 5, we consider the family of unstable k-subsets of $[n]$ and study the chromatic and independence numbers of the graph $U(n, k)$. Some proofs are omitted and can be found in the full version of this paper.

2 Preliminaries

2.1 Kneser and Schrijver Graphs

For integers n and k, let $\binom{[n]}{k}$ denote the family of all k-subsets of $[n]$. A subset of $[n]$ is called *stable* if it does not include two consecutive elements nor both 1 and n, equivalently, it forms an independent set in the cycle on the vertex set $[n]$ with the natural order along the cycle. Otherwise, the set is called *unstable*. The family of stable k-subsets of $[n]$ is denoted by $\binom{[n]}{k}_{\text{stab}}$. The Kneser graph and the Schrijver graph are defined as follows.

▶ **Definition 6.** *For integers n and k with $n \geq 2k$, the* Kneser graph $K(n, k)$ *is the graph on the vertex set $\binom{[n]}{k}$, where two sets $A, B \in \binom{[n]}{k}$ are adjacent if they satisfy $A \cap B = \emptyset$. The* Schrijver graph $S(n, k)$ *is the subgraph of $K(n, k)$ induced by the vertices of $\binom{[n]}{k}_{\text{stab}}$.*

Obviously, the number of vertices in $K(n, k)$ is $\binom{n}{k}$. The number of vertices in $S(n, k)$ is given by the following lemma (see, e.g., [16, Fact 4.1]).

▶ **Lemma 7.** *For all integers n and k with $n \geq 2k$, the number of stable k-subsets of $[n]$ is $\frac{n}{k} \cdot \binom{n-k-1}{k-1}$.*

As usual, we denote the independence number of a graph G by $\alpha(G)$, and its chromatic number by $\chi(G)$. The chromatic numbers of $K(n, k)$ and $S(n, k)$ were determined, respectively, by Lovász [22] and by Schrijver [28], as stated below.

▶ **Theorem 8** ([22, 28])**.** *For all integers n and k with $n \geq 2k$,*

$$\chi(K(n, k)) = \chi(S(n, k)) = n - 2k + 2.$$

2.2 Intersecting Families

A family $\mathcal{F}$ of sets is called *intersecting* if for every two sets $A, B \in \mathcal{F}$ it holds that $A \cap B \neq \emptyset$. Note that a family of k-subsets of $[n]$ is intersecting if and only if it forms an independent set in the graph $K(n, k)$. An intersecting family $\mathcal{F}$ is said to be *trivial* if there exists an element that belongs to all members of $\mathcal{F}$. Otherwise, the family $\mathcal{F}$ is *non-trivial*. The famous Erdös-Ko-Rado theorem [11] asserts that the largest size of an intersecting family

of k-subsets of $[n]$ is $\binom{n-1}{k-1}$, which is attained by the maximal trivial intersecting families. The following result of Hilton and Milner [18] determines the largest size of a non-trivial intersecting family in this setting and characterizes the extremal families attaining it.

▶ **Theorem 9** (Hilton–Milner Theorem [18]). *For integers $k \geq 3$ and $n \geq 2k$, let $\mathcal{F} \subseteq \binom{[n]}{k}$ be a non-trivial intersecting family. Then,*

$$|\mathcal{F}| \leq \binom{n-1}{k-1} - \binom{n-k-1}{k-1} + 1.$$

Moreover, if $n > 2k$ then equality holds if and only if there exist an element $i \in [n]$ and a k-subset A of $[n]$ with $i \notin A$ such that $\mathcal{F} = \left\{F \in \binom{[n]}{k} \;\middle|\; i \in F,\ F \cap A \neq \emptyset\right\} \cup \{A\}$, or $k = 3$ and there exists a 3-subset A of $[n]$ such that $\mathcal{F} = \left\{F \in \binom{[n]}{3} \;\middle|\; |F \cap A| \geq 2\right\}$.

2.3 Complexity Classes

The complexity class TFNP consists of the total search problems in NP, i.e., the search problems in which every input has a solution, where a solution can be verified in polynomial time. The complexity class PPA (Polynomial Parity Argument [26]) consists of the problems in TFNP that can be reduced in polynomial time to a problem called Leaf. The definition of the Leaf problem is not needed in this paper, but we mention it briefly below for completeness.

The Leaf problem asks, given a graph with maximum degree 2 and a leaf (i.e., a vertex of degree 1), to find another leaf in the graph. The input graph, though, is not given explicitly. Instead, the vertex set of the graph is defined to be $\{0,1\}^n$ for some integer n, and the graph is succinctly represented by a Boolean circuit that for a vertex of the graph computes its (at most two) neighbors. Note that the size of the graph might be exponential in the size of its description.

2.4 Computational Problems

We gather here several computational problems that will be studied and used throughout the paper. We start with a computational search problem associated with Schrijver graphs. This problem is studied in Section 3.

▶ **Definition 10** (Generalized Schrijver Problem). *For $m = m(n,k)$, the Schrijver(n,k,m) problem is defined as follows. The input is a coloring $c : \binom{[n]}{k}_{\text{stab}} \to [m]$ of the vertices of the graph $S(n,k)$ with m colors, and the goal is to find a monochromatic edge, i.e., two vertices $A, B \in \binom{[n]}{k}_{\text{stab}}$ such that $A \cap B = \emptyset$ and $c(A) = c(B)$. In the black-box input model, the coloring c is given as an oracle access that given a vertex A outputs its color $c(A)$. In the white-box input model, the coloring c is given by a Boolean circuit that for a vertex A computes its color $c(A)$. For $m = n - 2k + 1$, the problem Schrijver(n,k,m) is denoted by Schrijver.*

The Kneser problem is defined similarly to the Schrijver problem. Here, the input coloring $c : \binom{[n]}{k} \to [n-2k+1]$ is defined on the entire vertex set of $K(n,k)$. By Theorem 8, every input of the Schrijver and Kneser problems is guaranteed to have a solution. Moreover, whenever $m = m(n,k) \leq n - 2k + 1$, every input of the Schrijver(n,k,m) problem has a solution as well.

We remark that algorithms for the Schrijver(n,k,m) problem are considered in this paper with respect to the black-box input model. The running time of such an algorithm is referred to as polynomial if it is polynomial in n. Observe that a polynomial-time algorithm

for the SCHRIJVER(n, k, m) problem in the black-box input model yields an algorithm for the analogue problem in the white-box input model, whose running time is polynomial as well (in the input size). For computational complexity results, like reductions and PPA-completeness, we adopt the more suitable white-box input model. For example, the SCHRIJVER problem in the white-box input model was shown in [15] to be PPA-complete.

Another search problem studied in [15] is the following.

▶ **Definition 11** (Fair Independent Set in Cycle Problem). *In the FAIR-IS-CYCLE problem, the input consists of integers n and m along with a partition $V_1, \ldots, V_m$ of $[n]$ into m sets. The goal is to find a stable subset S of $[n]$ satisfying $|S \cap V_i| \geq \frac{1}{2} \cdot |V_i| - 1$ for all $i \in [m]$.*

The existence of a solution for every input of the FAIR-IS-CYCLE problem was proved in [1]. It was shown in [15] that the FAIR-IS-CYCLE problem is PPA-complete, even restricted to instances in which each part V_i of the given partition has an odd size larger than 2.

We next define the UNFAIR-IS-CYCLE problem, studied in Section 4.

▶ **Definition 12.** *The input of the UNFAIR-IS-CYCLE problem consists of two integers n and k with $n \geq 2k$ and ℓ subsets $V_1, \ldots, V_\ell$ of $[n]$, where $\ell \leq n - 2k + 1$ and $|V_i| \geq 2$ for all $i \in [\ell]$. The goal is to find a stable k-subset S of $[n]$ that satisfies the constraints $|S \cap V_i| \leq |V_i|/2$ for $i \in [\ell]$.*

Note that Definition 12 requires the sets $V_1, \ldots, V_\ell$ of an instance of the UNFAIR-IS-CYCLE problem to satisfy $|V_i| \geq 2$ for all $i \in [\ell]$. This requirement is justified by the observation that if $|V_i| = 1$ for some $i \in [\ell]$, then any solution for the instance does not include the single element of V_i. Hence, by removing this element from the given sets and from the ground set, such an instance can be reduced to an instance with ground set of size smaller by one. By repeatedly applying this reduction, one can get a "core" instance that fits Definition 12.

We observe that the UNFAIR-IS-CYCLE problem is total. The argument relies on the chromatic number of the graph $S(n, k)$.

▶ **Lemma 13.** *Every instance of the UNFAIR-IS-CYCLE problem has a solution.*

Proof. Consider an instance of the UNFAIR-IS-CYCLE problem, i.e., integers n and k with $n \geq 2k$ and ℓ subsets $V_1, \ldots, V_\ell$ of $[n]$, where $\ell \leq n - 2k + 1$ and $|V_i| \geq 2$ for all $i \in [\ell]$. For every $i \in [\ell]$, let

$$\mathcal{F}_i = \left\{ S \in \binom{[n]}{k}_{\text{stab}} \;\middle|\; |S \cap V_i| > |V_i|/2 \right\},$$

and notice that every two sets of $\mathcal{F}_i$ have a common element of V_i, hence $\mathcal{F}_i$ is an intersecting family. However, by Theorem 8, the chromatic number of $S(n, k)$ is $n - 2k + 2$, hence the family of stable k-subsets of $[n]$ cannot be covered by fewer than $n - 2k + 2$ intersecting families. By $\ell \leq n - 2k + 1$, this implies that there exists a set $S \in \binom{[n]}{k}_{\text{stab}}$ that does not belong to any of the families $\mathcal{F}_i$, hence it satisfies $|S \cap V_i| \leq |V_i|/2$ for all $i \in [\ell]$. This implies that S is a valid solution for the given instance, and we are done. ◀

We end this section with the definition of the CYCLE-PLUS-TRIANGLES problem.

▶ **Definition 14** (Cycle plus Triangles Problem). *In the CYCLE-PLUS-TRIANGLES problem, the input consists of an integer k and a graph G on $3k$ vertices, whose edge set is the disjoint union of a Hamilton cycle and k pairwise vertex-disjoint triangles. The goal is to find an independent set in G of size k.*

The existence of a solution for every input of the CYCLE-PLUS-TRIANGLES problem follows from a result of [13] (see also [27, 1]).

3 The Generalized Schrijver Problem

In this section, we prove our results on the SCHRIJVER(n, k, m) problem (see Definition 10). We start with Theorem 1.

Proof of Theorem 1. Fix some integer $d \geq 2$. For integers n and k with $n \geq 2k$, put $t = \lfloor \frac{n}{2k+d-2} \rfloor$ and $m = d \cdot t - 1$, and consider an instance of the SCHRIJVER(n, k, m) problem, i.e., a coloring $c : \binom{n}{k}_{\text{stab}} \to [m]$ of the vertices of $S(n, k)$. The definition of t allows us to consider t pairwise disjoint subsets $J_1, \ldots, J_t$ of $[n]$, where each of the subsets includes $2k + d - 2$ consecutive elements. For each $i \in [t]$, let $\mathcal{S}_i$ denote the family of all stable k-subsets of J_i with respect to the natural cyclic order of J_i (where the largest element precedes the smallest one), and notice that $\mathcal{S}_i \subseteq \binom{n}{k}_{\text{stab}}$. Consider the algorithm that given an oracle access to a coloring c as above, queries the oracle for the colors of all the sets of $\mathcal{S}_1 \cup \cdots \cup \mathcal{S}_t$, and returns a pair of disjoint sets from this collection that are assigned the same color by c.

For correctness, we show that the collection of sets $\mathcal{S}_1 \cup \cdots \cup \mathcal{S}_t$ necessarily includes two vertices that form a monochromatic edge. Indeed, since the number of colors used by the coloring c does not exceed $d \cdot t - 1$, it follows that either there exist distinct $i, j \in [t]$ for which a vertex of $\mathcal{S}_i$ and a vertex of $\mathcal{S}_j$ have the same color, or there exists an $i \in [t]$ for which the vertices of $\mathcal{S}_i$ are colored using fewer than d colors. For the former case, notice that for distinct i and j, every vertex of $\mathcal{S}_i$ is disjoint from every vertex of $\mathcal{S}_j$, hence the collection includes two vertices that form a monochromatic edge. For the latter case, let $i \in [t]$ be an index for which the vertices of $\mathcal{S}_i$ are colored using fewer than d colors. Observe that the subgraph of $S(n, k)$ induced by $\mathcal{S}_i$ is isomorphic to the graph $S(2k + d - 2, k)$, hence by Theorem 8, its chromatic number is $(2k + d - 2) - 2k + 2 = d$. Since the vertices of $\mathcal{S}_i$ are colored using fewer than d colors, it follows that they include two vertices that form a monochromatic edge, and we are done.

We finally analyze the running time of the algorithm. By Lemma 7, the number of vertices in the graph $S(n, k)$ is

$$\frac{n}{k} \cdot \binom{n-k-1}{k-1} = \frac{n}{k} \cdot \binom{n-k-1}{n-2k} \leq n \cdot (n-k-1)^{n-2k} \leq n^{n-2k+1}.$$

Since the subgraph of $S(n, k)$ induced by each $\mathcal{S}_i$ is isomorphic to $S(2k+d-2, k)$, it follows that the total number of queries that the algorithm makes does not exceed $t \cdot (2k+d-2)^{d-1} \leq n^{O(d)}$. This implies that in running time $n^{O(d)}$, it is possible to enumerate all the sets of $\mathcal{S}_1 \cup \cdots \cup \mathcal{S}_t$, to query the oracle for their colors, and to find the desired monochromatic edge. This completes the proof. ◀

We consider now the SCHRIJVER(n, k, m) problem with $m = \lfloor n/2 \rfloor - 2k + 1$. We first prove Theorem 2 that says that the problem is efficiently reducible to the KNESER problem (whose definition is given in Section 2.4).

Proof of Theorem 2. Put $m = \lfloor n/2 \rfloor - 2k + 1$, and let $c : \binom{[n]}{k}_{\text{stab}} \to [m]$ be an instance of the SCHRIJVER(n, k, m) problem. Consider the reduction that maps such a coloring c to a coloring $c' : \binom{[n]}{k} \to [n - 2k + 1]$ of the vertices of $K(n, k)$ defined as follows. For every set $A \in \binom{[n]}{k}$, if A is unstable then it includes an odd element, so denote its smallest odd element by $2i - 1$, and define $c'(A) = i$. Notice that this i satisfies $1 \leq i \leq \lceil n/2 \rceil$. Otherwise, A is a stable k-subset of $[n]$, and we define $c'(A) = c(A) + \lceil n/2 \rceil$. Notice that $m + \lceil n/2 \rceil = n - 2k + 1$, hence the colors used by c' are all in $[n - 2k + 1]$, as needed for an instance of the KNESER problem. Notice further that given a Boolean circuit that computes the coloring c, it is possible to efficiently produce a Boolean circuit that computes the coloring c'.

For correctness, we simply show that any solution for the produced instance of the Kneser problem is also a solution for the given instance of the Schrijver(n, k, m) problem. To see this, consider a solution for the former, i.e., two disjoint k-subsets A and B of $[n]$ with $c'(A) = c'(B)$. By the definition of c', the color assigned by c' to A and B cannot be some $i \leq \lceil n/2 \rceil$ because this would imply that the element $2i - 1$ belongs to both A and B, which are disjoint. It thus follows that A and B are stable k-subsets of $[n]$ satisfying $c'(A) = c(A)+\lceil n/2 \rceil$ and $c'(B) = c(B)+\lceil n/2 \rceil$. By $c'(A) = c'(B)$, it follows that $c(A) = c(B)$, hence A and B form a monochromatic edge in $S(n, k)$ and thus a solution for the given instance of the Schrijver(n, k, m) problem. This completes the proof. ◀

The reduction presented in the proof of Theorem 2 extends a given coloring of $S(n, k)$ to a coloring of the entire graph $K(n, k)$. To do so, it uses a proper coloring with $\lceil n/2 \rceil$ colors of the subgraph $U(n, k)$ of $K(n, k)$ induced by the *unstable* k-subsets of $[n]$. However, in order to obtain a coloring of $K(n, k)$ with $n-2k+1$ colors, as required for instances of the Kneser problem, one has to reduce from the Schrijver(n, k, m) problem with $m = \lfloor n/2 \rfloor - 2k + 1$. This suggests the question of whether $U(n, k)$ can be properly colored using fewer colors. Motivated by this question, we study some properties of this graph in Section 5, where we essentially answer this question in the negative (see Corollary 19 and the discussion that follows it).

We next show that the Schrijver(n, k, m) problem with $m = \lfloor n/2 \rfloor - 2k + 1$ is not harder than the restriction of the standard Schrijver problem to colorings of $S(n, k)$ with $n = 4k$. This confirms Theorem 3.

Proof of Theorem 3. Suppose that there exists a polynomial-time algorithm, called Algo, for the restriction of the Schrijver problem to colorings of $S(n, k)$ with $n = 4k$. Such an algorithm is able to efficiently find a monochromatic edge in the graph $S(4k, k)$ given an access to a coloring of its vertices with fewer than $\chi(S(4k, k))$ colors. By Theorem 8, it holds that $\chi(S(4k, k)) = 2k+2$. Suppose without loss of generality that the algorithm Algo queries the oracle for the colors of the two vertices of the monochromatic edge that it returns.

For integers n and k with $n \geq 4k$, put $m = \lfloor n/2 \rfloor - 2k + 1$, and let $c : \binom{n}{k}_{\text{stab}} \to [m]$ be an instance of the Schrijver(n, k, m) problem, i.e., a coloring of the vertices of $S(n, k)$ with m colors. We present an algorithm that finds a monochromatic edge in $S(n, k)$. It may be assumed that $n > 8k$. Indeed, otherwise it holds that $m \leq 2k + 1 < \chi(S(4k, k))$, hence a monochromatic edge can be found by running the given algorithm Algo on the restriction of the coloring c to the subgraph of $S(n, k)$ induced by the stable k-subsets of $[4k]$. Since this graph is isomorphic to $S(4k, k)$, Algo is guaranteed to find a monochromatic edge in this subgraph, which also forms a monochromatic edge in the entire graph $S(n, k)$.

Now, put $t = \lfloor \frac{n}{4k} \rfloor$, and let $J_1, \ldots, J_t$ be t pairwise disjoint subsets of $[n]$, where each of the subsets includes $4k$ consecutive elements. For each $i \in [t]$, let $\mathcal{S}_i$ denote the family of all stable k-subsets of J_i with respect to the natural cyclic order of J_i (where the largest element precedes the smallest one). Observe that the subgraph of $S(n, k)$ induced by the vertices of each $\mathcal{S}_i$ is isomorphic to $S(4k, k)$. Observe further that

$$t \cdot (2k + 2) > \left(\frac{n}{4k} - 1\right) \cdot (2k + 2) = \frac{n}{2} + \frac{n}{2k} - 2k - 2 > \left\lfloor \frac{n}{2} \right\rfloor - 2k + 1 = m, \tag{1}$$

where the last inequality holds because $n > 8k$.

Consider the algorithm that given an oracle access to a coloring c as above, for each $i \in [t]$, simulates the algorithm Algo on the restriction of the coloring c to the subgraph of $S(n, k)$ induced by the vertices of $\mathcal{S}_i$. If all the vertices queried throughout the ith simulation have at most $2k + 1$ distinct colors, then the algorithm returns the monochromatic edge

returned by Algo. Otherwise, for each $i \in [t]$, the algorithm uses the queries made in the ith simulation of Algo to produce a set $\mathcal{F}_i \subseteq \mathcal{S}_i$ of $2k+2$ vertices with distinct colors. Then, the algorithm finds a monochromatic edge that involves two vertices of $\mathcal{F}_1 \cup \cdots \cup \mathcal{F}_t$ and returns it. This completes the description of the algorithm. Since the running time of Algo is polynomial, the described algorithm can be implemented in polynomial time.

Let us prove the correctness of the algorithm. Suppose first that for some $i \in [t]$, all the vertices queried throughout the ith simulation of Algo have at most $2k+1$ distinct colors (including the two vertices of the returned edge). In this case, the answers of the oracle in the ith simulation is consistent with some coloring with at most $2k+1$ colors of the subgraph of $S(n,k)$ induced by $\mathcal{S}_i$. Since this graph is isomorphic to $S(4k,k)$, whose chromatic number is $2k+2$, Algo is guaranteed to find in the graph a monochromatic edge, which is also a monochromatic edge in $S(n,k)$, and thus a valid output of the algorithm. Otherwise, for each $i \in [t]$, the attempt to simulate Algo on the subgraph of $S(n,k)$ induced by $\mathcal{S}_i$ provides a set $\mathcal{F}_i$ of $2k+2$ vertices of $\mathcal{S}_i$ with distinct colors. By (1), the total number m of colors used by the coloring c is smaller than $t \cdot (2k+2)$. This implies that there exist distinct indices $i, j \in [t]$ for which a vertex of $\mathcal{F}_i$ and a vertex of $\mathcal{F}_j$ have the same color. Since the vertices of $\mathcal{S}_i$ are disjoint from those of $\mathcal{S}_j$, these two vertices form a monochromatic edge in $S(n,k)$ and form a valid output of the algorithm. ◀

We end this section with the observation that there exists an efficient randomized algorithm for the Schrijver(n,k,m) problem with $m = \lfloor n/2 \rfloor - 2k + 1$ on instances with $n = \Omega(k^4)$. This follows from the paper [17], which yields that for such n and k, the Schrijver(n,k,m) problem is essentially reducible to the Schrijver$(n-1,k,m-1)$ problem in randomized polynomial time (with exponentially small failure probability). By applying this reduction $m-1$ times, it follows that the Schrijver(n,k,m) problem with $m = \lfloor n/2 \rfloor - 2k + 1$ where $n = \Omega(k^4)$, is efficiently reducible to the Schrijver$(\lceil n/2 \rceil + 2k, k, 1)$ problem, which can obviously be solved efficiently.

4 The Unfair Independent Set in Cycle Problem

In this section, we study the Unfair-IS-Cycle problem (see Definition 12).

4.1 Hardness

We prove now Theorem 4, which asserts that Unfair-IS-Cycle is PPA-complete.

Proof of Theorem 4. We first show that the Unfair-IS-Cycle problem belongs to PPA. To do so, we show a polynomial-time reduction to the Schrijver problem in the white-box input model, which lies in PPA [15] (see Definition 10).

Consider an instance of the Unfair-IS-Cycle problem, i.e., integers n and k with $n \geq 2k$ and ℓ subsets $V_1, \ldots, V_\ell$ of $[n]$, where $\ell \leq n - 2k + 1$ and $|V_i| \geq 2$ for all $i \in [\ell]$. For such an instance, the reduction produces a Boolean circuit that given a stable k-subset A of $[n]$, outputs the smallest index $i \in [\ell]$ such that $|A \cap V_i| > |V_i|/2$ if such an i exists, and outputs ℓ otherwise. Note that this circuit represents a coloring $c : \binom{[n]}{k}_{\text{stab}} \to [\ell]$ of the vertices of the graph $S(n,k)$ with $\ell \leq n - 2k + 1$ colors, hence it is an appropriate instance of the Schrijver problem. Clearly, the Boolean circuit that computes c can be constructed in polynomial time.

For correctness, we show that a solution for the constructed Schrijver instance can be used to efficiently find a solution for the given Unfair-IS-Cycle instance. Consider a monochromatic edge of $S(n,k)$, i.e., two disjoint sets $A, B \in \binom{[n]}{k}_{\text{stab}}$ with $c(A) = c(B)$.

Since A and B are disjoint, it is impossible that $|A \cap V_i| > |V_i|/2$ and $|B \cap V_i| > |V_i|/2$ for some $i \in [\ell]$. By the definition of the coloring c, it follows that $c(A) = c(B) = \ell$, hence $|A \cap V_i| \leq |V_i|/2$ and $|B \cap V_i| \leq |V_i|/2$ for all $i \in [\ell - 1]$. Moreover, at least one of A and B intersects V_ℓ at no more than $|V_\ell|/2$ elements, and thus forms a valid solution for the given Unfair-IS-Cycle instance. Since it is possible to check in polynomial time which of the sets A and B satisfies this requirement, the proof of the membership of Unfair-IS-Cycle in PPA is completed.

We next prove that the Unfair-IS-Cycle problem is PPA-hard. To do so, we reduce from the Fair-IS-Cycle problem (see Definition 11). We use here the fact, proved in [15], that this problem is PPA-hard even when it is restricted to the instances in which the parts of the given partition have odd sizes larger than 2. Consider such an instance of the Fair-IS-Cycle problem, i.e., integers n and m along with a partition $V_1, \ldots, V_m$ of $[n]$ such that $|V_i|$ is odd and satisfies $|V_i| \geq 3$ for all $i \in [m]$. Notice that n and m have the same parity, and define $k = \frac{n-m}{2}$. Our reduction simply returns the integers n and k, which clearly satisfy $n \geq 2k$, and the sets $V_1, \ldots, V_m$. Note that $|V_i| \geq 2$ for all $i \in [m]$ and that the number m of sets is $n - 2k$. Since the latter does not exceed $n - 2k + 1$, this is a valid instance of the Unfair-IS-Cycle problem.

For correctness, we show that a solution for the constructed Unfair-IS-Cycle instance is also a solution for the given Fair-IS-Cycle instance. Let S be a solution for the Unfair-IS-Cycle instance, i.e., a stable k-subset of $[n]$ such that for all $i \in [m]$ it holds that $|S \cap V_i| \leq |V_i|/2$. Since the sizes of the sets $V_1, \ldots, V_m$ are odd, it follows that $|S \cap V_i| \leq \frac{|V_i|-1}{2}$ for all $i \in [m]$. Since the sets $V_1, \ldots, V_m$ form a partition of $[n]$, it further follows that

$$|S| = \sum_{i \in [m]} |S \cap V_i| \leq \sum_{i \in [m]} \tfrac{|V_i|-1}{2} = \frac{n-m}{2} = k. \tag{2}$$

However, by $|S| = k$, we derive from (2) that $|S \cap V_i| = \frac{|V_i|-1}{2}$ for all $i \in [m]$. This implies that S is a stable k-subset of $[n]$ satisfying $|S \cap V_i| \geq |V_i|/2 - 1$ for all $i \in [m]$, hence it forms a valid solution for the given Fair-IS-Cycle instance. This completes the proof. ◀

Given the PPA-hardness of the Unfair-IS-Cycle problem, it is interesting to identify the range of the parameters n and k for which the hardness holds. One can verify, using properties of the hard instances constructed in [15], that the hardness given in Theorem 4 holds for instances with $n = (2 + o(1)) \cdot k$, where the $o(1)$ term tends to 0 as n and k tend to infinity. The following simple result shows that for $n = 3k$ the problem is at least as hard as the Cycle-Plus-Triangles problem, whose tractability is an open question (see Definition 14). The proof can be found in the full version of this paper.

▶ **Proposition 15.** *The Cycle-Plus-Triangles problem is polynomial-time reducible to the restriction of the Unfair-IS-Cycle problem to instances that consist of k sets of size 3 that form a partition of $[n]$ where $n = 3k$.*

4.2 Algorithms

We next prove Theorem 5, which states that the Unfair-IS-Cycle problem can be solved efficiently on instances with $n \geq c \cdot k$ for some absolute constant c.

Proof of Theorem 5. We start by presenting a randomized algorithm, based on a probabilistic argument with alterations, and then derandomize it using the method of conditional expectations.

Consider an instance of the Unfair-IS-Cycle problem, i.e., integers n and k with $n \geq 2k$ and ℓ subsets $V_1, \ldots, V_\ell$ of $[n]$, where $\ell \leq n - 2k + 1$ and $|V_i| \geq 2$ for all $i \in [\ell]$. Put $r_i = |V_i| \geq 2$ for each $i \in [\ell]$. Suppose further that $n \geq c \cdot k$ for a sufficiently large constant c to be determined later. Let $p = 2k/n \leq 2/c$, and consider the following randomized algorithm.

1. Pick a random subset A of $[n]$ by including in A every element of $[n]$ independently with probability p.
2. Remove from A every element $j \in [n]$ that satisfies $\{j, j+1\} \subseteq A$ (where for $j = n$, the element $j + 1$ is considered as 1). Let A' denote the obtained set.
3. For every $i \in [\ell]$ that satisfies $|A' \cap V_i| > r_i/2$, remove from A' arbitrary $|A' \cap V_i| - \lfloor r_i/2 \rfloor$ elements of V_i. Let A'' denote the obtained set.
4. If $|A''| \geq k$, then return an arbitrary k-subset of A''. Otherwise, return "failure".

We first claim that unless the algorithm returns "failure", it returns a valid output. Indeed, Item 2 of the algorithm guarantees that the set A' is stable. Further, Item 3 guarantees that its subset A'' satisfies $|A'' \cap V_i| \leq \lfloor r_i/2 \rfloor$ for all $i \in [\ell]$. Therefore, in the case where $|A''| \geq k$, any k-subset of A'' returned in Item 4 of the algorithm is a valid solution for the given Unfair-IS-Cycle instance.

We next estimate the expected size of the set A'' produced by the algorithm. The set A chosen in Item 1 of the algorithm includes every element of $[n]$ with probability p. Hence, its expected size satisfies $\mathbf{E}[|A|] = p \cdot n$. In Item 2 of the algorithm, the probability of every element of $[n]$ to be removed from A is equal to the probability that both the element and its successor modulo n belong to A, which is p^2. By linearity of expectation, this implies that the expected size of the set A' satisfies $\mathbf{E}[|A'|] = (p - p^2) \cdot n$. It remains to estimate the expected number of elements removed from A' in Item 3 of the algorithm. Observe that for each $i \in [\ell]$, the algorithm removes from A' the smallest possible number of elements of V_i ensuring that the obtained set A'' includes at most $\lfloor r_i/2 \rfloor$ of them. Therefore, the number of removed elements of V_i does not exceed the number of subsets of V_i of size $\lfloor r_i/2 \rfloor + 1$ that are contained in A (because it suffices to remove one element from each of them). It thus follows that the expected number of elements of V_i that are removed from A' in Item 3 of the algorithm is at most

$$\binom{r_i}{\lfloor r_i/2 \rfloor + 1} \cdot p^{\lfloor r_i/2 \rfloor + 1} \leq 2^{r_i} \cdot p^{\lfloor r_i/2 \rfloor + 1} \leq (4p)^{\lfloor r_i/2 \rfloor + 1} \leq (4p)^2,$$

where in the last inequality we use the assumption $r_i \geq 2$ and the fact that $p \leq 1/4$ (which holds for any sufficiently large choice of the constant c). It therefore follows, using again the linearity of expectation, that the expected size of A'' satisfies

$$\mathbf{E}[|A''|] \geq (p - p^2) \cdot n - \ell \cdot (4p)^2 \geq (p - 17p^2) \cdot n \geq k,$$

where the second inequality holds by $\ell \leq n$, and the last inequality by the definition of $p = 2k/n$, assuming again that $n \geq c \cdot k$ for a sufficiently large constant c (say, $c = 68$). This implies that there exists a random choice for the presented randomized algorithm for which it returns a valid solution.

We next apply the method of conditional expectations to derandomize the above algorithm. Let us start with a few notations. For a set $S \subseteq [n]$, define

$$f(S) = |S| - |\{j \in [n] \mid \{j, j+1\} \subseteq S\}| - \sum_{i \in [\ell]} \left| \left\{ B \subseteq S \cap V_i \;\middle|\; |B| = \lfloor r_i/2 \rfloor + 1 \right\} \right|. \tag{3}$$

In words, $f(S)$ is determined by subtracting from the size of S the number of pairs of consecutive elements in S (modulo n) as well as the number of subsets of $S \cap V_i$ of size $\lfloor r_i/2 \rfloor + 1$ for each $i \in [\ell]$. For a vector $x \in \{0,1,*\}^n$, let S_x denote a random subset of $[n]$ such that for every $i \in [n]$, if $x_i = 1$ then $i \in S_x$, if $x_i = 0$ then $i \notin S_x$, and if $x_i = *$ then i is chosen to be included in S_x independently with probability $p = 2k/n$. We refer to the vector x as a *partial choice* of a subset of $[n]$. We further define a potential function $\phi : \{0,1,*\}^n \to \mathbb{R}$ that maps every vector $x \in \{0,1,*\}^n$ to the expected value of $f(S)$ where S is chosen according to the distribution S_x, that is, $\phi(x) = \mathbf{E}[f(S_x)]$.

We observe that given a partial choice $x \in \{0,1,*\}^n$, the value of $\phi(x)$ can be calculated efficiently, in time polynomial in n. Indeed, to calculate the expected value of $f(S_x)$, it suffices, by linearity of expectation, to calculate the expected value of each of the three terms in (3) evaluated at the set S_x. It is easy to see that the expected value of the first term is

$$|\{j \in [n] \mid x_j = 1\}| + p \cdot |\{j \in [n] \mid x_j = *\}|,$$

and that the expected value of the second term is

$$\begin{aligned} \left|\left\{j \in [n] \middle| x_j = x_{j+1} = 1\right\}\right| &+ p \cdot \left|\left\{j \in [n] \middle| \{x_j, x_{j+1}\} = \{1,*\}\right\}\right| \\ &+ p^2 \cdot \left|\left\{j \in [n] \middle| x_j = x_{j+1} = *\right\}\right|. \end{aligned}$$

As for the third term, by linearity of expectation, it suffices to determine the expected value of

$$\left|\left\{B \subseteq S_x \cap V_i \;\middle|\; |B| = \lfloor r_i/2 \rfloor + 1\right\}\right|$$

for $i \in [\ell]$. Letting $s_i = |\{j \in V_i \mid x_j = *\}|$ and $t_i = |\{j \in V_i \mid x_j = 1\}|$, one can check that the required expectation is precisely

$$\sum_{m=0}^{\lfloor r_i/2 \rfloor + 1} \binom{s_i}{m} \cdot \binom{t_i}{\lfloor r_i/2 \rfloor + 1 - m} \cdot p^m.$$

Since all the terms can be calculated in time polynomial in n, so can $\phi(x)$.

We describe a deterministic algorithm that finds a set $S \subseteq [n]$ satisfying $f(S) \geq k$. Given such a set, the algorithm is completed by applying Items 2, 3, and 4 of the algorithm presented above. Indeed, by applying Items 2 and 3 we obtain a stable set S'' such that $|S'' \cap V_i| \leq r_i/2$ for all $i \in [\ell]$. The fact that $f(S) \geq k$ guarantees that this set S'' satisfies $|S''| \geq k$, hence Item 4 returns a valid solution.

To obtain the desired set $S \subseteq [n]$ with $f(S) \geq k$, our algorithm maintains a partial choice $x \in \{0,1,*\}^n$ satisfying $\phi(x) \geq k$. We start with $x = (*, \ldots, *)$, for which the analysis of the randomized algorithm guarantees that $\phi(x) \geq k$, provided that $n \geq c \cdot k$ for a sufficiently large constant c. We then choose the entries of x, one by one, to be either 0 or 1. In the ith iteration, in which $x_1, \ldots, x_{i-1} \in \{0,1\}$, the algorithm evaluates ϕ at the two partial choices $x_{i \leftarrow 0} = (x_1, \ldots, x_{i-1}, 0, *, \ldots, *)$ and $x_{i \leftarrow 1} = (x_1, \ldots, x_{i-1}, 1, *, \ldots, *)$, and continues to the next iteration with one of them which maximizes the value of ϕ. By the law of total expectation, it holds that $\phi(x) = p \cdot \phi(x_{i \leftarrow 1}) + (1-p) \cdot \phi(x_{i \leftarrow 0})$, implying that the choice of the algorithm preserves the inequality $\phi(x) \geq k$. At the end of the process, we get a vector $x \in \{0,1\}^n$ with $\phi(x) \geq k$, which fully determines the desired set S with $f(S) \geq k$. Since the evaluations of ϕ can be calculated in time polynomial in n, the algorithm can be implemented in polynomial time. This completes the proof. ◀

Given the above result, it would be interesting to determine the smallest constant c for which the Unfair-IS-Cycle problem can be solved efficiently on instances with $n \geq c \cdot k$. Of particular interest is the restriction of the problem to instances with $n = 3k$ and with pairwise disjoint sets of size 3, because as follows from Proposition 15, an efficient algorithm for this restriction would imply an efficient algorithm for the Cycle-Plus-Triangles problem. Interestingly, it turns out that the restriction of the Unfair-IS-Cycle problem to instances with $n = 4k$ and with pairwise disjoint sets of size 4 does admit an efficient algorithm. This is a consequence of the following result derived from an argument of Alon [2] (see also [4]).

▶ **Proposition 16.** *There exists a polynomial-time algorithm that given an integer k and a partition of $[4k]$ into k subsets $V_1, \ldots, V_k$ with $|V_i| = 4$ for all $i \in [k]$, finds a partition of $[4k]$ into four stable k-subsets S_1, S_2, S_3, S_4 of $[4k]$ such that $|S_j \cap V_i| = 1$ for all $j \in [4]$ and $i \in [k]$.*

5 Unstable Sets

In this section, we consider two subgraphs of the Kneser graph $K(n, k)$ induced by families of unstable k-subsets of $[n]$. These subgraphs are defined as follows.

▶ **Definition 17.** *Let n and k be integers with $n \geq 2k$. Let $\widetilde{U}(n, k)$ denote the subgraph of $K(n, k)$ induced by the family of all k-subsets of $[n]$ that include a pair of consecutive elements (where the elements n and 1 are* not *considered as consecutive for $n > 2$). Let $U(n, k)$ denote the subgraph of $K(n, k)$ induced by the family of all k-subsets of $[n]$ that include a pair of consecutive elements modulo n, i.e., the family of unstable k-subsets of $[n]$.*

5.1 Chromatic Number

We study now the chromatic numbers of the graphs $U(n, k)$ and $\widetilde{U}(n, k)$. It is worth mentioning here that a result of Dol'nikov [8] generalizes the lower bound of Lovász [22] on the chromatic number of $K(n, k)$ to general graphs, using a notion called colorability defect (see also [24, Chapter 3.4] and [21]). This generalization implies a tight lower bound of $n - 2k + 2$ on the chromatic number of $K(n, k)$ and a somewhat weaker lower bound of $n - 4k + 4$ on the chromatic number of $S(n, k)$ (see, e.g., [25]). It turns out, though, that this generalized approach of [8] does not yield any meaningful bounds on the chromatic numbers of the graphs from Definition 17.

The following theorem determines the exact chromatic number of the graph $\widetilde{U}(n, k)$.

▶ **Theorem 18.** *For all integers n and k with $n \geq 2k$,*

$$\chi(\widetilde{U}(n, k)) = \min(n - 2k + 2, \lfloor n/2 \rfloor).$$

The proof of Theorem 18 relies on a topological argument and can be found in the full version of the paper. We derive the following result on the chromatic number of $U(n, k)$.

▶ **Corollary 19.** *For all integers n and k with $n \geq 2k$,*

$$\min(n - 2k + 2, \lfloor n/2 \rfloor) \leq \chi(U(n, k)) \leq \min(n - 2k + 2, \lceil n/2 \rceil).$$

Proof. For the upper bound, apply first Theorem 8 to obtain that

$$\chi(U(n, k)) \leq \chi(K(n, k)) = n - 2k + 2.$$

Next, since every vertex of $U(n,k)$ includes two consecutive elements modulo n, it must include an odd element. By assigning to every such vertex its minimal odd element, we obtain a proper coloring of $U(n,k)$ with $\lceil n/2 \rceil$ colors, hence $\chi(U(n,k)) \leq \lceil n/2 \rceil$. This completes the proof of the upper bound. The lower bound follows by combining Theorem 18 with the fact that $\widetilde{U}(n,k)$ is an induced subgraph of $U(n,k)$. ◀

We conclude this section with a discussion on the tightness of Corollary 19. Notice that the upper and lower bounds provided in Corollary 19 coincide whenever the integer n is even or satisfies $n \leq 4k-4$. For other values of n and k the two bounds differ by 1. Yet, it turns out that the proof technique of Theorem 18 can be used to show that the upper bound in Corollary 19 is tight for all integers n that are congruent to 1 modulo 4. This leaves us with a gap of 1 between the upper and lower bounds in Corollary 19 only for those integers n and k, where n is congruent to 3 modulo 4 and satisfies $n \geq 4k-1$.

We further observe that for an odd integer n and for every proper coloring of $U(n,k)$ that includes a trivial color class (all of whose members share a common element), the number of used colors is at least the upper bound in Corollary 19. Indeed, the restriction of such a coloring to the vertices that do not include the common element of the trivial color class is a proper coloring of a graph isomorphic to $\widetilde{U}(n-1,k)$, so by Theorem 18 it uses at least $\min(n-2k+1,(n-1)/2)$ colors. Together with the additional color of the trivial color class, the total number of colors is at least $\min(n-2k+2,\lceil n/2 \rceil)$, as claimed.

5.2 Independence Number

We next determine the largest size of an independent set in the graph $U(n,k)$. The proof uses the Hilton–Milner theorem (Theorem 9) and can be found in the full version of the paper.

▶ **Theorem 20.** *For all integers $k \geq 2$ and $n \geq 2k$, it holds that*

$$\alpha(U(n,k)) = \binom{n-1}{k-1} - \binom{n-k-1}{k-1}.$$

Abstract

The maximization of submodular functions have found widespread application in areas such as machine learning, combinatorial optimization, and economics, where practitioners often wish to enforce various constraints; the matroid constraint has been investigated extensively due to its algorithmic properties and expressive power. Though tight approximation algorithms for general matroid constraints exist in theory, the running times of such algorithms typically scale quadratically, and are not practical for truly large scale settings. Recent progress has focused on fast algorithms for important classes of matroids given in explicit form. Currently, nearly-linear time algorithms only exist for graphic and partition matroids [12]. In this work, we develop algorithms for monotone submodular maximization constrained by graphic, transversal matroids, or laminar matroids in time near-linear in the size of their representation. Our algorithms achieve an optimal approximation of $1 - 1/e - \varepsilon$ and both generalize and accelerate the results of Ene and Nguyen [12]. In fact, the running time of our algorithm cannot be improved within the fast continuous greedy framework of Badanidiyuru and Vondrák [6].

To achieve near-linear running time, we make use of dynamic data structures that maintain bases with approximate maximum cardinality and weight under certain element updates. These data structures need to support a weight decrease operation and a novel Freeze operation that allows the algorithm to freeze elements (i.e. force to be contained) in its basis regardless of future data structure operations. For the laminar matroid, we present a new dynamic data structure using the top tree interface of Alstrup, Holm, de Lichtenberg, and Thorup [2] that maintains the maximum weight basis under insertions and deletions of elements in $O(\log n)$ time. This data structure needs to support certain subtree query and path update operations that are performed every insertion and deletion that are non-trivial to handle in conjunction. For the transversal matroid the Freeze operation corresponds to requiring the data structure to keep a certain set S of vertices matched, a property that we call S-stability. While there is a large body of work on dynamic matching algorithms, none are S-stable *and* maintain an approximate maximum weight matching under vertex updates. We give the first such algorithm for bipartite graphs with total running time linear (up to log factors) in the number of edges.

1 Introduction

Submodular optimization is encountered in a variety of applications – combinatorial optimization, information retrieval, and machine learning, to name a few [7]. Many such applications involve constraints, which are often in the form of cardinality or weight constraints on certain subsets of elements, or combinatorial constraints such as connectivity or matching. A convenient abstraction which has been studied heavily in this context is that of a *matroid constraint*[1]. For instance, transversal matroids appear in ad placement and matching applications [4, 3], laminar and partition matroids capture capacity constraints on subsets which are widely used in recommendation settings (e.g. YouTube video recommendation algorithm [25]), and graphic matroids appear in applications for approximating Metric TSP [26]. Maximization of a submodular function subject to any of these constraints is an APX-hard problem, but a $(1 - 1/e)$-approximation is known in this setting for any matroid constraint [11], and the factor of $1 - 1/e$ is also known to be optimal [22, 13]. Considering this, it has been a long-standing quest to develop fast algorithms for the submodular maximization problem that achieve an approximation close to the optimal factor of $1 - 1/e$. In this work, we achieve this goal for several common classes of matroids.

Perhaps the first step in this direction was the *threshold-greedy technique* which gives a fast $(1/2 - \varepsilon)$-approximation [5] for the cardinality constraint. With more work, this technique can be extended to give approximations close to $1 - 1/e$ [6] and ultimately a $(1-1/e-\varepsilon)$-approximation in running time $O(n/\varepsilon)$ was found for the cardinality constraint.[2]

For general matroids, the fastest known algorithm is the *fast continuous greedy algorithm*, which uses $O(nr\varepsilon^{-4}\log^2(n/\varepsilon))$ oracle, where n is the number of elements in the matroid and r is the rank of the matroid [6]. (The exact running time would depend on the implementation of these queries, which [6] does not address.) We can assume that the rank r scales polynomially with n and hence this algorithm is not near-linear. Further work on fast submodular optimization developed in the direction of parallelized and distributed settings (see [18, 20, 21] and the references therein); we do not discuss these directions in this paper.

A recent line of work initiated by Ene and Nguyen [12] attempts to develop a "nearly-linear" continuous greedy algorithm, i.e., with a running time of $n \cdot \mathrm{poly}(1/\varepsilon, \log n)$. They achieved this goal for partition and graphic matroids. Prior to their work, the fastest known algorithm for any matroid class beyond cardinality was the work of Buchbinder, Feldman, and Schwartz [10], who showed an $O(n^{3/2})$-time algorithm for partition matroids.

This immediately leads to the question of whether such improvements are also possible for other classes of matroid constraints. As observed by Ene and Nguyen [12], even determining feasibility may take longer than linear time for certain matroids. One such example is for

[1] A matroid on N is a family of "independent sets" $\mathcal{I} \subset 2^N$ which is down-closed, and satisfies the extension axiom: For any $A, B \in \mathcal{I}$, if $|A| < |B|$ then there is an element $e \in B \setminus A$ such that $A \cup \{e\} \in \mathcal{I}$.
[2] Running time in this paper includes value queries to the objective function $f(S)$ as unit-time operations.

matroids represented by linear systems, as simply checking the independence of a linear system takes $O(\text{rank}(\mathcal{M})^\omega)$ time, where $\text{rank}(\mathcal{M})$ is the rank of the linear system and ω is the exponent for fast matrix multiplication.

1.1 Our contributions

In this paper, we generalize and significantly improve the work of Ene and Nguyen [12], to develop a $(1 - 1/e - \varepsilon)$-approximation for maximizing a monotone submodular function subject to a matroid constraint, for several important classes of matroids: namely for graphic, laminar, and transversal matroids. The technical developments behind these results are on two fronts:
(i) a refinement of the optimization framework of [12] and formulation of abstract data structures required for this framework;
(ii) implementation of such data structures for graphic, laminar and transversal matroids. (See Section 2 for definitions of these classes of matroids.)

To describe our results in more detail, the efficiency of optimizing a submodular function f can be broken down into two components: the number of oracle calls to f, and the number of additional arithmetic operations needed to support the algorithm optimizing f. The number of oracle calls to f that our framework need to achieve a $(1-1/e-\varepsilon)$-approximation is $O_\varepsilon(n \log^2(n))$ regardless of the matroid, where n is the number of elements in the matroid constraint. Thus for all results below, the running time is measured in the number of the number of arithmetic operations needed by the data structures supporting the optimization of f. Our contributions are as follows:

- We give nearly-linear time versions of continuous greedy for laminar, graphic, and transversal matroids. These algorithms are accelerated by special data structures we developed for each matroid and which might be of independent interest. For all of our matroids, it is impossible to improve our running time without improving the continuous greedy algorithm itself.
- For graphic matroids on n vertices and m edges, we improve the running time of [12] from $O_\varepsilon(n \log^5 n + m \log^2 n)$ to $O_\varepsilon(m \log^2 n)$.
- We generalize the partition matroids results of [12] to laminar matroids, and match their running time of $O_\varepsilon(n \log^2 n)$ for continuous greedy. As a by-product, we also develop the first data structure that maintains the maximum weight basis on a laminar matroid with $O(\log n)$ update time for insertions and deletions that may be of independent interest. This data structure uses the top tree interface of Alstrup, Holm, de Lichtenberg, and Thorup [2].
- For transversal matroids represented by a bipartite graph with m edges and the ground set being one side of the partition with n vertices, we give an algorithm running in $O_\varepsilon(m \log n + n \log^2 n)$ time.[3] This is the first such fast algorithm for transversal matroids. For this we develop a dynamic matching algorithm in a vertex-weighted, bipartite graph with a weighted vertex sets L and an unweighted vertex set R with the following conditions: (i) There exists a dynamically changing set $S \subseteq L$ such that every vertex in S must be matched in the current matching. (ii) The matching must give both an approximation in terms of cardinality in comparison to the maximum cardinality matching *as well as* the weight of the matching in comparison to the best matching that matches all vertices of S, where the weight of the matching is the sum of the weights of the matched vertices of L.

[3] Any transversal matroid with n elements can be represented as the family of matchable sets the left-hand side of an $n \times n^2$ bipartite graph, with degrees at most n. See Section 2 for more details.

We emphasize that our results are true running times, as opposed to black-box independence queries to the matroid. The only black box operation we need is the query to the objective function $f(S)$.

The performance of the dynamic matching data structure used in our transversal matroid algorithm is interesting as none of the earlier work on dynamic matching can maintain both a constant approximation to the weight as well as to the cardinality of the matching. Our algorithm builds on a recent fast algorithm for maximum-weight matching by Zheng and Henzinger [27]. We briefly mention a few relevant works:

- There is a conditional lower bound based on the OMv conjecture [16] that shows that maintaining a *maximum weight matching* in an edge weighted bipartite graph with only *edge weight increase operations* cannot be done in amortized time $O(n^{1-\delta})$ per edge weight increase and amortized time $O(n^{2-\delta})$ per query operation for any $\delta > 0$ [17]. The reduction from [17] can be adapted to the setting with only *edge weight decrement* operations, achieving the same lower bound. Thus, this shows that our running time bound cannot achieved if a *exact* maximum weight matching has to be maintained under edge weight decrement operations.
- Le, Milenkovic, Solomon, and Vassilevska-Williams [19] studied one-sided vertex updates (insertions and deletions) in bipartite graphs and gave a *maximal matching* algorithm whose total running time is $O(K)$, where K is the total number of inserted and deleted *edges*. Bosek el al. [8] studied one-sided vertex updates (either insertions-only or deletions-only) in bipartite graphs and gave algorithms that for any $\varepsilon > 0$ maintain a $(1-\varepsilon)$-approximate maximum cardinality matching in total time $O(m/\varepsilon)$. Gupta and Peng [15] developed the best known dynamic algorithm that allows both *edge* insertions and deletions and maintains a $(1-\varepsilon)$-approximate maximum cardinality matching (for any $\varepsilon > 0$). It requires time $O(\sqrt{m}/\varepsilon)$ amortized time per operation. For all these algorithms, they either cannot be extended to the weighted setting, or cannot maintain both a constant approximation to the weight as well as to the cardinality of the matching.

1.2 Technical Overview

The submodular optimization framework. Our framework is an adaptation and improvement over that of Ene and Nguyen [12]. The framework consists of two phases:

(1) a LazySamplingGreedy phase, which aims to build a partial solution that either provides a good approximation on its own, or reduces the problem to a residual instance with bounded marginal values of elements.

(2) a ContinuousGreedy phase, which is essentially the original fast continuous greedy algorithm [11, 6], with an improved analysis based on the fact the marginal values are bounded.

The original fast ContinuousGreedy runs in time $O_\varepsilon(nr\log^2 n)$, where the factor of $r\log^2 n$ is due to the cost in evaluating the multilinear extension of f. The multilinear extension is an average over values of f on randomly drawn subsets of the input. In ContinuousGreedy, $O(r\log^2 n)$ samples are needed to estimate the multilinear extension to sufficient accuracy.

The LazySamplingGreedy phase transforms f into a function $\tilde{f}$ such that (a) the number of samples required in ContinuousGreedy for $\tilde{f}$ is reduced by a factor of r and (b) the optimal solution of $\tilde{f}$ is within a $(1-\varepsilon)$ factor of the optimal solution f. LazySamplingGreedy does this by constructing an initial independent set S in our matroid $\mathcal{M}$ such that $\tilde{f}(T) = f(T \cup S)$ has relatively small marginal values. The final solution is obtained by running ContinuousGreedy on $\tilde{f}$ constrained by $\mathcal{M} \setminus S$ and

combining the solution with S. The construction of S relies on a fast data structure to get the maximum weight independent set of $\mathcal{M}$ at any given time, subject to weight changes on each element.

We begin by simplifying and improving the LazySamplingGreedy phase (Section 3.2). A significant part of LazySamplingGreedy in [12] is dedicated to randomly checking and refreshing estimates of marginal values for each element in the matroid. We show that (a) this random checking can be dramatically reduced, and (b) the maximum-weight independent set requirement for the data structure can be relaxed to a constant-factor approximation of the maximum-weight independent set. The relaxation to constant-factor approximations enables us to design much more efficient data structures than the previous work of [12], and also allows us to handle more classes of matroids.

In the ContinuousGreedy phase (Section 3.3), a subroutine requires an independence oracle to check if proposed candidate solutions are independent sets of the matroid. Ene and Nguyen use fully dynamic independence oracles to implement this, where independence queries require $O(\text{polylog } n)$ time. We show that only incremental independence oracles are needed. This opens the door to implementing such oracles for new classes of matroids, as sublinear fully dynamic independence oracles are provably hard in many settings (e.g. bipartite maximum-cardinality matchings are hard to maintain exactly in faster than $O(n^{2-\varepsilon})$ amortized time per update [1], which corresponds to finding the maximum independent set in a transversal matroid).

Dynamic data structures for various matroid constraints. From a data structures point of view, we give the first efficient data structure for two settings. (We refer the reader to Section 2 for definitions of laminar, graphic and transversal matroids.)

Maximum-weight basis in a laminar matroid. In a laminar matroid with n elements we are able to output the maximum-weight basis under an online sequence of insertions and deletions of weighted elements with $O(\log n)$ time per update, which we show to be worst-case optimal. The biggest challenge for laminar matroids is that each element may have as many as $O(n)$ constraints that need to be kept track of on each insertion and deletion. We leverage the tree structure induced by a laminar set system to build data structures. Specifically, we show there exists a data structure with $O(\log^2 n)$ query time using the heavy-light decomposition technique of [24]. Since the heavy-light decomposition technique decomposes the tree into paths, we store some carefully chosen auxiliary information at each vertex to transform our subtree queries into path queries. We further improve this to $O(\log n)$ using the top tree interface of Alstrup, Holm, de Lichtenberg, and Thorup [2] that more naturally support both path and subtree operations using a similar idea of carefully storing the right auxiliary information at each top tree node combined with lazily propagating path changes.

Approximate maximum-weight basis in a transversal matroid. In the case of transversal matroids, our LazySamplingGreedy+ algorithm requires what we call a (c, d)-*approximate maximum weight matching oracle*: a matching that is an c-approximation in weight and at least d of the cardinality of the maximum cardinality matching. In addition, the oracle must implement two update operations, (a) a Freeze operation that adds a vertex of L to S and (b) a Decrement operation that reduces the weight of a vertex of L to a given value. We give a novel algorithm that maintains a maximal (inclusion-wise) matching M in a weighted graph such that the weight of the matching is a $(1-\varepsilon)$-approximation of the max-weight solution in total time $O(m(1/\varepsilon + \log n))$. Thus our algorithm is a $(1-\varepsilon, 1/2)$-approximate maximum weight matching oracle. Due to standard rescaling techniques we can assume that the maximum weight $W = O(n)$.

To illustrate the challenges introduced by FREEZE operations, assume we want to maintain a $(1/2, 1/2)$-approximate maximum weight matching oracle and let $n \geq 5$ be an odd integer. Consider a graph consisting of the path $\ell_0, r_0, \ell_1, r_2, \ldots, \ell_{(n+1)/2}$ of length $n-1$ where the first and last edge have large weight $W<$ say $W = 100n$, and all other edges have weight 1. If the initial $(\Omega(1), \Omega(1))$-approximate matching has greedily picked every second edge, it achieves a weight of $W + \frac{n-1}{2} - 1$ versus an optimum weight of $2W + \frac{n-1}{2} - 2$. Now if the weight of the first edge is halved, the weight of the computed solution drops to $W/2 + \frac{n-1}{2} - 1$, which is no longer a 2-approximation of the weight of the optimum solution (for large enough W). Thus the algorithm needs to match the last edge in order to maintain a 2-approximation to the weight. This would only require two changes to the matching, namely un-matching the edge $(\ell_{(n-1)/2}, r_{(n-1)/2})$ and matching the last edge. However, if prior FREEZE operations added the vertices $\ell_1, \ell_2, \ldots \ell_{(n-1)/2}$ to S, i.e. $S = V \setminus \{\ell_0\}$, then we cannot un-match $\ell_{(n-1)/2}$. Thus, the edge $(\ell_{(n-1)/2}, r_{(n-3)/2})$ needs to be unmatched, which in turn un-matches the vertex $\ell_{(n-3)/2}$, leading to further un-matchings and matchings along the path. More specifically, all $(n-1)/2$ matched edges need to change. Next, the weight of the last edge is divided by 4 and the process along the path starts again. Thus, due to the prior FREEZE operations, each DECREMENT operation can lead to $\Theta(n) = \Theta(m)$ changes in the graph. As this can be repeated $\Theta(\log W) = \Theta(\log n)$ times it shows that work $\Omega(m \log n)$ is unavoidable if a 2-approximation to the weight is maintained with FREEZE operations. This is the running time that we achieve.

More precisely, for any $\varepsilon > 0$, we give an $(1-\varepsilon, 1/2)$-approximate maximum weight matching oracle under FREEZE and DECREMENT operations with total time $O(m(\log n + 1/\varepsilon))$. It follows that $O(m(\log n + 1/\varepsilon))$ is also an upper bound on the number of matching and un-matching operations of the algorithm. To do so we extend a recent algorithm [27] for fast $(1-\varepsilon)$-approximate maximum weight matching algorithm in bipartite graphs based on the multiplicative weight update idea. The analysis within [27] shows stability properties that makes the FREEZE operation trivial to implement. However, LAZYSAMPLINGGREEDY+ requires that the maintained matching is at least $1/2$ the size of the maximum matching. Furthermore, we need to support the DECREMENT operation. We show that both extensions are possible and obtain an algorithm with total time (for all operations) of $O(m(1/\varepsilon + \log n))$.

2 Preliminaries

Set notation shorthands. Given a set $S \subseteq \mathcal{N}$ and an element $u \in \mathcal{N}$, we denote $S \cup \{u\}$ and $S \setminus \{u\}$ by $S + u$ and $S - u$ respectively. Similarly, given sets $S, T \subseteq \mathcal{N}$, we denote $S \cup T$ and $S \setminus T$ by $S + T$ and $S - T$ respectively.

Submodular functions. Given a set $\mathcal{N}$, a set function $f \colon 2^{\mathcal{N}} \to \mathbb{R}$ is called *submodular* if for any two sets S and T we have

$$f(S) + f(T) \geq f(S + T) + f(S - T).$$

We only consider monotone submodular functions, where $f(S) \leq f(T)$ for any sets $S \subseteq T$.

Matroids. A set system is a pair $\mathcal{M} = (\mathcal{N}, \mathcal{I})$, where $\mathcal{I} \subseteq 2^{\mathcal{N}}$. We say that a set $S \subseteq \mathcal{N}$ is *independent* in $\mathcal{M}$ if $S \in \mathcal{I}$. The *rank* of the set system M is defined as the maximum size of an independent set in it. The independent sets must satisfy (i) $S \subseteq T, T \in \mathcal{I} \implies S \in \mathcal{T}$, and (ii) $S, T \in I, |S| < |T| \implies \exists e \in T \setminus S$ such that $S + e \in \mathcal{I}$.

A matroid constraint means that f is optimized over the independent sets of a matroid.

Graphic matroids. Let $G = (V, E)$ be a graph. A graphic matroid has $\mathcal{N} = E$ and $\mathcal{I}$ equal to the forests of G. The rank of $\mathcal{M}$ is $|V| - C$ where C is the number of connected components in G.

Laminar matroids. Let $\{S_1, S_2, \ldots, S_m\}$ be a collection of subsets of a set $\mathcal{N}$ such that for any two intersecting sets S_i and S_j where $i \neq j$, either $S_i \subset S_j$ or $S_j \subset S_i$. Furthermore, let there be non-negative integers $\{c_1, c_2, \ldots, c_m\}$ associated with the S_i's. Let $\mathcal{I}$ be the sets $S \subseteq \mathcal{N}$ for which $|S \cap S_i| \leq c_i$ for all i. $\mathcal{I}$ is then the collection of independent sets in a laminar matroid on $\mathcal{N}$. A laminar matroid has a natural representation as a tree on m nodes, which we describe in the full version.

Transversal matroids. Let $G = ((L, R), E)$ be a bipartite graph with a bipartition of vertices (L, R). Let $\mathcal{I}$ be the collection of sets $S \subseteq L$ such that there is a matching of all vertices in S to $|S|$ vertices in R. A transversal matroid has $\mathcal{N} = L$ and $\mathcal{I}$ as its independent sets. From the definition, it is clear that $\text{rank}(\mathcal{M})$ is the size of the maximum cardinality matching in G. It is known that every transveral matroid can be represented by a bipartite graph where L is the ground set of the matroid and $|R| = \text{rank}(\mathcal{M})$ (see [23], Volume B, equation (39.18)).

3 Improved nearly-linear submodular maximization

In what follows, f is the submodular function we want to maximize, $\mathcal{M}$ is the matroid constraint, n is the number of elements in $\mathcal{M}$, and OPT is the optimal independent set. Additionally, we can assume that $\text{rank}(\mathcal{M}) = \omega(\log n)$, as the standard ContinuousGreedy would run in $O(n \operatorname{polylog} n)$ time otherwise.

Our high-level framework adapts and improves upon the nearly-linear time framework of Ene and Nguyen [12]. We will do the following:

Algorithm 3.1: Overall Framework.

1. Run LazySamplingGreedy+ (see below), to obtain a partial solution S_0.
2. Run ContinuousGreedy on $\tilde{f}(T) = f(S_0 \cup T) - f(S_0)$ with the constraint $\mathcal{M}/S_0$, to obtain a solution S_1.
3. Return $S_0 \cup S_1$.

As previously discussed, the original ContinuousGreedy runs in time $O_\varepsilon(nr \log^2 n)$, where the $r \log^2 n$ is due to the number of samples needed to evaluate the multilinear extension of f. LazySamplingGreedy+ finds a set S_0 such that $\tilde{f}(T) := f(T \mid S_0) = f(S_0 \cup T) - f(S_0)$ has a tighter range of marginal values. This allows us to reduce the number of samples used in ContinuousGreedy by a factor of r.

The overall idea is to run LazySamplingGreedy+ until the marginals in $\tilde{f}$ are small enough to guarantee good performance in the ContinuousGreedy phase of our overall framework (Algorithm 3.1). To accelerate our algorithms, we construct specialized data structures for both LazySamplingGreedy+ and ContinuousGreedy.

3.1 Data structure requirements

We next describe the data structures needed for the two phases of our algorithm. In the LazySamplingGreedy+ phase we need a c-approximate dynamic max-weight independent set oracle. In the CountinuousGreedy phase we have two options of dynamic independence

oracles, both of them unweighted. In addition, our LazySamplingGreedy+ requires the ability to obtain a weighted sample from the approximate max-weight independent set. Since we use these data structures as subroutines in our static algorithm which uses the answers of the data structure to determine future updates, it is important that their running time bounds are valid against an *adaptive* adversary.

Dynamic (c, d)-approximate maximum weight oracle. Let $\mathcal{M} = (E, \mathcal{I})$ be a matroid. Given an independent set $S \subseteq E$ the *independent sets relative to* S are the independent sets of $\mathcal{M}$ that contain S. Let $rank(\mathcal{M})$ denote the size of the largest independent set, which equals the size of the largest independent set containing S. The weight of an independent set is the sum of the weights of its elements. A *maximum weight basis in* $\mathcal{M}$ *relative to* S is a basis B^* that maximizes the sum of w_e over all bases of $\mathcal{M}$ that contain S.

Let $c < 1$ and $d < 1$ be constants. An independent set B is called an (c, d)-*approximate independent set relative to* S if it fulfills the following conditions: (a) its size is at least $\text{rank}(\mathcal{M}) \cdot d$ and (b) its weight is at least a c-approximation to the weight of a maximum weight basis relative to S.

We study the dynamic setting where each element $e \in E$ has a dynamically changing weight $w_e \in \mathbb{R}^+$ and where S is a dynamically growing subset of E. A (c, d)-*approximate dynamic maximum weight oracle* is a data structure which maintains a (c, d)-approximate independent set B relative to S (i.e. in the matroid $\mathcal{M}/S$) while S and the weight of elements not in S can change. Initially S is an empty set and the data structure supports the following operations:

- Freeze(e): Add to S the element e, where e must belong to the current (c, d)-approximate basis relative to (the old) S and return the changes to B.
- Decrement(e, w): Return the weight w_e of $e \notin S$ to w, which is guaranteed to be smaller than the current weight of e and return the changes to B.
- ApproxBaseWeight(): Return the weight of the (c, d)-approximate independent set maintained by this data structure.

If $c = 1$ and $d = 1$ we call such a data structure a *dynamic maximum weight oracle relative to* S.

We will use (c, d)-approximate maximum weight oracles in the LazySamplingGreedy+ phase of the algorithm.

We will also need to augment this data structure with two additional sampling operations. Whenever the independent set B maintained by the data structure changes, we need to spend an extra $O(1)$ time updating a sampling data structure. This sampling data structure can be generically and efficiently implemented to augment any (c, d)-approximate maximum weight oracle as long as the (c, d)-approximate maximum weight oracle does not change the independent set B too much amortized over all calls to the data structure. This is described in the full version of the paper.

- Sample(t): Return a subset of $B \setminus S$, where each element is included independently with probability $\min\left(1, \frac{t}{w(B \setminus S)} w_e\right)$.
- UniformSample(): Return a uniformly random element from $B \setminus S$.

$(1 - \varepsilon)$-approximate independence oracles. For the second phase of our algorithm ContinuousGreedy we have a choice between two data structures. Both of them are unweighted, i.e., elements have no associated weights. We can either use an incremental (i.e. insertions-only) exact data structure or a dynamic $(1 - \varepsilon)$-approximate data structure, for a small $\varepsilon > 0$. Next we define both in more details.

Incremental independence oracle. The incremental independence oracle data structure maintains an independent set B and supports the following operation:

- Test(e): Given an element e, decide if $B \cup \{e\}$ is independent. If so, output YES, otherwise output NO.
- Insert(e): Given an element e such that $B \cup \{e\}$ is independent, add e to B.

$(1-\varepsilon)$-approximate dynamic maximum independent set data structure. Let $\varepsilon > 0$ be a small constant and let us call an independent set B of a matroid $\mathcal{M}$ that contains at least $(1-\varepsilon)\cdot\text{rank}(\mathcal{M})$ elements an $(1-\varepsilon)$-*approximate basis* of $\mathcal{M}$. The $(1-\varepsilon)$-approximate data structure maintains an $(1-\varepsilon)$-approximate basis B for a dynamically changing matroid $\mathcal{M}$ and supports the following operations.

- Batch-Insert(E'): Given a set E' of new elements, insert all elements of E' into the matroid $\mathcal{M}$ and compute a new $(1-\varepsilon)$-approximate basis B such that all elements that were in the basis before the update belong to B. Return all new elements that were introduced to B.
- Delete(e): Given an element e of $\mathcal{M}$, delete e from $\mathcal{M}$ and update the independent set B such that it consists of at least $(1-\varepsilon)\cdot\text{rank}(\mathcal{M})$ elements of the new $\mathcal{M}$. If any new elements were added to B, return this set of new elements. Otherwise, return $\emptyset$.

Depending on which version of the algorithm we use, we will need either an exact incremental oracle or a $(1-\varepsilon)$-approximate dynamic maximum independent set data structure.

3.2 The LazySamplingGreedy+ algorithm

In this section, we describe the implementation of LazySamplingGreedy+.

The LazySamplingGreedy+ algorithm is inspired by the Random Greedy algorithm of Buchbinder, Feldman, Naor, and Schwartz [9] and the Lazy Sampling Greedy algorithm of Ene and Nguyen [12]. The algorithm begins with an initially empty solution S, and runs until the function $\tilde{f}(T) = f(T|S)$ has small enough marginals to reduce the sampling requirements of ContinuousGreedy.

We denote the weight of an element by $w_e(S) := f(S \cup \{e\}) - f(S)$, and weight$(T)$ to denote $\sum_{e\in T} w_e(S)$. The algorithm will only ever add elements to S, so by submodularity, $w_e(S)$ can only decrease as the algorithm runs (satisfying the requirements of Section 3.1). Throughout this algorithm, we use a (c,d)-approximate maximum-weight oracle (Section 3.1) that maintains a maximum-weight independent set B as the weights $w_e(S)$ are updated. For the sake of exposition, we defer proofs to the full version of the paper and assume $c \geq 1/2$, and $d \geq 1/2$.

Discretizing the marginal weights. Whenever S is changed, the weight $w_e(S)$ of all elements e can be changed. To reduce the number of weight changes, we use a standard rounding trick. Assume we have some constant-factor approximation M to $f(OPT)$ (which can be computed in $O(n)$ time via well-known algorithms [10]). Instead of maintaining $w_e(S)$ exactly, we round $w_e(S)$ to one of logarithmically many weight classes, that is, $w_e(S)$ belongs to weight class j if $w_e(S) \in ((1-\varepsilon)^{j+1}M, (1-\varepsilon)^j M]$, with the lowest class containing all weights from $[0, O(\varepsilon M/r)]$. The value of the rounded weight is then $\tilde{w}_e = (1-\varepsilon)^{j_e}$. We denote by *bucket* $\mathcal{B}^{(j)}$ all elements that belong to weight class j. Throughout the algorithm, we maintain estimates $\tilde{j_e}$ for the weight class that e is in (and thus estimates of w_e as well). An estimate is called *stale* if $w_e(S)$ is not actually in the weight class indicated by $\tilde{j_e}$. To achieve a multiplicative error of $(1-\varepsilon)$, it suffices for the number of different weight classes to be at most $O(\varepsilon^{-1}\log(r/\varepsilon))$, where r is the rank of the matroid. We denote by weight(B) the sum of current weight estimates over the set B.

The analysis of our algorithm works with any constant-factor approximation to $f(OPT)$ and any constant c-approximate maximum weight independent set data structure, albeit with slight changes in the approximation factors.

Algorithm 3.2: LazySamplingGreedy+.

$S \leftarrow \emptyset$, and set the weight estimate $\tilde{w}_e$ to $w_e(\emptyset)$ for all $e \in \mathcal{M}$.
$\mathcal{D} \leftarrow (c, d)$-approximate dynamic maximum weight oracle on $\mathcal{M}$ and $\tilde{w}$.

While $\mathcal{D}$.ApproxBaseWeight() $\geq \frac{50}{\varepsilon} f(OPT)$:

1. $B' \leftarrow \mathcal{D}$.Sample($128 \log n$)
   (a random subset of $B \setminus S$, each element included independently with probability $p_e = \min\{1, \frac{128 \log n}{\tilde{w}(B \setminus S)} \tilde{w}_e\}$)
2. Update the weights of all stale elements $e \in B'$ by computing j_e, $\tilde{w}_e = (1-\varepsilon)^{j_e}$ and then calling $\mathcal{D}$.Decrement($e, \tilde{w}_e$).
3. If less than half of the elements in B' where $p_e = 1$ were stale (i.e. needed an update), and less than half of the elements in B' where $p_e < 1$ were stale, then add $e = \mathcal{D}$.UniformSample() to S by calling $\mathcal{D}$.Freeze(e).

Note that in each iteration, we check and update only the weights of some random sample of elements. This is for efficiency; we show the estimated weight $\tilde{w}(B)$ is still correct in expectation up to a constant multiplicative factor. We begin the correctness proof by showing the following lemma.

▶ **Lemma 1.** *Assume $0 < \varepsilon < 1/3$. With high probability, if less than $\frac{1}{2}$ of the estimated weight of B' is in elements which are stale, then*

$$\sum_{e \in B \setminus S} w_e(S) \geq \frac{4}{\varepsilon} f(OPT).$$

Next, we show a bound on the computational complexity of LazySamplingGreedy+.

▶ **Lemma 2.** LazySamplingGreedy+ *uses at most $O(n\varepsilon^{-1} \log(r/\varepsilon))$ arithmetic operations, calls to f, and calls to the maximum weight data structure.*

Next we observe that S cannot have too many elements, otherwise $f(S)$ is close to $f(OPT)$ and we are done.

▶ **Observation 3.** *With high probability, S at the end of the algorithm has at most $\varepsilon r/2$ elements.*

▶ **Theorem 4.** *Let S be the set returned at the end of* LazySamplingGreedy+, *$OPT := \arg\max_{T \in \mathcal{M}} f(T)$, and $OPT^* := \arg\max_{T \in \mathcal{M}/S} f(T|S)$. The following inequality holds:*

$$\mathbf{E}[f(OPT^* \cup S)] \geq (1 - 2\varepsilon) f(OPT).$$

3.3 The ContinuousGreedy algorithm

In this section we discuss our implementation of the ContinuousGreedy algorithm. The basis of our algorithm is the fast implementation from [6], with additional speed-up due to the fact that the LazySamplingGreedy+ stage reduces the marginal values of the remaining elements. The previous section shows that our LazySamplingGreedy+ algorithm runs

with at most $O_\varepsilon(n \log r)$ arithmetic operations, calls to f, and calls to the maximum weight data structure. In this section, we describe how LazySamplingGreedy+ helps the runtime of ContinuousGreedy. The proofs are given in the full version of the paper.

At the termination of LazySamplingGreedy+ it holds that $\tilde{w}(B) \leq \frac{50}{\varepsilon} f(OPT)$. Stale weights in B have true weights lower than its weight estimate $\tilde{w}_e$. Therefore, the true weight of elements of B must be also at most $\frac{50}{\varepsilon} f(OPT)$. Furthermore, since B is a constant-factor approximation to the true maximum weight basis $B^\star$, this implies that $\text{weight}(B^\star) = O(\frac{1}{\varepsilon} f(OPT))$.

Let $\tilde{f}(T) = f(T|S)$, where S is the set output at the termination of LazySampling-Greedy+. We observe that for any set $T \in \mathcal{M}/S$, $\sum_{e \in T} \tilde{f}(e) = O(\frac{1}{\varepsilon} f(OPT))$. When this is the case, [10] (Corollary 3.2) gives the following result:

▶ **Lemma 5** ([10]). ContinuousGreedy *to obtain a* $(1 - 1/e - \varepsilon)$*-approximation uses* $O(n\varepsilon^{-2} \log(n/\varepsilon))$ *independent set data structure operations and* $O(n\varepsilon^{-5} \log^2(n/\varepsilon))$ *queries to* $\tilde{f}$.

In this section, we make two observations that improve the number of independent set queries by a log factor. The inner loop of the ContinuousGreedy algorithm is essentially a greedy algorithm which operates on a function derived from the multilinear extension of $\tilde{f}$: $g(T) = F(\mathbf{x} + \varepsilon \mathbf{1}_T)$ where $F(\mathbf{x}) = \mathbf{E}[\tilde{f}(R)]$, R sampled independently with probabilities x_e. The inner loop of ContinuousGreedy finds an increment of the current fractional solution $\mathbf{x}$ by running a greedy algorithm to approximate a maximum-weight basis with respect to the function g. Let us define $w_e(T) = g(T + e) - g(T)$ to be the marginal values of this function.

A fast implementation of this inner loop is the DescendingThreshold subroutine of Badanidiyuru and Vondrák [6], which also appears in the algorithm of [10]. This subroutine uses the marginal values $w_e(B)$ defined above; the expectation requires $O(\varepsilon^{-1} \log^2(n/\varepsilon))$ samples to estimate for the required accuracy of ContinuousGreedy. In the algorithms below, $w_e(S)$ can be thought of as a black-box that issues $O(\varepsilon^{-1} \log^2(n/\varepsilon))$ calls to the function $\tilde{f}$.

Algorithm 3.3: DescendingThreshold.

$B \leftarrow \emptyset$
$\tau \leftarrow \max_{\{e\} \in \mathcal{M}} w_e(\emptyset)$
While $\tau \geq \frac{\varepsilon}{r} f(O)$:
1. Iterate through $e \in E$ one by one. If $B \cup \{e\} \in \mathcal{I}$ and $w_e(B) \geq \tau$, add e to B. Otherwise, if $B \cup \{e\} \notin \mathcal{I}$, remove e from E.
2. $\tau \leftarrow (1 - \varepsilon)\tau$

Return B

The number of independent set queries in ContinuousGreedy is dominated by the first line of the while loop in DescendingThreshold.

We make two observations about the DescendingThreshold algorithm of Badanidiyuru and Vondrák [6], resulting in two modifications to DescendingThreshold that uses the *incremental independence oracle* and *approximate maximum independent set data structure* outlined in Section 3.1.

▶ **Observation 6.** *Only* $O(n/\varepsilon)$ *independence oracle queries are required. Furthermore, it is sufficient to use an* ***incremental*** **independence oracle.**

Thus, we can modify the DescendingThreshold of [6] by simply ignoring elements that have been previously rejected within the descending threshold greedy subprocedure (see Algorithm 3.4). This yields the following:

▶ **Lemma 7.** ContinuousGreedy *uses* $O(n/\varepsilon)$ *incremental independent set data structure operations and* $O(n\varepsilon^{-5}\log^2(n/\varepsilon))$ *queries to* $\tilde{f}$.

Algorithm 3.4: DT-Incremental.

$\mathcal{D} \leftarrow$ Incremental independence oracle maintaining a set B (Section 3.1)
$\tau \leftarrow \max_{\{e\}\in\mathcal{M}} w_e(\emptyset)$
While $\tau \geq \frac{\varepsilon}{r} f(O)$:
1. $E_\tau \leftarrow \{e \mid w_e(B) \geq \tau, e \in E \setminus B\}$
2. Iterate through $e \in E_\tau$ one by one. If $\mathcal{D}$.Test(e) returns YES and $w_e(B) \geq \tau$, call $\mathcal{D}$.Insert(e) and add e to B. Otherwise, if $B \cup \{e\} \notin \mathcal{I}$, remove e from E.
3. $\tau \leftarrow (1-\varepsilon)\tau$

Return B

An alternative observation

In the case of transversal matroids, exact incremental independence oracle with polylogarithmic update times are not known. Instead, we will make the following observation: An approximate *decremental maximal independent set* data structure can be used instead of an incremental independence oracle. This results in the modification of descending threshold described in Algorithm 3.5.

Algorithm 3.5: DT-ApproxIndepSet.

$\mathcal{D} \leftarrow$ Approximate dynamic maximum independent set data structure maintaining a set B (Section 3.1)
$\tau \leftarrow \max_{\{e\}\in\mathcal{M}} w_e(\emptyset)$
While $\tau \geq \frac{\varepsilon}{r} f(O)$:
1. $E_\tau \leftarrow \{e \mid w_e(B) \geq \tau, e \in E \setminus B\}$
2. $B^+ \leftarrow \mathcal{D}$.Batch-Insert$(E_\tau)$
3. While $B^+ \neq \emptyset$:
   a. Get any $e \in B^+$. If $w_e(B) < \tau$, $D \leftarrow \mathcal{D}$.Delete(e) and set $B^+ \leftarrow B^+ \cup D$.
   b. Remove e from B^+.
4. $\tau \leftarrow (1-\varepsilon)\tau$

Return B

▶ **Observation 8.** *Instead of an incremental independence oracle,* ContinuousGreedy *can be implemented with a decremental approximate maximum independent set data structure. Furthermore,* ContinuousGreedy *will only make* $O(\varepsilon^{-1}\log r)$ *calls to* Batch-Insert *and* $O(n\varepsilon^{-1}\log r)$ *calls to* Delete.

Rounding the fractional solutions. The ContinuousGreedy algorithm makes $O(1/\varepsilon)$ calls to Algorithm 3.3, and outputs a fractional solution that is a convex combination of the $O(1/\varepsilon)$ bases returned by these calls [6]. This fractional solution then needs to be rounded to an integral solution efficiently. In the full version, we show that the data structures we develop can speed up the rounding as well, leading to the overall cost being dominated by the LazySamplingGreedy+ and ContinuousGreedy phases.

3.4 Analysis of the overall framework

▶ **Lemma 9.** *The approximation returned by our framework has approximation ratio at least* $1 - 1/e - \varepsilon$.

Proof. Let S_0 be the set returned by LazySamplingGreedy+. Recall that $\tilde{f}(T) := f(T|S_0)$. By the results in the previous sections, there exists a set $OPT^\star$ such that $OPT^\star \cup S_0$ is independent and $\mathbf{E}[\tilde{f}(OPT^\star)] \geq (1-\varepsilon/2)f(OPT) - f(S_0)$ (by running LazySamplingGreedy+ with $\varepsilon/4$ instead of ε). Running continuous greedy on $\tilde{f}$ yields a $(1-1/e-\varepsilon/2)$-approximation S_1 to $OPT^\star$. Thus the final value of our solution $f(S_0 + S_1)$ is:

$$\begin{aligned}\mathbf{E}[f(S_0 + S_1)] &= \mathbf{E}[\tilde{f}(S_1) + f(S_0)] \\ &\geq (1 - 1/e - \varepsilon/2)\mathbf{E}[\tilde{f}(OPT^\star) + f(S_0)] \\ &\geq (1 - 1/e - \varepsilon/2)(1 - \varepsilon/2)f(OPT) \\ &\geq (1 - 1/e - \varepsilon)f(OPT).\end{aligned}$$

◀

▶ **Observation 10.** *Our framework uses at most:*

- $O(n\varepsilon^{-5}\log^2(n/\varepsilon))$ *calls to the submodular function oracle* f.
- $O(n\varepsilon^{-1}\log(r/\varepsilon))$ *calls to an approximate maximum weight oracle (Section 3.2).*
- *Either* $O(n/\varepsilon)$ *incremental oracle data structure operations or* $O(\varepsilon^{-1}\log r)$ *calls to* BatchInsert *and* $O(n\varepsilon^{-1}\log r)$ *calls to* Delete *on a decremental approximate maximum independent set data structure (Section 3.3).*

The cost of evaluating f is dominated by the ContinuousGreedy phase (see Lemma 7), as LazySamplingGreedy+ only uses $O(n\varepsilon^{-1}\log(r/\varepsilon))$ oracle calls to f, where r is the rank of the matroid (Lemma 2).

4 Data structures for various matroids

In this section, we give dynamic (c, d)-approximate maximum weight oracles and $(1-\varepsilon)$-approximate independence oracles for laminar matroids, graphic matroids, and transversal matroids.

Limitations for further improvements. For both the laminar, graphic, and transversal matroid, the total runtime of the data structure operations in LazySamplingGreedy+ and ContinuousGreedy is $O_\varepsilon(|\mathcal{M}|\log^2|\mathcal{M}|)$, where $|\mathcal{M}|$ is the number of matroid elements. Without improving the original ContinuousGreedy algorithm itself, it is impossible to improve the runtime further. This is because the ContinuousGreedy phase requires at least $O_\varepsilon(|\mathcal{M}|\log^2|\mathcal{M}|)$ oracle calls to f, which is at least $O(1)$ cost in any reasonable model of computing.

Weighted sampling on (c, d)-approximate independent sets. Our (c, d)-approximate maximum weight oracles in Section 3.1 require the ability to sample from the independent set they maintain. This sampling operation can be handled independently from the other operations of the data structure, by augmenting the Decrement and Freeze operations. As this augmentation is the same in all our data structures, we describe it in the full version.

4.1 Laminar matroids

Laminar matroids generalize uniform and partition matroids. In the full version of the paper we present a data structure $\mathcal{D}$ using top trees [2] that maintains a fully dynamic maximum weight basis for a laminar matroid under insertions and deletions of elements with

arbitrary weights in $O(\log n)$ update time. This data structure satisfies the (c, d)-approximate maximum weight oracle requirements with $c = d = 1$ and satisfies the $(1 - \varepsilon)$-approximate independence oracle requirements with $\varepsilon = 0$.

Dynamic maximum weight oracle. The data structure $\mathcal{D}$ maintains the maximum weight basis under insertion and deletions. For FREEZE(e) operations, we don't need to do anything. For DECREMENT(e, w) operations, we can simulate a decrement with the deletion of e and an insertion of e with the changed weight. As we show in the appendix of the full version, deleting and inserting an element removes at most the deleted element and adds at most one element to the maximum weight basis, and thus would never remove a frozen element from the basis whose weight never decreases.

Incremental independence oracle. This data structure can also be used to implement an incremental independence oracle as follows: Run the data structure $\mathcal{D}$ where every element has the same weight and that maintains a maximum basis B. Both TEST and INSERT can easily be handled by our data structure.

4.2 Graphic matroids

A graphic matroid can be represented with a weighted undirected graph $G = (V, E, w)$ where the weight of and edge $e \in E$ is given by $w(e)$.

Dynamic $(1/2, 1/2)$-approximate maximum weight oracle. To obtain an approximate maximum spanning tree of a graph $G = (V, E)$, take the largest edge incident to every vertex, with ties broken according to the edge numbering. For every vertex $v \in V$, let E_v denote the set of edges incident to v. We can store the weights of edges in E_v in a heap H_v and maintain that the maximum element of H_v is part of our approximate maximum spanning tree. It is easy to show that the set of edges maintained, F, is a forest with at least $1/2$ the weights and $1/2$ the number of edges of the optimal maximum spanning tree T.

For the correctness of the algorithm we show first that there cannot be any cycle in F. Assume by contradiction that there is a cycle C in F. Direct each edge in C towards the vertex where it was the maximum weight edge, breaking ties according to the vertex number. If C is a cycle, then C must give a directed cycle, where each edge is larger than the next edge in the directed cycle in the lexicographic order induced by the edge weight and the vertex number. This is a contradiction.

Approximation factor. Root T at an arbitrary vertex and consider the vertices of T starting at the leaves. We will use a simple charging argument to show that F has at least $1/2$ the weight of T and that $|F| \geq |T|/2$. The edge of a vertex v going to its parent u in the tree T can be charged to the largest weight edge leaving v, which is in F. Since each edge of $e \in F$ can be charged at most twice from the two endpoints of e by edges of lesser or the same weight, F has at least half the weight of T and at least half the edges as well.

DECREMENT(e, w): When the weight of an edge $e = (u, v) \in E$ changes to w, we update H_u and H_v accordingly. This may change the maximum weight edge incident to u or v, but we can lookup and accordingly modify our approximate maximum spanning tree with the new maximum weight edge of T_u and T_v in $O(\log n)$ time and report these changes.

FREEZE(e): When we freeze an edge $e = (u, v) \in F$, we can contract the graph along the edge. To do so, we can merge the heaps H_u and H_v and associate the merged heap with the new merged vertex. This can be done in $O(\log n)$ time with binomial heaps or $O(1)$ time using the Fibonacci heaps of Fredman and Tarjan [14]. When we merge two vertices, the maximum weight edge incident to the new merged vertex may be added to the approximate maximum spanning tree.

Incremental independence oracle. Unweighted incremental maximum spanning tree involves checking if inserting any edge increases the size of the spanning tree. This can be done in $O(\alpha(n))$ update and query time with the disjoint set union data structure of Tarjan [24].

4.3 Transversal matroids

Representation of transversal matroids. As stated in Section 2, we assume that our transversal matroids are given as minimal representations. This means that the matroid $\mathcal{M}$ is represented by a bipartite graph $G = ((L, R), E)$ where $|R| = \text{rank}(\mathcal{M})$. For sake of notation let $n = |L|$ and $m = |E|$. As a reminder, each element of the matroid corresponds to a node in L, and an independent set I is a subset of L such that there exists a matching in G that matches every element of I. We will let $N(v)$ denote the neighbors of v in G, that is $N(v) = \{u \mid (u, v) \in E\}$. If $m > n^2$ we can remove neighbours from each vertex in L until their degree is at most n. This doesn't affect whether a vertex belongs to an independent set, as it can always be matched. This reduces m to at most $O(n^2)$.

Dynamic $(1 - \varepsilon, 1/2)$-approximate maximum weight oracles. Recall that in the case of transversal matroids, the weighted setting of LazySamplingGreedy+ leads to a dynamic matching problem on a *vertex-weighted* bipartite graph $G = ((L, R), E)$, where each vertex $\ell \in L$ has a non-negative weight $w(\ell)$ and all edges incident to L have weight $w(\ell)$. We assume that each vertex in L has a value $w_{min} \geq O(w_{max}\varepsilon/n)$ such that we may ignore the weight of any vertex that drops below w_{min}. For the purposes of LazySamplingGreedy+, we stop if the maximum weight basis decreases below $O(f(OPT)) \geq w_{max}$, and so even if we discard all items with weight less than $O(w_{max}\varepsilon/n)$, we can discard at most an ε fraction of $f(OPT)$. Thus after appropriate multiplicative rescaling, we may assume that $w_{min} = 1$ and $w_{max} = (1 + \varepsilon)^k$ for $k = O(\log_{1+\varepsilon} n)$. Furthermore we may assume that the weight of any $\ell \in L$ is $(1+\varepsilon)^j$ for some $j \geq 0$ as we can round all weights in the range of $[(1+\varepsilon)^j, (1+\varepsilon)^{j+1}]$ down to the nearest $(1 + \varepsilon)^j$ and lose only a $(1 + \varepsilon)^{-1}$ factor in the value of the solution.

We will design a data structure that maintains a matching M such that whenever a Decrement(ℓ, w) operation is performed on $\ell \in L$, then ℓ will be the only node of L that may potentially become unmatched in M. We will call a data structure that has this property *L-stable*. The basis we output will be the set of nodes of L matched in M. Note that L-stable data structures can handle the Freeze operation by not doing anything and always returning an empty set. No frozen element will be removed from the basis because frozen elements are never decremented.

The high level idea of our algorithm is as follows: We want to maintain a maximal matching according to some weights, as this guarantees that at least half as many nodes of L are matched as in the optimum solution. The question is just which weights to choose and which algorithm to use to guarantee maximality while fulfilling L-stability. Note that L-stability allows edges in the matching to change, just un-matching a matched vertex of L is forbidden. For this reason we chose an algorithm that is greedy for the vertices in R, i.e., each vertex in R is matched with a neighbor of largest weight for a suitable choice of weight. In order to maintain the invariant at every vertex r of R our greedy algorithm allows r to "steal" the matched neighbor l of another vertex r' of R. This maintains L-stability as l remains matched. However, the newly un-matched vertex r' might want to steal l right back from r. To avoid this, we do not use the original weights in the greedy algorithm, but instead we use "virtual weights" that are initialized by the original weights and that decrease by a factor of $(1 + \varepsilon)$ whenever l is (re-)matched. This makes l less attractive for r' and, as l

is never re-matched when its weight is below 1, it also guarantees that l is only re-matched $\tilde{O}_\varepsilon(1)$ times in total over all decrement operations. For formal details and the proof, see the full version of the paper.

▶ **Theorem 11.** *Given a bipartite graph $G = ((L, R), E)$ and a value w_{min}, there exists a L-stable data structure that handles* Decrement *operations and maintains a $(1-\varepsilon, 1/2)$-approximate maximum weighted matching provided that the maximum weighted matching has cost at least w_{min}. The total running time for preprocessing and all operations as well as the total number of changes to the set of matched vertices is $O(|E|(1/\varepsilon + \log|L|))$. Furthermore, the matching maintained is maximal.*

$(1-\varepsilon)$-approximate dynamic maximum independent set data structure. The fastest known algorithm for incremental maximum bipartite matching takes $O(m\sqrt{n})$ total time [8]. However, given a bipartite graph $G = (L, R)$ there is a $(1-\varepsilon)$-approximate maximum matching data structure $\mathcal{D}_M$ for deletions of vertices in L [8]. It has three properties that are crucial for our algorithm: (1) It does not unmatch a previously matched vertex of L as long as it is not deleted, (2) it maintains an explicit integral matching, i.e., it stores at each vertex whether and if so, along which edge it is matched, and (3) the total time for computing the initial matching and all vertex deletions is $O((m + |L|)/\varepsilon)$, where m is the number of edges in the initial graph.

Given an initial graph G_0 and a partial matching B of G_0 this algorithm can be modified to guarantee that the initial $(1-\varepsilon)$-approximate matching computed for G_0 matches all vertices of $B \cap L$. See teh full version of the paper for details. We use this data structure $\mathcal{D}_M$ to implement a $(1-\varepsilon)$-approximate dynamic maximum independent set data structure for the transversal matroid as follows:

Batch-Insert(E'): Let B be the $(1-\varepsilon)$-approximate matching before the update. Initialize a new data $\mathcal{D}_M$ with all current elements and compute an initial $(1-\varepsilon)$-approximate matching computed for G_0 matching all vertices in $B \cap L$. This is possible by the discussion above.

Delete(e): Execute a vertex deletion of vertex e in $\mathcal{D}_M$.

Test(e): Return YES if e is matched and NO otherwise.

▶ **Lemma 12.** *Given a transversal matroid there exists a $(1-\varepsilon)$-approximate dynamic maximum independent set data structure such that each* Batch-Insert*(B, E_1, E_2) and all* Delete *operations until the next* Batch-Insert *take $O((m' + |E_1| + |E_2|)/\varepsilon)$ total worst-case time and each* Test *operation takes $O(1)$ worst-case time.*

Twin-Width of Planar Graphs Is at Most 8, and at Most 6 When Bipartite Planar

Petr Hliněný
Masaryk University, Brno, Czech republic

Jan Jedelský
Masaryk University, Brno, Czech republic

Abstract

Twin-width is a structural width parameter introduced by Bonnet, Kim, Thomassé and Watrigant [FOCS 2020]. Very briefly, its essence is a gradual reduction (a contraction sequence) of the given graph down to a single vertex while maintaining limited difference of neighbourhoods of the vertices, and it can be seen as widely generalizing several other traditional structural parameters. Having such a sequence at hand allows us to solve many otherwise hard problems efficiently. Graph classes of bounded twin-width, in which appropriate contraction sequences are efficiently constructible, are thus of interest in combinatorics and in computer science. However, we currently do not know in general how to obtain a witnessing contraction sequence of low width efficiently, and published upper bounds on the twin-width in non-trivial cases are often "astronomically large".

We focus on planar graphs, which are known to have bounded twin-width (already since the introduction of twin-width), but the first explicit "non-astronomical" upper bounds on the twin-width of planar graphs appeared just a year ago; namely the bound of at most 183 by Jacob and Pilipczuk [arXiv, January 2022], and 583 by Bonnet, Kwon and Wood [arXiv, February 2022]. Subsequent arXiv manuscripts in 2022 improved the bound down to 37 (Bekos et al.), 11 and 9 (both by Hliněný). We further elaborate on the approach used in the latter manuscripts, proving that the twin-width of every planar graph is at most 8, and construct a witnessing contraction sequence in linear time. Note that the currently best lower-bound planar example is of twin-width 7, by Král' and Lamaison [arXiv, September 2022]. We also prove that the twin-width of every bipartite planar graph is at most 6, and again construct a witnessing contraction sequence in linear time.

1 Introduction

Twin-width is a relatively new structural width measure of graphs and relational structures introduced in 2020 by Bonnet, Kim, Thomassé and Watrigant [10]. Informally, twin-width of a graph measures how diverse the neighbourhoods of the graph vertices are. E.g., *cographs* – the graphs which can be built from singleton vertices by repeated operations of a disjoint union and taking the complement, have the lowest possible value of twin-width, 0, which means that the graph can be brought down to a single vertex by successively identifying twin vertices. (Two vertices x and y are called *twins* in a graph G if they have the same neighbours in $V(G) \setminus \{x, y\}$.) Hence the name, *twin-width*, for the parameter.

Importance of this new concept is clearly witnessed by numerous recent papers on the topic, such as the follow-up series [5–9, 11] and more related research papers represented by, e.g., [1, 2, 4, 13, 15, 20].

Twin-width definition. In general, the concept of twin-width can be considered over arbitrary binary relational structures of a finite signature, but here we will define it and deal with it for only finite *simple graphs*, i.e., graphs without loops and multiple edges. A *trigraph* is a simple graph G in which some edges are marked as *red*, and with respect to the red edges only, we naturally speak about *red neighbours* and *red degree* in G. However, when speaking about edges, neighbours and/or subgraphs without further specification, we count both ordinary and red edges together as one edge set denoted by $E(G)$. The edges of G which are not red are sometimes called (and depicted) black for distinction. For a pair of (possibly not adjacent) vertices $x_1, x_2 \in V(G)$, we define a *contraction* of the pair x_1, x_2 as the operation creating a trigraph G' which is the same as G except that x_1, x_2 are replaced with a new vertex x_0 (said to *stem from* x_1, x_2) such that:

- the (full) neighbourhood of x_0 in G' (i.e., including the red neighbours), denoted by $N_{G'}(x_0)$, equals the union of the neighbourhoods $N_G(x_1)$ of x_1 and $N_G(x_2)$ of x_2 in G except x_1, x_2 themselves, that is, $N_{G'}(x_0) = (N_G(x_1) \cup N_G(x_2)) \setminus \{x_1, x_2\}$, and
- the red neighbours of x_0, denoted here by $N^r_{G'}(x_0)$, inherit all red neighbours of x_1 and of x_2 and add those in $N_G(x_1) \Delta N_G(x_2)$, that is, $N^r_{G'}(x_0) = \big(N^r_G(x_1) \cup N^r_G(x_2) \cup (N_G(x_1) \Delta N_G(x_2))\big) \setminus \{x_1, x_2\}$, where Δ denotes the symmetric set difference.

A *contraction sequence* of a trigraph G is a sequence of successive contractions turning G into a single vertex, and its *width* d is the maximum red degree of any vertex in any trigraph of the sequence. We also then say that it is a d-contraction sequence of G. The *twin-width* of a trigraph G is the minimum width over all possible contraction sequences of G. In other words, a graph has twin-width at most d, if and only if it admits a d-contraction sequence.

To define the twin-width of an ordinary (simple) graph G, we consider G as a trigraph with no red edges.

Algorithmic aspects. Twin-width, as a structural width parameter, has naturally many algorithmic applications in the FPT area. Among the most important ones we mention that the first order (FO) model checking problem – that is, deciding whether a fixed first-order sentence holds in an input graph – can be solved in linear FPT-time [11]. This and other algorithmic applications assume that a contraction sequence of bounded width is given alongside with the input graph. Deciding the exact value of twin-width (in particular, twin-width 4) is in general NP-hard [4], but for many natural graph classes we know that they are of bounded twin-width. However, published upper bounds on the twin-width in non-trivial cases are often non-explicit or "astronomically large", and it is not usual that we could, alongside such a bound, compute a contraction sequence of provably "reasonably small" width efficiently and practically. We pay attention to this particular aspect; and we will accompany our fine mathematical upper bounds on the twin-width with rather simple linear-time algorithms for computing contraction sequences of the claimed widths.

Twin-width of planar graphs. The fact that the class of planar graphs is of bounded twin-width was mentioned already in the pioneering paper [10], but without giving any explicit upper bound on the twin-width. The first explicit (numeric) upper bounds on the twin-width of planar graphs have been published only quite recently; chronologically on arXiv, the bound of 183 by Jacob and Pilipczuk [18], of 583 by Bonnet, Kwon and Wood [12]

(this paper more generally bounds the twin-width of k-planar graphs by asymptotic $2^{\mathcal{O}(k)}$), and of 37 by Bekos, Da Lozzo, Hliněný, and Kaufmann [3] (this paper more generally bounds the twin-width of so-called h-framed graphs by $\mathcal{O}(h)$).

It is worth to mention that all three papers [3, 12, 18], more or less explicitly, use the product structure machinery of planar graphs (cf. [14]). We have then developed an alternative decomposition-based approach, leading to a single-digit upper bound of 9 for all planar graphs in [16], followed by an upper bound of 6 on the twin-width of *bipartite* planar graphs thereafter. However, the approach of [16] seems to be stuck right at 9, and new ideas were needed to obtain further improvements, even by 1.

Here we give the following strengthened upper bound, which uses an improved approach over previous [16] and also simplifies some cumbersome technical details of the former:

▶ **Theorem 1.** *The twin-width of any simple planar graph is at most* 8*, and a corresponding contraction sequence can be found in linear time.*

It is worth to note that, recently, Král' and Lamaison [19] have found a construction (with a proof) of a planar graph with twin-width 7. Hence, the lower bound is by just one off our upper bound, but the right maximum value (7 or 8?) is still an open question.

In an addition, we also prove an upper bound for bipartite planar graphs, which follows from an adaptation of our new techniques specially to the bipartite case. While the bipartite-case bound stays the same as in previous [16], its proof is significantly simpler now.

▶ **Theorem 2.** *The twin-width of any simple* bipartite *planar graph is at most* 6*, and a corresponding contraction sequence can be found in linear time.*

Due to space restrictions, proofs of the *-marked statements are left for the full paper [17].

2 Notation and Tools

We start with a few technical definitions and claims needed for the proofs.

BFS layering and contractions. Let G be a *connected* graph and $r \in V(G)$ a fixed vertex. The *BFS layering of G determined by r* is the vertex partition $\mathcal{L} = (L_0 = \{r\}, L_1, L_2, \ldots)$ of G such that L_i contains all vertices of G at distance exactly i from r. A path $P \subseteq G$ is *r-geodesic* if P is a subpath of some shortest path from r to any vertex of G (in particular, P intersects every layer of $\mathcal{L}$ in at most one vertex). Let T be a *BFS tree* of G rooted at the vertex r as above (that is, for every vertex $v \in V(G)$, the distance from v to r is the same in G as in T). A path $P \subseteq G$ is *T-vertical*, or shortly *vertical* with respect to implicit T, if P is a subpath of some root-to-leaf path of T. Notice that a T-vertical path is r-geodesic, but the converse may not be true. Analogously, an edge $e \in E(G)$ is *horizontal* (with respect to implicit $\mathcal{L}$) if both ends of G are in the same $\mathcal{L}$-layer.

Observe the following trivial claim (cf. also Claim 5):

▷ Claim 3. For every edge $\{v, w\}$ of G with $v \in L_i$ and $w \in L_j$, we have $|i - j| \leq 1$, and so a contraction of a pair of vertices from L_i may create new red edges only to the remaining vertices of $L_{i-1} \cup L_i \cup L_{i+1}$.

Plane graphs; Left-aligned BFS trees. We will deal with *plane graphs*, which are planar graphs with a given (combinatorial) embedding in the plane, and one marked *outer face* (the remaining faces are then *bounded*). A plane graph is a *plane triangulation* if every face of its embedding is a triangle. Likewise, a plane graph is a *plane quadrangulation* if every face of

its embedding is of length 4. It is easy to turn an embedding of any simple planar graph into a simple plane triangulation by adding vertices and incident edges into each non-triangular face. Furthermore, twin-width is non-increasing when taking induced subgraphs, and so it suffices to focus on plane triangulations in the proof of Theorem 1, and to similarly deal with plane quadrangulations in the proof of Theorem 2.

For algorithmic purposes, we represent a plane graph G in the standard combinatorial way – as a graph (the vertices and their adjacencies) with the counter-clockwise cyclic orders of the incident edges of each vertex, and we additionally mark the outer face of G.

In this planar setting, consider now a plane graph G, and a BFS tree T spanning G and rooted in a vertex r of the outer face of G, and picture (for clarity) the embedding G such that r is the vertex of G most at the top. For two adjacent vertices $u, v \in V(G)$, $\{u, v\} \in E(G)$, we say that u *is to the left of* v (wrt. T) if neither of u, v lies on the vertical path from r to the other, and the following holds; if r' is the least common ancestor of u and v in T and $P_{r',u}$ (resp., $P_{r',v}$) denote the vertical path from r' to u (resp., v), then the cycle $(P_{r',u} \cup P_{r',v}) + uv$ has the triple (r', u, v) in this counter-clockwise cyclic order.

A BFS tree T of G with the BFS layering $\mathcal{L} = (L_0, L_1, \ldots)$ is called *left-aligned* if there is no edge $f = uv$ of G such that, for some index i, $u \in L_{i-1}$ and $v \in L_i$, and u is to the left of v (an informal meaning is that one cannot choose another BFS tree of G which is "more to the left" of T in the geometric picture of G and T, such as by picking the edge uv instead of the parental edge of v in T).

▶ **Lemma 4.** *Given a simple plane graph G, and a vertex r on the outer face, there exists a left-aligned BFS tree of G and it can be found in linear time.*

Proof. For this proof, we have to extend the above relation of "being left of" to edges emanating from a common vertex of G. So, for an arbitrary BFS tree T of G and edges $f_1, f_2 \in E(G)$ incident to $v \in V(G)$, such that neither of f_1, f_2 is the parental edge of v in T, we write $f_1 \leq_l f_2$ if there exist adjacent vertices $u_1, u_2 \in V(G)$ such that u_1 is to the left of u_2, the least common ancestor of u_1 and u_2 in T is v and, for $i = 1, 2$, the edge f_i lies on the vertical path from u_i to v. Observe the following; if f_0 is the parental edge of v in T (or, in case of $v = r$, f_0 is a "dummy edge" pointing straight up from r), then $f_1 \leq_l f_2$ implies that the counter-clockwise cyclic order around v is (f_0, f_1, f_2). In particular, $\leq_l$ can be extended into a linear order on its domain.

We first run a basic linear-time BFS search from r to determine the BFS layering $\mathcal{L}$ of G. Then we start the construction of a left-aligned BFS tree $T \subseteq G$ from $T := \{r\}$, and we recursively (now in a "DFS manner") proceed as follows:

- Having reached a vertex $v \in V(T) \subseteq V(G)$ such that $v \in L_i$, and denoting by $X := (N_G(v) \cap L_{i+1}) \setminus V(T)$ all neighbours of v in L_{i+1} which are not in T yet, we add to T the nodes X and the edges from v to X.
- We order the vertices in X using the cyclic order of edges emanating from v to have it compatible with $\leq_l$ at v, and in this increasing order we recursively (depth-first, to be precise) call the procedure for them.

The result T is clearly a BFS tree of G. Assume, for a contradiction, that T is not left-aligned, and let $u_1 \in L_{i-1}$ and $u_2 \in L_i$ be a witness pair of it, where $\{u_1, u_2\} \in E(G)$ and u_1 is to the left of u_2. Let v be the least common ancestor of u_1 and u_2 in T, and let v_1 and v_2 be the children of v on the T-paths from v to u_1 and u_2, respectively. So, by the definition, $vv_1 \leq_l vv_2$ at v, and hence when v has been reached in the construction of T, its child v_1 has been taken for processing before the child v_2. Consequently, possibly deeper in the recursion, u_1 has been processed before the parent of u_2 and, in particular, the procedure has added the edge u_1u_2 into T, a contradiction to u_1 being to the left of u_2.

This recursive computation is finished in linear time, since every vertex of G is processed only in one branch of the recursion, and one recursive call takes time linear in the number of incident edges (to v). ◀

Notice that we have not assumed G to be a triangulation in the previous definition and in Lemma 4, which will be useful for the case of bipartite planar graphs.

Vertex levels in contraction sequences. We are going to work with contraction sequences which, preferably, preserve the BFS layers of $\mathcal{L}$ of connected G. However, we do *not always* preserve the layers, and so we need a notion which is related to the layers of $\mathcal{L}$, but it can differ from these layers when needed – informally, when this "causes no harm at all". For the graph G itself, we define $\lambda[G](v) = i$ if and only if $v \in L_i \in \mathcal{L}$. If G' is a trigraph along a contraction sequence of G, and a vertex $v' \in V(G')$ stems from a set $X \subseteq V(G)$ by (possible) contractions, then $\lambda[G'](v')$ equals the minimum i such that $L_i \cap X \neq \emptyset$. We say that $\lambda[G'](v')$ is the *level of* v' *in* G' along the considered contraction sequence of G, or simply the *level of* v' when the particular graph of a sequence is implicit. In other words, we can inductively say that if v'' of G'' results by the contraction of u' and v' of G', then $\lambda[G''](v'') := \min(\lambda[G'](u'), \lambda[G'](v'))$. If w' does not participate in a contraction along the subsequence from G' to G'', then $\lambda[G''](w') := \lambda[G'](w')$.

A *partial contraction sequence* of G is defined in the same way as a contraction sequence of G, except that it does not have to end with a single-vertex graph. A partial contraction sequence of G is *level-respecting* if every step contracts, in a trigraph G' along the sequence, only a pair $x, y \in V(G')$ such that the following inductively holds; the levels of x and y are the same, i.e. $\lambda[G'](y) = \lambda[G'](x)$, or all neighbours of y (red or black) in G' are on the same level as x is on, i.e. $\lambda[G'](z) = \lambda[G'](x)$ for all z such that $\{y, z\} \in E(G')$. (The conditions in the latter case, in particular, imply that $\lambda[G'](y) = \lambda[G'](x) + 1$; cf. Claim 5.)

Usefulness of level-respecting contraction sequences lies in the subsequent claim. Informally, we may say that our levels in G' behave analogously to the BFS layers of G; the levels form a layering (in the usual sense), albeit not ncessarily a BFS layering.

▷ Claim 5. Let a trigraph G' result from a level-respecting partial contraction sequence of a connected graph G. Then any vertex $z \in V(G')$ may have neighbours (red or black) only on the levels $\lambda[G](z) - 1$, $\lambda[G](z)$ and $\lambda[G](z) + 1$. Moreover, z must have some neighbour on the level $\lambda[G](z) - 1$.

Proof. We proceed easily by induction. The claim is trivial from the definition of a BFS layering when $G' = G$ and G is connected. Assume that $z \in V(G'')$ results from a contraction of a pair $x, y \in V(G')$, where $\lambda[G''](z) = \lambda[G'](x)$. Then $\lambda[G'](y) \in \{\lambda[G'](x), \lambda[G'](x) + 1\}$ by the definition of a level-respecting contraction and connectivity of G. So, there cannot be any neighbour of z on the levels lower than $\lambda[G''](z) - 1 = \lambda[G'](x) - 1$ from the induction. Regarding levels higher than $\lambda[G''](z) + 1$, they cannot host any neighbour of x in G' by the induction, and no neighbour of y as well by the definition of a level-respecting contraction (if $\lambda[G'](y) = \lambda[G'](x) + 1$). Lastly, since x has a neighbour on the level $\lambda[G''](z) - 1$ in G', so does z in G''. ◁

3 Proof of Theorem 1

3.1 Induction setup for a bounded region of the graph

Our main proof proceeds by induction on suitably defined subregions of the assumed plane triangulation G. In this subsection, we define the setup of this induction in Lemma 6, and show how it will imply the main result.

For a plane graph G and its cycle C, the *subgraph of G bounded by C*, denoted by G_C, is the subgraph of G formed by the vertices and edges of C and the vertices and edges of G drawn inside C – formally, in the region of the plane bounded by C and not containing the outer face. Let the vertices in the set $U := V(G_C) \setminus V(C)$ be called the *interior vertices* of C. We call a set $U_0 \subseteq U$ an *interior section of C* in G if all neighbours of vertices of U_0 belong to $U_0 \cup V(C)$ (in other words, U_0 is a collection of connected components of $G[U]$).

Consider a now fixed BFS tree T of G. Assume that a cycle C of G is formed as $C = (P_1 \cup P_2) + f$, where P_1 and P_2 are two T-vertical paths of length at least 1 with a common end $u \in V(P_1) \cap V(P_2)$ and $f \in E(G)$ is an edge joining the other ends v_1 of P_1 and v_2 of P_2. Observe that u is the (unique) vertex of G_C closest to the root r of T. Then we say that C is a *V-separator* in G with respect to implicit T ('V' as vertical), and we call u the *sink of C* and f the *lid of C*. If the vertices u, v_1, v_2 lie on C in this counter-clockwise order (equivalently, if v_1 is to the left of v_2 with respect to T), then we say that P_1 is the *left path* of C and P_2 is the *right path* of C (picture the sink at the top).

▶ **Lemma 6.** *Let G be a simple plane triangulation, and T be a left-aligned BFS tree of G rooted at a vertex $r \in V(G)$ of the outer triangular face and defining the initial levels $\lambda[G](\cdot)$. Assume that a cycle C of G is a V-separator of G, that G_C is the subgraph of G bounded by C, and u is the sink of C. Let the distance of u from the root r be ℓ, so $\lambda[G](u) = \ell$, and the maximum distance from a vertex of C to r be $m \geq \ell + 1$. Let $U \subseteq V(G_C)$ be an interior section of C in G, and denote by $W := V(G) \setminus (V(C) \cup U)$ the set of the "remaining" vertices.*

Then there exists a level-respecting partial contraction sequence of G which contracts only pairs of vertices that are in or stem from U, results in a trigraph G^*, and satisfies the following conditions for every trigraph G' along this sequence from G to G^*:

- **(I)** *For $U' := V(G') \setminus (V(C) \cup W)$ (which are the vertices that are in or stem from U in G'), every vertex of U' in G' has red degree at most 8,*
- **(II)** *every vertex of the left path of C has at most 5 red neighbours and every vertex of the right path of C has at most 3 red neighbours in U',*
- **(III)** *the sink u of C has no red neighbour in U', and if the least level of a vertex of U in G is $k \geq \ell + 2$, then the vertices of C on levels up to $k - 2$ in G have no red neighbours in U' as well and each of the (two) vertices of C on the level $k - 1$ in G has at most 1 red neighbour in U', and*
- **(IV)** *at the end of the partial contraction sequence, for the set $U^* := V(G^*) \setminus (V(C) \cup W)$ that stems from U in G^*, we have that if $z \in U^*$ is of level i, then $\ell < i \leq \max(m, \ell+2)$ and z is the only vertex in U^* of level i.*

Before proceeding further, we comment on two important things. First, we remark that, in Lemma 6, all vertices of U have the distance from r greater than ℓ, but on the other hand the distance from r to some vertices in U may be much larger than m (and our coming proof is aware of this possibility). Second, we observe that all vertices of U on level $\ell + 1$ must be adjacent to the sink u, since all other potential neighbours of them have the distance from r greater than ℓ. Consequently, contracting U on level $\ell + 1$ into one vertex within the claimed sequence indeed does not create a red edge to u, as long as we do not contract into it from higher levels (which we will explicitly avoid in the proof). We illustrate Lemma 6 in Figure 1.

We also observe that the assumptions and conditions of Lemma 6 directly imply some other properties useful for the coming proofs.

▷ Claim 7. *Respecting the notation and assumptions of Lemma 6, we also have that:*

- **(V)** *Every red edge in G' has one end in U' and the other end in $U' \cup V(C)$,*
- **(VI)** *if P_1 and P_2 are the left and right paths of C, respectively, and $v \in V(P_2)$ is of level j in G', then there is no edge of G' (red or black) from v to a vertex of $U' \cup (V(P_1) \setminus \{u\})$ of level $j - 1$ in G',*

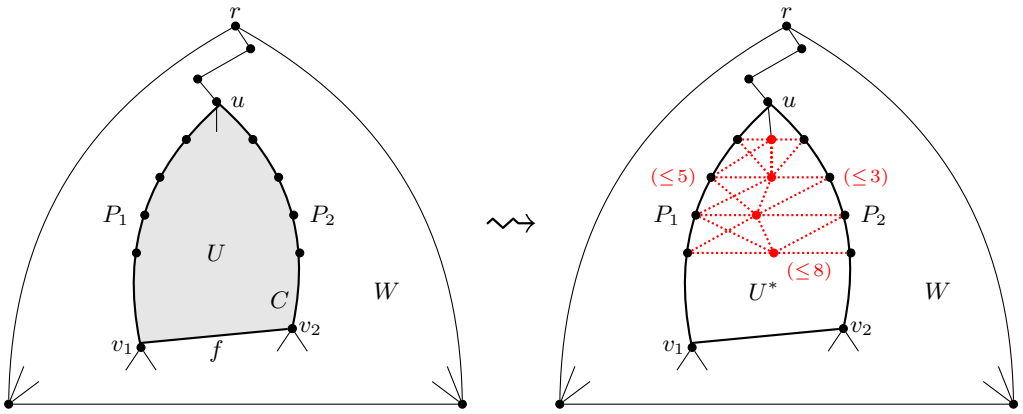

Figure 1 (left) The setup of Lemma 6, where P_1 and P_2 are the left and right paths of the chosen V-separator C. (right) The outcome of the claimed partial contraction sequence which contracts only vertices of U inside the shaded region from the left, and which maintains bounded red degrees in the region and on its boundary C. No other vertex than the sketched ones is affected by the contraction sequence. Not all depicted red edges do exist, and some of them may actually be black.

(VII) *at the end, that is, in G^*, every vertex of the left path of C has at most 3 red neighbours and every vertex of the right path of C has at most 2 red neighbours in U^*.*

Proof. Regarding (V), observe that since only vertices that stem from U participate in contractions, every red edge of G' must have an end in U'. Furthermore, since U is an interior section of C, no vertex of U is adjacent to a vertex of W in G, and hence no vertex of W is ever adjacent to a vertex being contracted in our sequence from G to G^*.

Concerning (VI), if v were adjacent to $x \in V(P_1)$ of level $j-1$, then this was already true in G; $\{x,v\} \in E(G)$. If v were adjacent to $x' \in U'$ of level $j-1$ in G', then, among the vertices of U contracted into x', there had to be $x \in U$ such that $\{x,v\} \in E(G)$. By the definition of a level-respecting sequence, possible vertices of level higher than $j-1$ contracted into x' cannot be adjacent to v of level j, and so $\lambda[G](x) = j-1$, too. Since, in both cases, such x would be to the left of v in G, this contradicts the assumption that T is left-aligned.

Finally, (VII) directly follows from Claim 5 and (IV) for the left path of C. For the right path we additionally apply (VI), which for $x \in V(P_2)$ of level j says that potential red neighbours of x are only on levels j and $j+1$. ◁

We also show how Lemma 6 implies the first part of our main result:

Proof of Theorem 1 (the upper bound). We start with a given simple planar graph H, and extend any plane embedding of H into a simple plane triangulation G such that H is an induced subgraph of G. Then we choose a root r on the outer face of G and, for some left-aligned BFS tree of G rooted in r which exists by Lemma 4, the facial cycle C of the outer face incident to r, and $u = r$, we apply Lemma 6.

This way we get a partial contraction sequence from G to a trigraph G^* of maximum red degree 8 (along the sequence). Observe by (IV) that the set $U^* = V(G^*) \setminus V(C)$ contains only two vertices, on levels 1 and 2. In the final phase, we may hence pairwise contract the remaining vertices in an arbitrary order. The restriction of this whole contraction sequence of G to only $V(H)$ then certifies that the twin-width of H is at most 8. ◀

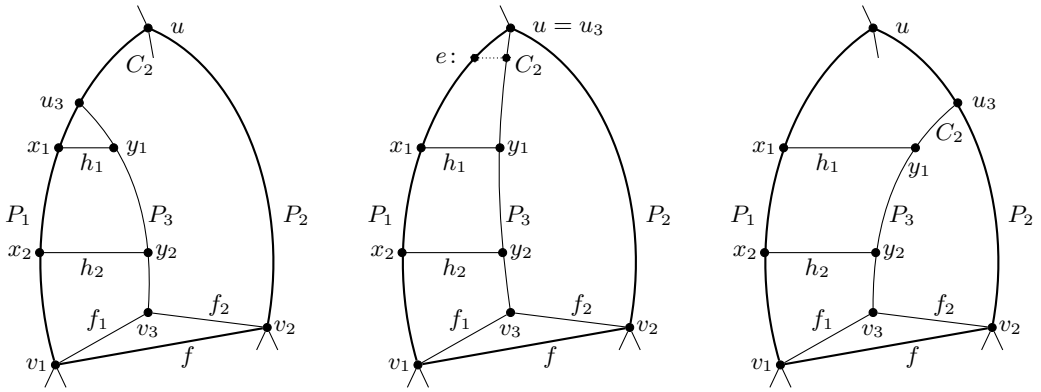

Figure 2 Three schematic cases of the vertical-horizontal division of G_C discussed in Section 3.2. The (possible) dotted horizontal edge e in the middle case is not counted as h_1 since no vertex of U is on a level above it in the picture.

3.2 Vertical-horizontal division into subregions

In order to apply induction in the proof of Lemma 6, we need to decompose the considered subgraph into suitable subregions, based on the plane drawing. Here we formulate the general decomposition step, while possible degenerate cases will be handled later in Section 3.3.

Let C be a V-separator in the plane triangulation G, formed by the left path P_1, the right path P_2 and the lid edge $f = \{v_1, v_2\}$ where v_i is an end of P_i. Let G_C be the subgraph bounded by C and $U \subseteq V(G_C)$ be an interior section of C in G. Moreover, assume that there exists a triangular face in G incident to f with the vertices v_1, v_2, v_3 where $v_3 \in U$, and that the T-vertical path from v_3 to the root r contains neither v_1 nor v_2. In particular, since T is left-aligned, we have that $\lambda[G](v_2) \leq \lambda[G](v_1)$ and $\lambda[G](v_3) \leq \lambda[G](v_1)$. Under these assumptions, we are going to define the *vertical-horizontal division* of G_C as follows.

Let $P \subseteq T$ be the vertical path connecting v_3 to the root r where, by $r \notin U$ and planarity of G, we have that P contains the sink u. Let $P_3 \subseteq P$ be the subpath of P from v_3 to the first vertex $u_3 \in V(P) \cap V(C)$ shared with the cycle C. We have $u_3 \neq v_3$. (It may be that $u_3 \in V(P_1)$ or $u_3 \in V(P_2)$ or even $u_3 = u$; see in Figure 2.) Let P_{31} denote the subpath of P from v_3 to the first intersection x with P_1 ($x \in \{u_3, u\}$), and P_{11} the subpath of P_1 from v_1 till x. Similarly, let P_{32} denote the subpath of P from v_3 to the first intersection y with P_2, and P_{22} be the subpath of P_2 from v_2 till y. Let $f_1 = \{v_1, v_3\}$ and $f_2 = \{v_2, v_3\}$. Observe that $P_{31}, P_{32} \subseteq G_C$, and that $C_1 := (P_{11} \cup P_{31}) + f_1$ and $C_2 := (P_{22} \cup P_{32}) + f_2$ are again V-separators in G, such that P_{31} is the right path of C_1 and P_{32} is the left path of C_2.

Furthermore, let $h_1, \ldots, h_a$, $a \geq 0$, be the collection of all horizontal edges of G_C such that, for $h_i = \{x_i, y_i\}$, we have $x_i \in V(P_1)$, $y_i \in V(P_3) \setminus V(C)$ and $\lambda[G](x_i) = \lambda[G](y_i)$, and that $\lambda[G](z) \leq \lambda[G](x_i) - 1$ holds for some $z \in U$ (the reason for this strange-looking restriction is in property (III) of Lemma 6). These edges $h_1, \ldots, h_a$ are ordered by their increasing level $\lambda[G](x_i)$. This is illustrated in Figure 2 (where the ordering of h_i's is top-down). For $i = 1, \ldots, a$, let $C_{1,i-1}$ denote the cycle passing through the sink of C_1 (which is u_3 or u) and formed by relevant subpaths of P_{11}, P_{31} and the edge h_i. Let $C_{1,a} = C_1$. Let $U_{1,0}$ denote the set of the interior vertices of $C_{1,0}$ in G, and for $i = 1, \ldots, a$, let $U_{1,i} := X \setminus U_{1,i-1}$ where X is the set of the interior vertices of $C_{1,i}$ in G. Let U_2 denote the set of the interior vertices of C_2 in G.

The system of the cycles $C_{1,0}, \ldots, C_{1,a}, C_2$ and of the sets $U_{1,0}, \ldots, U_{1,a}, U_2$ is called the *vertical-horizontal division* of G_C. The following is straightforward from the definition:

▷ Claim 8. For $i = 0, 1, \ldots, a$, the cycle $C_{1,i}$ is a V-separator in G, and each vertex of $U_{1,i}$ has neighbours only in $U_{1,i} \cup V(C_{1,i})$. Hence, $U_{1,i}$ is an interior section of $C_{1,i}$. Consequently, for every $z \in U_{1,i}$ where $i \geq 1$, we have $\lambda[G](z) \geq \lambda[G](x_i) + 1$ (where $\{x_i, y_i\} = h_i$ above).

The intended purpose of a vertical-horizontal division in the proof of Lemma 6 is to start the induction step, as precisely formulated in the next lemma with a straightforward proof:

▶ **Lemma 9.** *Assume the notation and assumptions of Lemma 6 for the graph G, cycle C and set U, and consider the vertical-horizontal division of the subgraph G_C as defined above; that is, the cycles $C_{1,0}, \ldots, C_{1,a}, C_2$ and the sets $U_{1,0}, \ldots, U_{1,a}, U_2$. Then the following hold:*
a) Each cycle $C^1 \in \{C_{1,0}, \ldots, C_{1,a}, C_2\}$ and the corresponding set $U^1 \in \{U_{1,0}, \ldots, U_{1,a}, U_2\}$ satisfy the assumptions of Lemma 6 (in the place of C and U).
b) Let $\tau_{1,i}$, $i = 0, \ldots, a$, denote the level-respecting partial contraction sequence of G claimed by Lemma 6 for the input as in (a) $C^1 := C_{1,i}$ and $U^1 := U_{1,i}$, and likewise, τ_2 be that for the input $C^1 := C_2$ and $U^1 := U_2$. Then the concatenated partial contraction sequence $\sigma_0 := \tau_2 \cdot \tau_{1,0} \cdot \ldots \tau_{1,a}$, i.e., one starting with τ_2 and ending with $\tau_{1,a}$, again satisfies the properties (I), (II) *and* (III) *of Lemma 6.*

Proof. Part (a) immediately follows from the definition and Claim 8.

In part (b), we first argue that the concatenation σ_0 is well-founded; that contractions in one of the subsequences of σ_0 have no effect on vertices being contracted in another of the subsequences. This is since, by Claim 8, neighbours of contracted pairs of one subsequence are only in the interior section of the same subsequence or on the bounding cycles which together form $V(C) \cup V(P_3)$ (and the latter set is not participating in the contractions of σ_0).

Following on the previous argument, we have that the only vertices of G_C that may potentially receive red edges from more than one of the subseqeunces forming σ_0, are those of $V(C) \cup V(P_3)$. See Figure 2. For all other vertices of G_C, we have that (I) is true for them along whole σ_0 since it has been true for them along their subsequences of σ_0.

For a vertex $z \in V(P_3) \setminus V(C)$, we see that z belongs to C_2 and to each of $C_{1,i}, \ldots, C_{1,a}$ for some $i \in \{0, \ldots, a\}$. However, even if $i \leq a - 2$, vertices of $U_{1,i+2}$ cannot be neighbours of z in G_C due to a combination of Claim 5 and Claim 8. Therefore, z may have neighbours (and so can get red edges from by contractions) only in the interior sections U_2 and $U_{1,i}$, and possibly in $U_{1,i+1}$ if z is an end of the horizontal edge h_{i+1}. Recall also that z belongs to the right path of $C_{1,i}$. Along the sequence σ_0, but before $\tau_{1,i+1}$, the vertex z has red degree at most $5 + 3 = 8$ by (II) applied to U_2 and $U_{1,i}$. After $\tau_{1,i}$ is finished, z has red degree at most $3 + 2 = 5 < 8$ by (VII) of Claim 7. So, along the rest of σ_0, (I) stays true for z with red degree at most $5 + 1 = 6$ by (III) applied possibly to $U_{1,i+1}$.

For the vertex u itself, (III) is true automatically. For $z \in V(P_1) \setminus \{u\}$ and $i \in \{0, \ldots, a\}$ being the least index such that $z \in V(C_{1,i})$, we get that the properties are true along $\tau_{1,i}$ and before by (II), and since $\tau_{1,i}$ ends, the vertex z has at most 3 red neighbours in $U_{1,i}$ by (VII). Additionally, z may get at most 1 red neighbour in $U_{1,i+1}$ (and none in $U_{1,i+2}, \ldots$) by (III), altogether at most 4, satisfying (II). In the special case of $z \in V(P_1) \setminus \{u\}$ covered by property (III) with respect to C, that is when all vertices belonging to the interior of C_1 are on levels higher than $\lambda[G](z)$, we get that this property is satisfied by (III) with respect to $C_{1,i}$, and there are no more red neighbours of z from elsewhere.

Finally, for $z \in V(P_2) \setminus \{u\}$, the conditions are simply true by (II) and possibly (III) for τ_2 and then along the whole sequence σ_0. ◀

3.3 Finishing the proof

Now we get to the core proof of Lemma 6 which will conclude our main result.

Proof of Lemma 6. We first resolve several special cases. If $U = \emptyset$, we are immediately done with the empty partial contraction sequence. So, assume $U \neq \emptyset$.

Recall the edge $f = \{v_1, v_2\} \in E(G)$ connecting the other ends of the left path P_1 and the right path P_2 of C. See again Figure 2. If v_1 has no neighbour in U, then $\{v_2, v_3\} \in E(G)$ where v_3 is the neighbour of v_1 on P_1. In such case, we simply apply Lemma 6 inductively to $P_1 - v_1$ and P_2, while the rest of the assumptions remain the same. The symmetric argument is applied when v_2 has no neighbour in U.

Otherwise, let $v_3 \in U$ be the vertex (unique in U) such that (v_1, v_2, v_3) bound a triangular face of G. Let $P \subseteq T$ be the vertical path connecting v_3 to the root r. If $v_1 \in V(P)$, then $P \supset P_1$ and we (similarly as above) apply Lemma 6 inductively to the V-separator $C^1 = P \cup P_2$ with the lid $\{v_2, v_3\}$, while the rest of the assumptions again remain the same. Note that in this case, $\lambda[G](v_1) = \lambda[G](v_3) - 1 = \lambda[G](v_2)$ since T is left-aligned. In the resulting trigraph G^1, we have the set $U^1 := V(G^1) \setminus (V(C^1) \cup W)$ that stems by contractions from the interior of C^1. There is no vertex in U^1 of level higher than $\lambda[G](v_3) \geq 2$ and at most one of level equal to $\lambda[G](v_3)$, by (IV) of Lemma 6. We contract the latter vertex with v_3, and then with the vertex of U^1 of the previous level $\lambda[G](v_1)$ unless v_1 is a neighbour of u (cf. the special case in (IV)). This clearly does not exceed red degree 8 there, and does not add new potential red neighbours to the vertices of C. Since (IV) is now satisfied, too, we are done. If $v_2 \in V(P)$, we solve the case similarly by induction applied to the V-separator $C^1 = P_1 \cup P$ with the lid $\{v_1, v_3\}$.

In all other cases, we have got a vertical-horizontal division of the subgraph G_C, with $P_3 \neq \{v_3, u\}$, with the horizontal edges $h_1, \ldots, h_a$, $h_i = \{x_i, y_i\}$, the cycles $C_{1,0}, \ldots, C_{1,a}, C_2$ and the interior sets $U_{1,0}, \ldots, U_{1,a}, U_2$, and we apply Lemma 9 to it. This way we get a level-respecting partial contraction sequence σ_0, which satisfies the properties (I), (II) and (III) of Lemma 6. Let G^0 denote the trigraph which results from G by σ_0, and let $U^0_{1,0}, \ldots, U^0_{1,a}, U^0_2$ denote the vertex sets of G^0 that stem from $U_{1,0}, \ldots, U_{1,a}, U_2$, respectively.

We first consider a subcase, that P_3 consists of a single edge $\{v_3, u_3\}$ and there is no vertex $z \in U$ in G such that $\lambda[G](z) \leq \lambda[G](u_3)$. This subcase has to be treated specially to fulfill (III) of Lemma 6. Then $a = 0$ in the vertical-horizontal division of G_C, and $\lambda[G](v_1) \leq \lambda[G](v_3) + 1 = \lambda[G](u_3) + 2$. Each of the sets $U^0_{1,0}$ and U^0_2 hence contains vertices at most on the levels $\lambda[G](v_3)$ and $\lambda[G](v_3) + 1$, by (IV) of Lemma 6.

We finish the desired partial contraction sequence from G^0 in this subcase by firstly contracting the two (if existing) vertices of $U^0_{1,0} \cup U^0_2$ on the level $\lambda[G](v_3) + 1$, and secondly by contracting each of the vertices of $U^0_{1,0} \cup U^0_2$ on the level $\lambda[G](v_3)$ with v_3. If $u_3 = u$ is the sink of C, then the only vertex on the level $\lambda[G](v_3) - 1 = \lambda[G](u)$ in G_C is u, and so every vertex of $U^0_{1,0} \cup U^0_2$ on the level $\lambda[G](v_3)$ must be adjacent to u (cf. Claim 5), and this is by a black edge due to an inductive invocation of (III). Therefore, the contractions into v_3 do not create a red edge to u. If $u_3 \neq u$, then let u'_3 denote the other vertex of $P_1 \cup P_2$ on the level $\lambda[G](u_3)$. Analogously to the previous case, one of the contractions into v_3 does not create a red edge to $\{u_3, u'_3\}$ and the other contraction can do so, but at most one red edge to each of u_3, u'_3. Therefore, (IV) is true here, and the remaining properties of Lemma 6 are fulfilled easily.

In the remaining cases, we possibly add the following bit in a sequence σ_1 after σ_0 (while this bit has not been possible in the special subcase above): If $u_3 \in V(P_1) \setminus \{u\}$ and u_3 is a neighbour of both x_1, y_1 (of h_1), then $U^0_{1,0}$ by (IV) consists of at most two vertices, which we

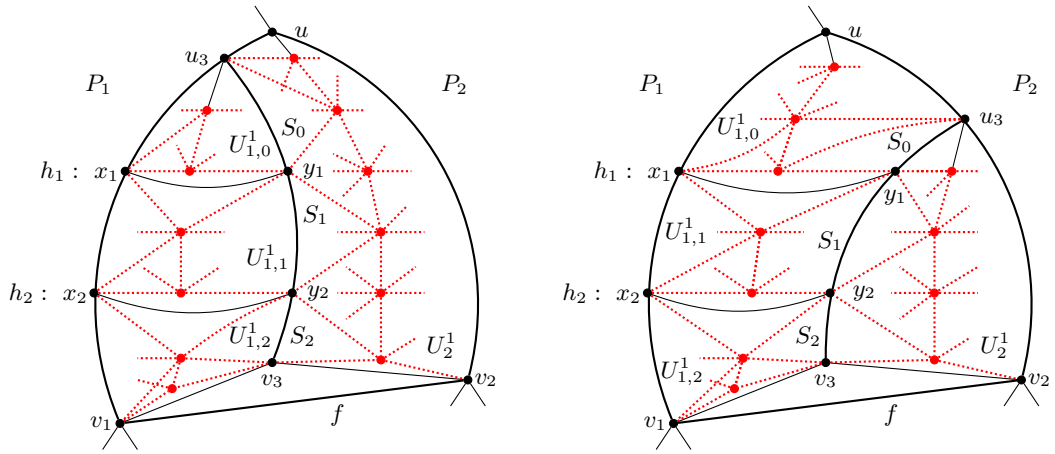

Figure 3 Proof of Lemma 6: a schematic picture of the situation after the parts of the depicted vertical-horizontal division of G_C have been recursively contracted (right before the σ_2-contractions start). The cases of u_3 on the left and right paths are not symmetric in general.

contract into one vertex in σ_1 – this move adds one red edge incident to u_3. Analogously, if $u_3 \in V(P_2) \setminus \{u\}$ and u_3 is a neighbour of both v_2, v_3 (of f_2), then we contract the at most two vertices of U_2^0 into one within σ_1. Although this contraction in σ_1 does not preserve levels, it is level-respecting by Claim 5 since $U_{1,0}$ and U_2 were interior sections of the triangles $C_{1,0}$ and C_2, respectively. In both cases, the added red edge incident to u_3 does not violate the properties of Lemma 6; this follows from the bounds in (VII) of Claim 7 which are by at least one lower than the bounds in (II) of Lemma 6, and property (III) is void for u_3 unless we have got the previous special subcase. Otherwise, we leave $\sigma_1 = \emptyset$.

After applying σ_1 to $U_{1,0}^0, \ldots, U_{1,a}^0, U_2^0$ in G^0, we get the trigraph G^1 and the sets $U_{1,0}^1, \ldots, U_{1,a}^1, U_2^1$ (which are identical to the former ones except possibly $U_{1,0}^0$ or U_2^0). See Figure 3.

In the next steps, we are going to define level-respecting partial contraction sequences $\sigma_{2,a}, \sigma_{2,a-1}, \ldots, \sigma_{2,0}$ which, when concatenated after $\sigma_0 \cdot \sigma_1$, give the desired outcome. If $a = 0$, the sequence $\sigma_{2,0}$ is going to contract the sets $U_{1,0}^1$ with $S_0 := V(P_3) \setminus \{u_3\}$ and $U_{2,0}^1 := U_2^1$. If $a > 0$, the sequence $\sigma_{2,a}$ is going to contract $U_{1,a}^1$ with the sets S_a and $U_{2,a}^1$, where $S_a \subseteq V(P_3) \setminus \{u_3\}$ and $U_{2,a}^1 \subseteq U_2$ are both the subsets of those vertices on levels greater than $\lambda[G](y_a)$. The sequence $\sigma_{2,i}$ for $0 \leq i < a$ is going to contract $U_{1,i}^1$ with the sets S_i and $U_{2,i}^1$, where $S_i \subseteq V(P_3) \setminus \{u_3\}$ and $U_{2,i}^1 \subseteq U_2^1$ are the subsets of those vertices on levels greater (if $i \geq 1$) than $\lambda[G](y_i)$ and not greater than $\lambda[G](y_{i+1})$. Of course, some of these sets may be empty, and hence some contractions may not happen.

Specifically, for $i \in \{0, \ldots, a\}$ let $p = \max_{z \in C_{1,i}} \lambda[G](z)$ and $q = 1 + \min_{z \in C_{1,i}} \lambda[G](z)$. Observe that there is no vertex in $U_{1,i}^1 \cup U_{2,i}^1$ of level lower than q or greater than p. This follows from an inductive invocation of (IV) of Lemma 6, and from the sequence σ_1. So, the union $U_1^1 := U_{1,0}^1 \cup \ldots \cup U_{1,a}^1$ has at most one vertex on each level. Likewise, each of the sets $V(P_3)$ and U_2^1 has at most one vertex on each level. The sequence $\sigma_{2,i}$ first runs over $j = p, p-1, \ldots, q$ in this order, and contracts the pair of vertices of $S_i \cup U_{2,i}^1$ of the equal level j in G^1 (or nothing if there is at most one such vertex there). In its second round, $\sigma_{2,i}$ again runs over $j = p, p-1, \ldots, q$ in this order, and contracts the vertex of level j that stems from $S_i \cup U_{2,i}^1$ in the first round, with the vertex of $U_{1,i}^1$ of equal level j in G^1.

Let σ_2 be the concatenation of the described sequences, $\sigma_2 := \sigma_{2,a} \cdot \sigma_{2,a-1} \cdot \ldots \sigma_{2,0}$ in this order, and G^2 denote the trigraph which results from G^1 by applying σ_2. Let $U^2 := V(G^2) \setminus (V(C) \cup W)$ denote the contracted vertices in the interior of C in G^2. Then G^2 and U^2 satisfy property (IV) of Lemma 6 (in the place of G^* and U^*), which is immediate from the previous definition of σ_2. It thus remains to verify the properties (I), (II) and (III) of Lemma 6 along the sequence σ_2 from G^1 to G^2, that is, for every trigraph G' along σ_2.

Denote by $U' := V(G') \setminus (V(C) \cup W)$ all interior vertices of C in G', and by $U'' := U' \setminus V(G^1)$ the (new) interior vertices that stem by σ_2-contractions from G^1 to G', and recall (from Section 3.2) that $P_{31} \supseteq P_3$ is the right path of C_1 and $P_{32} \supseteq P_3$ is the left path of C_2 in G_C.

We start with verification of (III) which has already been in parts addressed above. Regarding the sink vertex u, it has got red edges neither from the sequence σ_0 by an inductive invocation of (III), nor from the sequence σ_1. The vertices of C on levels up to $k-2$ as in (III) do not have any neighbour in U' by Claim 5. Consider the vertices $z, z' \in V(C)$ on the level $k-1$ as in (III) (if $k \geq \ell + 2$ there). If $\lambda[G](u_3) \geq k$, then no contraction on the level k happens within σ_2 (Figure 3), and so z and z' have each at most one red edge to U' by an inductive invocation of (III). Otherwise, up to symmetry, $z' = u_3$. Similarly as argued earlier in this proof, u_3 then has a black edge to $U^1_{1,0}$ (if $u_3 \in V(P_1)$) or to U^1_2 (if $u_3 \in V(P_2)$) in G^1, and so the contraction on the level k incident with this black edge does not create a new red edge to either of z, u_3. At the same time, each of z, u_3 has at most one red edge in G^1 by an inductive invocation of (III), and this stays true also (with the set U') during and after contractions on the level k within σ_2.

We move towards verification of (I). Let $z \in U'$ for the rest. If $z \in U^1_2$, then no σ_2-contraction has touched z so far. In this case z may have red edges to up to 3 vertices of $V(P_2) \cup U^1_2 \cup V(P_{32})$ of level $\lambda[G^1](z) - 1$, to 2 vertices of $V(P_2) \cup V(P_{32})$ of level $\lambda[G^1](z)$, and to 2 vertices of $V(P_{32}) \cup U^1_2 \cup U''$ of level $\lambda[G^1](z) + 1$, altogether at most 7. Note that there is no edge from z to the vertex of P_2 of level $\lambda[G^1](z) + 1$ by (VI) of Claim 7. If $z \in V(P_3) \setminus \{u_3\}$, then similarly, z may have red edges to up to $2 + 2$ vertices of $U^1_1 \cup U^1_2$ on the levels $\lambda[G^1](z) - 1$ and $\lambda[G^1](z)$, and to up to 2 vertices of $U^1_1 \cup U^1_2 \cup U''$ on the level $\lambda[G^1](z) + 1$. The case of $z \in U^1_1$ (not-yet touched by a σ_2-contraction) is similarly easy.

Assume now that $z \in U''$ has been created in G' by a contraction of $z_2 \in U^1_2$ and $z_3 \in V(P_3) \setminus \{u_3\}$ (i.e., within the first round of some $\sigma_{2,i}$ above), but z is not contracted with a vertex of U^1_1 yet. Let $t \in V(P_1) \setminus V(P_3)$ denote the possible (unless equal to u_3) vertex of P_1 of level $\lambda[G^1](z_3) - 1$. Then there is no edge in G^1 from t to z_2 by planarity, and no from t to z_3 by (VI) of Claim 7. The same applies to the possible vertex $t' \in U^1_1$ of level $\lambda[G^1](z_3) - 1$. Consequently, z may have red edges to up to 3 vertices of $V(P_2) \cup U^1_2 \cup V(P_{32})$ of level $\lambda[G'](z) - 1$, to 3 vertices of $V(P_2) \cup V(U^1_1) \cup V(P_1)$ of level $\lambda[G'](z)$, and to up to 3 vertices of $U'' \cup V(U^1_1) \cup V(P_1)$ of level $\lambda[G'](z)+1$, again using (VI). This sums to $3+3+3 = 9$, but we are going to show that this maximum of 9 cannot be achieved. Let $z_1 \in V(P_1)$ be such that $\lambda[G'](z_1) = \lambda[G'](z)$. If $\{z_1, z_3\} \notin E(G)$, then no red edge $\{z_1, z\}$ is created by the current contraction and the sum is at most 8, as needed. If $\{z_1, z_3\} = h_i \in E(G)$, then the sequence $\sigma_{2,i}$ has already contracted $S_i \cup U^1_{1,i}$ into U'', and so there are only 2 red neighbours of z in $U'' \cup V(P_1)$ on the level $\lambda[G'](z) + 1$, again summing to at most 8. If $\{z_1, z_3\} \in E(G)$, but $\{z_1, z_3\}$ has not been chosen as any h_i in the vertical-horizontal division above, then there are no vertices in $U^1_2 \cup (V(P_3) \setminus \{u_3\})$ on the level $\lambda[G'](z) - 1$, and so the sum is at most 8.

Assume that $z \in U''$ has already been created in G' by a contraction of all vertices in $U^1_2 \cup V(P_3) \cup U^1_1$ of the same level. Let this contraction be part of $\sigma_{2,i}$ for some $0 \leq i \leq a$. Then z may have red edges to up to 2 vertices of $V(P_2) \cup V(P_1)$ of level $\lambda[G'](z)$, to 2

vertices of $U'' \cup V(P_1)$ of level $\lambda[G'](z)+1$ (but not to $V(P_2)$ due to (VI)), and to vertices of $V(P_2) \cup U_2^1 \cup V(P_3) \cup V(U_1^1) \cup U'' \cup V(P_1) =: Y$ of level $\lambda[G'](z)-1$. However, at most 4 of the vertices of Y are potential red neighbours of z (so summing to at most 8), as we now show. If contractions on the level $\lambda[G'](z)-1$ are part of $\sigma_{2,i}$, too, then red neighbours of z in Y of level $\lambda[G'](z)-1$ actually belong to $V(P_2) \cup U'' \cup V(U_1^1) \cup V(P_1)$ with an upper bound of 4. Otherwise, if contractions on the level $\lambda[G'](z)-1$ are part of $\sigma_{2,i-1}$, then there is no edge from z to a vertex of U_{i-1}^1, or U_{i-1}^1 on the level $\lambda[G'](z)-1$ has already been contracted into U'', too. Then red neighbours of z in Y of level $\lambda[G'](z)-1$ belong to $V(P_2) \cup U_2^1 \cup V(P_3) \cup V(P_1)$ or to $V(P_2) \cup U'' \cup V(P_1)$, and we again get a bound of 4.

Finally, we want to verify (II) of Lemma 6. Consider $z \in V(P_2) \setminus \{u\}$. By the definition of σ_2, the vertex z may have at most one red neighbour of each level in U' (at any moment of σ_2). Then the bound of at most 3 red edges from z to U' follows immediately in view of Claim 5. Consider now $z \in V(P_1) \setminus \{u\}$, which is a bit more complicated case. On each of the levels $\lambda[G^1](z)-1$, $\lambda[G^1](z)$ and $\lambda[G^1](z)+1$ of U', there are clearly at most 2 red neighbours of z. Although, we now show that the maximum sum of 6 cannot be achieved. If $z = u_3$, then there is actually at most red neighbour of z on the level $\lambda[G^1](z)-1$. Otherwise, we denote the following vertices of G^1 of level $\lambda[G^1](z)+1$ by z_1, z_2, z_3 such that $z_1 \in U_1^1$, $z_2 \in U_2^1$, $z_3 \in V(P_3)$, and $\lambda[G^1](z_1) = \lambda[G^1](z_2) = \lambda[G^1](z_3) = \lambda[G^1](z)+1$. Then z_3 has no edge to $z \neq u_3$ by (VI) of Claim 7, and z_2 has no edge to z by planarity. If $z_3 \in U'$ (i.e., not contracted yet), then only z_1 may be a red neighbour of z. If z_2 and z_3 have already been contracted in G', but $z_1 \in U'$, then the new vertex again has no edge to z. Finally, if all of z_1, z_2, z_3 have been contracted in G', then U' has only (this) one vertex of level $\lambda[G^1](z)+1$. In any case, z has at most 5 red neighbours in U'.

We have verified all conditions of Lemma 6 for the partial contraction sequence $\sigma_0 \cdot \sigma_1 \cdot \sigma_2$, and so we can set $G^* := G^2$ and the proof is done. ◀

Proof of Theorem 1 (the algorithmic part). We can construct a simple plane triangulation $G \supseteq H$ in linear time using standard planarity algorithms, and then construct a left-aligned BFS tree $T \subseteq G$ again in linear time by Lemma 4. In the rest, we straightforwardly implement the recursive vertical-horizontal division of G as used in the proof of Lemma 6, and construct the contraction sequence of H on return from the recursive calls as defined in the proof. Note that we do not need at all to construct the intermediate trigraphs along the constructed contraction sequence, and so the construction of the sequence is very easy – each recursive call returns just a simple list of the vertices which stem from the recursive contractions, indexed by the levels. Then these (up to) two lists are easily in linear time "merged" together with the dividing path P_3, as specified by the proof of Lemma 6, into the resulting list of this call.

We may account total runtime in the "division part" of the algorithm to the edge(s) of v_3 into v_1 or v_2 and the edges of the path P_3 starting in v_3 in each call of the recursion, and these edges are not counted multiple times in different branches of the recursion. Likewise, runtime of the "merging" part of each recursive call can be counted to the individual steps of the resulting contraction sequence, which is of linear length. Hence, altogether, the algorithm runs in linear time. ◀

4 Proof of Theorem 2

On a high level, the proof will still proceed in the same way as in [16], and will prove the same bound. However, there are significant changes in the technical details, in which ideas from the previous section can save a lot of difficulties of the cumbersome proof from [16].

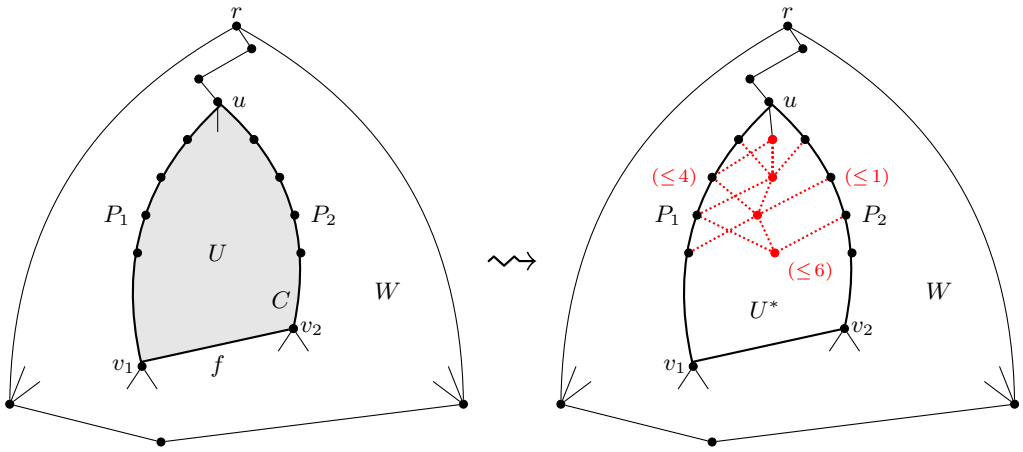

Figure 4 (left) The setup of Lemma 11, where P_1 and P_2 are the left and right paths of the chosen V-separator C. (right) The outcome of the claimed partial contraction sequence which contracts only vertices of U inside the shaded region from the left, and which maintains bounded red degrees in the region and on its boundary C.

In a nutshell, the bipartite case carries two major differences from the proof of the general planar case in Section 3:

- Since our graph is now bipartite, we will work with a plane quadrangulation (instead of a triangulation). However, with a suitable detailed analysis, it does not bring any significant new challenges to the proof.
- Since, again, our graph is bipartite, we immediately get that in any BFS layering, each layer is an independent set, and so we will never create a red edge inside the same layer. This is the crucial saving which allows us to derive a better upper bound on the red degree along the constructed sequence.

Before proceeding further, we need to adjust the concept of a level-respecting contraction sequence (beacuse of the fact that the definition from Section 2 possibly allowed to create new (red) edges inside the same level).

A partial contraction sequence of G is *bi-level-respecting* if every step contracts, in a trigraph G' along the sequence, only a pair $x, y \in V(G')$ such that the following inductively holds; the levels of x and y are the same, i.e. $\lambda[G'](y) = \lambda[G'](x)$, or all neighbours of y (red or black) in G' are on the level $\lambda[G'](x) + 1$, i.e. $\lambda[G'](z) = \lambda[G'](x) + 1$ is true for all z such that $\{y, z\} \in E(G')$. Again, we easily get by induction as in Claim 5:

▷ Claim 10. Let a trigraph G' result from a bi-level-respecting partial contraction sequence of a bipartite connected graph G. Then any vertex $z \in V(G')$ may have neighbours (red or black) only on the levels $\lambda[G](z) - 1$ and $\lambda[G](z) + 1$. In particular, the trigraph G' is again bipartite. Moreover, z must have some neighbour on the level $\lambda[G](z) - 1$.

Our proof is again by induction, precisely as set up in the following lemma. We illustrate this lemma in Figure 4. Before starting, note that a plane quadrangulation is always bipartite, and so it has all cycles (not only the faces) of length at least 4.

▶ **Lemma 11.*** *Let G be a simple plane quadrangulation, and T be a left-aligned BFS tree of G rooted at a vertex $r \in V(G)$ of the outer face and defining the initial levels $\lambda[G](\cdot)$. Assume that a cycle C of G is a V-separator of G, that G_C is the subgraph of G bounded by C, and u*

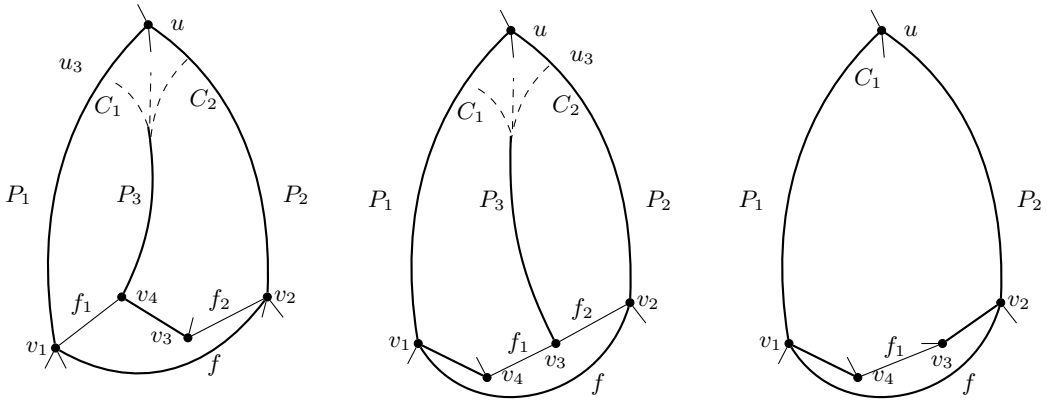

Figure 5 Three schematic cases of decomposing the drawing of G_C into subregions (bounded by C_1 and C_2) discussed in Lemma 13. They generally cover all possibilities in which $v_3, v_4 \notin V(P_1 \cup P_2)$. Vertical positions of the vertices of the 4-cycle $A = (v_1, v_2, v_3, v_4)$ outline their levels in G. Note that, in the right-most case, we have only one "nested" V-separator C_1, which is however not equal to $C = (P_1 \cup P_2) + f$, but instead C_1 passes through v_2, v_3, v_4, v_1 and has the lid edge $f_1 = \{v_3, v_4\}$.

is the sink of C. Let the distance of u from the root r be ℓ, so $\lambda[G](u) = \ell$, and the maximum distance from a vertex of C to r be $m \geq \ell + 2$. Let $U := V(G_C) \setminus V(C)$ be the interior vertices of C, and denote by $W := V(G) \setminus (V(C) \cup U)$ the set of the "remaining" vertices.

Then there exists a bi-level-respecting partial contraction sequence of G which contracts only pairs of vertices that are in or stem from U, results in a trigraph G^*, and satisfies the following conditions for every trigraph G' along this sequence from G to G^*:

- **(I)'** *For $U' := V(G') \setminus (V(C) \cup W)$ (which are the vertices that are in or stem from U in G'), every vertex of U' in G' has red degree at most 6,*
- **(II)'** *every vertex of the left path of C has at most 4 red neighbours and every vertex of the right path of C has at most 1 red neighbour in U',*
- **(III)'** *the sink u of C has no red neighbour in U',*
- **(IV)'** *if the next step of the sequence is going to contract a pair $x, y \in U'$ such that $\lambda[G'](y) > \lambda[G'](x)$, then y has no neighbour in the right path of C, and*
- **(V)'** *at the end of the partial contraction sequence, for the set $U^* := V(G^*) \setminus (V(C) \cup W)$ that stems from U in G^*, we have that if $z \in U^*$ is of level i, then $\ell < i \leq m + 1$ and z is the only vertex in U^* of level i.*

Lemma 11 already easily implies the first combinatorial part of Theorem 2, as we have seen with Theorem 1 in Section 3.1. Details of the algorithmic part again tightly follow the detailed proof steps which are present in the full paper.

In the proof of Lemma 11, we proceed analogously to Section 3. Namely, we start with a decomposition step analogous to Lemma 9 and illustrated in Figure 5. With a bit of technical work, we prove:

▶ **Lemma 13.*** *Assume the setting of Lemma 11, and with respect to it, let $U \neq \emptyset$ and $A \subseteq G_C$, $A = (v_1, v_2, v_3, v_4)$, denote the cycle bounding the 4-face incident to the lid edge f of the V-separator C and drawn in the closed disk of C.*

a) *There exists a vertical path $P_3 \subseteq G_C$ (internally disjoint from $C \cup A$ and possibly empty) such that the plane subgraph $C \cup A \cup P_3$ has two (if $P_3 = \emptyset$) or three distinct bounded faces, one of them being the face of A. The one or two bounded faces of $C \cup A \cup P_3$ other than that of A are bounded by cycles C_1 and C_2, where $v_1 \in V(C_1)$, and each of C_1 and C_2 (or just C_1 if $P_3 = \emptyset$) is again a V-separator whose lid edge is from $E(A) \setminus \{f\}$.*

b) *Assume now that $C \cup A \cup P_3$ has three bounded faces. Then $C_1 \cap C_2 = P_3$, and the sinks of C_1 and C_2 are in some order the sink u of C and the end u_3 of P_3 not in A (which may be the same vertex). If τ_i, $i = 1, 2$, is the bi-level-respecting partial contraction sequence of G obtained by inductively applying Lemma 11 to the cycle C_i, then the concatenation $\sigma_0 := \tau_2 \cdot \tau_1$ of these two sequences is a bi-level-respecting partial contraction sequence of G which satisfies the properties* (I)*' to* (IV)*' of Lemma 11.*

Then, we follow on the partial contraction sequence of Lemma 13 analogously to the proof in Section 3.3, albeit with slightly simpler arguments thanks to a simpler decomposition step with only at most two subregions. In this way we finish both Lemma 11 and Theorem 2, and the details are now left for the full paper [17].

5 Concluding Remarks

We have further improved by one the previous best upper bound [16] on the twin-width of planar graphs. This seemingly small improvement has required a careful reconsideration of the previous method and several new ideas, and although our new approach has simplified some cumbersome technical details in [16], new technical difficulties emerged which makes some parts of the proof again quite technical. This is probably to be expected since we are now very close to the currently best lower bound of 7 on the twin-width of planar graphs [19].

To recapitulate the fine improvements leading to the upper bound of 8 on the twin-width compared to previous larger bounds in [12, 18] and [3]; we communicate that the biggest (numerical) jump comes from the use of a specially tailored BFS-based decomposition formulated in Section 3.2, but we regard as the most important contribution in the quest the use of a left-aligned BFS tree (Section 2), which essentially "slashes down" additional up to three possible red neighbours from the analysis in the proof of Lemma 6. While both previous improvements have been introduced already in [16], the use of the "horizontal items" in the vertical-horizontal division of Section 3.2 then gives a final touch improving the bound to 8 (while 9 seemed to be unbeatable without this final trick).

Related to the twin-width is the notion of reduced bandwidth [12] which, informally stating, requires the subgraph induced by the red edges (along the sequence) to not only have bounded degrees, but also bounded bandwidth. Strictly speaking, as our construction of the contraction sequence creates arbitrarily large "red grids" in some cases, it does not directly imply any constant upper bound on the reduced bandwidth of planar graphs. However, a simple modification of the construction (informally, delaying contractions that would create red edges to the vertices of P_2 as in Figure 4) can easily bring a reasonable two-digit upper bound on the reduced bandwidth of planar graphs, which can possibly be further tightened with a specialized refined argument.

Besides the core question of the maximum twin-width of planar graphs, one may also reconsider the fact that our proof method is (distantly) based on the proof of the product structure of planar graphs [14] and ask whether we could possibly improve the product structure over the currently best variant in [21]. Unfortunately, our recursive decomposition of planar graphs is very tailored to the purpose of proving a good upper bound on the twin-width and it currently does not seem to yield an improvement in the planar product struture, or in the maximum queue number of planar graphs. This direction, however, is the subject of our ongoing research.

In the end we would like to dwell on the very idea of left-aligned BFS trees from Section 2. This seems like a quite general idea about planar graphs, related to other specialized BFS- and DFS-search routines in the algorithmic world, but we have not found this exact idea

anywhere in the published literature (the existing related concepts we are aware of do not feature the BFS property). We believe that this new idea could possibly find its use in other problems regarding planar graphs and drawings.

To finally conclude, the problem to determine the exact maximum value of the twin-width over all planar graphs is still open, but our continuing research suggests that the value of 7 is much more likely (than 8) to be the right answer. Likewise, the problem to determine the exact maximum value of the twin-width over bipartite planar graphs is open, and we cannot now decide whether the value of 6 is the right maximum value over bipartite planar graphs, or whether the upper bound may possibly be 5 (while an upper bound lower than 5 is not likely since a bipartite construction analogous to [19] seems to exclude it, but we are not aware of this claim being written up as a formal statement).

A Sparse Johnson-Lindenstrauss Transform Using Fast Hashing

Jakob Bæk Tejs Houen

BARC, Department of Computer Science, University of Copenhagen, Denmark

Abstract

The *Sparse Johnson-Lindenstrauss Transform* of Kane and Nelson (SODA 2012) provides a linear dimensionality-reducing map $A \in \mathbb{R}^{m \times u}$ in ℓ_2 that preserves distances up to distortion of $1 + \varepsilon$ with probability $1 - \delta$, where $m = O(\varepsilon^{-2} \log 1/\delta)$ and each column of A has $O(\varepsilon m)$ non-zero entries. The previous analyses of the Sparse Johnson-Lindenstrauss Transform all assumed access to a $\Omega(\log 1/\delta)$-wise independent hash function. The main contribution of this paper is a more general analysis of the Sparse Johnson-Lindenstrauss Transform with less assumptions on the hash function. We also show that the *Mixed Tabulation hash function* of Dahlgaard, Knudsen, Rotenberg, and Thorup (FOCS 2015) satisfies the conditions of our analysis, thus giving us the first analysis of a Sparse Johnson-Lindenstrauss Transform that works with a practical hash function.

1 Introduction

Dimensionality reduction is an often applied technique to obtain a speedup when working with high dimensional data. The basic idea is to map a set of points $X \subseteq \mathbb{R}^u$ to a lower dimension while approximately preserving the geometry. The Johnson-Lindenstrauss lemma [24] is a foundational result in that regard.

▶ **Lemma 1** ([24]). *For any $0 < \varepsilon < 1$, integers n, u, and $X \subseteq \mathbb{R}^u$ with $|X| = n$, there exists a map $f \colon X \to \mathbb{R}^m$ with $m = O(\varepsilon^{-2} \log n)$ such that*

$$\forall w, w' \in X,\ \left| \|f(w) - f(w')\|_2 - \|w - w'\|_2 \right| \leq \varepsilon \|w - w'\|_2 .$$

It has been shown in [6, 30] that the target dimension m is optimal for nearly the entire range of n, u, ε. More precisely, for any n, u, ε there exists a set of points $X \subseteq \mathbb{R}^u$ with $|X| = n$ such that for any map $f \colon X \to \mathbb{R}^m$ where the Euclidean norm is distorted by at most $(1 \pm \varepsilon)$ must have $m = \Omega(\min\{u, n, \varepsilon^{-2} \log(\varepsilon^2 n)\})$.

All known proofs of the Johnson-Lindenstrauss lemma constructs a linear map f. The original proof of Johnson and Lindenstrauss [24] chose $f(x) = \Pi x$ where $\Pi \in \mathbb{R}^{m \times u}$ is an appropriately scaled orthogonal projection into a random m-dimensional subspace. Another simple construction is to set $f(x) = \frac{1}{\sqrt{m}} Ax$ where $A \in \mathbb{R}^{m \times u}$ and each entry is an independent Rademacher variable.[1] In both cases, it can be shown that as long as $m = \Omega(\varepsilon^{-2} \log 1/\delta)$ then

$$\forall w \in \mathbb{R}^u, \ \Pr\left[\left|\|f(w)\|_2^2 - \|w\|_2^2\right| \geq \varepsilon \|w\|_2^2\right] \leq \delta. \tag{1}$$

The Johnson-Lindenstrauss lemma follows by setting $\delta < 1/\binom{n}{2}$ and taking $w = z - z'$ for all pairs $z, z' \in X$ together with a union bound. (1) is also known as the distributional Johnson-Lindenstrauss lemma and it has been shown that the target dimension m is tight, more precisely, m must be at least $\Omega(\min\left\{u, \varepsilon^{-2} \log 1/\delta\right\})$ [23, 26].

Sparse Johnson-Lindenstrauss Transform

One way to speed up the embedding time is replacing the dense A of the above construction by a sparse matrix. The first progress in that regard came by Achlioptas in [3] who showed that A can be chosen with i.i.d. entries where $A_{ij} = 0$ with probability $2/3$ and otherwise A_{ij} is chosen uniformly in $\pm\sqrt{\frac{3}{m}}$. He showed that this construction can achieve the same m as the best analyses of the Johnson-Lindenstrauss lemma. Hence this achieves essentially a 3x speedup, but the asymptotic embedding time is still $O(m \|x\|_0)$ where $\|x\|_0$ is number of non-zeros of x.

Motivated by improving the asymptotic embedding time, Kane and Nelson in [28], following the work in [14, 27, 8], introduced the Sparse Johnson-Lindenstrauss Transform which maps down to essentially optimal dimension $m = O(\varepsilon^{-2} \log n)$ and only has $s = O(\varepsilon^{-1} \log n)$ non-zeros entries per column. This speeds up the embedding time to $O(\varepsilon^{-1} \log n \|x\|_0) = O(\varepsilon m \|x\|_0)$ thus improving the embedding time by a factor of ε^{-1}. It nearly matches a sparsity lower bound by Nelson and Nguyen [31] who showed that any sparse matrix needs at least $s = \Omega(\varepsilon^{-1} \log(n)/\log(1/\varepsilon))$ non-zeros per column.

Using Hashing

When the input dimension, u, is large it is not feasible to store the matrix A explicitly. Instead, we use a hash function to calculate the non-zero entries of A. Unfortunately, the previous analyses of the Sparse Johnson-Lindenstrauss Transform [28, 10] assume access to a $\Omega(\log 1/\delta)$-wise independent hash function which is inefficient. This motivates the natural question:

What are the sufficient properties we need of the hash function for a Sparse Johnson-Lindenstrauss Transform to work?

The goal of this work is to make progress on this question. In particular, we provide a new analysis of a Sparse Johnson-Lindenstrauss Transform with fewer assumptions on the hash function. This improved analysis allows us to conclude that there exists a Sparse Johnson-Lindenstrauss Transform that uses Mixed Tabulation hashing which is efficient.

[1] A Rademacher variables, X, is a random variable that is chosen uniformly in ± 1, i.e., $\Pr[X = 1] = \Pr[X = -1] = \frac{1}{2}$.

Mixed Tabulation Hashing

Before introducing Mixed Tabulation hashing, we will first discuss *Simple Tabulation hashing* which was introduced by Zobrist [39]. Simple Tabulation hashing takes an integer parameter $c > 1$, and we view a key $x \in [u] = \{0, \dots, u-1\}$ as a vector of c characters, $x_0, \dots, x_{c-1} \in \Sigma = [u^{1/c}]$. For each character, we initialize a fully random table $T_i \colon \Sigma \to [2^r]$ and the hash value of x is then calculated as

$$h(x) = T_0[x_0] \oplus \ldots \oplus T_{c-1}[x_{c-1}],$$

where $\oplus$ is the bitwise XOR-operation. We say that h is a Simple Tabulation hash function with c characters.

We can now define *Mixed Tabulation hashing* which is a variant of Simple Tabulation hashing that was introduced in [11]. As with Simple Tabulation hashing, Mixed Tabulation hashing takes $c > 1$ as a parameter, and it takes a further integer parameter $d \geq 1$. Again, we view a key $x \in [u]$ as vector of c characters, $x_0, \dots, x_{c-1} \in \Sigma = [u^{1/c}]$. We then let $h_1 \colon \Sigma^c \to [2^r]$, $h_2 \colon \Sigma^c \to \Sigma^d$, and $h_3 \colon \Sigma^d \to [2^r]$ be independent Simple Tabulation hashing. Mixed Tabulation hashing is then defined as follows

$$h(x) = h_1(x) \oplus h_3(h_2(x)).$$

We say that h a mixed tabulation hash function with c characters and d derived characters. We call $h_2(x) \in \Sigma^d$ the *derived* characters. Mixed Tabulation hashing can be efficiently implemented by storing h_1 and h_2 as a single table with entries in $[2^r] \times \Sigma^d$, so the whole hash function can be computed with just $c + d$ lookups.

Our Contributions

Our main contribution is a new analysis of a Sparse Johnson-Lindenstrauss Transform that does not rely on the high independence of the hash function. Instead we show that it suffices that the hash function supports a decoupling-decomposition combined with strong concentration bounds.

We show that Mixed Tabulation hashing satisfies these conditions. This gives the first instance of a practical hash function that can support a Sparse Johnson-Lindenstrauss Transform.

1.1 Sparse Johnson-Lindenstrauss Transform

As mentioned earlier, the Sparse Johnson-Lindenstrauss Transform was introduced by Kane and Nelson [28] and they provided two different constructions with the same sparsity. Later a simpler analysis was given in [10] which also generalized the result to a more general class of constructions. In this paper, we will only focus on one of the constructions which is described below.

Before we discuss the construction of the Sparse Johnson-Lindenstrauss Transform, we will first consider the related CountSketch which was introduced in [9] and was analyzed for dimensionality reduction in [36]. In CountSketch, we construct the matrix A as follows: We pick a pairwise independent hash function, $h \colon [u] \to [m]$, and a 4-wise independent sign function $\sigma \colon [u] \to \{-1, 1\}$. For each $x \in [u]$, we set $A_{h(x),x} = \sigma(x)$ and the rest of the x'th column to 0. Clearly, this construction has exactly 1 non-zero entry per column. It was shown in [36] that if $m = \Omega(\varepsilon^{-2}\delta^{-1})$ then it satisfies the distributional Johnson-Lindenstrauss lemma, Equation (1). The result follows by bounding the second moment of $\|Ax\|_2^2 - \|x\|_2^2$ for any $x \in \mathbb{R}^d$ and then apply Chebyshev's inequality.

The bad dependence in the target dimension, m, on the failure probability, δ, is because we only use the second moment. So one might hope that you can improve the dependence by looking at higher moments instead. Unfortunately, it is not possible to improve the dependence for general $x \in \mathbb{R}^d$, and it is only possible to improve the dependence if $\|x\|_\infty^2 / \|x\|_2^2$ is small. Precisely, how small $\|x\|_\infty^2 / \|x\|_2^2$ has to be, has been shown in [17]. So to improve the dependence on δ, we need to increase the number of non-zero entries per column.

We are now ready to describe the construction of the Sparse Johnson-Lindenstrauss Transform. The construction is to concatenate s CountSketch matrices and scale the resulting matrix by $\frac{1}{\sqrt{s}}$. This clearly gives a construction that has s non-zero entries per column and as it has been shown in [28, 10] if $s = \Omega(\varepsilon^{-1} \log(1/\delta))$ then we can obtain the optimal target dimension $m = O(\varepsilon^{-2} \log(1/\delta))$. More formally, we construct the matrix A as follows:

1. We pick a hash function, $h\colon [s] \times [u] \to [m/s]$ and a sign function $\sigma\colon [s] \times [u] \to \{-1, 1\}$.
2. For each $x \in [u]$, we set $A_{i \cdot m/s + h(i,x), x} = \frac{\sigma(i,x)}{\sqrt{s}}$ for every $i \in [s]$ and the rest of the x'th column to 0.

In the previous analyses [28, 10], it was shown that if h and σ are $\Omega(\log 1/\delta)$-wise independent then the construction works. Unfortunately, it is not practical to use a $\Omega(\log 1/\delta)$-wise independent hash function so the goal of this work is to obtain an analysis of a Sparse Johnson-Lindenstrauss Transform with fewer assumptions about the hash function. In particular, we relax the assumptions of the hash function, h, and the sign function, σ, to just satisfying a decoupling-decomposition and a strong concentration property. The formal theorem is stated in Section 3.

We also show that Mixed Tabulation satisfies these properties and thus that the Sparse Johnson-Lindenstrauss Transform can be implemented using Mixed Tabulation. Let us describe more formally, what we mean by saying that Mixed Tabulation can implement the Sparse Johnson-Lindenstrauss Transform. We let $h_1\colon \Sigma^c = [u] \to [m/s]$, $h_2\colon \Sigma^c \to \Sigma^d$, and $h_3\colon \Sigma^d \to [m/s]$ be the independent Simple Tabulation hash functions that implement the Mixed Tabulation hash function, $h_1(x) \oplus h_3(h_2(x))$. We then extend it to the domain $[s] \times [u]$ as follows:

1. Let $h_2'\colon [s] \times \Sigma^c \to \Sigma^d$ be defined by $h_2'(i,x) = h_2(x) \oplus \underbrace{(i, \ldots, i)}_{d \text{ times}}$, i.e., each derived character gets xor'ed by i.
2. We then define $h\colon [s] \times [u] \to [m/s]$ and $\sigma\colon [s] \times [u] \to \{-1, 1\}$ by $h(i,x) = h_1(x) \oplus h_3(h_2'(i,x))$ and $\sigma(i,x) = \sigma_1(x) \cdot \sigma_3(h_2'(i,x))$, where h_1 and h_3 are the Simple Tabulation hash functions described above, and $\sigma_1\colon \Sigma^c \to \{-1, 1\}$ and $\sigma_3\colon \Sigma^d \to \{-1, 1\}$ are independent Simple Tabulation functions.

1.2 Hashing Speed

When we use tabulation schemes, it is often as a fast alternative to $\Omega(\log n)$-independent hashing. Typically, we implement a q-independent hash function using a degree $q-1$ polynomial in $O(q)$ time, and Siegel [34] has proved that this is best possible unless we use large space. More precisely, for some key domain $[u]$, if we want to do $t < q$ memory accesses, then we need space at least $u^{1/t}$. Thus, if we want higher than constant independence but still constant evaluation times, then we do need space $u^{\Omega(1)}$. In our application, we have to compute many hash values simultaneously, so an alternative strategy would be to evaluate the polynomial using multi-point evaluation. This would reduce the time per hash value to $O(\log^2 q)$ but this is still super constant time.

With tabulation hashing, we use tables of size $O(|\Sigma|)$ where $|\Sigma| = u^{1/c}$ and $c = O(1)$. The table lookups are fast if the tables fit in cache, which is easily the case for 8-bit characters. In connection with each lookup, we do a small number of very fast AC^0 operations: a cast, a bit-wise xor, and a shift. This is incomparable to polynomial in the sense of fast cache versus multiplications, but the experiments from [1, Table 1] found Simple Tabulation hashing to be faster than evaluation a 2-wise independent polynomial hashing.

Tabulation schemes are most easily compared by the number of lookups. Storing h_1 and h_2 in the same table, Mixed Tabulation hashing uses $c + d$ lookups. With $d = c$, the experiments from [1] found Mixed Tabulation hashing to be slightly more than twice as slow as Simple Tabulation hashing, and the experiments from [12] found Mixed Tabulation hashing to be about as fast as 3-wise independent polynomial hashing. This motivates our claim that Mixed Tabulation hashing is practical.

In theory, we could also use a highly independent hash function that uses large space, but we don't know of any efficient construction. Siegel states about his construction, it is "far too slow for any practical application" [34], and while Thorup [35] has presented a simpler construction than Siegel's, it is still not efficient. The experiments in [1] found it to be more than an order magnitude slower than Mixed Tabulation hashing.

2 Related Work

Even Sparser Johnson-Lindenstrauss Transforms

As touched upon earlier, there is a lower bound by Nelson and Nguyen [31] that rules out significant improvements, but never the less there has been research into sparser embedding. In the extreme, Feature Hashing of [38] considers the case of $s = 1$. The lower bound excludes Feature Hashing from working for all vectors, but in [17] they gave tight bounds for which vectors it works in terms of the measure $\|w\|_\infty^2 / \|w\|_2^2$. This was later generalized in [21] to a complete understanding between the tradeoff between s and the measure $\|w\|_\infty^2 / \|w\|_2^2$. In this paper, we will only focus on the case $s = \Theta(\varepsilon^{-1} \log 1/\delta)$ and $m = \Theta(\varepsilon^{-2} \log 1/\delta)$

Fast Johnson-Lindenstrauss Transform

Another direction to speed-up the evaluation of Johnson-Lindenstrauss transforms is to exploit dense matrices with fast matrix-vector multiplication. This was first done by Ailon and Chazelle [4] who introduced the Fast Johnson-Lindenstrauss Transform. Their original construction was recently [16] shown to give an embedding time $O(u \log u + m(\log 1/\delta + \varepsilon \log^2(1/\delta)/\log(1/\varepsilon)))$.

This has generated a lot follow-up work that has tried to improve the running to a clean $O(u \log u)$. Some of the work sacrifice the optimal target dimension, $m = O(\varepsilon^{-2} \log 1/\delta)$, in order to speed-up the construction, and are satisfied with sub-optimal $m = O(\varepsilon^{-2} \log n \log^4 u)$ [29], $m = O(\varepsilon^{-2} \log^3 n)$ [15], $m = O(\varepsilon^{-1} \log^{3/2} n \log^{3/2} u + \varepsilon^{-2} \log n \log^4 u)$ [29], $m = O(\varepsilon^{-2} \log^2 n)$ [19, 37, 18], and $m = O(\varepsilon^{-2} \log n \log^2(\log n) \log^3 u)$ [22]. Another line of progress is to assume that the target dimension, m, is substantially smaller then the starting dimension, u. Under the assumption that $m = o(u^{1/2})$ the work in [5, 7] achieves embedding time $O(u \log m)$. The only construction that for some regimes improves on the original Fast Johnson-Lindenstrauss Transform is the recent analysis [22] of the Kac Johnson-Lindenstrauss Transform, which uses the Kac random walk [25]. They show that it can achieve an embedding time of $O(u \log u + \min\{u \log n, m \log n \log^2(\log n) \log^3 u\})$.

Previous Work on Tabulation Hashing

The work by Patrascu and Thorup [33] initiated the study of tabulation based hashing that goes further than what 3-wise independence of constructions would suggest. A long line of papers have shown tabulation based hashing to work for min-wise hashing [32, 13], hashing for k-statistics [11], and the number of non-empty-bins [2]. Furthermore, multiple papers have been concerned with showing strong concentration results for tabulation based hashing [33, 32, 1, 20]. Tabulation based hashing has also been studied experimentally where they have been shown to exhibit great performance [12, 1].

Preliminaries

In this section, we will introduce the notation which will be used throughout the paper. First we introduce p-norms.

▶ **Definition 2** (p-norm). *Let $p \geq 1$ and X be a random variable with $\mathrm{E}[|X|^p] < \infty$. We then define the p-norm of X by $\|X\|_p = \mathrm{E}[|X|^p]^{1/p}$.*

Throughout the paper, we will repeatedly work with value functions $v\colon U \times [m] \to \mathbb{R}$. We will allow ourself to sometime view them as vectors, and in particular, we will write

$$\|v\|_2 = \sqrt{\sum_{x\in U}\sum_{j\in[m/s]} v(x,j)^2},$$
$$\|v\|_\infty = \max_{x\in U, j\in[m/s]} |v(x,j)|\,.$$

We will also use the Ψ_p-function introduced in [20].

▶ **Definition 3.** *For $p \geq 2$ we define the function $\Psi_p\colon \mathbb{R}_+ \times \mathbb{R}_+ \to \mathbb{R}_+$ as follows,*

$$\Psi_p(M,\sigma^2) = \begin{cases} \left(\frac{\sigma^2}{pM^2}\right)^{1/p} M & \text{if } p < \log\frac{pM^2}{\sigma^2} \\ \frac{1}{2}\sqrt{p}\sigma & \text{if } p < e^2\frac{\sigma^2}{M^2} \\ \frac{p}{e\log\frac{pM^2}{\sigma^2}} M & \text{if } \max\left\{\log\frac{pM^2}{\sigma^2}, e^2\frac{\sigma^2}{M^2}\right\} \leq p \end{cases}.$$

It was shown in [20] that $\Psi_p(1,\lambda)$ is within a constant factor of the p-norm of a Poisson distributed random variable with parameter λ. They also showed that $\Psi_p(M,\sigma^2)$ can be used to upper bound expressions involving a fully random hash function $h\colon U \to [m]$. Let $v\colon U \times [m] \to \mathbb{R}$ be a value function then they showed that

$$\left\|\sum_{x\in U} v(x,h(x))\right\|_{\leq} C\Psi_p(\|v\|_\infty, \|v\|_2^2/m)\,,$$

where C is a universal constant.

3 Overview of the New Analysis

Our main technical contribution is a new analysis of the Sparse Johnson-Lindenstrauss Transform that relaxes the assumptions on the hash function, h. We show that if h satisfies a decoupling decomposition property and a strong concentration property then we obtain

the same bounds for the Sparse Johnson-Lindenstrauss Transform. Both of these properties are satisfied by h if h is $\Omega(\log 1/\delta)$-wise independent so our assumptions are weaker than those of the previous analyses.

In this section, we will give an informal overview of new approach. The technical details and the formal statement of the result will be in Section 4.

In order to describe our approach, we look at the random variable

$$Z = \|Aw\|_2^2 - 1 = \frac{1}{s}\sum_{i\in[s]}\sum_{x\neq y\in[u]} \sigma(i,x)\sigma(i,y)\left[h(i,x)=h(i,y)\right] w_x w_y. \tag{2}$$

Here $w \in \mathbb{R}^u$ is a unit vector. With this notation the goal becomes to bound $\Pr[|Z| \geq \varepsilon]$.

The first step in our analysis is that we want to decouple Equation (2). Decoupling was also used in one of the proofs in [10], but since we want to prove the result for more general hash functions, we cannot directly use the standard decoupling inequalities. We will instead assume that our hash function allows a *decoupling-decomposition*. This will formally be defined in Section 4 and we will for now assume that our hash function allows for the standard decoupling inequality. If we apply Markov's inequality and a standard decoupling inequality for fully random hashing we obtain the expression.

$$\begin{aligned}\Pr[|Z|\geq\varepsilon] &\leq \varepsilon^{-p}\,\mathrm{E}[|Z|^p] \\ &\leq \left(\varepsilon^{-1}\frac{4}{s}\right)^p \mathrm{E}\left[\left|\sum_{i\in[s]}\sum_{x,y\in[u]}\sigma(i,x)\sigma'(i,y)\left[h(i,x)=h'(i,y)\right]w_x w_y\right|^p\right] \end{aligned}\tag{3}$$

where (h',σ') are independent copies of (h,σ) and $p \geq 2$. The power of decoupling stems from the fact that it breaks up some of the dependencies and allows for a simpler analysis.

The goal is now to analyse $\left\|\sum_{i\in[s]}\sum_{x,y\in[u]}\sigma(i,x)\sigma'(i,y)\left[h(i,x)=h'(i,y)\right]w_x w_y\right\|_p$. This is done by first fixing (h',σ') and bounding $\left\|\sum_{i\in[s],j\in[m/s]}\sum_{x\in[u]}\sigma(i,x)\left[h(i,x)=j\right]w_x a_{ij}\right\|_p$ using the randomness of (h,σ) where $a_{ij} = \sum_{y\in[u]}\sigma'(i,y)\left[h'(i,y)=j\right]w_y$. In order to do this, we will assume that the pair (h,σ) is *strongly concentrated*. Again the formal definition of this is postponed to Section 4, but informally, we say that the pair is strongly concentrated if it has concentration results similar to those of fully random hashing.

We now take the view that $|a_{ij}|$ is the load of the bin $(i,j) \in [s]\times[m/s]$. The idea is then to split $[s]\times[m/s]$ into heavy and light bins and handle each separately. We choose a parameter k and let I be the heaviest k bins. Using the triangle inequality, we then get that

$$\begin{aligned}\left\|\sum_{i\in[s],j\in[m/s]}\sum_{x\in[u]}\sigma(i,x)\left[h(i,x)=j\right]w_x a_{ij}\right\|_p &\leq \left\|\sum_{(i,j)\in I}\sum_{x\in[u]}\sigma(i,x)\left[h(i,x)=j\right]w_x a_{ij}\right\|_p \\ &+ \left\|\sum_{(i,j)\in[s]\times[m/s]\setminus I}\sum_{x\in[u]}\sigma(i,x)\left[h(i,x)=j\right]w_x a_{ij}\right\|_p.\end{aligned}$$

We show that the contribution from the light bins is as if the collisions are independent. This should be somewhat intuitive since if we only have few collisions in each bin then the collisions behave as if they were independent. In contrast, we show that the contribution from the heavy bins is dominated by the heaviest bin. This turns out to be exactly what we need to finish the analysis.

4 Technical Results

In this section, we will expand on the description from Section 3 and formalize the ideas.

Decoupling

Ideally, we would like to use the standard decoupling inequality, Equation (3). Unfortunately, we cannot expect more general hash functions to support such a clean decoupling. We therefore introduce the notion of a decoupling-decomposition.

▶ **Definition 4** (Decoupling-decomposition). *Let $p \geq 2$, $L \geq 1$, and $0 \leq \gamma \leq 1$. We say that a collection of possibly randomized sets, (U_α), is a* (p, L, γ)-decoupling-decomposition *for a property P of a pair (h, σ), if there exist hash functions $h_\alpha \colon [s] \times U_\alpha \to [m/s]$ and sign functions $s \colon [s] \times U_\alpha \to \{-1, 1\}$ for all α such that*

$$\Pr[|Z| \geq \varepsilon] \leq \left(\varepsilon^{-1} \sum_\alpha \frac{L}{s} \left\| \sum_{i \in [s]} \sum_{x,y \in U_\alpha} \sigma_\alpha(i,x)\sigma'_\alpha(i,y) \left[h_\alpha(i,x) = h'_\alpha(i,y)\right] w_x w_y \right\|_p \right)^p + \gamma \tag{4}$$

where $(h_\alpha, \sigma_\alpha)$ and $(h'_\alpha, \sigma'_\alpha)$ has the same distribution, and $(h_\alpha, \sigma_\alpha)$ satisfies the property P when conditioned on $(h'_\alpha, \sigma'_\alpha)$ and U_α.

The reader should compare Equation (3) for fully random hashing with Equation (4). There are 3 main differences between the expressions.

1. The first thing to notice is that, in the decoupling-decomposition we sum over different sets (U_α), where this is not needed for fully random hashing. We allow the decoupling-decomposition to use a different decoupling on each of the sets U_α. This is very powerful since general hash functions are not necessarily uniform over the input domain.
2. For the decoupling-decomposition, we allow an additive error probability γ. This is useful if the hash function allows for decoupling most of the time except when some unprobable event is happening.
3. The last difference is that a much larger loss-factor is allowed by the decoupling-decomposition than Equation (3). In the case of fully random hashing, we only lose a factor of 4 but for more general hash functions this loss might be bigger.

Finally, we note that Equation (3) implies if (h, σ) is $2p$-wise independent for an integer $p \geq 2$ then $[u]$ is a decoupling-decomposition of (h, σ) for any property P that is satisfied by (h, σ).

Strong Concentration

The second property we need is that the hash function is strongly concentrated.

▶ **Definition 5** (Strong concentration). *Let $h \colon [s] \times U \to [m/s]$ be a hash function and $\sigma \colon [s] \times U \to \{-1, 1\}$ be a sign function. We say that the pair (h, σ) is* (p, L)-strongly-concentrated *if*

1. *For all value functions,* $v\colon [s]\times[m/s]\to\mathbb{R}$*, and all vectors,* $w\in\mathbb{R}^U$*,*

$$\left\|\sum_{i\in[s]}\sum_{x\in U}\sigma(i,x)v(i,h(i,x))w_x\right\|_p \leq \Psi_p\left(L\left\|v\right\|_\infty\left\|w\right\|_\infty, L\frac{s}{m}\left\|v\right\|_2^2\left\|w\right\|_2^2\right)\,, \tag{5}$$

$$\left\|\sum_{i\in[s]}\sum_{x\in U}\sigma(i,x)v(i,h(i,x))w_x\right\|_p \leq \sqrt{L\frac{p}{\log(m/s)}\left\|v\right\|_2^2\left\|w\right\|_2^2}\,. \tag{6}$$

2. *For all vectors,* $w\in\mathbb{R}^U$*,*

$$\left\|\sum_{i\in[s]}\sum_{j\in[m/s]}\left(\sum_{x\in U}\sigma(i,x)\left[h(i,x)=j\right]w_x\right)^2\right\|_{p/2} \leq L\max\left\{s\left\|w\right\|_2^2, \frac{p}{\log m/s}\left\|w\right\|_2^2\right\}. \tag{7}$$

3. *If* $p\leq\log m$*,*

$$\left\|\max_{i\in[s],j\in[m/s]}\left|\sum_{x\in U}\sigma(i,x)\left[h(i,x)=j\right]w_x\right|\right\|_p \leq e\sqrt{L\frac{\log m}{\log m/s}}\left\|w\right\|_2. \tag{8}$$

We need essentially 3 different properties of our hash function to say that it is strongly concentrated.

1. The first property is a concentration result on the random variable

$$\sum_{i\in[s]}\sum_{x\in U}\sigma(i,x)v(i,h(i,x))w_x.$$

   Here we need two different concentration results: The first concentration result, Equation (5), roughly corresponds to a p-norm version of what you would obtain by applying Bennett's inequality to a fully random hash function, while the second concentration result, Equation (5), corresponds to the best hypercontractive result you can obtain for weighted sums of independent Bernoulli-Rademacher variables with parameter s/m.[2]
2. The second property bounds the sum of squares

$$W=\sum_{i\in[s]}\sum_{j\in[m/s]}\left(\sum_{x\in U}\sigma(i,x)\left[h(i,x)=j\right]w_x\right)^2.$$

   The condition, Equation (7), bounds $\left\|W\right\|_{p/2}$ by the maximum of two cases. The first case corresponds to $\mathrm{E}[W]$, and the second case is motivated by applying Equation (6) to

$$\sup_{\substack{z\in\mathbb{R}^{[s]\times[m/s]},\\ \left\|z\right\|_2=1}}\left\|\sum_{i\in[s]}\sum_{j\in[m]}\sum_{x\in U}\sigma(i,x)z_{i,h(i,x)}w_x\right\|_p^2.$$

   While this at first glance might seem odd, it is roughly the best you can do, since one can show that

$$\max\left\{\mathrm{E}[W]\,, \sup_{\substack{z\in\mathbb{R}^{[s]\times[m/s]},\\ \left\|z\right\|_2=1}}\left\|\sum_{i\in[s]}\sum_{j\in[m]}\sum_{x\in U}\sigma(i,x)z_{i,h(i,x)}w_x\right\|_p^2\right\} \leq \left\|W\right\|_{p/2}.$$

[2] A Bernoulli-Rademacher variable with parameter α is random variable, $X\in\{-1,0,1\}$, with $\Pr[X=1]=\Pr[X=-1]=\alpha/2$ and $\Pr[X=0]=1-\alpha$.

3. The final property is a bound on the largest coordinate, $\max_{i\in[s],j\in[m/s]} \left|\sum_{x\in U} \sigma(i,x)\,[h(i,x)=j]\,w_x\right|$. The bound is a natural consequence of Equation (6) for fully random hashing. Namely, for fully random hashing we get that

$$\begin{aligned}
&\left\| \max_{i\in[s],j\in[m/s]} \left|\sum_{x\in U} \sigma(i,x)\,[h(i,x)=j]\,w_x\right| \right\|_p \\
&\qquad \le \left\| \max_{i\in[s],j\in[m/s]} \left|\sum_{x\in U} \sigma(i,x)\,[h(i,x)=j]\,w_x\right| \right\|_{\log m} \\
&\qquad \le e \max_{i\in[s],j\in[m/s]} \left\| \left|\sum_{x\in U} \sigma(i,x)\,[h(i,x)=j]\,w_x\right| \right\|_{\log m} \\
&\qquad \le e\sqrt{L\frac{\log m}{\log m/s}}\,\|w\|_2\,.
\end{aligned}$$

   This derivation is not true for general hash function, but the hash function can still satisfy Equation (8).

The results of [20] show that if the hash function $h\colon [s]\times U \to [m/s]$ and the sign function $\sigma\colon [s]\times U \to [m/s]$ is p-wise independent for an integer $p \ge 2$ then the pair (h,σ) is (p,K)-strongly-concentrated where K is a universal constant.

The Main Result

We are now ready to state our main result which is a new analysis of a Sparse Johnson-Lindenstrauss Transform that only assumes that the hash function has a decoupling-decomposition for the strong concentration property.

▶ **Theorem 6.** *Let $h\colon [s]\times[u]\to[m/s]$ be a hash function and $\sigma\colon [s]\times[u]\to\{-1,1\}$ be a sign function. Furthermore, let $0<\varepsilon<1$ and $0<\delta<1$ be given, and define $p=\log 1/\delta$.*

Assume that there exists constants L_1, L_2, L_3, and $0\le\gamma<1$, that only depends on (h,σ) and p, such that

1. *There exists a (p,L_1,γ)-decoupling-decomposition, (U_α), for the (p,L_2)-strong-concentration property of (h,σ)*
2. *For all vectors $w\in\mathbb{R}^u$, $\sum_\alpha \sum_{x\in U_\alpha} w_x^2 \le L_3\,\|w\|_2^2$.*
3. *$m \ge \left(16e^7 L_1^2 L_2^3 L_3^2\right)\cdot\varepsilon^{-2}\log(1/\delta)$.*
4. *$s \ge \left(64e^3 L_1 L_2^{3/2} L_3\right)\cdot\varepsilon^{-1}\log(1/\delta)$.*

Then the following is true

$$\Pr[|Z|\ge\varepsilon] \le \delta+\gamma.$$

As discussed earlier, a fully random hash function satisfies all the property needed of the theorem and thus gives a new analysis of the Sparse Johnson-Lindenstrauss Transform for fully random hashing. We will also later show that Mixed Tabulation satisfies the assumption of the theorem hence giving the first analysis of a Sparse Johnson-Lindenstrauss Transform with a practical hash function that works.

The main difficulty in the analysis of Theorem 6 is contained in the following technical lemma. The idea in the proof of Theorem 6 is to use the decoupling-decomposition and apply the following lemma to each part.

▶ **Lemma 7.** *Let $h, \overline{h}\colon [s] \times U \to [m/s]$ be hash functions and $\sigma, \overline{\sigma}\colon [s] \times U \to \{-1, 1\}$ be sign functions. Let $p \geq 2$ and assume that there exists a constant L such that (h, σ) is (p, L)-strongly concentrated when conditioning on $(\overline{h}, \overline{\sigma})$, and similarly, $(\overline{h}, \overline{\sigma})$ is (p, L)-strongly concentrated when conditioning on (h, σ). Then for all vectors $w \in \mathbb{R}^U$,*

$$\left\| \sum_{i \in [s]} \sum_{x,y \in U} \sigma(i,x)\overline{\sigma}(i,y) \left[h(i,x) = \overline{h}(i,y)\right] w_x w_y \right\|_p \leq \Psi_p \left(32e^3 L^{3/2} \|w\|_2^2 , 32e^6 L^3 \frac{s^2}{m} \|w\|_2^4 \right) + 36e^3 L \frac{p}{\log m/s} \|w\|_2^2 .$$

The lemma shows that the expression has two different regimes. The first regime, $\Psi_p \left(32e^3 L^{3/2} \|w\|_2^2 , 32e^6 L^3 \frac{s^2}{m} \|w\|_2^4 \right)$, is essentially what we would expect if each of the collisions, $\left[h(i,x) = \overline{h}(i,y)\right]$, are independent of each other. The other regime, $36e^3 L \frac{p}{\log m/s} \|w\|_2^2$, is essentially what you expect the largest coordinate to contribute.

Our analysis is inspired by these two regimes and tries to exploit them explicitly. We start by fixing (h, σ) and divide the coordinates into heavy and light coordinates. We then show that contribution of the light coordinates is $\Psi_p \left(32e^3 L^{3/2} \|w\|_2^2 , 32e^6 L^3 \frac{s^2}{m} \|w\|_2^4 \right)$ which matches the intuition that if we only have few collisions on each coordinate then the collisions behave as if they were independent. Similarly, we show that the contribution of the heavy coordinates is dominated by the heaviest coordinate, namely, the contribution is $36e^3 L \frac{p}{\log m/s} \|w\|_2^2$.

Mixed Tabulation Hashing

Our main result for Mixed Tabulation hashing is the following.

▶ **Theorem 8.** *Let $h\colon [s] \times [u] \to [m/s]$ and $\sigma\colon [s] \times [u] \to \{-1, 1\}$ be Mixed Tabulation functions as described in Section 1.1. Furthermore, let $0 < \varepsilon < 1$ and $0 < \delta < 1$ be given, and define $p = \log 1/\delta$.*

If $m \geq \gamma_p^{3c} \varepsilon^{-2} \log(1/\delta)$ and $s \geq \gamma_p^{3/2c} \varepsilon^{-1} \log(1/\delta)$ where $\gamma_p = Kc \max\left\{1, \frac{p}{\log|\Sigma|}\right\}$ for a universal constant K.

Then the following is true

$$\Pr[|Z| \geq \varepsilon] \leq \delta + \varepsilon 3^c |\Sigma|^{-d} .$$

The result follows by proving that Mixed Tabulation hashing has a $(p, 4^{c+2}, 4\varepsilon^{-2} 3^c \frac{s}{m} |\Sigma|^{-d})$-decoupling-decomposition and that Mixed Tabulation has the strong concentration property. The main new part is in showing the decoupling-decomposition while the analysis of the strong concentration property is modification of the analysis in [20].

Due to space constraints, the proof is deferred to the full version.

5 Analysis of the Sparse Johnson-Lindenstrauss Transform

Lets us start by showing how Lemma 7 implies our main result, Theorem 6.

Proof of Theorem 6. We start by using Equation (4) of the decoupling decomposition to get that

$$\Pr[|Z| \geq \varepsilon] \leq \left(\varepsilon^{-1} \sum_{\alpha} \frac{L_1}{s} \left\| \sum_{i \in [s]} \sum_{x,y \in U_\alpha} \sigma_\alpha(i,x)\sigma'_\alpha(i,y) \left[h_\alpha(i,x) = h'_\alpha(i,y) \right] v_x v_y \right\|_p \right)^p + \gamma$$

Now we fix α and apply Lemma 7 while fixing U_α

$$\left\| \sum_{i \in [s]} \sum_{x,y \in U_\alpha} \sigma_\alpha(i,x)\sigma'_\alpha(i,y) \left[h_\alpha(i,x) = h'_\alpha(i,y) \right] v_x v_y \right\|_p \leq \Psi_p \left(32e^3 L_2^{3/2}, 32e^6 L^3 \frac{s^2}{m} \right) \sum_{x \in U_\alpha} w_x^2 + 36e^3 L_2 \frac{p}{\log m/s} \sum_{x \in U_\alpha} w_x^2$$

Using this we get that

$$\sum_{\alpha} \frac{L_1}{s} \left\| \sum_{i \in [s]} \sum_{x,y \in U_\alpha} \sigma_\alpha(i,x)\sigma'_\alpha(i,y) \left[h_\alpha(i,x) = h'_\alpha(i,y) \right] v_x v_y \right\|_p \leq \sum_{\alpha} \frac{L_1}{s} \left(\Psi_p \left(32e^3 L_2^{3/2}, 32e^6 L^3 \frac{s^2}{m} \right) \sum_{x \in U_\alpha} w_x^2 + 36e^3 L_2 \frac{p}{\log m/s} \sum_{x \in U_\alpha} w_x^2 \right)$$

We now use that $\sum_\alpha \sum_{x \in U_\alpha} w_x^2 \leq L_3 \|w\|_2^2$ to get that

$$\sum_{\alpha} \frac{L_1}{s} \left(\Psi_p \left(32e^3 L_2^{3/2}, 32e^6 L^3 \frac{s^2}{m} \right) \sum_{x \in U_\alpha} w_x^2 + 36e^3 L_2 \frac{p}{\log m/s} \sum_{x \in U_\alpha} w_x^2 \right) \leq \frac{L_3 L_1}{s} \left(\Psi_p \left(32e^3 L_2^{3/2}, 32e^6 L^3 \frac{s^2}{m} \right) + 36e^3 L_2 \frac{p}{\log m/s} \right) \|w\|_2^2$$

It can now be checked that if m and s satisfies the stated assumptions then

$$\frac{L_3 L_1}{s} \left(\Psi_p \left(32e^3 L_2^{3/2}, 32e^6 L^3 \frac{s^2}{m} \right) + 36e^3 L_2 \frac{p}{\log m/s} \right) \|w\|_2^2 \leq e^{-1}\varepsilon$$

Combining all the facts, we get that

$$\Pr[|Z| \geq \varepsilon] \leq \left(\varepsilon^{-1}(e^{-1}\varepsilon) \right)^p + \gamma = \delta + \gamma.$$

This finishes the proof. ◀

The rest of the section is concerned with proving our main technical lemma, Lemma 7. First we need the following two lemmas from [20].

▶ **Lemma 9.** *Let $f\colon \mathbb{R}^n_{\geq 0} \to \mathbb{R}_{\geq 0}$ be a non-negative function which is monotonically increasing in every argument, and assume that there exists positive reals $(\alpha_i)_{i\in[n]}$ and $(t_i)_{i\in[n]}$ such that for all $\lambda \geq 0$,*

$$f(\lambda^{\alpha_0} t_0, \ldots, \lambda^{\alpha_{n-1}} t_{n-1}) \leq \lambda f(t_0, \ldots, t_{n-1}) \,.$$

Let $(X_i)_{i\in[n]}$ be non-negative random variables. Then for all $p \geq 1$ we have that

$$\|f(X_0, \ldots, X_{n-1})\|_p \leq n^{1/p} \max_{i\in[n]} \left(\frac{\|X_i\|_{p/\alpha_i}}{t_i} \right)^{1/\alpha_i} f(t_0, \ldots, t_{n-1}) \,.$$

▶ **Lemma 10.** *Let $p \geq 2$, $M > 0$, and $\sigma^2 > 0$ then*

$$\frac{1}{2}\sqrt{p}\sigma \leq \Psi_p(M, \sigma^2) \leq \max\left\{ \frac{1}{2}\sqrt{p}\sigma, \frac{1}{2e} pM \right\} .$$

We are now ready to prove Lemma 7.

Proof of Lemma 7. We start by defining $v_h, v_{\bar{h}}\colon [s] \times [m/s] \to \mathbb{R}$ by,

$$v_h(i,j) = \sum_{x\in U} \sigma(i,x) w_x \left[h(i,x) = j\right] \,,$$
$$v_{\bar{h}}(i,j) = \sum_{y\in U} \overline{\sigma}(i,y) w_y \left[\overline{h}(i,y) = j\right] \,.$$

We then want to prove that

$$\left\| \sum_{i\in[s], j\in[m/s]} v_h(i,j) v_{\bar{h}}(i,j) \right\|_p \leq \Psi_p\left(32e^3 L^{3/2} \|w\|_2^2 , 32e^6 L^3 \|w\|_2^4 \right) + 4e^3 L \frac{p}{\log m/s} \|w\|_2^2 \,.$$

First we consider the case where $\frac{p}{\log m/s} \|w\|_2^2 \geq s \|w\|_2^2$. By Cauchy-Schwartz and Equation (7) we get that

$$\left\| \sum_{i\in[s], j\in[m/s]} v_h(i,j) v_{\bar{h}}(i,j) \right\|_p \leq \left\| \sum_{i\in[s], j\in[m/s]} v_h(i,j)^2 \right\|_p \leq L \frac{p}{\log m/s} \|w\|_2^2 \,.$$

We now focus on the case where $\frac{p}{\log m/s} \|w\|_2^2 < s \|w\|_2^2$. We define $\pi\colon [m] \to [s] \times [m/s]$ to be a bijection which satisfies that

$$|v_h(\pi(0))| \geq |v_h(\pi(1))| \geq \ldots \geq |v_h(\pi(m-1))| \,.$$

We note that π is a random function but we can define π such that it only depends on the randomness of h and σ. We define $k = \lfloor p/\log(m/p) \rfloor$, $I = \{\pi(i) \,|\, i \in [k]\}$, and the random functions $v'_h, v''_h\colon [s] \times [m/s] \to \mathbb{R}$ by

$$v'_h(i,j) = v_h(i,j) \left[(i,j) \in I\right] ,$$
$$v''_h(i,j) = v_h(i,j) \left[(i,j) \notin I\right] .$$

Again we note that v'_h and v''_h only depends on the randomness of h and σ. We can then write our expression as

$$\left\| \sum_{i\in[s],j\in[m/s]} v_h(i,j)v_{\bar{h}}(i,j) \right\|_p = \left\| \sum_{i\in[s]} \sum_{y\in U} \overline{\sigma}(i,y)v_h(i,\overline{h}(i,y))w_y \right\|_p$$
$$\leq \left\| \sum_{i\in[s]} \sum_{y\in U} \overline{\sigma}(i,y)v'_h(i,\overline{h}(i,y))w_y \right\|_p + \left\| \sum_{i\in[s]} \sum_{y\in U} \overline{\sigma}(i,y)v''_h(i,\overline{h}(i,y))w_y \right\|_p .$$

We will bound each of the term separately. We start by bounding $\left\|\sum_{i\in[s]} \sum_{y\in U} \overline{\sigma}(i,y)v'_h(i,\overline{h}(i,y))w_y\right\|_p$. We fix h and σ and use Equation (6) to get that

$$\left\| \sum_{i\in[s]} \sum_{y\in U} \overline{\sigma}(i,y)v'_h(i,\overline{h}(i,y))w_y \right\|_p \leq \left\| \sqrt{L\frac{p}{\log m/s}\left\|w\right\|_2^2 \left\|v'_h\right\|_2^2} \right\|_p$$
$$= \sqrt{L\frac{p}{\log m/s}}\left\|w\right\|_2 \left\| \sqrt{\sum_{(i,j)\in I} v'_h(i,j)^2} \right\|_p .$$

We note that $\sum_{(i,j)\in I} v'_h(i,j)^2 = \max_{J\subseteq[s]\times[m/s],|J|=k} \sum_{(i,j)\in J} v_h(i,j)^2$. We then get that

$$\left\| \sqrt{\sum_{(i,j)\in I} v'_h(i,j)^2} \right\|_p = \left\| \sqrt{\max_{J\subseteq[s]\times[m/s],|J|=k} \sum_{(i,j)\in J} v_h(i,j)^2} \right\|_p$$
$$\leq \left(\sum_{J\subseteq[s]\times[m/s],|J|=k} \left\| \sqrt{\sum_{(i,j)\in J} v_h(i,j)^2} \right\|_p^p \right)^{1/p}$$
$$\leq \binom{ms}{k}^{1/p} \max_{J\subseteq[s]\times[m/s],|J|=k} \left\| \sqrt{\sum_{(i,j)\in J} v_h(i,j)^2} \right\|_p$$

We use Sterling's bound and get that $\binom{ms}{k}^{1/p} \leq \left(\frac{ems}{k}\right)^{k/p} \leq \left(\frac{ems\log(ms/p)}{p}\right)^{1/\log(ms/p)} \leq e^3$. So we get that

$$\left\| \sqrt{\sum_{(i,j)\in I} v'_h(i,j)^2} \right\|_p \leq e^3 \max_{J\subseteq[s]\times[m/s],|J|=k} \left\| \sqrt{\sum_{(i,j)\in J} v_h(i,j)^2} \right\|_p$$

A standard volumetric argument gives that there exists a 1/4-net, $Z \subseteq \mathbb{R}^J$, with $|Z| \leq 9^k$, such that

$$\begin{aligned}
\left\|\sqrt{\sum_{(i,j)\in J} v_h(i,j)^2}\right\|_p &= \left\|\sup_{z\in\mathbb{R}^J,\|z\|_2=1}\sum_{(i,j)\in J} z_{i,j}v_h(i,j)\right\|_p \\
&\leq \left\|\sup_{z\in Z}\sum_{(i,j)\in J} z_{i,j}v_h(i,j)\right\|_p \\
&\quad + \left\|\sup_{z\in\mathbb{R}^J,\|z\|_2=1}\sum_{(i,j)\in J} (z_{i,j}-z'_{i,j})v_h(i,j)\right\|_p \\
&\leq \left\|\sup_{z\in Z}\sum_{(i,j)\in J} z_{i,j}v_h(i,j)\right\|_p \\
&\quad + \sup_{z\in\mathbb{R}^J,\|z\|_2=1}\|z-z'\|_2\left\|\sqrt{\sum_{(i,j)\in J} v_h(i,j)^2}\right\|_p
\end{aligned}$$

where $z' \in Z$ is the closest element to z, and as such $\|z-z'\|_2 \leq 1/4$. Since there are at most 9^k elements in Z then $\left\|\sup_{z\in Z}\sum_{(i,j)\in J} z_{i,j}v_h(i,j)\right\|_p \leq 9\sup_{z\in Z}\left\|\sum_{(i,j)\in J} z_{i,j}v_h(i,j)\right\|_p$, where we used that $k \leq p$. Collecting the fact we get that

$$\left\|\sqrt{\sum_{(i,j)\in J} v_h(i,j)^2}\right\|_p \leq 36\sup_{z\in Z}\left\|\sum_{(i,j)\in J} z_{i,j}v_h(i,j)\right\|_p$$

Using this we get that

$$\begin{aligned}
&e^3\max_{J\subseteq[s]\times[m/s],|J|=k}\left\|\sqrt{\sum_{(i,j)\in J} v_h(i,j)^2}\right\|_p \\
&\quad\leq 36e^3\max_{J\subseteq[s]\times[m/s],|J|=k}\max_{z\in Z}\left\|\sum_{(i,j)\in J} z_{i,j}v_h(i,j)\right\|_p \\
&\quad= 36e^3\max_{J\subseteq[s]\times[m/s],|J|=k}\max_{\substack{z\in\mathbb{R}^{s\times m/s},\\ \|z\|_2=1}}\left\|\sum_{i\in[s]}\sum_{x\in U}\sigma(i,x)z_{i,h(i,x)}\left[(i,h(i,x))\in J\right]w_x\right\|_p
\end{aligned}$$

We can then use Equation (6) to get that

$$\begin{aligned}
&36e^3\max_{J\subseteq[s]\times[m/s],|J|=k}\max_{\substack{z\in\mathbb{R}^{s\times m/s},\\ \|z\|_2=1}}\left\|\sum_{i\in[s]}\sum_{x\in U}\sigma(i,x)z_{i,h(i,x)}\left[(i,h(i,x))\in J\right]w_x\right\|_p \\
&\quad\leq 36e^3\max_{J\subseteq[s]\times[m/s],|J|=k}\max_{\substack{z\in\mathbb{R}^{s\times m/s},\\ \|z\|_2=1}}\sqrt{L\frac{p}{\log m/s}}\,\|w\|_2\,\|z\|_2 \\
&\quad= 36e^3\sqrt{L\frac{p}{\log m/s}}\,\|w\|_2
\end{aligned}$$

Combining the facts, we get that $\left\|\sum_{i\in[s]}\sum_{y\in U}\overline{\sigma}(i,y)v'_h(i,\overline{h}(i,y))w_y\right\|_p \leq 36e^3L\frac{p}{\log m/s}\,\|w\|_2^2$.

We will now bound $\left\|\sum_{i\in[s]}\sum_{y\in U}\overline{\sigma}(i,y)v_h''(i,\overline{h}(i,y))w_y\right\|_p$. We fix h and ε and use Equation (5) to get that

$$\begin{aligned}\left\|\sum_{i\in[s]}\sum_{y\in U}\overline{\sigma}(i,y)v_h''(i,\overline{h}(i,y))w_y\right\|_p &\leq \left\|\Psi_p\left(L\left\|w\right\|_\infty\left\|v_h'\right\|_\infty, L\frac{s}{m}\left\|w\right\|_2^2\left\|v_h'\right\|_2^2\right)\right\|_p \\ &\leq \left\|\Psi_p\left(L\left\|w\right\|_\infty\left|v_h'(\pi(k+1))\right|, L\frac{s}{m}\left\|w\right\|_2^2\left\|v_h\right\|_2^2\right)\right\|_p .\end{aligned}$$

Now we use Lemma 9 to get that,

$$\begin{aligned}&\left\|\Psi_p\left(L\left\|w\right\|_\infty\left|v_h'(\pi(k+1))\right|, L\frac{s}{m}\left\|w\right\|_2^2\left\|v_h\right\|_2^2\right)\right\|_p \\ &\qquad\leq \sqrt{2}\Psi_p\left(L\left\|w\right\|_\infty\left\|\left|v_h'(\pi(k+1))\right|\right\|_p, L\frac{s}{m}\left\|w\right\|_2^2\left\|\left\|v_h\right\|_2^2\right\|_{p/2}\right).\end{aligned}$$

Since we assume that $\frac{p}{\log m}\left\|w\right\|_2^2 < s\left\|w\right\|_2^2$ then Equation (7) give us that $\left\|\left\|v_h\right\|_2^2\right\|_{p/2} \leq Ls\left\|w\right\|_2^2$.

We will now bound $\left\|v_h'(\pi(k+1))\right\|_p$. For this, we will distinguish between two cases: Either $p \geq \log m$ or $p < \log m$. Let us first case where $p \geq \log m$. We will use that $|v_h'(\pi(k+1))| \leq \frac{\sum_{i\in[k+1]}|v_h'(\pi(i))|}{k+1}$. We then get that

$$\begin{aligned}&\left\|v_h'(\pi(k+1))\right\|_p \\ &\leq \left\|\frac{\sum_{i\in[k+1]}|v_h'(\pi(i))|}{k+1}\right\|_p \\ &\leq \left(\binom{m}{k+1}2^{k+1}\max_{\substack{J\subseteq[s]\times[m/s],\,(\sigma_{i,j})_{(i,j)\in J}\in\{-1,1\}^J\\|J|=k+1}}\left(\frac{\left\|\sum_{(i,j)\in J}\sigma_{i,j}v_h(i,j)\right\|_p}{k+1}\right)^p\right)^{1/p} \\ &\leq \max_{\substack{J\subseteq[s]\times[m/s],\,(s_{i,j})_{(i,j)\in J}\in\{-1,1\}^J\\|J|=k+1}} 2\binom{m}{k+1}^{1/p}\frac{\left\|\sum_{(i,j)\in J}\sigma_{i,j}v_h(i,j)\right\|_p}{k+1}\end{aligned}$$

We note that $\left\|\sum_{(i,j)\in J}\sigma_{i,j}v_h(i,j)\right\|_p = \left\|\sum_{x\in U}\sum_{(i,j)\in J}\sigma(i,x)s_{i,j}\left[h(i,x)=j\right]w_x\right\|_p$. Since we have that $p \geq \log m$ then $k \geq 1$ which implies that $k+1 \leq 2\frac{p}{\log(m/p)}$. We then get that $\binom{m}{k+1}^{1/p} \leq \left(\frac{em}{2p/\log(m/p)}\right)^{2/\log(m/p)} \leq 2e^3$. We now use Equation (6) to get that,

$$\begin{aligned}\left\|\sum_{x\in U}\sum_{(i,j)\in J}\sigma(i,x)s_{i,j}\left[h(i,x)=j\right]w_x\right\|_p &= \left\|\sum_{i\in[s]}\sum_{x\in U}\sigma(i,x)\left[(i,h(i,x))\in J\right]s_{i,h(i,x)}w_x\right\|_p \\ &\leq \sqrt{L\frac{p}{\log m/s}}\sqrt{|J|}\left\|w\right\|_2 \\ &= \sqrt{L\frac{p}{\log m/s}}\sqrt{k+1}\left\|w\right\|_2\end{aligned}$$

Combining this we get that $\|v'_h(\pi(k+1))\|_p \leq 4e^3\sqrt{L\frac{p}{\log m/s}}\frac{\|w\|_2}{\sqrt{k+1}}$. We then obtain that,

$$\begin{aligned}\left\|\sum_{i\in[s]}\sum_{y\in U}\overline{\sigma}(i,y)v''_h(i,\overline{h}(i,y))w_y\right\|_p &\\ \leq \sqrt{2}\Psi_p\left(4e^3L\sqrt{L\frac{p}{(k+1)\log m/s}}\|w\|_\infty\|w\|_2, L^2\frac{s^2}{m}\|w\|_2^4\right)&\\ \leq \sqrt{2}\Psi_p\left(4e^3L\sqrt{L\frac{\log m/p}{\log m/s}}\|w\|_2^2, L^2\frac{s^2}{m}\|w\|_2^4\right)&\end{aligned}$$

If $\log m/p \leq 4\log m/s$ then we get that,

$$\begin{aligned}\left\|\sum_{i\in[s]}\sum_{y\in U}\overline{\sigma}(i,y)v''_h(i,\overline{h}(i,y))w_y\right\|_p &\leq \sqrt{2}\Psi_p\left(16e^3L^{3/2}\|w\|_2^2, L^2\frac{s^2}{m}\|w\|_2^4\right)\\ &\leq \Psi_p\left(32e^3L^{3/2}\|w\|_2^2, 2L^2\frac{s^2}{m}\|w\|_2^4\right)\end{aligned}$$

If $\log m/p > 4\log m/s$ then $m/p > (m/s)^4$ which implies that $\frac{pm}{s^2} \leq \sqrt{p}m$. Using this we get that $\frac{p16e^6L^3\frac{\log m/p}{\log m/s}\|w\|_2^4}{L^2\frac{s^2}{m}\|w\|_2^4} \leq 16e^6L\sqrt{p}m\log m/p \leq 16e^6L$. Where we have used that $\sqrt{s}\log 1/x \leq 1$. Now we use Lemma 10 to get that

$$\begin{aligned}\left\|\sum_{i\in[s]}\sum_{y\in U}\overline{\sigma}(i,y)v''_h(i,\overline{h}(i,y))w_y\right\|_p &\leq \sqrt{2}\Psi_p\left(32e^3L^{3/2}\|w\|_2^2, L^2\frac{s^2}{m}\|w\|_2^4\right)\\ &\leq \sqrt{2}\sqrt{pL^3 16e^6\frac{s^2}{m}\|w\|_2^4}\\ &\leq \Psi_p\left(8e^3L^{3/2}\|w\|_2, 32e^6L^3\frac{s^2}{m}\|w\|_2^4\right)\end{aligned}$$

Now let us consider the case where $p < \log m$. By Equation (8), we get that

$$\|v'_h(\pi(k+1))\|_p \leq \left\|\max_{i\in[s],j\in[m/s]}\left|\sum_{x\in U}\sigma(i,x)\left[h(i,x)=j\right]w_x\right|\right\|_p \leq e\sqrt{L\frac{\log m}{\log m/s}}\|w\|_2$$

We then obtain that,

$$\begin{aligned}\left\|\sum_{i\in[s]}\sum_{y\in U}\overline{\sigma}(i,y)v''_h(i,\overline{h}(i,y))w_y\right\|_p &\leq \sqrt{2}\Psi_p\left(eL\sqrt{L\frac{\log m}{\log m/s}}\|w\|_\infty\|w\|_2, L\frac{s^2}{m}\|w\|_2^4\right)\\ &\leq \sqrt{2}\Psi_p\left(eL\sqrt{L\frac{\log m}{\log m/s}}\|w\|_2^2, L\frac{s^2}{m}\|w\|_2^4\right)\end{aligned}$$

If $s \leq m^{3/4}$ then we get that $\log m \leq 4\log m/s$ and

$$\sqrt{2}\Psi_p\left(eL\sqrt{L\frac{\log m}{\log m/s}}\|w\|_2^2, L\frac{s^2}{m}\|w\|_2^4\right) \leq \sqrt{2}\Psi_p\left(4eL^{3/2}\|w\|_2^2, L\frac{s^2}{m}\|w\|_2^4\right)$$

as wanted. If $s \geq m^{3/4}$ then we get that $\frac{peL^3 \log m}{L^2 s^2/m} \leq \frac{eLm \log^2 m}{s^2} \leq \frac{eL \log^2 m}{m^{1/2}} \leq 16/eL$, where we have used that $\sqrt{x} \log^2 1/x \leq 16/e^2$. Again we use Lemma 10 to get that

$$\begin{aligned}\sqrt{2}\Psi_p\left(4eL^{3/2}\left\|w\right\|_2^2, L\frac{s^2}{m}\left\|w\right\|_2^4\right) &\leq \sqrt{p32/eL^3\frac{s^2}{m}}\left\|w\right\|_2^2 \\ &\leq \Psi_p\left(8L^{3/2}\left\|w\right\|_2^2, 32L^3\frac{s^2}{m}\left\|w\right\|_2^4\right).\end{aligned}$$

Combining everything we get that

$$\begin{aligned}\left\|\sum_{i\in[s]}\sum_{y\in U}\overline{\sigma}(i,y)v''_h(i,\overline{h}(i,y))w_y\right\|_p &\leq \Psi_p\left(32e^3L^{3/2}\left\|w\right\|_2, 32e^6L^3\frac{s^2}{m}\left\|w\right\|_2^4\right), \\ \left\|\sum_{i\in[s]}\sum_{y\in U}\overline{\sigma}(i,y)v'_h(i,\overline{h}(i,y))w_y\right\|_p &\leq 4e^3L\frac{p}{\log m/s}\left\|w\right\|_2^2.\end{aligned}$$

Now we conclude that

$$\begin{aligned}&\left\|\sum_{i\in[s],j\in[m/s]} v_h(i,j)v_{\overline{h}}(i,j)\right\|_p \\ &\quad\leq \left\|\sum_{i\in[s]}\sum_{y\in U}\overline{\sigma}(i,y)v'_h(i,\overline{h}(i,y))w_y\right\|_p + \left\|\sum_{i\in[s]}\sum_{y\in U}\overline{\sigma}(i,y)v''_h(i,\overline{h}(i,y))w_y\right\|_p \\ &\quad\leq \Psi_p\left(32e^3L^{3/2}\left\|w\right\|_2^2, 32e^6L^3\left\|w\right\|_2^4\right) + 4e^3L\frac{p}{\log m/s}\left\|w\right\|_2^2.\end{aligned}$$

Thus finishing the proof. ◀

Approximating Max-Cut on Bounded Degree Graphs: Tighter Analysis of the FKL Algorithm

Jun-Ting Hsieh

Abstract

In this note, we describe a $\alpha_{GW} + \widetilde{\Omega}(1/d^2)$-factor approximation algorithm for Max-Cut on weighted graphs of degree $\leqslant d$. Here, $\alpha_{GW} \approx 0.878$ is the worst-case approximation ratio of the Goemans-Williamson rounding for Max-Cut. This improves on previous results for unweighted graphs by Feige, Karpinski, and Langberg [1] and Florén [3]. Our guarantee is obtained by a tighter analysis of the solution obtained by applying a natural local improvement procedure to the Goemans-Williamson rounding of the basic SDP strengthened with triangle inequalities.

1 Introduction

In 1994, Goemans and Williamson [4] described a polynomial time algorithm based on rounding the natural semidefinite relaxation for the Max-Cut problem to obtain an approximation ratio of $\alpha_{\mathrm{GW}} \approx 0.878$. Assuming the Unique Games Conjecture [5], this rounding algorithm is in fact worst-case optimal [6].

When the underlying graph has bounded degree, the complexity landscape of Max-Cut is much less clear. In particular, the Goemans-Williamson (GW) rounding algorithm can be improved by an elementary local-search based post-processing step applied to the cut obtained by GW rounding of the SDP relaxation strengthened by adding triangle inequalities. The first such result was shown by Feige, Karpinski, and Langberg [1] (FKL) to obtain an approximation ratio of $\alpha_{\mathrm{GW}} + \epsilon(d)$ for $\epsilon(d) = \Omega(1/d^4)$ for unweighted degree d graphs. Florén [3] later improved the FKL analysis to obtain $\epsilon(d) = \Omega(1/d^3)$ in the same setting.

In this note, we refine the local search scheme of FKL and give a tighter analysis to show that $\epsilon(d) = \widetilde{\Omega}(1/d^2)$. Moreover, we extend the result to weighted instances of Max-2LIN, which generalizes Max-Cut.

▶ **Theorem 1.** *There is a polynomial time algorithm that takes input a (weighted) Max-2LIN instance φ on a graph with n vertices and degree $\leqslant d$ and outputs an assignment that satisfies a number of constraints that is within an $\alpha_{\mathrm{GW}} + \Omega\left(\frac{1}{d^2 \log d}\right)$ of the optimum.*

[1] https://simons.berkeley.edu/talks/title-tba-5

As in FKL, the high-level plan is to show that when the "edgewise" analysis of the Goemans-Williamson rounded solution is "tight" (otherwise, we already obtain an improvement on the worst-case GW guarantee), the rounded solution is locally suboptimal. That is, there is a c_d-fraction of vertices, for some constant c_d depending only on d, such that switching them to the other side should cut more of the edges to their neighbors and thus increase the cut by at least one edge. But flipping a vertex may kill the increase from others. So we may not be able to "win" from every one of the candidates. The analysis then involves managing this dependency and lower bounding c_d. Specifically, FKL and Florén accomplish this by analyzing the chance that more than half of a vertex's neighbors lie on the same side of the partition generated by GW rounding. In such a plan, they have to handle vertices of odd and even degrees slightly differently and generalizations to weighted graphs seem to lose additional factors in the approximation ratio.

Instead of trying to gain only a single edge from a vertex flip, our analysis directly focuses on lower bounding the quantitative gain in the weighted cut by such an operation. This strategy also allows us to easily generalize our results to Max-2LIN and to arbitrary weighted graphs.

There is still a wide gap between approximation algorithms and hardness for Max-Cut in the bounded degree setting. In particular, for every $\epsilon > 0$, the best known hardness result by Trevisan [7] rules out polynomial time algorithms with an approximation ratio $> \alpha_{GW} + 5/\sqrt{d} + \epsilon$ for graphs of large enough constant degree d. Improving the approximation ratio to get closer to this bound (this will likely need a scheme different from FKL's) or obtaining a better inapproximability results are outstanding open questions.

2 The Algorithm and Analysis

▶ **Algorithm 2** (Max-2LIN on bounded degree graphs).

Given: A graph $G = (V, E)$ on n vertices, m edges and maximum degree d, signs $b_{ij} \in \{\pm 1\}$, and non-negative weights $w_{ij} > 0$ for each $\{i, j\} \in E$.

Operation:

1. Find unit vectors[a] $v_1, \ldots, v_n \in \mathbb{R}^n$ that maximize $\frac{1}{m} \sum_{\{i,j\} \in E} w_{ij} \frac{1}{2}(1 + b_{ij} \langle v_i, v_j \rangle)$, and, satisfy $\|a_i v_i - a_j v_j\|^2 + \|a_j v_j - a_k v_k\|^2 \geqslant \|a_i v_i - a_k v_k\|^2$ for every triple $\{i, j, k\}$ and $(a_i, a_j, a_k) \in \{\pm 1\}^3$.
2. Sample $g \sim \mathcal{N}(0, \mathbb{I}_n)$[b] , and set $x_i = \operatorname{sgn}(\langle g, v_i \rangle) \in \{\pm 1\}$.
3. Set $\varepsilon = \frac{1}{Cd\sqrt{\log d}}$ for some large enough constant $C > 0$. Define $S \coloneqq \{i \in V : \langle g, v_i \rangle \in (-\varepsilon, \varepsilon)\}$ to be the *candidate set* of suboptimal vertices. For each $i \in S$, partition its neighbors $N(i)$ into 3 disjoint sets:
   (a) $A_i = N(i) \cap S = \{j \in N(i) : \langle g, v_j \rangle \in (-\varepsilon, \varepsilon)\}$,
   (b) $B_i = \{j \in N(i) : b_{ij} x_i \langle g, v_j \rangle \leqslant -\varepsilon\}$,
   (c) $C_i = \{j \in N(i) : b_{ij} x_i \langle g, v_j \rangle \geqslant \varepsilon\}$.
4. Output x' obtained by flipping x_i for every $i \in S$ such that $\sum_{j \in B_i} w_{ij} > \sum_{j \in A_i \cup C_i} w_{ij}$.

[a] Approximately solving an SDP in poly(n) time produces such vectors with value at most $2^{-\operatorname{poly}(n)}$ smaller.

[b] As in standard implementations of the GW rounding scheme, truncating Gaussian samples to rationals of poly(n)-bits suffices to recover the stated guarantees up to a loss of an additive $2^{-\operatorname{poly}(n)}$ in the approximation ratio. We will omit a detailed discussion of issues of numerical precision in this note.

Analysis. We will appeal to the following three elementary facts.

▶ **Fact 3** (Gaussian Measure in the Core). *For any $\varepsilon > 0$,*

$$\frac{\varepsilon}{\sqrt{2\pi}} e^{-\varepsilon^2/2} \leqslant \Pr_{g \sim \mathcal{N}(0,1)} [g \in (0, \varepsilon)] \leqslant \frac{\varepsilon}{\sqrt{2\pi}} .$$

▶ **Fact 4** (Sheppard's Lemma [2]). *Let g_1, g_2 be standard Gaussian variables with covariance $\sigma = \mathbb{E}[g_1 g_2] \in [-1, 1]$. Then, $\mathbf{Pr}[g_1 \geqslant 0 \wedge g_2 \geqslant 0] = \frac{1}{2} - \frac{1}{2\pi} \arccos(\sigma)$.*

▶ **Fact 5** (Corollary of Schur Product Theorem). *Let $A \in \mathbb{R}^{n \times n}$ be positive semidefinite. For any $t \in \mathbb{N}$, the matrix $B \in \mathbb{R}^{n \times n}$ with entries $B_{ij} = A_{ij}^t$ is positive semidefinite.*

Our analysis crucially relies on the following basic fact about the arcsin function.

▶ **Lemma 6** (Basic Facts about Taylor Approximation for arcsin). *Let the Taylor expansion of the* arcsin *function be* $\arcsin(x) = \sum_{k=0}^{\infty} c_k x^{2k+1}$ *for* $|x| \leqslant 1$ *where* $c_k = \frac{(2k)!}{2^{2k}(k!)^2(2k+1)}$. *For any $\tau \in \mathbb{N}$, $\tau > \tau_0$ where τ_0 is a universal constant,*
(1) *for $x > 0$,* $\arcsin(x) \geqslant \sum_{k=0}^{\tau} c_k x^{2k+1}$,
(2) *for $|x| \leqslant 1/2$,* $\arcsin(x) \geqslant \sum_{k=0}^{\tau} c_k x^{2k+1} - O(\tau^{-1/2} \cdot 2^{-2\tau})$,
(3) *for $x = 1$,* $\arcsin(1) = \frac{\pi}{2} = \sum_{k=0}^{\tau} c_k + \Theta(\tau^{-1/2})$.

Proof. We first show that $c_k = \Theta(k^{-3/2})$ by Stirling's approximation:

$$c_k = (1 + O(1/k)) \cdot \frac{\sqrt{4\pi k}(2k/e)^{2k}}{2^{2k} \cdot 2\pi k (k/e)^{2k} \cdot (2k+1)} = \frac{1}{2\sqrt{\pi}} k^{-3/2} (1 + O(1/k)) .$$

Therefore, for any $\tau > \tau_0$ where τ_0 is a universal constant,

$$\sum_{k=\tau}^{\infty} c_k = \Theta(1) \sum_{k=\tau}^{\infty} k^{-3/2} = \Theta(1) \int_{\tau}^{\infty} x^{-3/2} \, dx = \Theta(\tau^{-1/2}) .$$

Now we prove the lemma. (1) is straightforward because $c_k > 0$ for all k. (2) holds since

$$\left| \sum_{k=\tau+1}^{\infty} c_k x^{2k+1} \right| \leqslant \sum_{k=\tau+1}^{\infty} c_k |x|^{2k+1} \leqslant 2^{-2\tau} \sum_{k=\tau+1}^{\infty} c_k \leqslant O(\tau^{-1/2} \cdot 2^{-2\tau}) .$$

Finally, (3) follows directly from $\sum_{k=\tau+1}^{\infty} c_k = \Theta(\tau^{-1/2})$. ◀

Lemma 6 states that for some large threshold τ, the Taylor approximation error for $|x| \leqslant 1/2$ is a factor $2^{-2\tau}$ smaller than the error for $x = 1$. This gap allows us to prove the key lemma below:

▶ **Lemma 7.** *Let $d \in \mathbb{N}$, $d \geqslant 2$. Let $A \in \mathbb{R}^{d \times d}$ be a positive semidefinite matrix such that $A_{ii} = 1$ and $A_{ij} \geqslant -1/2$ for all $i, j \in [d]$. Let $w \in \mathbb{R}^d_{\geqslant 0}$ be a vector with non-negative entries. Then,*

$$\sum_{i,j=1}^{d} w_i w_j \arcsin(A_{ij}) \geqslant \Omega\left(\frac{\|w\|_1^2}{d\sqrt{\log d}} \right) .$$

Proof. Pick a threshold $\tau = C \log_2 d$ for a large enough constant C. Since we have the assumption that $A_{ij} \geqslant -1/2$ and $w_i \geqslant 0$ for all i, j, we can bound the off-diagonal entries using (1) and (2) of Lemma 6,

$$\sum_{i\neq j}^{d} w_i w_j \arcsin(A_{ij}) \geqslant \sum_{i\neq j}^{d} w_i w_j \left(\sum_{k=0}^{\tau} c_k A_{ij}^{2k+1} - O(\tau^{-1/2}2^{-2\tau})\right)$$
$$= \sum_{k=0}^{\tau} c_k \sum_{i\neq j}^{d} w_i w_j A_{ij}^{2k+1} - \widetilde{O}\left(\frac{\|w\|_1^2}{d^{2C}}\right).$$

The diagonal entries are $\arcsin(1) = \sum_{k=0}^{\tau} c_k + \Theta(\tau^{-1/2})$ by (3) of Lemma 6. Thus, we get

$$\sum_{i,j=1}^{d} w_i w_j \arcsin(A_{ij}) \geqslant \sum_{k=0}^{\tau} c_k \sum_{i,j=1}^{d} w_i w_j A_{ij}^{2k+1} + \sum_{i=1}^{d} w_i^2 \cdot \Omega(\tau^{-1/2}) - \widetilde{O}\left(\frac{\|w\|_1^2}{d^{2C}}\right)$$
$$= \sum_{k=0}^{\tau} c_k \sum_{i,j=1}^{d} w_i w_j A_{ij}^{2k+1} + \Omega\left(\frac{\|w\|_2^2}{\sqrt{\log d}}\right) - \widetilde{O}\left(\frac{\|w\|_1^2}{d^{2C}}\right).$$

Since $A \succeq 0$, by Fact 5 we know that $\sum_{ij=1}^{d} w_i w_j A_{ij}^{2k+1} \geqslant 0$ for all $k \geqslant 0$. Finally, any $w \in \mathbb{R}^d$ satisfies $\|w\|_2^2 \geqslant \frac{1}{d}\|w\|_1^2$. This completes the proof. ◀

2.1 Proof of Theorem 1

Let $\rho_* = \arg\min_{\rho\in[-1,1]} \frac{1+\frac{2}{\pi}\arcsin(\rho)}{1+\rho} \approx 0.689$ such that $\frac{1+\frac{2}{\pi}\arcsin(\rho_*)}{1+\rho_*} = \alpha_{\mathrm{GW}}$. Following [1], we can assume without loss of generality that for all $(i,j) \in E$ with sign b_{ij}, the SDP solution satisfies $b_{ij}\langle v_i, v_j\rangle \in [\rho_* - 0.01, \rho_* + 0.01]$.

Observe that after Item 2 of Algorithm 2, for every i in the candidate set S, by definition all edges between i and B_i are violated, while all edges between i and C_i are satisfied. Moreover, it is crucial that B_i and C_i are *disjoint* from S, so their assignments will not be flipped in Item 4. For edges between i and A_i, in the worst case all of them are violated after flipping. Thus, if $\sum_{j\in B_i} w_{ij} > \sum_{j\in A_i\cup C_i} w_{ij}$, then flipping x_i will increase the Max-2LIN value.

We will prove that the expected gains from such local updates are large. For a vertex $i \in S$, let $W_i \coloneqq \sum_{j\in N(i)} w_{ij}$ be the total weight of edges incident to i. Define the *local gain* from i to be

$$\Delta_i \coloneqq \left(\sum_{j\in B_i} w_{ij} - \sum_{j\in A_i\cup C_i} w_{ij}\right)_+ = \left(2\sum_{j\in B_i} w_{ij} - W_i\right)_+,$$

where we denote $(z)_+ = \max(0, z)$. The following is the key lemma of our analysis showing that conditioned on $i \in S$, the expected local gain from vertex i is at least $\widetilde{\Omega}(\frac{W_i}{d})$.

▶ **Lemma 8** (Expected local gain). *Let $d \in \mathbb{N}, d \geqslant 2$ and $\varepsilon = \frac{1}{Cd\sqrt{\log d}}$ for a large enough constant C. For a vertex $i \in V$ with degree d, the expected local gain $\mathbb{E}[\Delta_i | i \in S] \geqslant \Omega\left(\frac{W_i}{d\sqrt{\log d}}\right)$.*

Proof. Consider vertex $i \in S$ and its d neighbors, denoted $[d]$. We first introduce some notations for the analysis.

- We can assume that $v_i = (1, 0, \ldots, 0)$ without loss of generality due to rotational symmetry.
- For every neighbor $j \in [d]$, let $v_j = (\rho_j, v_j')$ where the first coordinate is $\rho_j \in b_{ij}\cdot[\rho_* \pm 0.01]$ and $v_j' \in \mathbb{R}^{n-1}$ since we assume that $b_{ij}\langle v_i, v_j\rangle \approx \rho_*$ for all $(i,j) \in E$.

- Denote the unit vector $\widehat{v}_j = v'_j/\|v'_j\|_2$.
- Let $g = (g_1, \ldots, g_n) \sim \mathcal{N}(0, \mathbb{I}_n)$ be the sampled Gaussian vector, and let $g' = (g_2, \ldots, g_n)$.
- Let $h_j \coloneqq b_{ij} x_i \langle \widehat{v}_j, g' \rangle$. The random vector $h = (h_1, \ldots, h_d)$ is a multivariate Gaussian variable with covariance matrix $\Sigma \in \mathbb{R}^{d \times d}$ where $\Sigma_{jj} = 1$ and $\Sigma_{jk} = b_{ij} b_{ik} \langle \widehat{v}_j, \widehat{v}_k \rangle$.

Since $\|v_j\|_2 = 1$, we have $\|v'_j\|_2 = \sqrt{1-\rho_j^2} \in [0.726 \pm 0.01]$, and $\langle v_j, g \rangle = \rho_j g_1 + \sqrt{1-\rho_j^2}\langle \widehat{v}_j, g' \rangle$. Recall that $S = \{i \in V : \langle g, v_i \rangle \in (-\varepsilon, \varepsilon)\}$. Thus, $i \in S$ means that $\langle v_i, g \rangle = g_1 \in (-\varepsilon, \varepsilon)$. Next, we define the following random variable

$$Z \coloneqq \sum_{j=1}^{d} w_{ij} \cdot \mathbf{1}\left(h_j \leqslant -3\varepsilon\right) .$$

Conditioned on the event that $|g_1| < \varepsilon$,

$$h_j \leqslant -3\varepsilon \implies b_{ij} x_i \langle v_j, g \rangle \leqslant |\rho_j g_1| + \sqrt{1-\rho_j^2} \cdot h_j \leqslant -\varepsilon .$$

Therefore, we have $Z \leqslant \sum_{j \in B_i} w_{ij}$ (recall that $B_i = \{j \in N(i) : b_{ij} x_i \langle v_j, g \rangle \leqslant -\varepsilon\}$). Then,

$$\Delta_i = \left(2 \sum_{j \in B_i} w_{ij} - W_i \right)_+ \geqslant (2Z - W_i)_+ .$$

Thus, it suffices to lower bound $\mathbb{E}[(2Z - W_i)_+]$.

First, every h_j is a standard Gaussian, so let $p \coloneqq \mathbf{Pr}[h_j \leqslant -3\varepsilon] = \frac{1}{2} - c\varepsilon$ for some $c \leqslant \frac{3}{\sqrt{2\pi}}$ by Fact 3. Then, $\mathbb{E}[Z] = pW_i$. Next, we lower bound $\mathbb{E}[(Z - W_i/2)^2]$.

$$\begin{aligned}
\mathbb{E}\left[(Z - W_i/2)^2\right] &= \mathbb{E}\left(\sum_{j=1}^{d} w_{ij} \left(\mathbf{1}(h_j \leqslant -3\varepsilon) - \frac{1}{2} \right) \right)^2 \\
&= \frac{1}{4} \sum_{j=1}^{d} w_{ij}^2 + \sum_{j \neq k}^{d} w_{ij} w_{ik} \left(\mathbf{Pr}\left[h_j \leqslant -3\varepsilon \wedge h_k \leqslant -3\varepsilon\right] - p + \frac{1}{4} \right) \\
&\geqslant \frac{1}{4} \sum_{j=1}^{d} w_{ij}^2 + \sum_{j \neq k}^{d} w_{ij} w_{ik} \left(\frac{1}{2} - \frac{1}{2\pi} \arccos(\Sigma_{jk}) - 2c\varepsilon - \left(\frac{1}{4} - c\varepsilon \right) \right) \\
&\geqslant \frac{1}{2\pi} \sum_{j,k=1}^{d} w_{ij} w_{ik} \arcsin(\Sigma_{jk}) - c\varepsilon W_i^2 . \qquad (1)
\end{aligned}$$

The third line follows from $\mathbf{Pr}[h_j \leqslant -3\varepsilon \wedge h_k \leqslant -3\varepsilon] \geqslant \mathbf{Pr}\left[h_j \leqslant 0 \wedge h_k \leqslant 0\right] - 2 \cdot \mathbf{Pr}[-3\varepsilon \leqslant h_j \leqslant 0]$ and applying Fact 4. The final inequality is because $\frac{\pi}{2} - \arccos(\theta) = \arcsin(\theta)$ and $\arcsin(\Sigma_{jj}) = \arcsin(1) = \frac{\pi}{2}$.

By the triangle inequality of the SDP solution, for any $j \neq k$, $\|v_i - b_{ij} v_j\|^2 + \|v_i - b_{ik} v_k\|^2 \geqslant \|b_{ij} v_j - b_{ik} v_k\|^2$. Expanding this, we get

$$b_{ij} b_{ik} \left(\rho_j \rho_k + \sqrt{1-\rho_j^2}\sqrt{1-\rho_k^2} \langle \widehat{v}_j, \widehat{v}_k \rangle \right) \geqslant b_{ij}\rho_j + b_{ik}\rho_k - 1 .$$

Since $b_{ij}\rho_j \in [\rho_* \pm 0.01]$ for all $j \in [d]$, we have

$$\Sigma_{jk} = b_{ij} b_{ik} \langle \widehat{v}_j, \widehat{v}_k \rangle \geqslant -0.2 .$$

This is crucial since we can now apply Lemma 7 to Equation (1) and get

$$\mathbb{E}\left[(Z - W_i/2)^2\right] \geqslant \Omega\left(\frac{W_i^2}{d\sqrt{\log d}}\right) - O(\varepsilon W_i^2)\,.$$

Finally, we lower bound $\mathbb{E}[(2Z - W_i)_+]$. Let $\overline{Z} = Z - W_i/2$, and let $\overline{Z}_+ = \max(0, \overline{Z})$ and $\overline{Z}_- = \max(0, -\overline{Z})$. Thus, $\overline{Z} = \overline{Z}_+ - \overline{Z}_-$ and $\overline{Z}^2 = \overline{Z}_+^2 + \overline{Z}_-^2$ by definition, and both $\overline{Z}_+$ and $\overline{Z}_-$ lie in $[0, W_i/2]$. Furthermore, $\mathbb{E}[\overline{Z}] = \mathbb{E}[\overline{Z}_+] - \mathbb{E}[\overline{Z}_-] = pW_i - W_i/2 = -c\varepsilon W_i$. Then,

$$\mathbb{E}\left[\overline{Z}^2\right] = \mathbb{E}\left[\overline{Z}_+^2 + \overline{Z}_-^2\right] \leqslant \frac{W_i}{2} \cdot \mathbb{E}\left[\overline{Z}_+ + \overline{Z}_-\right] = W_i \cdot \mathbb{E}[\overline{Z}_+] + \frac{c}{2}\varepsilon W_i^2\,.$$

Setting $\varepsilon \leqslant \frac{1}{Cd\sqrt{\log d}}$ for a large enough C, we have $\mathbb{E}[\overline{Z}_+] \geqslant \Omega\left(\frac{W_i}{d\sqrt{\log d}}\right)$. This completes the proof. ◀

We can now prove Theorem 1.

Proof of Theorem 1. We first assume that for all $(i,j) \in E$ with sign b_{ij}, the SDP solution satisfies $b_{ij}\langle v_i, v_j\rangle \in [\rho_* - 0.01, \rho_* + 0.01]$ where $\rho_* \approx 0.689$. Recall that in Algorithm 2, for every $i \in S$, all edges between i and B_i are violated, and all edges between i and C_i are satisfied. Further, since B_i and C_i are disjoint from S, the vertices in B_i and C_i will not be flipped. For edges between i and A_i, in the worst case all of them are violated after flipping. Thus, we have a local gain of at least $\Delta_i = (\sum_{j\in B_i} w_{ij} - \sum_{j\in A_i\cup C_i} w_{ij})_+$.

The expected total gain from the local updates (over the random sample of g) is

$$\mathbb{E}[\Delta] = \mathbb{E}\sum_{i\in S}\Delta_i = \sum_{i\in V}\mathbb{E}\left[\mathbf{1}(i\in S)\Delta_i\right] = \sum_{i\in V}\mathbf{Pr}[i\in S]\cdot\mathbb{E}[\Delta_i | i\in S] \geqslant \Omega(\varepsilon)\sum_{i\in V}\mathbb{E}[\Delta_i | i\in S]\,,$$

where $\mathbf{Pr}[i \in S] = \Omega(\varepsilon)$ is due to Fact 3. Then, setting $\varepsilon = \frac{1}{Cd\sqrt{\log d}}$ for a large enough constant C, by Lemma 8 and the fact that the total weight $W = \frac{1}{2}\sum_{i\in V} W_i$, we have

$$\mathbb{E}[\Delta] \geqslant \Omega(\varepsilon)\cdot\sum_{i\in V}\Omega\left(\frac{W_i}{d\sqrt{\log d}}\right) = W\cdot\Omega\left(\frac{1}{d^2\log d}\right)\,.$$

Therefore, if the Max-2LIN instance φ has optimum $\mathsf{OPT} \leqslant W$, then in expectation we can find an assignment that satisfies

$$\varphi(x) \geqslant \alpha_{\mathrm{GW}}\cdot\mathsf{OPT} + W\cdot\Omega\left(\frac{1}{d^2\log d}\right) \geqslant \left(\alpha_{\mathrm{GW}} + \Omega\left(\frac{1}{d^2\log d}\right)\right)\cdot\mathsf{OPT}\,.$$

From here on, we follow the same argument as [1]. Let $\delta = \Omega(\frac{1}{d^2\log d})$ be the improvement above. If more than $\delta/2$ fraction of the (weighted) edges satisfy $b_{ij}\langle v_i, v_j\rangle \notin [\rho_* \pm 0.01]$, then hyperplane rounding already gives us $\alpha_{\mathrm{GW}} + \Omega(\delta)$ approximation ratio. If at most $\delta/2$ fraction of the edges have $b_{ij}\langle v_i, v_j\rangle \notin [\rho_* \pm 0.01]$, then we can simply ignore those edges and get an approximation of $(1 - \delta/2)(\alpha_{\mathrm{GW}} + \delta) \geqslant \alpha_{\mathrm{GW}} + \Omega(\delta)$. This completes the proof. ◀

Abstract

In [11, 13], Saunderson, Parrilo, and Willsky asked the following elegant geometric question: what is the largest $m = m(d)$ such that there is an ellipsoid in $\mathbb{R}^d$ that passes through $v_1, v_2, \ldots, v_m$ with high probability when the v_is are chosen independently from the standard Gaussian distribution $N(0, I_d)$? The existence of such an ellipsoid is equivalent to the existence of a positive semidefinite matrix X such that $v_i^\top X v_i = 1$ for every $1 \leqslant i \leqslant m$ – a natural example of a *random* semidefinite program. SPW conjectured that $m = (1 - o(1))d^2/4$ with high probability. Very recently, Potechin, Turner, Venkat and Wein [10] and Kane and Diakonikolas [8] proved that $m \gtrsim d^2/\log^{O(1)}(d)$ via a certain natural, explicit construction.

In this work, we give a substantially tighter analysis of their construction to prove that $m \gtrsim d^2/C$ for an absolute constant $C > 0$. This resolves one direction of the SPW conjecture up to a constant. Our analysis proceeds via the method of *Graphical Matrix Decomposition* that has recently been used to analyze correlated random matrices arising in various areas [3, 2]. Our key new technical tool is a refined method to prove singular value upper bounds on certain correlated random matrices that are tight up to absolute dimension-independent constants. In contrast, all previous methods that analyze such matrices lose logarithmic factors in the dimension.

1 Introduction

Given vectors $v_1, \ldots, v_m \in \mathbb{R}^d$, we say that these vectors satisfy the *ellipsoid fitting property* if there exists an origin-centered ellipsoid that passes through all these points, i.e., if there exists a matrix Λ such that

1. $v_i^T \Lambda v_i = 1$ for all $i \in [m]$,
2. $\Lambda \succeq 0$.

In this work, we study vectors sampled i.i.d. from the standard Gaussian distribution. It is known that when $m \leqslant d+1$, the vectors satisfy the ellipsoid fitting property with probability 1 [12]. On the other hand, when $m > \binom{d+1}{2}$, by a simple dimension argument, the vectors

don't satisfy the ellipsoid fitting property with probability 1. This prompts the question: *what is the largest $m = m(d)$ such that $v_1, \ldots, v_m \sim \mathcal{N}(0, I_d)$ satisfy the ellipsoid fitting property with probability at least $1 - o_d(1)$ (taking $d \to \infty$)?*

In a series of work, Saunderson et. al. [11, 12, 13] studied this problem in the context of diagonal and low-rank matrix decomposition. Motivated by numerical experiments, they conjectured that the ellipsoid fitting property for Gaussian random v_is exhibits a phase transition at $m \sim \frac{d^2}{4}$ (see also the experiments presented in [10]).

▶ **Conjecture 1** (SCPW conjecture). *Let $\varepsilon > 0$ be a constant and $v_1, \ldots, v_m \sim \mathcal{N}(0, I_d)$ be i.i.d. standard Gaussian vectors in $\mathbb{R}^d$. Then,*

1. *If $m \leqslant (1 - \varepsilon)\frac{d^2}{4}$, then $v_1, \ldots, v_m$ have the ellipsoid fitting property with probability $1 - o_d(1)$.*
2. *If $m \geqslant (1 + \varepsilon)\frac{d^2}{4}$, then $v_1, \ldots, v_m$ have the ellipsoid fitting property with probability $o_d(1)$.*

Prior works have focused on establishing the positive result – that is, part (1) of the above conjecture. Early works [11, 13] established that the ellipsoid fitting property holds for $m \leqslant O(d^{6/5-\varepsilon})$ independent Gaussian vector whp. In the context of proving Sum-of-Squares lower bounds for the Sherringtin-Kirkpatrick model, the work [4] obtains a result that, as an immediate corollary, improves the above bound to $O(d^{3/2-\varepsilon})$. In fact, their work gives an implicit bound of $m \leqslant O(d^2/\operatorname{polylog}(d))$ for ellipsoid fitting when restricted to degree-2 Sum-of-Squares.

Very recently, two independent works of Potechin et. al. [10] and Kane and Diakonikolas [8] proposed new constructions of Λ (that differ from the constructions obtained by the method of pseudo-calibration in [4]) and recovered the bound of $m \leqslant O(d^2/\operatorname{polylog}(d))$. In their works [10, 8], the authors ask the question of analyzing their construction (or a different one) to obtain an improved and almost optimal estimate of $m = d^2/C$ for some absolute constant $C > 0$. The main result of this paper accomplishes this goal. Specifically, we prove:

▶ **Theorem 2** (Main result). *There is a universal constant $c > 0$ such that if $m \leqslant cd^2$, then $v_1, \ldots, v_m \sim \mathcal{N}(0, I_d)$ have the ellipsoid fitting property with probability $1 - o_d(1)$.*

We establish Theorem 2 by analyzing the construction of Kane and Diakonikolas [8] (which is a variant of the construction proposed in [10]). Our key idea is to depart from the analysis conducted by [8] and instead rely on the *graphical matrix decomposition* method. This method decomposes a random matrix with correlated entries into a sum of structured random matrices called *graph matrices*. Graph matrices can be thought of as an analog of the *Fourier basis* in the analysis of functions over product spaces. This method was first employed in the works establishing tight sum-of-squares lower bound on the planted clique problem [5, 1, 3, 7] and has since then been employed in several follow-up works on proving sum-of-squares lower bounds and more recently in analyzing well-conditionedness of linear algebraic algorithms for generalizations of tensor decomposition [2]).

The key technical work in the analysis then becomes understanding the smallest and largest singular values of graph matrices. All prior works rely on arguments that establish bounds on the largest singular values that are accurate up to polylogarithmic factors in the underlying dimension of the matrices. The work of [2] recently showed how to use such bounds to also obtain estimates of the smallest singular values of graph matrices (which, otherwise are significantly more challenging to prove). Nevertheless, the slack in such bounds does not allow us to obtain any improvement on the previous estimates [8] in our application.

Our main technical contribution is a new technique to establish bounds on the largest singular values of graph matrices that are tight up to dimension-independent absolute constants. This allows us to obtain substantially improved estimates for the SCPW conjecture. Given the host of previous applications of such bounds, we expect that our results will have many more applications down the line.

Table 1 Comparison of our result with prior work.

Construction	Bound on m
Conjectured	$d^2/4$
[11, 13]	$O(d^{6/5-\varepsilon})$
[4]	$O(d^{3/2-\varepsilon})$ *
[10]	$O(d^2/\operatorname{polylog}(d))$
[8]	$O(d^2/\log^4(d))$
this paper	$O(d^2)$

*The bound $O(d^2/\operatorname{polylog}(d))$ is implicit in their work.

1.1 Technical overview

Following the convention of [8], for the rest of the paper we will assume that $v_1, \ldots, v_m \sim \mathcal{N}(0, \frac{1}{d} I_d)$ such that each vector has expected norm 1. Note that this does not change the problem as we can simply scale Λ.

Our construction of Λ is the "identity perturbation construction", which is the same one analyzed in [8] and was proposed in [10]. As an intuition, observe that $\Lambda = I_d$ almost works: $v_i^T I_d v_i = \|v_i\|_2^2 \approx 1$. Thus, the idea is to define Λ as a perturbation of I_d: $\Lambda = I_d - \sum_{i=1}^m w_i v_i v_i^T$, where $w = (w_1, \ldots, w_m) \in \mathbb{R}^m$. To determine w, observe that the constraints $v_i^T \Lambda v_i = 1$ give m linear constraints on w, and this can be written as a linear system represented by a matrix $M \in \mathbb{R}^{m \times m}$ with entries $M[i,j] = \langle v_i, v_j \rangle^2$. Thus, given that M is full rank, w is uniquely determined by $w = M^{-1}\eta$ for some vector η (see Eq. (2)). This construction satisfies $v_i^T \Lambda v_i = 1$ automatically, so the next thing is to prove that $\Lambda \succeq 0$. Therefore, we have two high-level goals:

1. Prove that M is full rank and analyze M^{-1}.
2. Prove that $R \coloneqq \sum_{i=1}^n w_i v_i v_i^T$ has spectral norm bounded by 1.

Proving the second statement immediately implies that Λ is a valid construction.

To achieve the first goal, we *decompose* M into several components. Roughly, we write $M = A + B$ where A is a perturbed identity matrix $A = I_m - T$ and B is a rank-2 matrix (see Section 2.2). We first show that $\|T\|_{\mathrm{op}} \leqslant O(\frac{\sqrt{m}}{d}) < 0.5$ with $m \leqslant O(d^2)$ (Lemma 9), hence A is well-conditioned. Then, using the fact that B has rank 2, we can apply the Woodbury matrix identity (Fact 7 and Fact 8) – a statement on the inverse of low-rank corrections of matrices – to conclude that M is invertible and obtain an expression for M^{-1}. This is carried out in Section 2.3.

Next, for the second goal, we need to further expand A^{-1}. Since $\|T\|_{\mathrm{op}} < 1$, we can apply the Neumann series and write $A^{-1} = (I_m - T)^{-1} = \sum_{k=0}^{\infty} T^k$. For the analysis, we select certain thresholds to truncate this series such that the truncation error is small. Then, we write M^{-1} in terms of the truncated series plus a small error, which will be useful later for the analysis of R. This is carried out in the full version.

Finally, given the expression of M^{-1}, R naturally decomposes into 4 matrices. Then, all we need to do is to bound the spectral norm of each of these matrices (see the full version). Bounding $\|R\|_{\mathrm{op}} \leqslant 1$ implies that $\Lambda \succeq 0$, completing the proof.

Requiring tight norm bounds. Our main technical lemmas are the spectral norm bounds of T (Lemma 9) and the matrices in the decomposition of R. Clearly, we need our norm bound $\|T\|_{\mathrm{op}} \leqslant O(\frac{\sqrt{m}}{d})$ to be tight without polylog factors so that $m \leqslant O(d^2)$ suffices, and similarly for matrices from R.

The standard starting point is the *trace moment method*: for any symmetric matrix $M \in \mathbb{R}^{n\times n}$ and $q \in \mathbb{N}$ (usually taking $q = \mathrm{polylog}(n)$ suffices),

$$\|M\|_{\mathrm{op}}^{2q} \leqslant \mathrm{tr}(M^{2q}) = \sum_{i_1,i_2,\ldots,i_{2q}\in[n]} M[i_1,i_2]M[i_2,i_3]\cdots M[i_{2q},i_1]\,.$$

We view the summand as a closed walk $i_1 \to i_2 \to \cdots \to i_{2q} \to i_1$ on n vertices. For a random matrix, we study the expected trace $\mathbb{E}\,\mathrm{tr}(M^{2q})$. In the simple case when M is a Gaussian matrix (GOE), we see that after taking the expectation, the non-vanishing terms are closed walks where each edge (u, v) is traversed even number of times. This is in fact true for any symmetric M with independent random entries as long as the odd moments of the entries are zero. Thus, a precise upper bound on $\mathbb{E}\,\mathrm{tr}(M^{2q})$ can be obtained by carefully counting such closed walks (see [14]).

Our matrices are more complicated; each entry is a mean-zero *polynomial* of Gaussian random variables. To carry out the trace method, we represent the matrices as graphs, hence the term *graph matrices*. The framework of graph matrices was first introduced by [3], and over the years, off-the-shelf norm bounds (e.g. [1]) for graph matrices have been developed and successfully used in several works [9, 4, 6, 7, 2]. However, the currently known norm bounds are only tight up to polylog factors, hence not sufficient for us. Therefore, the bulk of our paper is to prove norm bounds for these matrices that are tight up to constant factors. In fact, some of our bounds on graph matrices are even tight in the constant factor. However, we do not pursue the exact constants for two reasons. First, obtaining bounds which are tight in the constant factor would require additional technical work. Second, numerical experiments from [10] show that the identity perturbation construction we analyze has a threshold of $\frac{d^2}{C_{IP}}$ where $C_{IP} \approx 10$, so it falls short of the $\frac{d^2}{4}$ threshold and we would need a different construction to reach this threshold.

Key idea towards tight norm bounds. Here, we briefly discuss the high-level ideas for proving tight norm bounds. To illustrate our techniques, in Section 3 we will give a full proof for a matrix that arises in our analysis as an example, and also discuss key ideas that allow us to analyze more complicated matrices.

The key to counting walks is to specify an *encoding*, which we view as *information* required for a *walker* to complete a walk. If we can show that such an encoding uniquely identifies a walk, then we can bound the walks by bounding the number of possible encodings. Thus, it suffices to come up with an (efficient) encoding scheme and prove that the walker is able to complete a walk. Using standard encoding schemes, we quickly realize that the walker may be *confused* during the walk, i.e., the walker does not have enough information to perform the next step. Thus, we need to *pay* for additional information in the encoding to resolve confusions. So far, this is the same high-level strategy that was used in prior work [14, 1, 7], and this extra pay is often the source of extra log factors in the norm bounds.

Our key innovation is to pay for the extra information during steps that require much less information than normal. Roughly speaking, we label each step of the walk as either (1) visiting a new vertex, (2) visiting an old vertex via a new edge, (3) using an old edge but not the last time, (4) using an old edge the last time (see Definition 20). The high level idea is that the dominating walks in the trace are the ones that use only the 1st and 4th

types, while the 2nd and 3rd types require less information (which we call *gaps*). The main observation is that the walker will be confused only when there are steps of the 2nd and 3rd type involved, but we can pay extra information during these steps to resolve potential (future) confusions. This is illustrated in Section 3.5.

1.2 Comparison to prior work

Comparison to Kane and Diakonikolas [8]. Our candidate matrix Λ is the same as theirs. A slight difference is that they write $\Lambda = I_d + \sum_{i=1}^m \delta_i \overline{v}_i \overline{v}_i^T$ where $\overline{v}_1, \ldots, \overline{v}_m$ are the vectors normalized to the unit sphere. Then, same as our w vector, $(\delta_1, \ldots, \delta_m)$ must satisfy a linear system represented by a matrix $\overline{M} \in \mathbb{R}^{m \times m}$ where $\overline{M}[i,j] = \langle \overline{v}_i, \overline{v}_j \rangle^2$. This is closely related to our M matrix, and to prove that $\overline{M}$ is invertible, they also decompose $\overline{M}$ into several components and bound their spectral norms. However, they were only able to bound the spectral norm by $O(\frac{\sqrt{m}\log^2 d}{d})$, which requires $m \leqslant O(d^2/\log^4(d))$. We also point out that they explicitly emphasize the gap from spectral norm bound poses a significant hurdle in their analysis, which is indeed a major contribution of our work.

Next, to bound the spectral norm of $\overline{R} := \sum_{i=1}^m \delta_i \overline{v}_i \overline{v}_i^T$, they use an elegant cover (or ε-net) argument which is significantly different than ours. They show that for any fixed unit vector $u \in \mathcal{S}^{d-1}$, $|u^T \overline{R} u| = |\sum_{i=1}^m \delta_i \langle \overline{v}_i, u \rangle^2| \leqslant 1/2$ with *exponentially* small failure probability. This allows then to take a union bound over all $2^{O(d)}$ unit vectors in an ε-net. To do this, they use the elegant trick that $\overline{v}_i$ and $\|v_i\|_2$ are independent random variables, so $u^T \overline{R} u$ can be written as a sum of independent variables: $u^T \overline{R} u = \langle \varepsilon, \gamma \rangle$, where ε_i only depends on $\|v_i\|_2$ and γ is a function of u and the $\overline{v}_i$'s. By Hoeffding's inequality, they get a tail probability of $\exp\Big(-\Omega\Big(\frac{d^3}{m\log^2(d)}\Big)\Big)$. In order to union bound over $2^{O(d)}$ vectors, this also requires that $m \leqslant O(d^2/\log^2(d))$. Thus, while the main source of their polylog gap is their matrix norm bound, another source is the epsilon-net argument. This is partially why we adopt the proof strategy of using graph matrix decompositions which is seemingly more complicated.

Comparison to Potechin, Turner, Venkat and Wein [10]. They study a construction of "least-square minimization" proposed by [11], which is equivalent to projecting out the identity mass onto the subspace of matrices satisfying the constraints. In particular, their matrix analysis proceeding via Woodbury expansion and Neumann series using graph matrices serves as a road-map for our current work, and gives rise to a motivating question in the beginning for our work: can a more careful analysis get us all the way to a constant factor gap, or is the polylog gap inherent in the analysis? A priori, it is not clear whether this kind of matrix analysis, forsaking the underlying geometric insight, might get us anywhere beyond a single polylog factor, as it is conceivable that some polylog factor is inherent for matrices that may arise in the analysis. In this work, we answer this question affirmatively and en-route we develop a more refined understanding of the structured random matrices that we believe would be useful in further and more fine-grained investigations of problems in average-case complexity.

Comparison to Ghosh et. al. [4]. In the context of the Planted Affine Plane problem, and its downstream application for the Sherrington-Kirkpatrick Hamiltonian, Ghosh et. al. reaches the threshold of $\widetilde{O}(d^{3/2-\varepsilon})$ for $n^{O(\varepsilon)}$-degree Sum-of-Squares. They adopt the framework of pseudo-calibration [3] to obtain a candidate matrix, and follow a similar recipe as ours via graph matrix decompositions and spectral analysis. Even though their stated result falls

short of the $\widetilde{O}(d^2)$ threshold for fitting ellipsoid, it is folklore among the SoS lower bounds community that their proof implicitly extends to $\widetilde{O}(d^2)$ when restricted to degree-2 SoS. That said, it is an interesting question whether solutions coming from a pseudo-calibration type of construction might give us some extra mileage in ultimately closing the constant gap. A natural idea is to analyze the planted distribution pioneered in [9, 4]: unfortunately, it can be easily verified that the low-degree polynomial hardness for the particular planted distribution actually falls apart even if we assume an arbitrary constant gap. Since the low-degree hardness is usually deemed as a precursor for SoS lower bounds, an analysis based on pseudo-calibration that gets us the right constant (or in fact, any constant) lands one on a pursuit for a "quieter" planting.

2 Proof of main result

Given $v_1, v_2, \ldots, v_m$ that are i.i.d. samples from $\mathcal{N}(0, \frac{1}{d} I_d)$, recall that we must construct a matrix Λ such that (1) $v_i^T \Lambda v_i = 1$ for any $i \in [m]$, and (2) $\Lambda \succeq 0$.

In this section, we describe our candidate matrix (Definition 3). To prove that it satisfies the two conditions above, we need to analyze certain random matrices (and their inverses) that arise in the construction, which involves decomposing the matrices into simpler components. We will state our key spectral norm bounds (Lemma 9 and Lemma 13) whose proofs are deferred to later sections, and complete the proof of Theorem 2 in Section 2.4.

2.1 Candidate construction

The following is our candidate matrix Λ, which is the same as the one used in [8].

▶ **Definition 3** (Candidate matrix). *Given $v_1, \ldots, v_m \sim \mathcal{N}(0, \frac{1}{d} I_d)$, we define the matrix $\Lambda \in \mathbb{R}^{d \times d}$ to be*

$$\Lambda := I_d - \sum_{i=1}^{m} w_i v_i v_i^T \tag{1}$$

where we take $w = (w_1, w_2, \ldots, w_m)$ to be the solution to the linear system $Mw = \eta$ for $\eta \in \mathbb{R}^m$ given by

$$\eta_i := \|v_i\|_2^2 - 1, \quad \forall i \in [m]\,, \tag{2}$$

and $M \in \mathbb{R}^{m \times m}$ with entries given by

$$M[i,j] := \langle v_i, v_j \rangle^2, \quad \forall i, j \in [m]\,. \tag{3}$$

We first make the following simple observation.

▶ **Observation 4.** *For any $i \in [m]$, the constraint $v_i^T \Lambda v_i = 1$ is satisfied.*

Proof. For any $i \in [m]$,

$$v_i^T \Lambda v_i = v_i^T I_d v_i - \sum_{j \in [m]} w_j \langle v_i, v_j \rangle^2 = \|v_i\|_2^2 - \langle M[i], w \rangle = \|v_i\|_2^2 - \eta_i = 1\,.$$

Here $M[i]$ is the i-th row of M, and the equality above follows from $Mw = \eta$ and $\eta_i = \|v_i\|_2^2 - 1$ from Eq. (2). ◀

Structure of subsequent sections. For Λ to be well-defined, we require that M is full rank (hence invertible). Note that it is easy to see that M is positive semidefinite, since M is a Gram matrix with $M[i,j] = \langle v_i^{\otimes 2}, v_j^{\otimes 2} \rangle$. To analyze M, we will show a decomposition of M in Section 2.2 that allows us to more easily analyze its inverse. In Section 2.3, we will prove that M is in fact positive definite (Lemma 12).

Next, to prove that $\Lambda \succeq 0$, we will write $\Lambda = I_d - R$ where

$$R \coloneqq \sum_{i=1}^{m} w_i v_i v_i^T = \sum_{i=1}^{m} \left(M^{-1}\eta\right)[i] \cdot v_i v_i^T \,, \tag{4}$$

and prove that $\|R\|_{\mathrm{op}}$ is bounded by 1. Finally, combining the analyses, we finish the proof of Theorem 2 in Section 2.4.

2.2 Decomposition of M

The proof of Theorem 2 requires careful analysis of the matrix M from Eq. (3) and its inverse. To this end, we first decompose M as $M = A + B$ such that intuitively, A is perturbation of a (scaled) identity matrix and B has rank 2. We will later see how this decomposition allows us to analyze M^{-1} more conveniently.

▶ **Proposition 5** (Decomposition of M)**.**

$$M = \underbrace{M_\alpha + M_\beta + M_D + \left(1 + \frac{1}{d}\right) I_m}_{\coloneqq A} + \underbrace{\frac{1}{d} J_m + \frac{1}{d}\left(1_m \cdot \eta^T + \eta \cdot 1_m^T\right)}_{\coloneqq B} \tag{5}$$

where J_m is the all-ones matrix, M_α, M_β are matrices with zeros on the diagonal and M_D is a diagonal matrix, defined as follows:

- $M_\alpha[i,j] \coloneqq \sum_{a \neq b \in [d]} v_i[a] \cdot v_i[b] \cdot v_j[a] \cdot v_j[b]$ *for* $i \neq j \in [m]$,
- $M_\beta[i,j] \coloneqq \sum_{a \in [d]} \left(v_i[a]^2 - \frac{1}{d}\right)\left(v_j[a]^2 - \frac{1}{d}\right)$ *for* $i \neq j \in [m]$,
- $M_D[i,i] \coloneqq \|v_i\|_2^4 - \frac{2}{d}\|v_i\|_2^2 - 1$ *for* $i \in [m]$.

Proof. For any off-diagonal entry $i \neq j \in [m]$, on the right-hand side we have

$$\begin{aligned} M[i,j] = \langle v_i, v_j \rangle^2 &= \left(\sum_{a \in [d]} v_i[a] v_j[a]\right)^2 \\ &= \sum_{a \neq b \in [d]} v_i[a] \cdot v_i[b] \cdot v_j[a] \cdot v_j[b] + \sum_{a \in [d]} v_i[a]^2 \cdot v_j[a]^2 \,. \end{aligned}$$

The first term is exactly $M_\alpha[i,j]$. For the second term,

$$\begin{aligned} \sum_{a \in [d]} v_i[a]^2 \cdot v_j[a]^2 &= \sum_{a \in [d]} \left(v_i[a]^2 - \frac{1}{d}\right)\left(v_j[a]^2 - \frac{1}{d}\right) + \frac{1}{d}\left(\|v_i\|_2^2 + \|v_j\|_2^2\right) - \frac{1}{d} \\ &= \underbrace{\sum_{a \in [d]} \left(v_i[a]^2 - \frac{1}{d}\right)\left(v_j[a]^2 - \frac{1}{d}\right)}_{M_\beta[i,j]} + \underbrace{\frac{\|v_i\|_2^2 - 1}{d}}_{\frac{1}{d}\eta_i} + \underbrace{\frac{\|v_j\|_2^2 - 1}{d}}_{\frac{1}{d}\eta_j} + \frac{1}{d} \,. \end{aligned}$$

Thus, $M[i,j] = M_\alpha[i,j] + M_\beta[i,j] + \frac{1}{d} + \frac{1}{d}\left(1_m \cdot \eta^T + \eta \cdot 1_m^T\right)[i,j]$.

For the diagonal entries, the right-hand side of the (i,i) entry is

$$M_D[i,i] + \left(1+\frac{1}{d}\right) + \frac{1}{d} + \frac{2}{d}\eta_i = \left(\|v_i\|_2^4 - \frac{2}{d}\|v_i\|_2^2 - 1\right) + 1 + \frac{2}{d} + \frac{2}{d}(\|v_i\|_2^2 - 1)$$
$$= \|v_i\|_2^4 = M[i,i]\,.$$

This completes the proof. ◀

▶ Remark 6. The intention behind this decomposition is that for $v_i \sim \mathcal{N}(0, \frac{1}{d}I_d)$, M_α, M_β, M_D are all mean 0 (though their variances are not the same) since $\mathbb{E}\|v_i\|_2^2 = 1$ and $\mathbb{E}\|v_i\|_2^4 = 1 + \frac{2}{d}$. Therefore, we expect $\|M_\alpha + M_\beta + M_D\|_{\text{op}}$ to be small, which implies that A is positive definite and well-conditioned. Furthermore, observe that B has rank 2:

$$B = \frac{1}{d}J_m + \frac{1}{d}\left(1_m \cdot \eta^T + \eta \cdot 1_m^T\right) = \frac{1}{d}\begin{bmatrix}1_m & \eta\end{bmatrix} \cdot \begin{bmatrix}1 & 1\\ 1 & 0\end{bmatrix} \cdot \begin{bmatrix}1_m\\ \eta\end{bmatrix}. \tag{6}$$

2.3 Inverse of M

The decomposition of M into A and a rank-2 matrix B (Eq. (5)) allows us to apply the Woodbury matrix identity about the inverse of low-rank corrections of invertible matrices.

▶ **Fact 7** (Matrix Invertibility). *Suppose $A \in \mathbb{R}^{n_1\times n_1}$ and $C \in \mathbb{R}^{n_2\times n_2}$ are both invertible matrices, and $U \in \mathbb{R}^{n_1\times n_2}$ and $V \in \mathbb{R}^{n_2\times n_1}$ are arbitrary. Then, $A+UCV$ is invertible if and only if $C^{-1}+VA^{-1}U$ is invertible.*

▶ **Fact 8** (Woodbury matrix identity [15]). *Suppose $A \in \mathbb{R}^{n_1\times n_1}$ and $C \in \mathbb{R}^{n_2\times n_2}$ are both invertible matrices, and $U \in \mathbb{R}^{n_1\times n_2}$ and $V \in \mathbb{R}^{n_2\times n_1}$ are arbitrary. Then*

$$(A+UCV)^{-1} = A^{-1} - A^{-1}U\left(C^{-1}+VA^{-1}U\right)^{-1}VA^{-1}\,.$$

In light of Fact 8, we can write B in Eq. (6) as $B = UCU^T$ where $U = V^T = \frac{1}{\sqrt{d}}\begin{bmatrix}1_m & \eta\end{bmatrix} \in \mathbb{R}^{m\times 2}$ and $C = \begin{bmatrix}1 & 1\\ 1 & 0\end{bmatrix}$, and $M = A + UCU^T$. Note that $C^{-1} = \begin{bmatrix}0 & 1\\ 1 & -1\end{bmatrix}$, and we have

$$C^{-1} + U^TA^{-1}U = \begin{bmatrix}\frac{1_m^TA^{-1}1_m}{d} & 1+\frac{\eta^TA^{-1}1_m}{d}\\ 1+\frac{\eta^TA^{-1}1_m}{d} & -1+\frac{\eta^TA^{-1}\eta}{d}\end{bmatrix} \coloneqq \begin{bmatrix}r & s\\ s & u\end{bmatrix}. \tag{7}$$

We first need to show that A is invertible. Recall from Eq. (5) that $A = (1+\frac{1}{d})I_m + M_\alpha + M_\beta + M_D$. We will prove the following lemma, whose proof is deferred to the full version.

▶ **Lemma 9** (M_α, M_β, M_D are bounded). *Suppose $m \leqslant cd^2$ for a small enough constant c. With probability $1-o_d(1)$, we have*

1. $\|M_\alpha\|_{\text{op}} \leqslant 0.1$,
2. $\|M_\beta\|_{\text{op}} \leqslant 0.1$,
3. $\|M_D\|_{\text{op}} \leqslant O\left(\sqrt{\frac{\log d}{d}}\right)$.

As an immediate consequence, we get the following:

▶ **Lemma 10** (A is well-conditioned). *With probability $1-o_d(1)$, the matrix A from Eq. (5) is positive definite (hence full rank), and*

$$0.5I_m \preceq A \preceq 1.5I_m\,.$$

Proof. Since $A = (1+\frac{1}{d})I_m + M_\alpha + M_\beta + M_D$, by Lemma 9 the eigenvalues of A must lie within $1 \pm 0.2 \pm \widetilde{O}(1/\sqrt{d}) \in (0.5, 1.5)$ (we assume d is large). ◀

Next, from Fact 7, we can prove that M is invertible (Lemma 12) by showing that the 2×2 matrix $C^{-1} + U^T A^{-1} U$ is invertible, which is in fact equivalent to $ru - s^2 \neq 0$. We first need the following bound on the norm of η, whose proof is deferred to the full version.

▷ Claim 11. With probability at least $1 - o_d(1)$, $\|\eta\|_2^2 \leqslant (1 + o_d(1))\frac{2m}{d}$.

▶ **Lemma 12** (Bounds on r, s, u; M is invertible). *Suppose $m \leqslant cd^2$ for a small enough constant c. Let $r, s, u \in \mathbb{R}$ be defined as in Eq. (7). With probability at least $1 - o_d(1)$, we have*

1. $r \in \frac{m}{d} \cdot [2/3, 2]$,
2. $|s| \leqslant O(\sqrt{d})$,
3. $u \in [-1, -1/2]$.

Thus, we have $s^2 - ru \geqslant \Omega\left(\frac{m}{d}\right)$. As a consequence, M is invertible.

Proof. By Lemma 10, we know that $\frac{2}{3}I_m \preceq A^{-1} \preceq 2I_m$. Thus, $r = \frac{1}{d}1_m^T A^{-1} 1_m \in \frac{1}{d}\|1_m\|_2^2 \cdot [2/3, 2]$, hence $r \in \frac{m}{d} \cdot [2/3, 2]$.

For s, we know that $\|\eta\|_2^2 \leqslant (1 + o(1))\frac{2m}{d}$ by Claim 11. Thus,

$$\frac{1}{d}\left|\eta^T A^{-1} 1_m\right| \leqslant \frac{1}{d}\|A^{-1}\|_{\mathrm{op}} \cdot \|\eta\|_2 \cdot \|1_m\|_2 < (1 + o_d(1)) \cdot 2\sqrt{\frac{2m^2}{d^3}} \leqslant O(\sqrt{d})\,.$$

Thus, $|s| = \left|1 + \frac{\eta^T A^{-1} 1_m}{d}\right| \leqslant O(\sqrt{d})$.

For u, we have

$$\frac{1}{d}\left|\eta^T A^{-1} \eta\right| \leqslant \frac{1}{d}\|A^{-1}\|_{\mathrm{op}} \cdot \|\eta\|_2^2 < (1 + o_d(1)) \cdot \frac{4m}{d^2} < \frac{1}{2}\,,$$

where the last inequality follows for some $m < cd^2$ for small enough c. Thus, $u = -1 + \frac{\eta^T A^{-1} \eta}{d} \in [-1, -1/2]$.

With the bounds on r, s and u, we immediately get $s^2 - ru \geqslant \Omega(\frac{m}{d})$.

To prove that M is invertible, let us first recall that we write $M = A + UCU^T$ where A is defined in Eq. (5) and $U = V^T = \frac{1}{\sqrt{d}}\begin{bmatrix} 1_m & \eta \end{bmatrix} \in \mathbb{R}^{m \times 2}$ and $C = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}$.

By Lemma 10, A is invertible. Then by Fact 7, we know that M is invertible if and only if $C^{-1} + U^T A^{-1} U := \begin{bmatrix} r & s \\ s & u \end{bmatrix}$ (see Eq. (7)) is invertible, which is equivalent to $ru - s^2 \neq 0$. Thus, $s^2 - ru \geqslant \Omega(\frac{m}{d})$ suffices to conclude that M is invertible. ◀

2.4 Finishing the proof of Theorem 2

The final piece of proving Theorem 2 is to show that $R = \sum_{i=1}^m w_i v_i v_i^T$ has spectral norm bounded by 1, which immediately implies that the candidate matrix $\Lambda = I_d - R \succeq 0$.

▶ **Lemma 13** (R is bounded). *There exists some absolute constant c_R s.t.for $m \leqslant \frac{d^2}{c_R}$, whp*

$$\|R\|_{\mathrm{op}} \leqslant \frac{1}{2}\,.$$

The proof is deferred to the full version. In particular, we will write an expanded expression of M^{-1} and obtain a decomposition of R. Then, we prove tight spectral norm bounds for matrices in the decomposition, which then completes the proof of Lemma 13.

Combining Lemma 12 and Lemma 13 we can finish the proof of Theorem 2.

Proof of Theorem 2. The matrix M (recall Eq. (3)) is invertible due to Lemma 12, thus our candidate matrix $\Lambda = I_d - R$ matrix defined in Definition 3 is well-defined. Furthermore, by the norm bound in Lemma 13, we have $\|R\|_{\mathrm{op}} < 1$. This proves that $\Lambda \succ 0$. ◀

3 Machinery for tight norm bounds of graph matrices

One of the main technical contributions of this paper is providing tight spectral norm bounds (up to constants per vertex/edge) for *structured random matrices with correlated entries* (a.k.a. graph matrices). We note that prior to this work, most known norm bounds for such matrices are only tight up to some logarithmic factors [1], while not much is known in terms of precise bounds without log factors except for several specific cases (see e.g. [14]).

3.1 Preliminaries

We first give a lightweight introduction to the theory of graph matrices. For interested readers who seek a thorough introduction or a more formal treatment, we refer them to its origin in a sequence of works in Sum-of-Squares lower bounds [3, 1]. We will follow the notations used in [1]. Throughout this section, we assume that there is an underlying (random) input matrix G and a Fourier basis $\{\chi_t\}_{t\in\mathbb{N}}$.

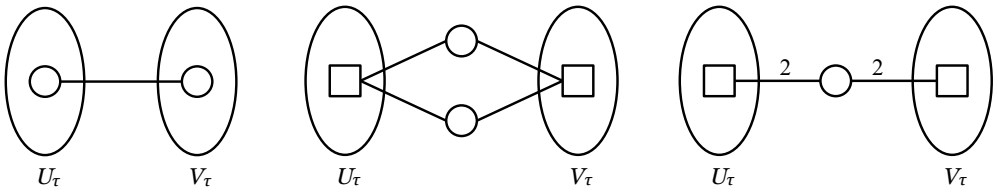
We first define *shapes*, which are representations of structured matrices whose entries depend on G.

▶ **Definition 14** (Shape). *A shape τ is a tuple $(V(\tau), U_\tau, V_\tau, E(\tau))$ associated with a (multi) graph $(V(\tau), E(\tau))$. Each vertex in $V(\tau)$ is associated with a vertex-type that indicates the range of the labels for the particular vertex. Each edge $e \in E(\tau)$ is also associated with a Fourier index $t(e) \in \mathbb{N}$. Moreover, we have $U_\tau, V_\tau \subseteq V(\tau)$ as the left and right boundary of the shape.*

We remind the reader that V_τ should be distinguished from $V(\tau)$, where V_τ is the right boundary set, while $V(\tau)$ is the set of all vertices in the graph.

Figure 1 show the shapes for matrices M_α and M_β defined in Proposition 5. For these shapes, there are two vertex-types (square and circle). The two ovals in each shape indicate the left and right boundaries U_τ and V_τ.

We next describe how to associate a shape to a matrix (given the underlying matrix G).



(a) GOE, zero diagonal. **(b)** M_α. **(c)** M_β.

Figure 1 Graph matrix representation of a $d \times d$ GOE matrix with zero diagonal, and the $m \times m$ matrices M_α and M_β as defined in Proposition 5. Square vertices take labels in $[m]$ and circle vertices take labels in $[d]$. The two ovals indicate the left and right boundaries of the shapes. If an edge e is not labeled with an index, then $t(e) = 1$ by default.

▶ **Definition 15** (Mapping of a shape). *Given a shape τ, we call a function $\sigma : V(\tau) \to \mathbb{N}$ a mapping of the shape if*

1. *σ assigns a label for each vertex according to its specified vertex-type;*
2. *σ is an injective mapping for vertices of the same type.*

▶ **Definition 16** (Graph matrix for shape). *Given a shape τ, we define its graphical matrix M_τ to be the matrix indexed by all possible boundary labelings of S, T, and for each of its entry, we define*

$$M_\tau[S,T] = \sum_{\substack{\sigma: V(\tau)\to\mathbb{N} \\ \sigma(U_\tau)=S,\ \sigma(V_\tau)=T}} \prod_{e\in E(\tau)} \chi_{t(e)}(G[\sigma(e)])\,.$$

Observe that for each entry $M_\tau[S,T]$, since σ must map U_τ and V_τ to S and T, $M_\tau[S,T]$ is simply a sum over labelings of the "middle" vertices $V(\tau)\setminus(U_\tau\cup V_\tau)$. Take Figure 1 for example. Suppose $G\in\mathbb{R}^{m\times d}$ and square and circle vertices take labels in $[m]$ and $[d]$ respectively, then we can write out the entries of the matrix: for $i\neq j\in[m]$,

$$M_\alpha[i,j] = \sum_{a\neq b\in[d]} \chi_1(G[i,a])\cdot\chi_1(G[i,b])\cdot\chi_1(G[j,a])\cdot\chi_1(G[j,b])\,,$$
$$M_\beta[i,j] = \sum_{a\in[d]} \chi_2(G[i,a])\cdot\chi_2(G[j,a])\,.$$

Note also that since σ must be injective for vertices of the same type and $U_\tau\neq V_\tau$ in both examples, there is no mapping such that $\sigma(U_\tau)=\sigma(V_\tau)$. Thus, by Definition 16, both matrices have zeros on the diagonal.

Adaptation to our setting. The above is a general introduction for graph matrices. In this work, we specialize to the following setting:

- $G\in\mathbb{R}^{m\times d}$ is a random Gaussian matrix whose rows are $v_1,\dots,v_m\sim\mathcal{N}(0,\frac{1}{d}I_d)$.
- The Fourier characters $\{\chi_t\}_{t\in\mathbb{N}}$ are the (scaled) Hermite polynomials.
- For all graph matrices that arise in our analysis,
  - $|S|=|T|=1$,
  - There are two vertex-types: square vertices take labels in $[m]$ and circle vertices take labels in $[d]$.

▶ Remark 17. For our technical analysis, we also employ our techniques on a generalization of graph matrices where we relax the injectivity condition. That said, for the purpose of illustrating our techniques, it suffices to consider ordinary graph matrices.

▶ **Definition 18** (D_V size constraint). *Let D_V be a size constraint such that for each graph matrix τ considered in this work, $|V(\tau)|\leqslant D_V$.*

For concreteness, we will take $D_V=\mathrm{polylog}(d)$ throughout this work.

Trace moment method. For all our norm bounds, we will use the trace moment method: for any graph matrix M_τ with underlying random matrix G and any $q\in\mathbb{N}$,

$$\mathbb{E}\|M_\tau\|_{\mathrm{op}}^{2q}\leqslant\mathbb{E}\,\mathrm{tr}\left((M_\tau M_\tau^T)^q\right)=\mathbb{E}\sum_{\substack{S_1,T_1,S_2,T_2,\dots S_{q-1},T_{q-1}: \\ \text{boundaries}}} M_\tau[S_1,T_1]M_\tau^T[T_1,S_2]\cdots M_\tau^T[T_{q-1},S_1]\,.$$

where the expectation is taken over G.

Notice that the summation is over *closed walks* across the boundaries: $S_1\to T_1\to S_2\to T_2\to\cdots\to S_1$, where $S_1,T_1,\dots$ are boundary labelings of M_τ. In particular, the walk is consist of $2q$-steps of a "block walk", with the $(2t-1)$-th step across a block described by M_τ and the $(2t)$-th step across a block described by M_τ^T.

The crucial observation is that after taking expectation, all closed walks must walk on each labeled edge (i.e., Fourier character) an *even* number of times, since all odd moments of the Fourier characters are zero. Therefore, bounding the matrix norm is reduced to bounding the contribution of all such walks.

$$\mathbb{E}\|M_\tau\|_{\mathrm{op}}^{2q} \leqslant \sum_{\mathcal{P}\text{: closed walk}} \prod_{e\in E(\mathcal{P})} \mathbb{E}\left[\chi_{t(e)}(G[e])^{\mathrm{mul}_{\mathcal{P}}(e)}\right], \tag{8}$$

where $E(\mathcal{P})$ denotes the set of labeled edges used by the walk $\mathcal{P}$, $\mathrm{mul}_{\mathcal{P}}(e)$ denotes the number of times e appears in the walk, and $t(e)$ denotes the Fourier index (with slight abuse of notation).

▶ Remark 19. We remind the reader not to confuse vertices/edges in the walk with vertices/edges in the shape. The vertices in a walk are "labeled" by elements in $[m]$ or $[d]$ (depending on the vertex-type). Similarly, each edge $e \in E(\mathcal{P})$ in a walk is labeled by an element in $[m] \times [d]$. We will use the terms "labeled vertex" and "labeled edge" unless it is clear from context.

3.2 Global bounds via a local analysis

Observe that Eq. (8) is a weighted sum of closed walks of length $2q$. To obtain an upper bound, the standard approach is to specify an efficient *encoding scheme* that uniquely identifies each closed walk, and then upper bound the total number of such encodings.

We begin by defining a step-labeling – a categorization of each step in the closed walk.

▶ **Definition 20** (Step-labeling). *For each step throughout the walk, we assign it the following label,*

1. *F (a fresh step): it uses a new labeled edge making the first appearance and leads to a destination not seen before;*
2. *S (a surprise step): it uses a new labeled edge to arrive at a vertex previously visited in the walk;*
3. *H (a high-mul step): it uses a labeled edge that appears before, and the edge is making a middle appearance (i.e., it will appear again in the subsequent walk);*
4. *R (a return step): it uses a labeled edge that appears before, and the edge is making its last appearance.*

Analogously, for any shape τ , we call $\mathcal{L}_\tau : E(\tau) \to \{F, R, S, H\}$ a step-labeling *of the block. The subscript τ is ignored when it is clear.*

We note that the terms "fresh", "high-mul" and "return" are adopted from the GOE matrix analysis in [14]. Next, to obtain a final bound for Eq. (8), we consider two *factors* for each step (which depend on the step-label):

1. **Vertex factor**: a combinatorial factor that specifies the destination of the step;
2. **Edge factor**: an analytical factor from the edge which accounts for the $\mathbb{E}[\chi_{t(e)}(G[e])^{\mathrm{mul}(e)}]$ term in Eq. (8).

For example, a vertex factor for an F step to a circle vertex can be d, an upper bound on the number of possible destinations. One can think of vertex factors as the information needed for a *decoder* to complete a closed walk. Essentially, the step-labeling and appropriate vertex factors should uniquely identify a closed walk, and combined with edge factors, we can obtain an upper bound for Eq. (8).

We note that the approach stated above is a *global* encoding scheme. One may proceed via a global analysis – carefully bounding the number of step-labelings allowed (e.g., using the fact that the F and R steps must form a Dyck word [14]), and then combining all vertex and edge factors to obtain a final bound. However, to get tight norm bounds for complicated graph matrices (like M_α), the global analysis becomes unwieldy.

Local analysis. One of our main insights is to use a *local* analysis. We now give a high-level overview of our strategy while deferring the specific details of our vertex/edge factor assignment scheme to subsequent sections. Recall that a closed walk consists of "block-steps" described by the shape τ. Thus, we treat each walk as a "block walk" and bound the contributions of a walk block by block. This prompts us to bound the contribution of the walk at a given block-step to the final trace in Eq. (8) by

$$\mathsf{vtxcost} \cdot \mathsf{edgeval} \leqslant B_q(\tau)$$

where $B_q(\tau)$ is some desired upper bound that depends on the vertex/edge factor assignment scheme. We define it formally in the following.

▶ **Definition 21** (Block value function). *Fix $q \in \mathbb{N}$ and a shape τ. For any vertex/edge factor assignment scheme, we call $B_q(\tau)$ a valid block-value function for τ of the given scheme if*

$$\mathbb{E}\left[\mathrm{tr}\left((M_\tau M_\tau^T)^q\right)\right] \leqslant (\textit{matrix dimension}) \cdot B_q(\tau)^{2q}\,,$$

and for each block-step $\mathsf{BlockStep}_i$ throughout the walk,

$$\mathsf{vtxcost}(\mathsf{BlockStep}_i) \cdot \mathsf{edgeval}(\mathsf{BlockStep}_i) \leqslant B_q(\tau)\,.$$

We point out that the block-value function B should be considered as a function of both the shape τ and the length of the walk q (we will drop the subscript when it is clear throughout this work), and it also depends on the assignment scheme. Thus, our task is to find a vertex/edge factor assignment scheme such that $B_q(\tau)$ is as small as possible. Moreover, the matrix dimension, which is at most $\mathrm{poly}(d)$ in our case, is the factor that comes up in the start of the walk to specify the original vertex, and can be ignored as it is ultimately an $1 + o(1)$ factor once we take a long enough walk.

Given Definition 21, the norm bound follows immediately.

▶ **Proposition 22.** *Let M_τ be a graph matrix with dimension $\mathrm{poly}(d)$, and let $q = \Omega(\log^2 d)$. Suppose $B_q(\tau)$ is a valid block-value function. Then, with probability $1 - \frac{1}{\mathrm{poly}(d)}$,*

$$\|M_\tau\|_{\mathrm{op}} \leqslant (1 + o_d(1)) \cdot B_q(\tau)\,.$$

Proof. We apply Markov's inequality: for any $\varepsilon > 0$,

$$\begin{aligned}\mathbf{Pr}\left[\|M_\tau\|_{\mathrm{op}} > (1+\varepsilon)B_q(\tau)\right] &\leqslant \mathbf{Pr}\left[\mathrm{tr}\left((M_\tau M_\tau^T)^q\right) > (1+\varepsilon)^{2q} B_q(\tau)^{2q}\right] \\ &\leqslant (1+\varepsilon)^{-2q}\,\mathrm{poly}(d) \\ &\leqslant \frac{1}{\mathrm{poly}(d)}\end{aligned}$$

for $q = \Omega(\frac{1}{\varepsilon}\log d)$. Setting $\varepsilon = \frac{1}{\log d}$, we can conclude that $\|M_\tau\|_{\mathrm{op}} \leqslant (1 + o_d(1)) \cdot B_q(\tau)$ with high probability. ◀

The next proposition shows that we can easily obtain a valid $B_q(\tau)$ once we have an appropriate factor assignment scheme.

▶ **Proposition 23.** *For any graph matrix M_τ and any valid factor assignment scheme,*

$$B_q(\tau) = \sum_{\mathcal{L}:\text{step-labelings for } E(\tau)} \mathsf{vtxcost}(\mathcal{L}) \cdot \mathsf{edgeval}(\mathcal{L})$$

is a valid block-value function for τ.

Proof. The second requirement in Definition 21 is clear. For the first requirement, observe that the trace can be bounded by the matrix dimension (specifying the start of the walk) times

$$\sum_{\substack{\mathcal{L}_1,\ldots,\mathcal{L}_{2q}:\\ \text{step-labelings for } E(\tau)}} \prod_{i=1}^{2q} \mathsf{vtxcost}(\mathcal{L}_i) \cdot \mathsf{edgeval}(\mathcal{L}_i) \leqslant \left(\sum_{\mathcal{L}:\text{step-labelings for } E(\tau)} \mathsf{vtxcost}(\mathcal{L}) \cdot \mathsf{edgeval}(\mathcal{L}) \right)^{2q}. \quad \blacktriangleleft$$

With this set-up, the main task is then to find an appropriate vertex/edge factor assignment scheme and obtain a good upper bound on $B_q(\tau)$.

3.3 Vertex factor assignment scheme

We now proceed to bound the vertex factors for each step-label. We note that in this section, "vertices" refer to "labeled vertices" in the walk (having labels in $[m]$ or $[d]$; recall Remark 19). First, we define the weight of a square (resp. circle) vertex to be m (resp. d), since we need an element in $[m]$ (resp. $[d]$) to specify which vertex to go to in the walk.

We first show a "naive" vertex factor assignment scheme. In the following scheme, we use a *potential unforced return* factor, denoted Pur, to specify the destination of any R step. We will defer the specific details of Pur to Section 3.5.

Vanilla vertex factor assignment scheme.

1. For each vertex i that first appears via an F step, a label in $\mathsf{weight}(i)$ is required;
2. For each vertex i that appears beyond the first time:
   - If it is arrived via an R step, the destination may need to be specified, and this is captured by the Pur factor.
   - If it is *not* arrived via an R step, then it must be an S or H step. A vertex cost in $2q \cdot D_V$ is sufficient to identify the destination, where we recall $2q$ is the length of our walk, and D_V the size upper bound of each block.

The first thing to check is that this scheme combined with an step-labeling uniquely identifies a closed walk (given the start of the walk). This is immediate for F and R steps by definition. For S and H steps, since the destination is visited before in the walk, $2q \cdot D_V$ is sufficient as it is an upper bound on the number of vertices in the walk.

A potential complication with analyzing the above assignment scheme directly is that it exhibits a significant difference in the vertex factors. For example, consider a vertex that appears only twice in the walk on a tree. Its first appearance requires a label in $[n]$, while its subsequent appearance does not require any cost if it is reached using an R step because backtracking from a tree is fixed (since there is only one parent). This disparity can result in a very loose upper bound for the trace when applying Proposition 23; in fact, the norm bound for M_τ obtained in this manner is equivalent to using the naive row-sum bound.

Redistribution. One of our main technical insights is to split the factors such that both first and last appearance contributes a factor of comparable magnitude; we call this *redistribution*.

We first formally define "appearance" in a block-step to clarify our terminology,

▶ **Definition 24** (Vertex appearance in block-step). *Each labeled vertex appearance can be "first", "middle" and "last". Moreover, each vertex on the block-step boundary (U_τ or V_τ) appears in both adjacent blocks.*

For example, suppose a vertex first appears in the right-boundary of block i and last appears in the left-boundary of block j, then it will make middle appearances in the left-boundary of block $i+1$ and right-boundary of block $j-1$ as well.

We are now ready to introduce the following vertex-factor assignment scheme with redistribution that assigns vertex-factor to each vertex's appearance to handle the disparity.

Vertex factor assignment scheme with redistribution.

1. For each vertex i that makes its first appearance, assign a cost of $\sqrt{\mathsf{weight}(i)}$;
2. For any vertex's middle appearance, if it is not arrived at via an R step, assign a cost of $2q \cdot D_V$ (where we recall $2q$ is the length of our walk, and D_V the size constraint of each block);
3. For any vertex's middle appearance, if it is at arrived via an R step, its cost is captured by Pur;
4. For each vertex i that makes its last appearance, assign a cost of $\sqrt{\mathsf{weight}(i)}$ that serves as a *backpay*.

Deducing vertex factor from local step-labeling. As presented, the vertex factor assignment scheme requires knowing which vertex is making first/middle/last appearance. We further show that the vertex appearances, or more accurately, an upper bound of the vertex factors, can be deduced by a given step-labeling of the block. Fix traversal direction from U to V,

Localized vertex factor assignment from step-labeling.

1. For any vertex v that is on the left-boundary U, it cannot be making the first appearance since it necessarily appears in the previous block;
2. For any vertex v that is on the right-boundary V, it cannot be making the last appearance since it necessarily appears in the subsequent block;
3. For any vertex v reached via some $S/R/H$ step, it cannot be making its first appearance;
4. For any vertex v that incident to some $F/S/H$ step, it cannot be making its last appearance since the edge necessarily appears again.

The first two points are due to Definition 24. The last point is because each labeled edge (i.e., Fourier character) must be traversed by an R step to close it.

3.4 Bounding edge-factors

To bound the contribution of the walks, we need to consider factors coming from the edges traversed by the walk. Recall from Eq. (8) that each edge e in a closed walk P gets a factor $\mathbb{E}[\chi_{t(e)}^{\mathrm{mul}_P(e)}]$, where $t(e)$ is the Fourier index associated with the edge.

In our case, the Fourier characters are the scaled Hermite polynomials. Recall that we assume that our vectors are sampled as $v_i \sim \mathcal{N}(0, \frac{1}{d} I_d)$. Thus, we define the polynomials $\{H_t\}_{t\in\mathbb{N}}$ such that they are orthogonal and $\mathbb{E}_{x\sim\mathcal{N}(0,1/d)}[H_t(x)^2] = t! \cdot d^{-t}$. Specifically,

1. $H_1(x) = x$,
2. $H_2(x) = x^2 - \frac{1}{d}$.

We first state the following bound on the moments of H_t, which follows directly from standard bounds on the moments of Hermite polynomials:

▶ **Fact 25** (Moments of Hermite polynomials). *Let $d \in \mathbb{N}$. For any $t \in \mathbb{N}$ and even $k \in \mathbb{N}$,*

$$\mathbb{E}_{x\sim\mathcal{N}(0,1/d)}\left[H_t(x)^k\right] \leqslant \frac{1}{d^{kt/2}}(k-1)^{kt/2}(t!)^{k/2} \leqslant (t!)^{k/2}\left(\frac{k}{d}\right)^{kt/2}.$$

For matrices that arise in our analysis, we only have H_1 and H_2 edges. The following is our edge-factor assignment scheme to account for contributions from the Fourier characters.

Edge-factor assignment scheme.

For an H_1 edge,

1. F/S: assign a factor of $\frac{1}{\sqrt{d}}$ for its first appearance;
2. H: assign a factor of $\frac{2q}{\sqrt{d}}$ for its middle appearance;
3. R: assign a factor of $\frac{1}{\sqrt{d}}$ for its last appearance.

For an H_2 edge,

1. F/S: assign a factor of $\frac{\sqrt{2}}{d}$ for its first appearance (equivalently, we can view a single H_2 edge as two edge-copies of H_1 and assign each a factor of $\frac{\sqrt{2}}{\sqrt{d}}$ which is a valid upper bound);
2. H: assign a factor of $\frac{8q^2}{d}$ for its middle appearance;
3. R: assign a factor of $\frac{\sqrt{2}}{d}$ for its last appearance (equivalently, we can view a single H_2 edge as two edge-copies of H_1 and assign each a factor of $\frac{\sqrt{2}}{\sqrt{d}}$ which is a valid upper bound).

▶ **Proposition 26.** *The above scheme correctly accounts for the edge factors from H_1 and H_2 edges.*

Proof. If an edge has multiplicity 2, then it must be traversed by one F/S step and one R step.

- If it is an H_1 edge, then the scheme assigns a factor $\frac{1}{d}$, which equals $\mathbb{E}_{x\sim\mathcal{N}(0,1/d)}[H_1(x)^2]$.
- If it is an H_2 edge, then the scheme assigns a factor $\frac{2}{d^2}$, which equals $\mathbb{E}_{x\sim\mathcal{N}(0,1/d)}[H_2(x)^2]$.

For an edge with multiplicity $k > 2$, it must be traversed by one F/S step, one R step and $k-2$ H steps. Moreover, since k is even and $2q$ is the length of the walk, we have $4 \leqslant k \leqslant 2q$.

- If it is an H_1 edge, then the scheme assigns a factor $\frac{1}{d}\cdot(\frac{2q}{\sqrt{d}})^{k-2} \geqslant d^{-k/2}(2q)^{k/2} \geqslant (\frac{k}{d})^{k/2}$. By Fact 25, it is an upper bound on $\mathbb{E}_{x\sim\mathcal{N}(0,1/d)}[H_1(x)^k]$.
- If it is an H_2 edge, then the scheme assigns a factor $\frac{2}{d^2}\cdot(\frac{8q^2}{d})^{k-2} \geqslant d^{-k}2^{k/2}(2q)^k \geqslant 2^{k/2}(\frac{k}{d})^k$. By Fact 25, it is an upper bound on $\mathbb{E}_{x\sim\mathcal{N}(0,1/d)}[H_2(x)^k]$.

This shows that the edge factor assignment scheme above is correct. ◀

3.5 Bounding return cost (Pur factors)

In our vertex factor assignment scheme described in Section 3.3, we use a *potential unforced return* factor, denoted Pur, to specify the destination of any return (R) step. Note that the term "unforced return" is adopted from [14] as well. In this section, we complete the bound of vertex factors by bounding the Pur factor.

For starters, we will define a potential function for each vertex at time t, which measures the number of returns R pushed out from the particular vertex by time t that may require a label in $2q \cdot D_V$. Notice that a label in $2q \cdot D_V$ is sufficient for any destination vertex arrived via an R step because the vertex appears before; however, this may be a loose bound.

We observe the following: a label in $2q \cdot D_V$ may be spared if the vertex is incident to only one un-closed F/S edge; we call this a *forced* return. Formally, we define a return step as *unforced* if it does not fall into the above categories,

▶ **Definition 27** (Unforced return). *We call a return (R) step an* unforced return *if the source vertex is incident to more than* 1 *(or* 2 *in the case of a square vertex) unclosed edge.*

We now proceed to formalize the above two observations by introducing a potential function to help us bound the number of unforced returns from any given vertex throughout the walk. The number of unforced returns throughout the walk would then be immediately given once we sum over all vertices in the walk.

▶ **Definition 28** (Potential-unforced-return factor Pur). *For any time t and vertex v, let* $\mathsf{Pur}_t(v)$ *be defined as the number of potential unforced return from v throughout the walk until time t.*

3.5.1 Pur bound for circle vertices

In our setting, each circle vertex pushes out at most 1 edge during the walk, analogous to the case of typical adjacency matrix. This serves as a starting point for our Pur bound for circle vertices.

▶ **Lemma 29** (Bounding Pur_t for circle vertices). *For any time t, suppose the walker is currently at a circle vertex v, then*

$$\begin{aligned}\mathsf{Pur}_t(v) &\leqslant \#(R \text{ steps closed from } v) + \#(\text{unclosed edges incident to } v \text{ at time } t) - 1\\ &\leqslant 2 \cdot s_t(v) + h_t(v)\,,\end{aligned}$$

where we define the following counter functions:

1. *$s_t(v)$ is the number of S steps arriving at v by time t;*
2. *$h_t(v)$ is the number of H steps arriving at v by time t.*

Proof. We first prove the first inequality. The R steps closed from v may all be unforced returns, and the unclosed edges incident to v may be closed by unforced returns in the future. Note that we have a -1 in the above bound because for each vertex we may by default assume the return is using a particular edge, hence at each time we know there is an edge presumed-to-be forced.

We prove the second inequality by induction. Define $P_t(v) \coloneqq \#(\text{R steps closed from } v) + \#(\text{unclosed edges incident to } v \text{ at time } t) - 1$ for convenience. At the time when v is first created by an F step, $P_t(v) = 0$ (1 open edge minus 1) and $s_t(v) = h_t(v) = 0$.

At time t, suppose the last time v was visited was at time $t' < t$, and suppose that the inequality holds true for t'. Note that at time $t' + 1$, $P_{t'+1}(v) = P_{t'}(v) + 1$ if a new edge was created by an F or N step leaving v, otherwise $P_{t'+1}(v) = P_{t'}(v)$ (for R step it adds 1 to the number of closed edges closed from v, but decreases 1 open edge). On the other hand, $s_{t'}(v)$ and $h_{t'}(v)$ remain the same (we don't count out-going steps for $s_t(v), h_t(v)$).

When we reach v at time t, we case on the type of steps:

- Arriving by an R step: the edge is now closed, but the R step was not from v. So $P_t(v) = P_{t'+1}(v) - 1 \leqslant P_{t'}(v)$, while $s_t(v) = s_{t'}(v)$ and $h_t(v) = h_{t'}(v)$.
- Arriving by an S step: the edge is new, so $P_t(v) = P_{t'+1}(v) + 1 \leqslant P_{t'}(v) + 2$, and we have $s_t(v) = s_{t'}(v) + 1$.
- Arriving by an H step: $P_t(v) = P_{t'+1}(v) \leqslant P_{t'}(v) + 1$, and $h_t(v) = h_{t'}(v) + 1$.

In all three cases, assuming $P_{t'}(v) \leqslant 2 \cdot s_{t'}(v) + h_{t'}(v)$, we have $P_t(v) \leqslant 2 \cdot s_t(v) + h_t(v)$, completing the induction. ◀

3.5.2 Pur bound for square vertices

The argument of Lemma 29 does not apply well for vertices incident to multiple edges in a single step. In particular, this may happen for square vertices in M_α as each is arrived via 2 edges and each pushes out 2 edges (recall Figure 1). This is not an issue for M_β, but we will treat square vertices in M_β the same way to unify the analysis; in the context of Pur for square vertices, one may think of M_β as collapsing the two circle vertices in M_α.

To handle this issue, we observe that it suffices for us to pay an extra cost of [2] for each square vertex, which would allow us to further presume 2 edges being forced. We then generalize the prior argument to capture this change.

▶ **Lemma 30** (Bounding Pur_t for square vertices)**.** *For any time t, suppose the walker is currently at a square vertex v, then*

$$\begin{aligned}\mathsf{Pur}_t(v) &\leqslant \#(R \text{ steps closed from } v) + \#(\text{unclosed edges incident to } v \text{ at time } t) - 2 \\ &\leqslant 2(s_t(v) + h_t(v))\,.\end{aligned}$$

where $s_t(v)$ and $h_t(v)$ are the number of S and H steps arriving at v by time t, respectively.

Proof. We prove this by induction. Note that this is immediate for the base case when v first appears since a square vertex is incident to 2 edges. Define $P_t(v) := \#(\text{R steps closed from } v) + \#(\text{unclosed edges incident to } v \text{ at time } t) - 2$ for convenience. Suppose the inequality is true at time t', and assume vertex v appears again at time t. The departure at time $t' + 1$ from v may open up at most 2 edges, hence $P_{t'+1}(v) \leqslant P_{t'}(v) + 2$.

When we reach v at time t (via 2 edges), we case on the type of steps:

- Arriving by two R steps: the two edges closed by the R steps are not closed from v. So $P_t(v) = P_{t'+1} - 2 \leqslant P_{t'}(v)$, while $s_t(v) = s_{t'}(v)$ and $h_t(v) = h_{t'}(v)$.
- Arriving by one S/H and one R step: in this case, $P_t(v) = P_{t'+1}(v) \leqslant P_{t'}(v) + 2$ and $s_t(v) + h_t(v) = s_{t'}(v) + h_{t'}(v) + 1$.
- Arriving by two S/H steps: in this case, $P_t(v) = P_{t'+1}(v) + 2 \leqslant P_{t'}(v) + 4$, whereas $s_t(v) + h_t(v) = s_{t'}(v) + h_{t'}(v) + 2$.

In all three cases, we have $P_t(v) \leqslant 2(s_t(v) + h_t(v))$, completing the induction. ◀

▶ **Corollary 31.** *For each surprise/high-mul visit, it suffices for us to assign a* Pur *factor of 2, which is a cost of $(2q \cdot D_V)^2$ so that each* Pur *factor throughout the walk is assigned.*

3.6 Wrapping up with a toy example

Recall Proposition 23 that for a graph matrix of shape τ,

$$B_q(\tau) = \sum_{\mathcal{L}\text{: step-labelings for } E(\tau)} \mathsf{vtxcost}(\mathcal{L}) \cdot \mathsf{edgeval}(\mathcal{L}) \tag{9}$$

is a valid block-value function for τ (Definition 21). Moreover, by Proposition 22, we can take $q = \text{polylog}(d)$ and conclude that with probability $1 - o(1)$,

$$\|M_\tau\|_{\text{op}} \leqslant (1 + o(1)) \cdot B_q(\tau)\,.$$

For each given shape, it suffices for us to bound the block-value for each edge-labeling. We demonstrate how this may be readily done given the above bounds using the GOE example, and defer the analysis of the specific matrices that show up in our setting to the full version of the paper.

3.6.1 Tight bound for GOE

We now show how the above framework allows us to readily deduce a tight norm bound for $G \sim \text{GOE}(0, \frac{1}{d})$, where G is a $d \times d$ symmetric matrix with each (off-diagonal) entry sampled from $\mathcal{N}(0, \frac{1}{d})$. It is well-known that the correct norm of G is $2 + o_d(1)$ [14]. Figure 1a shows the shape τ associated with G, which simply consists of one edge. We now proceed to bound Eq. (9).

Edge factor. According to our edge factor scheme described in Section 3.4 (for H_1 edges), an $F/R/S$ step-label gets a factor of $\frac{1}{\sqrt{d}}$ while an H step-label gets $\frac{2q}{\sqrt{d}}$.

Pur factor. By Lemma 29, there is no Pur factor for F/R, while S and H get 2 and 1 Pur factors respectively.

Vertex factor. The weight of a circle vertex is d, thus any vertex making a first or last appearance gets a factor of $\sqrt{d}$. We now case on the step-label and apply the vertex factor assignment scheme described in Section 3.3.

- F: the vertex in U_τ must be making a middle appearance; it is not first due to Definition 24, and it is not last as otherwise the edge appears only once throughout the walk. The vertex in V_τ is making a first appearance, so it gets a factor of $\sqrt{d}$;
- R: the vertex in V_τ is making a middle appearance, since it is incident to an R edge (hence not first appearance), and it is on the boundary hence bound to appear again the next block. The vertex in U_τ may be making its last appearance, so it gets a factor of $\sqrt{d}$;
- S: the vertex in U_τ is making a middle appearance (same as F), and the vertex in V_τ is making a middle appearance since it cannot be first and must appear again. In addition, it gets 2 factors of Pur, which gives a bound of $(2q \cdot D_V)^2$;
- H: analogous to the above, both vertices are making middle appearance, and it gets 1 factor of Pur, giving a bound of $2q \cdot D_V$.

Combining the vertex and edge factors, we can bound Eq. (9):

$$B_q(\tau) = \sqrt{d} \cdot \frac{1}{\sqrt{d}} + \sqrt{d} \cdot \frac{1}{\sqrt{d}} + (2q \cdot D_V)^2 \cdot \frac{1}{\sqrt{d}} + (2q \cdot D_V) \cdot \frac{2q}{\sqrt{d}} \leqslant 2 + o_d(1)\,,$$

since q and D_V are both $\text{polylog}(d)$. Therefore, by Proposition 22, we can conclude that $\|G\|_{\text{op}} \leqslant 2 + o_d(1)$ with high probability, which is the correct bound.

Abstract

This paper addresses a graph optimization problem, called the Witness Tree problem, which seeks a spanning tree of a graph minimizing a certain non-linear objective function. This problem is of interest because it plays a crucial role in the analysis of the best approximation algorithms for two fundamental network design problems: Steiner Tree and Node-Tree Augmentation. We will show how a wiser choice of witness trees leads to an improved approximation for Node-Tree Augmentation, and for Steiner Tree in special classes of graphs.

1 Introduction

Network connectivity problems play a central role in combinatorial optimization. As a general goal, one would like to design a cheap network able to satisfy some connectivity requirements among its nodes. Two of the most fundamental problems in this area are *Steiner Tree* and *Connectivity Augmentation*.

Given a network $G = (V, E)$ with edge costs, and a subset of terminals $R \subseteq V$, Steiner Tree asks to compute a minimum-cost tree T of G connecting the terminals in R. In Connectivity Augmentation, we are instead given a k-edge-connected graph $G = (V, E)$ and an additional set of edges $L \subseteq V \times V$ (called *links*). The goal is to add a minimum-cardinality subset of links to G to make it $(k + 1)$-edge-connected. It is well-known that the problem for odd k reduces to $k = 1$ (called Tree Augmentation), and for even k reduces to $k = 2$ (called Cactus Augmentation) (see [9]). All these problems are NP-hard, but admit a constant factor approximation. In the past 10 years, there have been several exciting breakthrough results in the approximation community on these fundamental problems (see [5, 13, 4, 16, 17, 6, 19, 14, 1, 7, 8, 11, 2, 18, 20]).

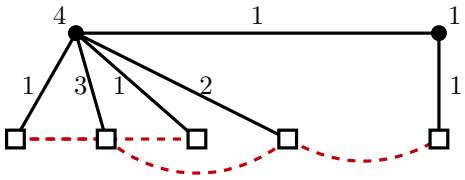

Figure 1 In black, the tree $T = (R \cup S, E)$. The dashed edges represent a witness tree W. The labels on edges of E and vertices of S indicate $\bar{w}(e)$ and $w(v)$, respectively. We have $\nu_T(W) = (H_4 + H_1)/2 = 1.541\bar{6}$. Assuming unit cost on the edges of E, we have $\bar{\nu}_T(W) = (4H_1 + H_2 + H_3)/6 = 1.\bar{2}$.

Several of these works highlight a deep relation between Steiner Tree and Connectivity Augmentation: the approximation techniques used for Steiner Tree have been proven to be useful for Connectivity Augmentation and vice versa. This fruitful exchange of tools and ideas has often lead to novel results and analyses. This paper continues bringing new ingredients in this active and evolving line of work.

Specifically, we focus on a graph optimization problem which plays a crucial role in the analysis of some approximation results mentioned before. This problem, both in its edge- and node-variant, is centered around the concept of *witness trees*. We now define this formally (see Figure 1 for an example).

Edge Witness Tree (EWT) problem. Given is a tree $T = (V, E)$ with edge costs $c : E \to \mathbb{R}_{\geq 0}$. We denote by R the set of leaves of T. The goal is to find a tree $W = (R, E_W)$, where $E_W \subseteq R \times R$, which minimizes the non-linear objective function $\bar{\nu}_T(W) = \frac{1}{c(E)} \sum_{e \in E} c(e) H_{\bar{w}(e)}$, where $c(E) = \sum_{e \in E} c(e)$, the function $\bar{w} : E \to \mathbb{Z}_{\geq 0}$ is defined as

$$\bar{w}(e) \coloneqq |\{pq \in E_W : e \text{ is an internal edge of the } p\text{-}q \text{ path in } T\}|$$

and H_ℓ denotes the ℓ^{th} harmonic number ($H_\ell = 1 + \frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{\ell}$).

Node Witness Tree (NWT) problem. Given is a tree $T = (V, E)$. We denote by R the set of leaves of T, and $S = V \setminus R$. The goal is to find a tree $W = (R, E_W)$, where $E_W \subseteq R \times R$, which minimizes the non-linear objective function $\nu_T(W) = \frac{1}{|S|} \sum_{v \in S} H_{w(v)}$, where $w : S \to \mathbb{Z}_{\geq 0}$ is defined as

$$w(v) \coloneqq |\{pq \in E_W : v \text{ is an internal node of the } p\text{-}q \text{ path in } T\}|$$

and again H_ℓ denotes the ℓ^{th} harmonic number.

We refer to a feasible solution W to either of the above problems as a *witness tree*. We call $\bar{w}$ (resp. w) the *vector imposed on* E (resp. S) by W. We now explain how these problems relate to Steiner Tree and Connectivity Augmentation.

EWT and relation to Steiner Tree

Currently, the best approximation factor for Steiner Tree is $(\ln(4) + \varepsilon)$, which can be achieved by three different algorithms [13] [5] [20]. These algorithms yield the same approximation because in all three of them, the analysis at some point relies on constructing witness trees.

More in detail, suppose we are given a Steiner Tree instance $(G = (V, E), R, c)$ where $c : E \to \mathbb{R}_{\geq 0}$ gives the edge costs. We can define the following:

$$\gamma_{(G,R,c)} \coloneqq \min_{\substack{T^* = (R \cup S^*, E^*):\ T^* \text{ is} \\ \text{optimal Steiner tree of } (G,R,c)}} \ \min_{\substack{W:\ W \text{ is a} \\ \text{witness tree} \\ \text{of } T^*}} \bar{\nu}_{T^*}(W)$$

We also define the following constant γ:

$$\gamma \coloneqq \sup\{\gamma_{(G,R,c)} : (G,R,c) \text{ is an instance of Steiner Tree}\}.$$

Byrka et al. [5] were the first to essentially prove the following.

▶ **Theorem 1.** *For any $\varepsilon > 0$, there is a $(\gamma+\varepsilon)$-approximation algorithm for Steiner Tree.*

Furthermore, the authors in [5] showed that $\gamma \leq \ln(4)$, and hence they obtained the previously mentioned $(\ln(4)+\varepsilon)$-approximation for Steiner Tree.

NWT and relation to Connectivity Augmentation

Basavaraju et al [3] introduced an approximation-preserving reduction from Cactus Augmentation (which is the hardest case of Connectivity Augmentation)[1] to special instances of Node-Steiner Tree, named *CA-Node-Steiner-Tree* instances in [2]: the goal here is to connect a given set R of terminals of a graph G via a tree that minimizes the number of non-terminal nodes (Steiner nodes) in it. The special instances have the crucial property that each Steiner node is adjacent to at most 2 terminals.

Byrka et al. [4] built upon this reduction to prove a 1.91-approximation for CA-Node-Steiner-Tree instances. This way, they were the first to obtain a better-than-2 approximation factor for Cactus Augmentation (and hence, for Connectivity Augmentation). Interestingly, Nutov [16] realized that a similar reduction also captures a fundamental node-connectivity augmentation problem: the *Node-Tree Augmentation* (defined exactly like Tree Augmentation, but replacing edge-connectivity with node-connectivity). This way, he could improve over an easy 2-approximation for Node-Tree Augmentation that was also standing for 40 years [12]. Angelidakis et al. [2] subsequently explicitly formalized the problem at the heart of the approximation analysis: namely, the NWT problem.

More in detail, given a CA-Node-Steiner-Tree instance $(G=(V,E),R)$, we can define the following:

$$\psi_{(G,R)} \coloneqq \min_{\substack{T^*=(R\cup S^*,E^*)\text{: } T^* \text{ is} \\ \text{optimal Steiner tree of } (G,R)}} \; \min_{\substack{W\text{: } W \text{ is a} \\ \text{witness tree} \\ \text{of } T^*}} \nu_{T^*}(W),$$

We also define the constant ψ:

$$\psi \coloneqq \sup\{\psi_{(G,R)} : (G,R) \text{ is an instance of CA-Node-Steiner-Tree}\}.$$

Angelidakis et al. [2] proved the following.

▶ **Theorem 2.** *For any $\varepsilon > 0$, there is a $(\psi+\varepsilon)$-approximation algorithm for CA-Node-Steiner Tree.*

Furthermore, the authors of [2] proved that $\psi < 1.892$, and hence obtained a 1.892-approximation algorithm for Cactus Augmentation and Node-Tree Augmentation. This is currently the best approximation factor known for Node-Tree Augmentation (for Cactus Augmentation there is a better algorithm [6]).

[1] Tree Augmentation can be easily reduced to Cactus Augmentation by introducing a parallel copy of each initial edge.

Our results and techniques

Our main result is an improved upper bound on ψ. In particular, we are able to show $\psi < 1.8596$. Combining this with Theorem 2, we obtain a 1.8596-approximation algorithm for CA-Node-Steiner-Tree. Hence, due to the above mentioned reduction, we improve the state-of-the-art approximation for Node-Tree Augmentation.

▶ **Theorem 3.** *There is a 1.8596-approximation algorithm for CA-Node-Steiner-Tree (and hence, for Node-Tree Augmentation).*

Our result is based on a better construction of witness trees for the NWT problem. At a very high level, the witness tree constructions used previously in the literature use a *marking-and-contraction* approach, that can be summarized as follows. First, root the given tree T at some internal Steiner node. Then, every Steiner node v chooses (*marks*) an edge which connects to one of its children: this identifies a path from v to a terminal. Contracting the edges along this path yields a witness tree W. The way this marking choice is made varies: it is random in [5], it is biased depending on the nature of the children in [4], it is deterministic and taking into account the structure of T in [2]. However, all such constructions share the fact that decisions can be thought of as being taken "in one shot", at the same time for all Steiner nodes. Instead, here we consider a bottom-up approach for the construction of our witness tree, where a node takes a marking decision only after the decisions of its children have been made. A sequential approach of this kind allows a node to have a more precise estimate on the impact of its own decision to the overall non-linear objective function cost, but it becomes more challenging to analyze. Overcoming this challenge is the main technical contribution of this work, and the insight behind our improved upper-bound on ψ.

We complement this result with an almost-tight lower-bound on ψ, which improves over a previous lower bound given in [2].

▶ **Theorem 4.** *For any $\varepsilon > 0$, there exists a CA-Node-Steiner-Tree instance $(G_\varepsilon, R_\varepsilon)$ such that $\psi_{(G_\varepsilon,R_\varepsilon)} > 1.841\bar{6} - \varepsilon$.*

The above theorem implies that, in order to significantly improve the approximation for Node-Tree Augmentation, very different techniques need to be used. To show our lower-bound we prove a structural property on optimal witness trees, called *laminarity*, which in fact holds for optimal solutions of both the NWT problem and the EWT problem.

As an additional result, we also improve the approximation bound for Steiner Tree in the special case of *Steiner-claw free* instances. A Steiner-Claw Free instance is a Steiner-Tree instance where the subgraph $G[V \setminus R]$ induced by the Steiner nodes is claw-free (i.e., every node has degree at most 2). These instances were introduced in [10] in the context of studying the integrality gap of a famous LP relaxation for Steiner Tree, called the *bidirected cut relaxation*, that is long-conjectured to have integrality gap strictly smaller than 2.

▶ **Theorem 5.** *There is a $(\frac{991}{732} + \varepsilon < 1.354)$-approximation for Steiner Tree on Steiner-claw free instances.*

We prove the theorem by showing that, for any Steiner-Claw Free instance (G, R, c), $\gamma_{(G,R,c)} \leq \frac{991}{732}$. The observation we use here is that an optimal Steiner Tree solution T in this case is the union of components that are caterpillar graphs[2]: this knowledge can be

[2] A caterpillar graph is defined as a tree in which every leaf is of distance 1 from a central path.

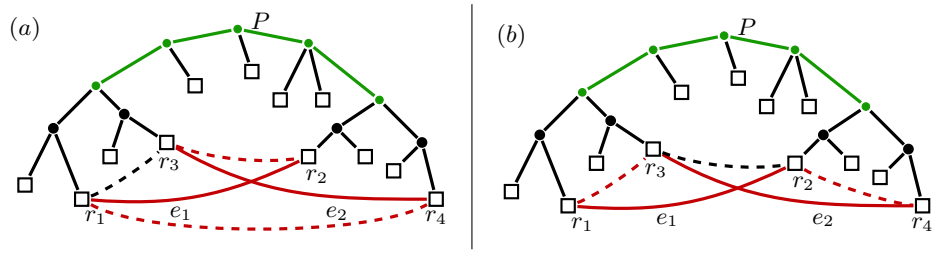

Figure 2 In both figures we have a tree, T, shown with black edges and green edges, with leaves, R, denoted by squares. Crossing edges e_1 and e_2 are shown with solid red edges. The green edges denote the path P. Figure (a): In this case, r_1 and r_3 are in the same component of $W \backslash \{e_1, e_2\}$, represented by the dashed black edge. We can replace e_1 with r_2r_3 or replace e_2 with r_1r_4 (red dashed edges). Figure (b): In this case, r_3 and r_2 are in the same component, denoted by the black dashed edge. We can replace e_1 and e_2 with r_1r_3 and r_2r_4 (red dashed edges).

exploited to design ad-hoc witness trees. Interestingly, we can also show that this bound is tight: once again, the proof of this lower-bound result relies on showing laminarity for optimal witness trees.

▶ **Theorem 6.** *For any $\varepsilon > 0$, there exists Steiner-Claw Free instance $(G_\varepsilon, R_\varepsilon, c_\varepsilon)$ such that $\gamma_{(G_\varepsilon, R_\varepsilon, c_\varepsilon)} > \frac{991}{732} - \varepsilon$.*

As a corollary of our results, we also get an improved bound on the integrality gap of the bidirected cut relaxation for Steiner-Claw Free instances (this follows directly from combining our upper bound with the results in [10]). Though these instances are quite specialized, they serve the purpose of passing the message: exploiting the structure of optimal solutions helps in choosing better witnesses, hopefully arriving at tight (upper and lower) bounds on γ and ψ.

2 Laminarity

In this section, we prove some key structural properties of witness trees. We assume to be given a Node (Edge) Witness Tree instance $T = (V, E)$ with leaves R (and edge costs $c : E \to \mathbb{R}_{\geq 0}$), where R denotes the leaves of T, we will show that we can characterize witness trees minimizing $\nu_T(W)$ ($\bar{\nu}_T(W)$) using the following notion of *laminarity*. Given a witness tree $W = (R, E_W)$, we say edges $f_1f_2, f_3f_4 \in E_W$ *cross* if the f_1-f_2 and f_3-f_4 paths in T share an internal node but not an endpoint. We say that W is *laminar* if it has no crossing edges. For nodes $u, v \in V$, we denote by T_{uv} the path in T between the nodes u and v. Similarly, for $e \in E_W$, we denote by T_e the path in T between the endpoints of e.

The following Theorem shows that there is always a witness tree minimizing $\nu_T(W)$ that is laminar.

▶ **Theorem 7.** *Given an instance of the Node Witness Tree problem $T = (V, E)$, let $\mathcal{W}$ be the family of all witness trees for T. Then there exists a laminar witness tree W such that $\nu_T(W) = \min_{W' \in \mathcal{W}} \nu_T(W')$.*

Proof. We first show that there is a witness tree W minimizing $\nu_T(W)$ such that the induced subgraph of W on any maximal set of terminals that share a neighbour in $V \backslash R$ is a star. We assume for the sake of contradiction that there is a maximal set of terminals $S \subseteq R$ sharing a neighbour $v \in V \backslash R$, such that the induced subgraph of W on S is a set of connected components $W_1, \ldots, W_i$ for $i > 1$. Without loss of generality, suppose the shortest path

between two components is from W_1 to W_2, and let e denote the edge of this path incident to W_2. We define $W' \coloneqq W \cup \{f\} \backslash \{e\}$, where f is an arbitrary edge between W_1 and W_2. Since $\{v\} = T_f \backslash R \subsetneq T_e \backslash R$, we have $\nu_T(W') < \nu_T(W)$, contradicting the minimality of W. Therefore, the induced subgraph on S is connected. We can rearrange the edges of this subgraph to be a star as this will not affect $\nu_T(W)$, so we assume this holds on W for any such S.

For a maximal set of terminals $S \subseteq R$ that share a neighbour, by a slight abuse of notation, we denote by S the induced star subgraph of W on S, and denote its center by $s \in S$. We will assume without loss of generality that edges of W incident to S have endpoint s. To see this, as S is a connected subgraph of W, any pair of edges incident to S cannot share an endpoint outside of S, otherwise we have found a cycle in W. Furthermore, for any edge of W incident to S where s is not an endpoint, we can change the endpoint in S of that edge to be s and maintain the connectivity of W since S is connected. Edges changed in this way will have the same interior nodes between their endpoints, so this does not increase $\nu_T(W)$.

We assume for the sake of contradiction that the witness tree W minimizing $\nu_T(W)$ is not a laminar witness tree. As W is not laminar, there exist distinct leaves $r_1, r_2, r_3, r_4 \in R$ such that $e_1 = r_1r_2, e_2 = r_3r_4 \in E_W$ are crossing. We denote the path $T_{e_1} \cap T_{e_2}$ by P. We denote by P_i the (potentially empty) set of internal nodes of the shortest path from P to r_i in T.

Since e_1 and e_2 are crossing edges, one of $T_{r_1r_3}$ or $T_{r_1r_4}$ contains exactly one node of P. The same is true for r_2. Without loss of generality, let us assume that the paths $T_{r_1r_3}$ and $T_{r_2r_4}$ contain exactly one node of P. We consider by cases which component of $W \backslash \{e_1, e_2\}$ contains two nodes among r_1, r_2, r_3 and r_4. See Figure 2 for an example.

- Case: r_1 and r_3 (or similarly, r_2 and r_4) are in the same component of $W \backslash \{e_1, e_2\}$. If $P_1 = P_3 = \emptyset$, then r_1 and r_3 share a neighbour and thus, as shown above, e_1 and e_2 are assumed to share an endpoint, and are thus not crossing.
  Consider $W' \coloneqq W \cup \{r_2r_3\} \backslash \{e_1\}$ and $W'' \coloneqq W \cup \{r_1r_4\} \backslash \{e_2\}$. If $\nu_T(W) - \nu_T(W') > 0$, this contradicts the minimality of $\nu_T(W)$. Therefore, we can see

$$0 \leq |V \backslash R|(\nu_T(W') - \nu_T(W)) = \sum_{u \in P_3} \frac{1}{w(u)+1} - \sum_{u \in P_1} \frac{1}{w(u)}$$
$$< \sum_{u \in P_3} \frac{1}{w(u)} - \sum_{u \in P_1} \frac{1}{w(u)+1} = |V \backslash R|(\nu_T(W) - \nu_T(W''))$$

  Clearly, we have $\nu_T(W'') < \nu_T(W)$, contradicting minimality of $\nu_T(W)$.
- Case: r_2 and r_3 (or similarly, r_1 and r_4) are in the same component of $W \backslash \{e_1, e_2\}$. Without loss of generality we can assume that $|V(P)| > 1$, because if $|V(P)| = 1$ then we can reduce to the previous case by relabelling the nodes r_1, r_2, r_3 and r_4. In this case, consider $W' \coloneqq W \cup \{r_1r_3, r_2r_4\} \setminus \{e_1, e_2\}$. Therefore, we can see

$$|V \backslash R| \left(\nu_T(W') - \nu_T(W)\right) \leq -\sum_{u \in P} \frac{1}{w(u)} < 0$$

Thus, we have $\nu_T(W') < \nu_T(W)$, contradicting the minimality of $\nu_T(W)$. ◀

The following theorem, similar to Theorem 7, shows that there are laminar witness trees that are optimal for the EWT problem. The proof is deferred to the full version of the paper.

▶ **Theorem 8.** *Given an instance of the Edge Witness Tree problem $T = (V, E)$ with edge costs c, let $\mathcal{W}$ be the family of all witness trees for T. Then there exists a laminar witness tree W such that $\bar{\nu}_T(W) = \min_{W' \in \mathcal{W}} \bar{\nu}_T(W')$.*

We now show that laminar witness trees are precisely the set of trees that one could obtain with a marking-and-contraction approach. The proof of this Theorem can be found in the full version of the paper.

▶ **Theorem 9.** *Given a tree $T = (V, E)$ with leaves R, a witness tree $W = (R, E_W)$ for T can be found by marking-and-contraction if and only if W is laminar.*

Incidentally, this has the following side implication. The authors of [13] gave a dynamic program (that is also a bottom-up approach) to compute the best possible witness tree obtainable with a marking-and-contraction scheme. Our structural results imply that their dynamic program computes an optimal solution for the EWT problem (though for the purpose of the approximation analysis, being able to compute the best witness tree is not that relevant: being able to bound ψ and γ is what matters).

3 Improved approximation for CA-Node-Steiner Tree

The goal of this section is to prove Theorem 3. We will achieve this by showing $\psi < 1.8596$, and by using Theorem 2. From now on, we assume we are given a tree $T = (R \cup S^*, E^*)$, where each Steiner node is adjacent to at most two terminals.

3.1 Preprocessing

We first apply some preprocessing operations as in [2], that allow us to simplify our witness tree construction. The first one is to remove the terminals from T, and then decompose T into smaller components which will be held separately. We start by defining a *final* Steiner node as a Steiner node that is adjacent to at least one terminal. We let $F \subseteq S^*$ denote the set of final Steiner nodes. Since we remove the terminals from T, we will construct a spanning tree W on F with edges in $F \times F$. With a slight abuse of notation, we refer to W as a witness tree: this is because [2, Section 4.1] showed that one can easily map W to a witness tree for our initial tree T (with terminals put back), and the following can be considered the vector imposed on S^* by W:

$$w(v) \coloneqq |\{pq \in E_W : v \text{ belongs to the } p\text{-}q \text{ path in } T[S^*]\}| + \mathbb{1}[v \in F] \tag{1}$$

where $\mathbb{1}[v \in F]$ denotes the indicator of the event "$v \in F$", and $T[S^*]$ is the subtree of T induced by the Steiner nodes. See Figure 3.

So, from now on, we consider $T = T[S^*]$. The next step is to root T at an arbitrary final node $r \in F$. Following [2] we can decompose T into a collection of rooted components $T_1, \dots T_\tau$, where a component is a subtree whose leaves are final nodes and non-leaves are non-final nodes. The decomposition will have the following properties: each T_i is rooted at a final node r_i that has degree one in T_i, $r_1 \coloneqq r$ is the root of T_1, $\cup_{j<i} T_j$ is connected, and $T = \cup_{i=1}^{\tau} T_i$. We will compute a witness tree W_i for each component T_i, and then show that we can join these witness trees $\{W_i\}_{i \geq 1}$ together to get a witness tree W for T.

3.2 Computing a witness tree W_i for a component T_i

Here we deal with a component T_i rooted at r_i, and describe how to construct a witness tree W_i. If T_i is a single edge $e = r_i v$, we simply let $W_i = (\{r_i, v\}, \{r_i v\})$.

Now we assume that T_i is not a single edge. We will construct a witness tree with a bottom-up procedure. At a high level, each node $u \in T_i \backslash r_i$ looks at the subtree Q_u of T_i rooted at u, and constructs a portion of the witness tree: namely, a subtree $\overline{W}^u$ spanning

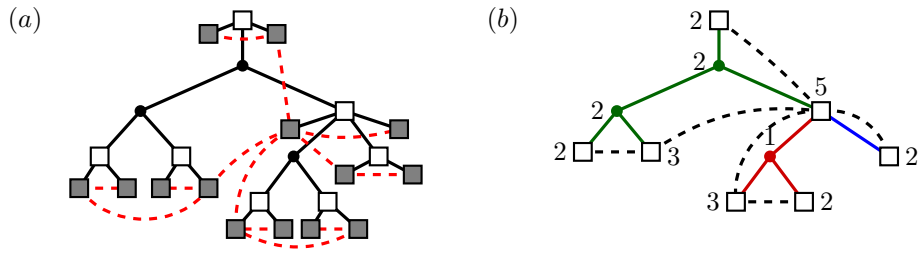

Figure 3 Figure (a): A tree T is shown by black edges. The terminals are shown by grey squares. The final Steiner nodes are shown by white squares, non-final Steiner nodes are shown by black dots. Figure (b): The tree T after the terminals have been removed. The color edges indicate the three components. A witness tree W is shown by the black dashed lines. The numbers indicate the values of w imposed on T computed according to (1). Red dashed lines in Figure (a) show how W can be mapped back.

the leaves of Q_u (note that, in case the degree of u is 1 in Q_u, we do not consider u to be a leaf of Q_u but just its root). Assume u has children $u_1, \ldots, u_k$. Because of the bottom-up procedure, each child u_j has already constructed a subtree $\overline{W}^{u_j}$. That is, u has to decide how to join these subtrees to get $\overline{W}^u$.

To describe how this is done formally, we first need to introduce some more notation. For every node $u \in T_i \backslash F$, we select one of its children as the "marked child" of u (according to some rule that we will define later). In this way, for every $u \in T_i$ there is a unique path along these marked children to a leaf. We denote this path by $P(u)$, and we let $\ell(u)$ denote the leaf descendent of this path. For final nodes $u \in F$, we define $\ell(u) := u$ and $P(u) := u$. For a subtree Q_u of T_i rooted at u and a witness tree $\overline{W}^u$ over the leaves of Q_u, let $\overline{w}^u$ be the vector imposed on the nodes of Q_u by $\overline{W}^u$ according to (1). Next, we define the following quantity (which, roughly speaking, represents the cost-increase incurred after increasing $\overline{w}^u(v)$ for each $v \in P(u)\backslash\ell(u)$ for the $(j+1)^{th}$ time):

$$C_j^u := \sum_{v \in P(u)\backslash\ell(u)} \left(H_{\overline{w}^u(v)+j+1} - H_{\overline{w}^u(v)+j}\right) = \sum_{v \in P(u)\backslash\ell(u)} \frac{1}{\overline{w}^u(v)+j+1}$$

Algorithm 1 Computing the tree $\overline{W}^u$.

u has Steiner node children $u_1, u_2, \ldots, u_k$, and $\overline{W}^{u_j}$ have been defined
if *$u_1, \ldots, u_k$ are all non-final,* **then**
  The *marked* child is u_m, minimizing $C_1^{u_m}$
else
  Assume $\{u_1, \ldots, u_{k_1}\}$, $1 \le k_1 \le k$, are final node children of u
  if *$k_1 = k$, or, for all $j \in \{k_1+1, \ldots, k\}$, $C_1^{u_j} \ge \phi - \delta - H_2$* **then**
    The *marked* child of u is u_m for $1 \le m \le k_1$ such that $C_1^{u_m}$ is minimized.
  if *There is a $j \in \{k_1+1, \ldots, k\}$ such that $C_1^{u_j} < \phi - \delta - H_2$* **then**
    The *marked* child of u is u_m for $k_1 < m \le k$ such that $C_1^{u_m}$ is minimized.
$\overline{W}^u \leftarrow \left(\bigcup_{j=1}^k V[Q_{u_j}], \bigcup_{j=1}^k \overline{W}^{u_j} \bigcup_{j \ne m} \{\ell(u_m)\ell(u_j)\}\right)$
Return $\overline{W}^u$

We can now describe the construction of the witness tree more formally. We begin by considering the leaves of T_i; for a final node (leaf) u, we define a witness tree on the (single) leaf of Q_u as $\overline{W}^u = (\{u\}, \emptyset)$. For a non-final node u, with children $u_1, \ldots, u_k$ and

corresponding witness trees $\overline{W}^{u_1}, \dots, \overline{W}^{u_k}$, we select a marked child u_m for u as outlined in Algorithm 1, setting $\phi = 1.86 - \frac{1}{2100}$ and $\delta = \frac{97}{420}$. With this choice, we compute $\overline{W}^u$ by joining the subtrees $\overline{W}^{u_1}, \dots, \overline{W}^{u_k}$ via the edges $\ell(u_m)\ell(u_j)$ for $j \neq m$. Finally, let v be the unique child of r_i. We let W_i be equal to the tree $\overline{W}^v$ plus the extra edge $\ell(v)r_i$, to account for the fact that r_i is also a final node.

3.3 Bounding the cost of W_i

It will be convenient to introduce the following definitions. For a component T_i and a node $u \in T_i \setminus r_i$, we let W^u be the tree $\overline{W}^u$ plus one extra edge e^u, defined as follows. Let $a(u)$ be the first ancestor node of u with $\ell(a(u)) \neq \ell(u)$ (recall $\ell(r_i) = r_i$). We then let the edge $e^u \coloneqq \ell(u)\ell(a(u))$. We denote by w^u the vector imposed on the nodes of Q_u by $W^u \coloneqq \overline{W}^u + e^u$. Note that, with this definition, $W_i = W^v$ for v being the unique child of r_i.

We now state two useful lemmas. The first one relates the functions w^u and w^{u_j} for a child u_j of u. The statements (a)-(c) below can be proved similarly to Lemma 4 of [2]. We defer its proof to the full version of the paper.

▶ **Lemma 10.** *Let $u \in T_i \setminus r_i$ have children $u_1, \dots, u_k$, and u_1 be its marked child. Then:*

a $w^u(u) = k$.

b *For every $j \in \{2, \dots, k\}$ and every node $v \in Q_{u_j}$, $w^u(v) = w^{u_j}(v)$.*

c *For every $v \in Q_{u_1} \setminus P(u_1)$, $w^u(v) = w^{u_1}(v)$.*

d $\sum_{v \in P(u_1) \setminus \ell(u_1)} H_{w^u(v)} = \sum_{v \in P(u_1) \setminus \ell(u_1)} H_{w^{u_1}(v)} + \sum_{j=1}^{k-1} C_j^{u_1}$.

Next lemma relates the "increase" of cost C_j^u to the *degree* of some nodes in T_i.

▶ **Lemma 11.** *Let $u \in T_i \setminus r_i$ have children $u_1, \dots, u_k$, and u_1 be its marked child. Then, $C_1^u = C_k^{u_1} + \frac{1}{k+1}$. Furthermore, if u_1 is non-final and has degree d in T_i, then:*
1) $\sum_{j=1}^{k}(C_j^{u_1} - C_1^{u_j}) \leq \sum_{j=1}^{k-1}\left(\frac{1}{d+j} - \frac{1}{d}\right)$; 2) $H_{w^u(\ell(u_1))} - H_{w^{u_1}(\ell(u_1))} \leq \sum_{j=1}^{k-1} \frac{1}{d+j}$

Proof.

1. First observe that since $C_1^{u_1} = \min_{j \in [k]} C_1^{u_j}$, we have $C_j^{u_1} - C_1^{u_j} \leq C_j^{u_1} - C_1^{u_1}$. Consider $j \geq 1$, $C_j^{u_1} - C_1^{u_1}$ is equal to

$$= \sum_{v \in P(u_1) \setminus \ell(u)} \left(H_{w^{u_1}(v)+j} - H_{w^{u_1}(v)+j-1} - H_{w^{u_1}(v)+1} + H_{w^{u_1}(v)}\right)$$

$$= \sum_{v \in P(u_1) \setminus \ell(u)} \left(\frac{1}{w^{u_1}(v)+j} - \frac{1}{w^{u_1}(v)+1}\right) \leq \frac{1}{w^{u_1}(u_1)+j} - \frac{1}{w^{u_1}(u_1)+1}$$

   Where the inequality follows since every term in the sum is negative. We know that $w^{u_1}(u_1) = d - 1$ by Lemma 10.(a), therefore, $C_j^{u_1} - C_1^{u_1} \leq \frac{1}{d+j-1} - \frac{1}{d}$, and the claim is proven by summing over $j = 1, \dots, k$.

2. To prove the second inequality, first observe that $w^u(\ell(u_1)) = w^{u_1}(\ell(u_1)) + k - 1$. This follows by recalling that W^u is equal to $\overline{W}^{u_1}, \dots, \overline{W}^{u_k}$ plus the edges $\ell(u_1)\ell(u_j)$ for $j \neq 1$, and e^u. Thus, $H_{w^u(\ell(u_1))} - H_{w^{u_1}(\ell(u_1))} = H_{w^{u_1}(\ell(u_1))+k-1} - H_{w^{u_1}(\ell(u_1))} = \sum_{i=1}^{k-1} \frac{1}{w^{u_1}(\ell(u_1))+i}$. Recall u_1 is not a final node, so $w^{u_1}(\ell(u_1)) > d$. Therefore,

$$\sum_{i=1}^{k-1} \frac{1}{w^{u_1}(\ell(u_1))+i} \leq \sum_{i=1}^{k-1} \frac{1}{d+i}.$$

◀

3.4 Key Lemma

To simplify our analysis, we define $h_{W^u}(Q_u) \coloneqq \sum_{\ell \in Q_u} H_{w^u(\ell)}$, and we let $|Q_u|$ be the number of nodes in Q_u. The next lemma is the key ingredient to prove Theorem 3.

▶ **Lemma 12.** *Let $\delta = \frac{97}{420}$ and $\phi = 1.86 - \frac{1}{2100}$. Let $u \in T_i \setminus r_i$ and k be the number of its children. Let $\beta(k)$ be equal to 0 for $k = 0, \ldots, 8$ and $\frac{1}{3} - \delta$ for $k \geq 9$. Then*

$$h_{W^u}(Q_u) + C_1^u + \delta + \beta(k) \leq \phi \cdot |Q_u|$$

Proof. The proof of Lemma 12 will be by induction on $|Q_u|$. The base case is when $|Q_u| = 1$, and hence u is a leaf of T_i. Therefore, W^u is just the edge e^u, and so by definition of w^u we have $w^u(u) = 2$. We get $h_{W^u}(Q_u) = 1.5$, $C_1^u = 0$, $\beta(k) = 0$ and the claim is clear.

For the induction step: suppose that u has children $u_1, \ldots, u_k$. We will distinguish 2 cases: (i) u has no children that are final nodes; (ii) u has some child that is a final node (which is then again broken into subcases). We report here only the proof of case (i), and defer the proof of the other case to the full version of the paper as the reasoning follows similar arguments.

Case (i): No children of u are final

According to Algorithm 1, we mark the child u_m of u that minimizes $C_1^{u_j}$. Without loss of generality, let $u_m = u_1$. Furthermore, let $\ell \coloneqq \ell(u_1)$. We note the following.

$$h_{W^u}(Q_u) = \sum_{j=1}^{k} h_{W^u}(Q_{u_j}) + H_{w^u(u)}$$

By applying Lemma 10.(a) we have $H_{w^u(u)} = H_k$. By Lemma 10.(b) we see $h_{W^u}(Q_{u_j}) = h_{W^{u_j}}(Q_{u_j})$ for $j \geq 2$. Using Lemma 10.(c) and (d) we get $h_{W^u}(Q_{u_1}) = h_{W^{u_1}}(Q_{u_1}) + \sum_{j=1}^{k-1} C_j^{u_1} + H_{w^u(\ell)} - H_{w^{u_1}(\ell)}$. Therefore:

$$h_{W^u}(Q_u) = \sum_{j=1}^{k} h_{W^{u_j}}(Q_{u_j}) + \sum_{j=1}^{k-1} C_j^{u_1} + H_k + H_{w^u(\ell)} - H_{w^{u_1}(\ell)}$$

We apply our inductive hypothesis on $Q_{u_1}, \ldots, Q_{u_k}$, and use $\beta(j) \geq 0$ for all j:

$$\begin{aligned} h_{W^u}(Q_u) &\leq \sum_{j=1}^{k} \left(\phi|Q_{u_j}| - \delta - C_1^{u_j}\right) + \sum_{j=1}^{k-1} C_j^{u_1} + H_k + H_{w^u(\ell)} - H_{w^{u_1}(\ell)} \\ &= \phi(|Q_u| - 1) - k\delta - C_k^{u_1} + \sum_{j=1}^{k} \left(C_j^{u_1} - C_1^{u_j}\right) + H_k + H_{w^u(\ell)} - H_{w^{u_1}(\ell)} \end{aligned}$$

Using Lemma 11, we get

$$\begin{aligned} &\leq \phi(|Q_u| - 1) - k\delta - C_1^u + \sum_{j=1}^{k-1} \left(\frac{1}{d+j} - \frac{1}{d}\right) + H_{k+1} + \sum_{j=1}^{k-1} \frac{1}{d+j} \\ &\leq \phi|Q_u| - \delta - C_1^u - \beta(k) \end{aligned}$$

where the last inequality follows since one checks that for any $k \geq 1$ and $d \geq 2$ we have $-\phi - (k-1)\delta + \sum_{j=1}^{k-1} \left(\frac{1}{d+j} - \frac{1}{d}\right) + H_{k+1} + \sum_{j=1}^{k-1} \frac{1}{d+j} \leq -\beta(k)$. We show this inequality the full version of the paper. ◀

3.5 Merging and bounding the cost of W

Once the $\{W_i\}_{i\geq 1}$ are computed for each component T_i, we let the final witness tree be simply the union $W = \cup_i W_i$. Our goal now is to prove the following.

▶ **Lemma 13.** $\nu_T(W) \leq \phi = 1.86 - \frac{1}{2100}$.

Proof. Recall that we decomposed T into components $\{T_i\}_{i=1}^{\tau}$, such that $\cup_{j\leq i} T_j$ is connected for all $i \in [\tau]$. For a given i, define $T' = \cup_{j<i} T_j$, $W' = \cup_{j<i} W_i$, and let w' be the vector imposed on the nodes of T' by W' (for $i = 1$, set $T' = \emptyset$, $W' = \emptyset$, and $w' = 0$). Finally, define $W'' = W_i \cup W'$ and let w'' be the vector imposed on the nodes of $T'' := T' \cup T_i$. By induction on i, we will show that $\nu_{T''}(W'') \leq \phi$. The statement will then follow by taking $i = \tau$. Recall that, for any i, r_i is adjacent to a single node v in T_i, and $W_i = W^v$.

First consider $i = 1$. Hence, $W'' = W_1 = W^v$ and $w''(r_1) = 2$. By applying Lemma 12 to the subtree Q_v we get

$$\sum_{u\in T''} H_{w''(u)} = h_{W^v}(Q_v) + H_{w''(r_i)} \leq \phi(|Q_v|) + H_2 \leq \phi(|Q_v| + 1) \Rightarrow \nu_{T''}(W'') \leq \phi$$

Now consider $i > 1$. In this case, $w''(r_i) = w'(r_i) + 1 \geq 3$. Therefore:

$$\sum_{u\in T''} H_{w''(u)} = \sum_{u\in T_i\setminus r_i} H_{w^v(u)} + \sum_{u\in T'} H_{w'(u)} - H_{w'(r_i)} + H_{w'(r_i)+1}$$
$$= \sum_{u\in T_i\setminus r_i} H_{w^v(u)} + \sum_{u\in T'} H_{w'(u)} + \frac{1}{w'(r_i)+1} \leq \sum_{u\in T_i\setminus r_i} H_{w^v(u)} + \sum_{u\in T'} H_{w'(u)} + \frac{1}{3}$$

If v is a final node, then $\sum_{u\in T_i\setminus r_i} H_{w^v(u)} = H_{w^v(v)} = H_2$ and by induction

$$\sum_{u\in T''} H_{w''(u)} \leq H_3 + \sum_{u\in T'} H_{w'(u)} \leq \phi|T''| \Rightarrow \nu_{T''}(W'') \leq \phi$$

If v is not a final node, then by induction on T' and by applying Lemma 12 to the subtree Q_v, assuming that v has k children, we can see

$$\sum_{u\in T''} H_{w''(u)} \leq \phi|T''| - C_1^v - \delta - \beta(k) + \frac{1}{3} \leq \phi|T''| - \frac{1}{k+1} - \delta - \beta(k) + \frac{1}{3}$$

If $1 \leq k \leq 8$, then $\beta(k) = 0$, but we have $\frac{1}{3} < 431/1260 = \frac{1}{9} + \delta \leq \frac{1}{k+1} + \delta$. If $k \geq 9$, $\beta(k) = \frac{1}{3} - \delta$ and $\frac{1}{3} - \delta - \beta(k) = 0$. In both cases, $\nu_{T''}(W'') \leq \phi$. ◀

Note that we did not make any assumption on T, other than being a CA-Node-Steiner-Tree. Hence, Lemma 13 yields the following corollary.

▶ **Corollary 14.** $\psi \leq 1.86 - \frac{1}{2100} < 1.8596$.

Combining Corollary 14 with Theorem 2 yields a proof of Theorem 3.

4 Improved Lower Bound on ψ

The goal of this section is to prove Theorem 4. For the sake of brevity, we will omit several details. (see the full version of the paper for a completed proof).

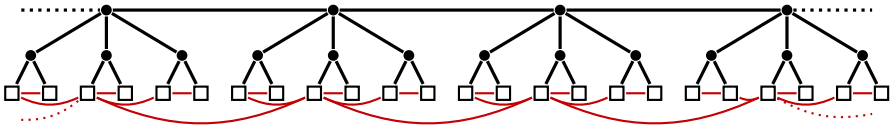

Figure 4 Lower bound instance shown in black. The white squares are terminals and black circles are Steiner nodes. Red edges form the laminar witness tree W^*.

Sketch of Proof of Theorem 4

Consider a CA-Node-Steiner-Tree instance (G, R), where G consists of a path of Steiner nodes $s_1, \ldots, s_q$ such that, for all $i \in [q]$, s_i is adjacent to Steiner nodes t_{i1}, t_{i2}, t_{i3}, and each t_{ij} is adjacent to two terminals r^1_{ij} and r^2_{ij}. See Figure 4. We will refer to B_i as the subgraph induced by $s_i, t_{ij}, r^1_{ij}, r^2_{ij}$ $(j = 1, 2, 3)$. Since G is a tree connecting the terminals, clearly the optimal Steiner tree for this instance is $T = G$.

Let W^* be a witness tree that minimizes $\nu_T(W^*)$. Recall that we can assume W^* to be laminar by Theorem 7. We arrive at an explicit characterization of W^* in three steps. First, we observe that, without loss of generality, we can assume that every pair of terminals r^1_{ij} and r^2_{ij} are adjacent in W^* and that r^2_{ij} is a leaf of W^*. Second, using the latter of these observations and laminarity, we show that for all i, the subgraph of W induced by $r^1_{i1}, r^1_{i2}, r^1_{i3}$ can only be either (a) a star, or (b) three singletons, adjacent to a unique terminal $f \notin B_i$. We say that B_i is a *center* in W^* if (a) holds. Finally, we get rid of case (b), and essentially arrive at the next lemma, whose proof can be found in the full version of the paper.

▶ **Lemma 15.** *Let $\mathcal{W}$ be the family of all laminar witness trees over T, and let W^* be a laminar witness tree such that for every $i \in [q]$, B_i is a center in W^*. Then $\nu_T(W^*) = \min_{W \in \mathcal{W}} \nu_T(W)$.*

Once we impose the condition that all B_i are centers, one notes that the tree W^* essentially must look like the one shown in Figure 4. So it only remains to compute $\nu_T(W^*)$. For every B_i, we can compute $\sum_{v \in B_i} H_{w^*(v)}$, where w^* is the vector imposed on the set S of Steiner nodes by W^*. For $i \in \{2, \ldots, q-1\}$, one notes that $\frac{1}{4}\sum_{v \in B_i} H_{w^*(v)} = \frac{1}{4}(2H_2 + H_4 + H_5) = 221/120 = 1.841\bar{6}$. Similarly, for $i = 1$ and q we have $\frac{1}{4}\sum_{v \in B_1} H_{w^*(v)} = \frac{1}{4}\sum_{v \in B_q} H_{w^*(v)} = \frac{1}{4}(2H_2 + H_3 + H_4) = \frac{83}{48} = 1.729\bar{16}$. Therefore, we can see that $\nu_T(W^*) = \sum_{v \in S} \frac{H_{w^*(v)}}{|S|} = \frac{1.841\bar{6}q - 2(1.841\bar{6} - 1.729\bar{16})}{q}$. Thus, for $q > \frac{1}{\varepsilon}$ we have $\nu_T(W^*) > 1.841\bar{6} - \frac{1}{q}$.

5 Tight bound for Steiner-Claw Free Instances

We here prove Theorem 5. Our goal is to show that for any Steiner-Claw Free instance (G, R, c), $\gamma_{(G,R,c)} \leq \frac{991}{732}$, improving over the known $\ln(4)$ bound that holds in general. From now on, we assume that we are given an optimal solution $T = (R \cup S^*, E^*)$ to (G, R, c).

Simplifying Assumptions

As standard, note that T can be decomposed into components $T_1, \ldots, T_\tau$, where each component is a maximal subtree of T whose leaves are terminals and internal nodes are Steiner nodes. Since components do not share edges of T, it is not difficult to see that one can compute a witness tree W_i for each component T_i separately, and then take the union of the $\{W_i\}_{i \geq 1}$ to get a witness tree W whose objective function $\bar{\nu}_T(W)$ will be bounded

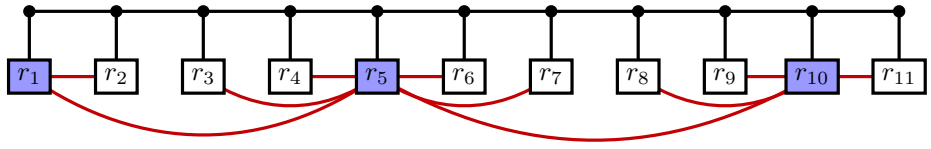

Figure 5 Edges of T are shown in black. Red edges show W. Here, $q = 11$, $t_\alpha = 5$ and $\sigma = 5$. Initially r_5 and r_{10} are picked as the centers of stars in W. Since $\sigma > \lceil \frac{t_\alpha}{2} \rceil$, r_1 is also the center of a star. Since $\sigma + t_\alpha \lfloor \frac{q-\sigma}{t_\alpha} \rfloor > q - \lceil \frac{t_\alpha}{2} \rceil$, r_q is not the center of a star.

by the maximum among $\bar{\nu}_{T_i}(W_i)$. Hence, from now on we assume that T is made by one single component. Since T is a solution to a Steiner-claw free instance, each Steiner node is adjacent to at most 2 Steiner nodes. In particular, the Steiner nodes induce a path in T, which we enumerate as $s_1, \ldots, s_q$. We will assume without loss of generality that each s_j is adjacent to exactly one terminal $r_j \in R$: this can be achieved by replacing a Steiner node incident to p terminals, with a path of length p made of 0-cost edges, if $p > 1$, and with an edge of appropriate cost connecting its 2 Steiner neighbors, if $p = 0$. We will also assume that $q > 4$. For $q \leq 4$, it is not hard to compute that $\gamma_{(G,R,c)} \leq \frac{991}{732}$. (For sake of completeness we explain this in the full version of the paper)

Witness tree computation and analysis

We denote by $L \subseteq E^*$ the edges of T incident to a terminal, and by $O = E^* \setminus L$ the edges of the path $s_1, \ldots, s_q$. Let $\alpha := c(O)/c(L)$. For a fixed value of $\alpha \geq 0$, we will fix a constant t_α as follows: If $\alpha \in [0, 32/90]$, then $t_\alpha = 5$, if $\alpha \in (32/90, 1)$, then $t_\alpha = 3$, and if $\alpha \geq 1$, then $t_\alpha = 1$. Given α (and thus t_α), we construct W using the randomized process outlined in Algorithm 2. At a high level, starting from a random offset, Algorithm 2 adds sequential stars of t_α terminals to W, connecting the centers of these stars together in this sequence. See Figure 5 for an example.

Algorithm 2 Computing the witness tree W.

Initialize $W = (R, E_W = \emptyset)$
Sample uniformly at random σ from $\{1, \ldots, t_\alpha\}$.
$E_W \leftarrow \{r_\sigma r_{\sigma+k} | 1 \leq |k| \leq \lfloor \frac{t_\alpha}{2} \rfloor, 1 \leq \sigma + k \leq q\}$
Initialize j=1
while $j \leq \frac{q-\sigma}{t_\alpha}$ **do**
  $\ell := \sigma + t_\alpha j$
  $E_W \leftarrow E_W \cup \{r_\ell r_{\ell+k} | 1 \leq |k| \leq \lfloor \frac{t_\alpha}{2} \rfloor, 1 \leq \ell + k \leq q\}$
  $E_W \leftarrow E_W \cup \{r_{\sigma+t_\alpha(j-1)} r_{\sigma+t_\alpha j}\}$
  $j \leftarrow j + t_\alpha$
if $\sigma > \lceil \frac{t_\alpha}{2} \rceil$ **then**
  $E_W \leftarrow E_W \cup \{r_1 r_k | 2 \leq k \leq \sigma - \lceil \frac{t_\alpha}{2} \rceil\} \cup \{r_1 r_\sigma\}$
$j \leftarrow \lfloor \frac{q-\sigma}{t_\alpha} \rfloor$
if $\sigma + t_\alpha j \leq q - \lceil \frac{t_\alpha}{2} \rceil$ **then**
  $E_W \leftarrow E_W \cup \{r_k r_q | \sigma + t_\alpha j + \lceil \frac{t_\alpha}{2} \rceil \leq k \leq q - 1\} \cup \{r_{\sigma+t_\alpha j} r_q\}$
Return W

Under this random scheme, we define $\lambda_L(t_\alpha) := \max_{e \in L} \mathbb{E}[H_{\bar{w}(e)}]$, and $\lambda_O(t_\alpha) := \max_{e \in O} \mathbb{E}[H_{\bar{w}(e)}]$.

▶ **Lemma 16.** *For any $\alpha \geq 0$, $\lambda_L(t_\alpha) \leq \frac{1}{t_\alpha} H_{t_\alpha+1} + \frac{t_\alpha - 1}{t_\alpha}$, and $\lambda_O(t_\alpha) \leq \frac{1}{t_\alpha} + \frac{2}{t_\alpha} \sum_{i=2}^{\lceil \frac{t_\alpha}{2} \rceil} H_i$.*

Proof. Let $W = (R, E_W)$ be a witness tree returned from running Algorithm 2 with α and $t \coloneqq t_\alpha$, and let w be the vector imposed on E^* by W. If Algorithm 2 samples $\sigma \in \{1, \ldots, t\}$, then we say that the terminals $r_{\sigma+tj}$ are *marked* by the algorithm. Moreover, if $\sigma > \lceil \frac{t_\alpha}{2} \rceil$ (resp. $\sigma + t_\alpha \lfloor \frac{q-\sigma}{t_\alpha} \rfloor \leq q - \lceil \frac{t_\alpha}{2} \rceil$) then r_1 (resp. r_q) is also considered marked.

1. Consider edge $e = s_j s_{j+1} \in O$, with $j \in \{\lceil \frac{t}{2} \rceil, \ldots, q - \lceil \frac{t}{2} \rceil\}$. Let $m \in \{j - \lfloor \frac{t}{2} \rfloor, \ldots, j + \lfloor \frac{t}{2} \rfloor\}$, such that $\sigma \mod t = m \mod t$. Observe that in this case r_m is marked. If $m = j - x$ for $x \in \{0, \ldots, \lfloor \frac{t}{2} \rfloor\}$, then $w(s_j s_{j+1}) = \lceil \frac{t}{2} \rceil - x$. Similarly if $m = j + x$ for $x \in \{1, \ldots, \lfloor \frac{t}{2} \rfloor\}$, then $w(s_j s_{j+1}) = \lceil \frac{t}{2} \rceil - x + 1$. Since $m \mod t = \sigma \mod t$ with probability $\frac{1}{t}$, we have $\mathbb{E}[H_{w(s_j s_{j+1})}] = \frac{1}{t} + \frac{2}{t} \sum_{k=2}^{\lceil \frac{t}{2} \rceil} H_k$.
   Now assume $j < \lceil \frac{t}{2} \rceil$ (the case $j > q - \lceil \frac{t}{2} \rceil$ can be handled similarly). Recalling that since t is odd it is not hard to determine the value of $w(s_j s_{j+1})$ by cases, depending on the value of σ.
   - **a.** $1 \leq \sigma \leq j$: Then $w(s_j s_{j+1}) = \lceil \frac{t}{2} \rceil + \sigma - j$.
   - **b.** $j + 1 \leq \sigma \leq \lceil \frac{t}{2} \rceil$: Then $w(s_j s_{j+1}) = j$.
   - **c.** $\lceil \frac{t}{2} \rceil + 1 \leq \sigma \leq j + \lfloor \frac{t}{2} \rfloor$: Then $w(s_j s_{j+1}) = \lceil \frac{t}{2} \rceil - \sigma + j + 1$.
   - **d.** $j + \lceil \frac{t}{2} \rceil \leq \sigma \leq t$: Then $w(s_j s_{j+1}) = \sigma - j - \lceil \frac{t}{2} \rceil + 1$.

   $$\begin{aligned}
   &\mathbb{E}[H_{w(s_j s_{j+1})}] = \\
   &= \frac{1}{t} \left(\sum_{\sigma=1}^{j} H_{\lceil \frac{t}{2} \rceil + \sigma - j} + \sum_{\sigma=j+1}^{\lceil \frac{t}{2} \rceil} H_j + \sum_{\sigma=\lceil \frac{t}{2} \rceil + 1}^{j + \lfloor \frac{t}{2} \rfloor} H_{\lceil \frac{t}{2} \rceil - \sigma + j + 1} + \sum_{\sigma=j+\lceil \frac{t}{2} \rceil}^{t} H_{\sigma - j - \lceil \frac{t}{2} \rceil + 1} \right) \\
   &= \frac{1}{t} \left(\sum_{i=\lceil \frac{t}{2} \rceil - j + 1}^{\lceil \frac{t}{2} \rceil} H_i + \left(\left\lceil \frac{t}{2} \right\rceil - j \right) H_j + \sum_{i=2}^{j} H_i + \sum_{i=1}^{\lceil \frac{t}{2} \rceil - j} H_i \right) \\
   &= \frac{1}{t} \left(\sum_{i=1}^{\lceil \frac{t}{2} \rceil} H_i + \left(\left\lceil \frac{t}{2} \right\rceil - j \right) H_j + \sum_{i=2}^{j} H_i \right) < \frac{1}{t} \left(1 + 2 \sum_{i=2}^{\lceil \frac{t}{2} \rceil} H_i \right).
   \end{aligned}$$

2. Consider edge $e = s_j r_j \in L$. We first show the bound for $j \in \{1, \ldots, q\}$. Algorithm 2 marks terminal r_i with probability $\frac{1}{t}$. If r_i is marked, then $w(e) \leq t$. If r_i is not marked, then $w(e) = 1$. Therefore, $\mathbb{E}[H_{w(e)}] \leq \frac{1}{t} H_{t+1} + \frac{t-1}{t}$
   Now consider edge $e = s_1 r_1$ (the case $e = s_q r_q$ can be handled similarly). We consider specific values of $\sigma \in \{1, \ldots, t\}$ sampled by Algorithm 2. With probability $\frac{1}{t}$, we have $\sigma = 1$, so r_1 is marked initially and $w(e) = \lceil t/2 \rceil$. For $\sigma = 2, \ldots, \lceil t/2 \rceil$, r_1 is unmarked and $w(e) = 1$. If $\sigma > \lceil t/2 \rceil$, then r_1 is marked by the algorithm and $w(e) = \sigma - \lceil t/2 \rceil$. Therefore, we can see

   $$\mathbb{E}[H_{w(r_1 s_1)}] = \frac{1}{t} \left(H_{\lceil t/2 \rceil} + \left\lfloor \frac{t}{2} \right\rfloor + \sum_{k=1}^{t - \lceil t/2 \rceil} H_k \right)$$

   We let $g(t)$ be equal to the equality above. It remains to show that $g(t) \leq \frac{1}{t} H_{t+1} + \frac{t-1}{t} \coloneqq f(t)$ for $t \in \{1, 3, 5\}$.

   $$\begin{aligned}
   g(1) &= H_1 = 1 < H_2 = f(1) \\
   g(3) &= \frac{1}{3} (H_2 + 1 + H_1) = 1.1\bar{6} < 1.36\bar{1} = \frac{1}{3}(H_4 + 2) = f(3) \\
   g(5) &= \frac{1}{5} (H_3 + 2 + H_1 + H_2) = 1.2\bar{6} < 1.29 = \frac{1}{5}(H_6 + 4) = f(5)
   \end{aligned}$$

Combining these two facts gives us the bound on $\lambda_{L_i}(t)$, for $t \in \{1, 3, 5\}$. ◀

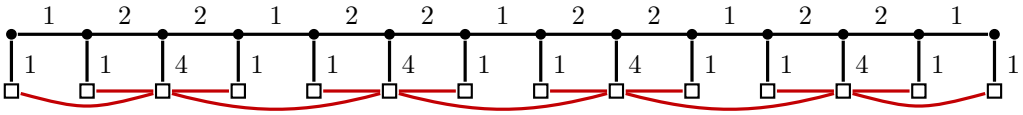

Figure 6 Lower bound instance shown in black with $c(e) = 1$ for all the edges in L and $c(e) = \alpha$ for all the edges in O, for $\alpha = \frac{32}{90}$. The white squares are terminals and black circles are Steiner nodes. Red edges form the laminar witness tree W^*, with the numbers next to each edge the value of w imposed on T.

The following Lemma is proven in the full version of the paper.

▶ **Lemma 17.** *For any $\alpha \geq 0$, the following bounds holds:*

$$\frac{1}{\alpha+1}\left(\frac{1}{t_\alpha}H_{t_\alpha+1} + \frac{t_\alpha - 1}{t_\alpha} + \alpha\left(\frac{1}{t_\alpha} + \frac{2}{t_\alpha}\sum_{i=2}^{\lceil \frac{t_\alpha}{2} \rceil} H_i\right)\right) \leq \frac{991}{732}$$

We are now ready to prove the following:

▶ **Lemma 18.** $\mathbb{E}[\bar{\nu}_T(W)] \leq \frac{991}{732}$.

Proof. One observes:

$$\sum_{e\in L\cup O} c(e)\mathbb{E}[H_{\bar{w}(e)}] \leq \sum_{e\in L} c(e)\lambda_L(t_\alpha) + \sum_{e\in O} c(e)\lambda_O(t_\alpha) = (\lambda_L(t_\alpha) + \alpha\lambda_O(t_\alpha))\sum_{e\in L} c(e)$$

Therefore $\mathbb{E}[\nu_T(W)]$ is bounded by:

$$\frac{\sum_{e\in L\cup O} c(e)\mathbb{E}[H_{\bar{w}(e)}]}{\sum_{e\in L\cup O} c(e)} \leq \frac{(\lambda_L(t_\alpha) + \alpha\lambda_O(t_\alpha))\sum_{e\in L} c(e)}{(\alpha+1)\sum_{e\in L} c(e)} = \frac{\lambda_L(t_\alpha) + \alpha\lambda_O(t_\alpha)}{\alpha+1} \leq \frac{991}{732}.$$

where the last inequality follows using Lemma 16 and 17. ◀

Now Theorem 5 follows by combining Lemma 18 with Theorem 1 in which γ is replaced by the supremum taken over all Steiner-claw free instances (rather than over all Steiner Tree instances).

Tightness of the bound

We conclude this section by spending a few words on Theorem 6. Our lower-bound instance is obtained by taking a tree T on q Steiner nodes, each adjacent to one terminal, with $c(e) = 1$ for all the edges in L and $c(e) = \alpha$ for all the edges in O, for $\alpha = \frac{32}{90}$. Similar to Section 3, a crucial ingredient for our analysis is in utilizing Theorem 8 stating that there is an optimal laminar witness tree. See Figure 6. We use this to show that there is an optimal witness tree for our tree T, whose objective value is at least $\frac{991}{732} - \varepsilon$. Details can be found in the full version of the paper.

Abstract

Online caching is among the most fundamental and well-studied problems in the area of online algorithms. Innovative algorithmic ideas and analysis – including potential functions and primal-dual techniques – give insight into this still-growing area. Here, we introduce a new analysis technique that first uses a potential function to upper bound the cost of an online algorithm and then pairs that with a new dual-fitting strategy to lower bound the cost of an offline optimal algorithm. We apply these techniques to the Caching with Reserves problem recently introduced by Ibrahimpur et al. [10] and give an $O(\log k)$-competitive fractional online algorithm via a marking strategy, where k denotes the size of the cache. We also design a new online rounding algorithm that runs in polynomial time to obtain an $O(\log k)$-competitive randomized integral algorithm. Additionally, we provide a new, simple proof for randomized marking for the classical unweighted paging problem.

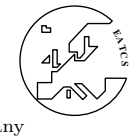
1 Introduction

Caching is a critical component in many computer systems, including computer networks, distributed systems, and web applications. The idea behind caching is simple: store frequently used data items in a cache so that subsequent requests can be served directly from the cache to reduce the resources required for data retrieval. In the classical unweighted caching problem, a sequence of page requests arrives one-by-one and an algorithm is required to maintain a small set of pages to hold in the cache so that the number of requests not served from the cache is minimized.

Traditional caching algorithms, both in theory and practice, are designed to optimize the global efficiency of the system and aim to maximize the *hit rate*, i.e., fraction of requests that are served from the cache. However, such a viewpoint is not particularly suitable for



cache management in a multi-user or multi-processor environment. Many cloud computing services allow multiple users to share the same physical workstations and thereby share the caching system. In such multi-user environments, traditional caching policies can lead to undesirable outcomes as some users may not be able to reap any benefits of the cache at all. Recently, Ibrahimpur et al. [10] introduced the *Caching with Reserves* model that ensures certain user-level fairness guarantees while still attempting to maximize the global efficiency of the system. In this formulation, a cache of size k is shared among m agents and each agent i is guaranteed a reserved cache size of k_i. An algorithm then attempts to minimize the total number of requests that are not served from the cache while guaranteeing that any time step, each agent i holds at least k_i pages in the cache. Unlike the classical paging problem, *Caching with Reserves* is NP-complete even in the offline setting when the algorithm knows the entire page request sequence ahead of time and Ibrahimpur et al. [10] gave a 2-approximation algorithm. They also gave an $O(\log k)$-competitive online fractional algorithm for *Caching with Reserves* via a primal-dual technique and then design a rounding scheme to obtain an $O(\log k)$-competitive online randomized algorithm. Unfortunately, the rounding scheme presented in [10] does not run in polynomial time and the fractional primal-dual algorithm, while simple to state, also does not yield itself to easy implementation.

Caching and its many variants have been among the most well-studied problems in theoretical computer science. It has long been a testbed for novel algorithmic and analysis techniques and it has been investigated via general techniques such as potential function analysis, primal-dual algorithms, and even learning-augmented algorithms. For the classical unweighted caching problem, a particularly simple algorithm, *randomized marking* [9], is known to yield the optimal competitive ratio (up to constant factors). At any point in time, the randomized marking algorithm partitions the set of pages in cache into *marked* and *unmarked* pages and upon a cache miss, it evicts an unmarked page chosen uniformly at random. Cache hits and pages brought into the cache are marked. When a cache miss occurs, but there are no more unmarked pages, a new *phase* begins, and all pages in the cache become unmarked. In this paper, we build upon this algorithm, adapting it to caching with reserves.

Our Contributions

We study the *Caching with Reserves* model of Ibrahimpur et al. [10] in the online setting and improve upon those results. Our first main result is a simpler fractional algorithm that is a generalization of randomized marking for classical caching.

▶ **Theorem 1.** *There is an $O(\log k)$-competitive fractional* marking *algorithm for online* Caching with Reserves*. The competitive guarantee holds even when the optimal offline algorithm is allowed to hold fractional pages in the cache.*

We remark that our algorithm in Theorem 1 and its analysis are more involved than those of the classical randomized marking algorithm. One complication is that due to the reserve constraints, a marking-style algorithm for the caching with reserves setting cannot evict an arbitrary unmarked page. Another key difficulty comes from the fact that even the notion of a *phase* is non-trivial to define in our setting. In particular, unlike in classical caching, it can happen that the cache still contains unmarked pages, but none of them can be evicted to make space for a new page, because of the reserve constraints. Thus, we need a rule to isolate agents whose reserve constraints prevent the algorithm from having a clean end of a phase, while also ensuring that the already marked pages of such isolated agents are not erased prematurely. To this end, we introduce the notion of *global* and *local* phases to effectively model the state of each agent. We elaborate on this in Section 3.1.

Our analysis of the fractional marking algorithm introduces two novel components that may be of independent interest. First, we upper-bound the total cost incurred by our fractional marking algorithm using a new potential function. This potential function, introduced in Section 3.3, depends only on the decisions of the algorithm and is independent of the optimal solution. To the best of our knowledge, all previous potential function based analyses of (variants of) caching [4, 5, 6, 10] define a potential function that depends on the optimal solution. Second, we introduce a new lower bound for the cost of the optimal solution via the dual-fitting method. Our techniques also yield a new simple proof that the classical *randomized marking* [9] for unweighted paging is $O(\log k)$-competitive (see the full version [11] for more details).

We also design a new online rounding algorithm that converts a deterministic, fractional algorithm into a randomized, integral algorithm while only incurring a constant factor loss in the competitive ratio. Via a careful discretization technique (inspired by Adamaszek et al. [2]), the new rounding algorithm runs in polynomial time and only uses limited randomization. Our fractional marking algorithm (Algorithm 1) maintains that at any point in time, a particular page p is either completely in the cache or at least $1/k$ fraction of the page has been evicted. We exploit this key property to show that the fractional solution at any time t can be discretized so that the fraction of any page that is evicted is an integral multiple of $1/k^3$. This discretization allows us to maintain a distribution over feasible integer cache states with bounded support.

▶ **Theorem 2.** *There is a polynomial-time $O(\log k)$-competitive randomized integral algorithm for online caching with reserves.*

Other Related Work

The unweighted caching (also known as paging) problem has been widely studied and its optimal competitive ratio is well-understood even up to constant factors. Tight algorithms [1, 14] are known that yield a competitive ratio of exactly H_k, where H_k is the kth harmonic number. Recently, Agrawal et al. [3] consider the *parallel paging* model where a common cache is shared among p agents – each agent is presented with a request sequence of pages and the algorithm must decide how to partition the cache among agents at any time. It allows the p processors to make progress simultaneously, i.e., incur cache hits and misses concurrently. Multi-agent paging has also been extensively studied in the systems community [7, 16, 17] often in the context of caching in multi-core systems. Closely related to the *Caching with Reserves* setting, motivated by fairness constraints in multi-agent settings, a number of recent systems [12, 13, 15, 18] aim to provide *isolation guarantees* to each user, i.e., guarantee that the cache hit rate for each user is at least as much as what it would be if each user is allocated its own isolated cache. Also motivated by fairness constraints, Chiplunkar et al. [8] consider the Min-Max paging problem where the goal is to minimize the maximum number of page faults incurred by any agent.

2 Preliminaries and Notation

Formally, an instance of the *Caching with Reserves* problem consists of the following. We are given a number of agents m and a total (integer) cache capacity k. Let $[m]$ denote the set $\{1, \ldots, m\}$. Each agent $i \in [m]$ owns a set of pages $\mathcal{P}(i)$ (referred to as i-pages) and has a *reserved cache size* $k_i \geq 0$. Pages have a unique owner, i.e. $\mathcal{P}(i) \cap \mathcal{P}(j) = \varnothing$ for all $i \neq j$, and we use $\mathcal{P} \triangleq \cup_{i \in [m]} \mathcal{P}(i)$ to refer to the universe of all pages. For any page $p \in \mathcal{P}$, let $ag(p)$ be

the unique agent that owns p. We assume without loss of generality that at least one unit of cache is not reserved: $\sum_{i\in[m]} k_i < k$.[1] At each timestep t, a page $p_t \in \mathcal{P}$ is requested. We can wrap all these into an instance tuple: $\sigma = (m, k, \{\mathcal{P}(i)\}, \{k_i\}, \{p_t\})$.

An *integral* algorithm for the *Caching with Reserves* problem maintains a set of k pages in the cache such that for each agent i, the cache always contains at least k_i pages from $\mathcal{P}(i)$. At time t, the page request p_t is revealed to the algorithm. If this page is not currently in the cache, then the algorithm is said to incur a *cache miss* and it must fetch p_t into the cache by possibly evicting another page q_t. For any (integral) algorithm $\mathcal{A}$ we write its total cache misses on instance σ as $\text{cost}_{\mathcal{A}}(\sigma)$.

A *fractional* algorithm for the *Caching with Reserves* problem maintains a fraction $x_p \in [0, 1]$ for how much each page $p \in \mathcal{P}$ is in the cache such that the total size of pages in the cache is at most k, i.e, $\sum_{p\in\mathcal{P}} x_p \le k$, and the total size of i-pages is at least k_i, i.e., $\sum_{p\in\mathcal{P}(i)} x_p \ge k_i$. At time t, the page request p_t is revealed to the algorithm, which incurs a fractional cache miss of size $1 - x_{p_t}$. The algorithm must then fully fetch p_t into cache ($x_{p_t} \leftarrow 1$) by possibly evicting other pages. For any (fractional) algorithm $\mathcal{A}$ we again write its total size of cache misses on instance σ as $\text{cost}_{\mathcal{A}}(\sigma)$.

Let $\text{cost}_{OPT}(\sigma)$ be the cost of the optimal offline algorithm on instance σ.

▶ **Definition 3** (Competitive Ratio). *An online algorithm $\mathcal{A}$ for* Caching with Reserves *is said to be c-competitive, if for any instance σ, $\mathbb{E}[\text{cost}_{\mathcal{A}}(\sigma)] \le c \cdot \text{cost}_{OPT}(\sigma) + b$, where b is a constant independent of the number of page requests in σ. The expectation is taken over all the random choices made by the algorithm (if any).*

3 Fractional $O(\log k)$-Competitive Algorithm for Caching with Reserves

For any time t and page $p \in \mathcal{P}$, the algorithm maintains a variable $y_p^t \in [0, 1]$ representing the portion of page p that is outside the cache. Then $x_p^t \triangleq 1 - y_p^t$ represents the portion of p that is in cache. Algorithm 1 ensures feasibility at all times t: the total of all y values is exactly the complementary cache size $|\mathcal{P}| - k$, i.e., $\sum_{p\in\mathcal{P}} y_p^t = |\mathcal{P}| - k$; and the total y value for pages of any agent i is within its respective complementary reserve size, $\sum_{p\in\mathcal{P}(i)} y_p^t \le |\mathcal{P}(i)| - k_i$. When a request for page p_t arrives at time t, the algorithm fully fetches p_t into the cache by paying a fetch-cost of $y_{p_t}^t$ while simultaneously evicting a total of $y_{p_t}^t$ amount of other suitably chosen pages.

3.1 Fractional Algorithm

The complete algorithm (referred to as Algorithm $\mathcal{A}$ in the proofs) is presented in Algorithm 1. We present a high-level discussion here. At any time t, we say that an agent i is *tight* if $\sum_{p\in\mathcal{P}(i)} x_p^t = k_i$, i.e., the algorithm is not allowed to further evict any pages (even fractionally) of agent i. Conversely, an agent i is *non-tight* if $\sum_{p\in\mathcal{P}(i)} x_p^t > k_i$.

The algorithm is a fractional marking algorithm and runs in phases where each phase corresponds to a maximal sequence of page requests that can be served while maintaining feasibility and ensuring that no "marked" pages are evicted. Within each phase, the currently requested page p_t is fully fetched into cache by continuously evicting an infinitesimal amount of an "available" (described below) unmarked page q with the smallest y_q value; if there are multiple choices of q, then all of them are simultaneously evicted at the same rate. Page p_t gets marked after it has been served and this mark may only be erased at the end of a phase.

[1] If all of cache is reserved, the problem decomposes over agents into the standard caching task.

At the end of a phase, an agent i is designated as *isolated* if strictly fewer than k_i i-pages are marked in the cache at this time point. This designation changes to non-isolated as soon as k_i i-pages get marked at some point in the future. An isolated agent essentially runs a separate instance of caching on its own pages and in its own reserved space. At the end of a phase, the marks of pages owned by non-isolated agents (i.e., agents with at least k_i marked i-pages) are erased.

It remains to describe when a page q is considered available for eviction. Clearly, $y_q^t < 1$ must hold, since otherwise page q is already fully outside the cache. Moreover, $ag(q)$ must be *non-tight*, i.e., evicting page q must not violate the reserve constraint of the agent that owns it. The last condition for q to be considered available for eviction depends on whether the agent $i_t := ag(p_t)$ is *isolated* or not: (i) if agent i_t is isolated, then $ag(q) = i_t$ should hold, i.e., only unmarked i_t-pages are available for eviction; and (ii) if agent i_t is not isolated, then $ag(q)$ should also be non-isolated. We recall again that among all available pages for eviction, pages with the smallest y_q^t value are evicted first.

Notation. Let $\mathcal{I}(t) \subsetneq [m]$ denote the set of isolated agents at time t. For a global phase r_0, we use $\mathcal{I}(r_0)$ to denote the set of isolated agents at the end of phase r_0. Let $\mathcal{T}(t)$ denote the set of *tight* agents at time t. At any time t, let r_i^t denote the value of the local phase counter r_i for agent i, and let $R_i = r_i^T$ be the total number of local phases for agent i. By definition, for any agent $i \in [m]$, $P(i, r_i - 1)$ and $P(i, r_i)$ denote the set of i-pages in the cache (integrally) at the beginning of the r_ith local phase and the end of the r_ith local phase for agent i, respectively. For any agent $i \in [m]$, let $M(i,t) \subseteq \mathcal{P}(i)$ denote the set of marked i-pages in the cache and $U(i,t) = P(i, r_i^t - 1) \setminus M(i,t)$ denote the set of unmarked i-pages.

We emphasize that the notion of *unmarked* pages will only be relevant while referring to pages in $P(i, r_i^t - 1)$ for some i, t; in particular, every i-page $q \in \mathcal{P}(i) \setminus (P(i, r_i^t - 1) \cup M(i,t))$ is not *marked*, but we do not refer to it as *unmarked*. Analogous to the notion of clean and stale pages used by the randomized marking algorithm [9], we define *clean, pseudo-clean* and *stale* pages as follows. Fix an agent i and let r_i be its local phase counter at time t. Any i-page $q \in P(i, r_i - 1)$ is considered *stale*. The currently requested page p_t is said to be *clean* if $p_t \notin P(i, r_i - 1)$. Next, we say that the currently requested page p_t is *pseudo-clean* if $p_t \in P(i, r_i - 1)$ and $y_{p_t}^t = 1$ holds right before Algorithm $\mathcal{A}$ starts to fetch p_t into the cache. Lemmas 7 and 8 show that a pseudo-clean page necessarily belongs to an agent who was isolated at the start of (global) phase r_0 but is non-isolated at time t. To simplify notation, we drop the superscript t from all notation whenever the time index is clear from the context.

The following lemma compiles a list of key invariants that are maintained throughout the execution of the algorithm that follow directly from an examination of Algorithm 1.

▶ **Lemma 4.** *Algorithm 1 maintains the following invariants.*

- **(i)** *When a new phase begins, all marked pages belong to isolated agents.*
- **(ii)** *At any time t, all isolated agents are tight.*
- **(iii)** *At any time t and for any agent i, all unmarked pages of agent i have the same y value.*
- **(iv)** *Any page belonging to an isolated agent is (fractionally) evicted only in those timesteps when a different page of the same agent has been requested.*

The following lemmas show that the algorithm is well-defined and that the operations in Lines 12 and 18 of Algorithm 1 are always feasible.

[2] Agent i_t is considered non-tight here because fetching p_t while evicting other $q \in \mathcal{P}(i_t) \setminus p_t$ does not violate reserve feasibility.

Algorithm 1 Fractional Marking Algorithm for *Caching with Reserves*.

```
/* Initialization */
r_0 ← 1                                                  /* global phase counter */
r_i ← 1, ∀i ∈ [m]                                        /* local phase counters */
Let P(i,0) ⊂ P(i) be set of i-pages in the initial cache (assume |P(i,0)| ≥ k_i) ∀i ∈ [m]
All agents i ∈ [m] are non-isolated and all pages p in the cache are unmarked
for each page request p_t of agent i_t do
    if y_{p_t} = 0, i.e., x_{p_t} = 1, then
        Mark page p_t and serve the request.
    else if agent i_t is isolated, then
        /* Continuously fetch page p_t while uniformly evicting all unmarked
           i_t-pages. */
        Set y_{p_t} ← 0, mark page p_t and serve the request.
        Increase y_q at the same rate for all unmarked i_t-pages in the cache until the cache
          becomes feasible, i.e. Σ_{p∈P} y_p ≥ |P| − k holds.
        if agent i_t now has k_i marked pages then
            Designate i_t as non-isolated
    else if ∃ page q owned by some non-tight agent[2] and satisfying y_q < 1, then
        /* Continuously fetch page p_t while uniformly evicting all unmarked
           pages (belonging to any non-tight agent) with the least y-value. */
        Set y_{p_t} ← 0, mark page p_t and serve the request.
        Increase y_q at the same rate for all unmarked pages of non-tight agents with the
          smallest y values until the cache becomes feasible, i.e. Σ_{p∈P} y_p ≥ |P| − k holds.
    else
        /* End of phase */
        for each agent i ∈ [m] do
            if i has strictly fewer than k_i marked pages, then
                Designate i as isolated.
            else
                /* i is non-isolated and undergoes a phase reset */
                Set P(i, r_i) ← collection of all (integral and marked) i-pages in cache.
                Set r_i ← r_i + 1
                All marked i-pages are now unmarked
        Set r_0 ← r_0 + 1
        Re-process the current page request p_t in the new phase
```

▶ **Lemma 5.** *If the requested page p_t has $x^t_{p_t} \in [0,1)$ and agent i_t is isolated, then p_t can be fetched fully by evicting unmarked pages of agent i_t.*

Proof. As agent i_t is isolated when page p_t is requested, $\sum_{p\in\mathcal{P}(i)} x^t_p = k_i$ (by invariant (ii) in Lemma 4) and i_t has fewer than k_i marked pages in cache. Hence $\sum_{p\in U(i,t)} x^t_p \geq 1$ and $\sum_{p\in U(i,t)\setminus\{p_t\}} x^t_p \geq 1 - x^t_{p_t}$. ◀

▶ **Lemma 6.** *If the requested page p_t has $0 < x^t_{p_t} < 1$ and its owner i_t is non-isolated, then there is always enough fractional mass of pages belonging to non-tight agents that can be evicted to fully fetch page p_t. In particular, line 18 of Algorithm 1 is well-defined.*

Proof. Suppose page p_t is fetched in a continuous manner. To show that page p_t can be fetched fully, it suffices to show that at any instantaneous time t when $x^t_{p_t} < 1$, there always exists an unmarked page q belonging to a non-tight agent i such that $x^t_q > 0$, i.e. page

q can be evicted. Observe that $k = \sum_{q\in\mathcal{P}} x_q^t = \sum_{i\in\mathcal{T}(t)} k_i + \sum_{i\notin\mathcal{T}(t)} \sum_{q\in\mathcal{P}(i)} x_q^t$. Due to integrality of k and $\{k_i\}_{i\in[m]}$, we must have $\sum_{i\notin\mathcal{T}(t)} \sum_{q\in\mathcal{P}(i)} x_q^t$ is an integer. Since any marked page q always has $x_q^t = 1$, $\mu := \sum_{i\notin\mathcal{T}(t)} \sum_{q\in U(i,t)} x_q^t$ is also an integer. Further, since $i_t \notin \mathcal{T}(t)$ and $x_{p_t}^t > 0$, we must have $\mu \geq 1$ and hence there exists a page q belonging to some non-tight agent i with $x_q^t > 0$ as desired. ◀

Since we always evict an available page with the least y value, at any time step t, all available pages (i.e., unmarked pages q belonging to non-tight agents and satisfying $y_q < 1$) have the same y value at all times. We denote this common y-value by h^* and refer to the corresponding set of evictable pages (with y-value h^*) as the *frontier*. The following two key structural lemmas formalize this property.

▶ **Lemma 7.** *At any time t, let i be an agent that was isolated at the beginning of the current phase, and let q be one of its unmarked pages. Then $y_q^t < 1$ if and only if i is still isolated at time t.*

Proof. For the *if* direction, suppose that i is still isolated. By invariant (ii), it is also tight. By invariant (iii), all its unmarked pages have the same x-value and in total they occupy $k_i - |M(i,t)| > 0$ units of cache space. Thus, $x_q^t > 0$ and $y_q^t < 1$.

For the *only if* direction, suppose that i is no longer isolated. Just before the k_ith i-page to be marked was requested, $(k_i - 1)$ i-pages were marked. Since i was tight, the total x value of all its unmarked pages must have been 1. Then the algorithm replaced all of them with the k_ith marked page, and the x-value of all remaining unmarked pages became 0. Thus, the property holds for a newly non-isolated agent i. This property continues to hold for the rest of the phase since y_q never decreases for an unmarked page. ◀

▶ **Lemma 8.** *At any time t, there is a value $h_t^* \in [0,1]$ such that: for any agent i that was non-isolated at the beginning of the current phase and any unmarked i-page q, $y_q \leq h_t^*$ holds and $y_q = h_t^*$ holds whenever i is non-tight.*

Proof. We prove the lemma by induction. Clearly, the lemma holds at the start of the phase: all unmarked pages belonging to non-isolated agents have y-value 0. Now consider a time t during phase r such that the lemma holds for all timepoints before t in this phase. We may also assume that $y_{p_t} > 0$, since otherwise none of the variables are modified in this timestep.

By induction hypothesis, any unmarked i-page q satisfies $y_q \leq h_{t-1}^*$, and this inequality is tight whenever i is non-tight. If agent i_t is non-tight, then its unmarked pages are already part of the frontier. Otherwise, Algorithm $\mathcal{A}$ fetches p_t fully into the cache by increasing the y-value of other unmarked i_t-pages until one of the following happens: (a) p_t is fully fetched. In this case, i_t continues to remain tight; or (b) The y-value of unmarked i_t-pages becomes equal to the frontier's y-value, h_{t-1}^*. In the latter case, unmarked i_t-pages become part of the frontier and the y-value of the frontier is uniformly increased until p_t gets fully fetched into the cache. If some agent i' becomes tight before the fetch operation is completed, then its unmarked pages get excluded from the frontier and the corresponding y-values remain unchanged for the rest of this timestep. In all cases, the lemma continues to hold since the y-value of the frontier is never decreased and only tight agents get dropped from the frontier. ◀

▶ Remark 9. Within any phase, h_t^* is non-decreasing over time and takes values 0 and 1 at the endpoints. This follows from the fact that $\mathcal{A}$ never decreases y_q for an unmarked page $q \neq p_t$.

The following lemma shows that any page that is not completely in Algorithm $\mathcal{A}$'s cache must be evicted to at least a $1/k$ portion. This property will be useful to us in Sections 3.3 and 4.

▶ **Lemma 10.** *At the end of any time step t, for any page $p \in \mathcal{P}$, we have $y_p^t = 0$ or $y_p^t \geq 1/k$.*

Proof. First, note that for all marked pages, we have $y_p^t = 1 - x_p^t = 0$. Let $i \in \mathcal{T}(t)$ be any tight agent. Then we have $k_i = \sum_{p \in \mathcal{P}(i)} x_p^t = |M(i,t)| + \sum_{p \in U(i,t)} x_p^t$. By Lemma 4 (part iii), all unmarked pages of agent i have the same y value: $y_p^t = 1 - x_p^t = h_i$ (say). Since k_i is integral, we have either $h_i = 0$ or h_i. Rearranging, we have $|U(i,t)|h_i = |M(i,t)| + |U(i,t)| - k_i$. Since all terms on the RHS are integral, we have either $h_i = 0$ or $h_i \geq 1/|U(i,t)| \geq 1/k$.

By Lemma 8, all unmarked pages p belonging to non-tight agents satisfy $y_p^t = h_t^*$. Let $U(t)$ be the set of all unmarked pages belonging to all non-tight agents that were also non-isolated at the beginning of the phase. Recall that by definition, we have $|U(t)| \leq k$ since all pages in $U(t)$ must have been fully in the cache at the beginning of the current phase. Since we have $k = \sum_{i \in \mathcal{T}(t)} k_i + \sum_{i \notin \mathcal{T}(t)} \sum_{p \in \mathcal{P}(i)} x_p^t$, once again by integrality of k and $\{k_i\}$, we must have that $\sum_{p \in U(t)} y_p^t = \sum_{p \in U(t)} h_t^*$ is an integer. Hence, either $h_t^* = 0$ or $h_t^* \geq 1/|U(t)| \geq 1/k$. ◀

3.2 Analysis Overview

At any time t, we consider the set of y values of pages in $\bigcup_{i \in [m]} P(i, r_i - 1)$ as the *state* of the system. We define a non-negative potential function Ψ that is purely a function of this state. For any page request p_t, we attempt to bound the algorithm's cost by an increase in the potential function, thereby bounding the total cost incurred by the algorithm by the final value of the potential function. There are two difficulties with this approach: (i) when a phase ends, the potential function abruptly drops since all the unmarked pages that were fully evicted no longer contribute to the state, and (ii) when the agent i_t was isolated at the beginning of the phase but is now non-isolated, the change in potential is not sufficient to cover the fetch cost. In both these situations we charge the cost incurred by the online algorithm to a new quantity that is a function of the sets $\{P(i, r_i)\}$. To complete the analysis, we show that this quantity is upper-bounded by the cost of the optimal solution.

3.3 Potential Function Analysis

Consider the function $\phi : [0,1] \to \mathbb{R}_{\geq 0}$ defined as:

$$\phi(h) \triangleq 2h \cdot \ln(1 + kh) \tag{1}$$

As h goes from 0 to 1, $\phi(h)$ increases from 0 to $2\ln(1+k)$.

The potential at any time t is defined as follows:

$$\Psi(t) \triangleq \sum_{i=1}^{m} \sum_{p \in U(i,t)} \phi(y_p^t) \tag{2}$$

Note that only unmarked pages at any time t contribute to the potential. So when page p_t is fetched at time t and marked, it stops contributing to the potential. But since ϕ is monotone, the newly evicted pages increase their contribution to the potential. We remark that the potential is purely a function of the state of the system as defined by the y values of unmarked pages in the cache and is thus always bounded by a quantity independent of the length of the page request sequence.

▶ **Lemma 11.** *For any $h \geq 1/k$, we have $\phi(h) \geq h$ and $\phi'(h) \geq 1 + 2\ln(1+kh)$.*

Proof. The first conclusion follows from the logarithmic inequality $\ln(1+x) \geq x/(1+x)$ which holds for any nonnegative x: we have $\phi(h) = 2h\ln(1+kh) \geq h \cdot 2kh/(1+kh) \geq h$ whenever $kh \geq 1$. Next, $\phi'(h) = \frac{d\phi}{dh} = 2(1 - 1/(1+kh) + \ln(1+kh))$. So, for any $h \geq 1/k$ we have $1/2 \geq 1/(1+kh)$, which gives the other conclusion. ◀

The rest of this section is devoted to proving the following theorem where we bound the total cost incurred by the algorithm in terms of the sets $\{P(i, r_i)\}$ and the number of requests to pseudo-clean pages.

▶ **Theorem 12.** *The following bound holds on the cost incurred by $\mathcal{A}$ to process the first T page requests:*

$$\text{cost}_{\mathcal{A}}(\sigma) \leq 2\ln(1+k) \cdot \left(mk + \sum_{t=1}^{T} \mathbb{1}_{p_t \text{ is pseudo-clean}} + \sum_{i \in [m]} \sum_{r_i=1}^{R_i} |P(i, r_i - 1) \setminus P(i, r_i)| \right).$$

Recall that the algorithm incurs a cost of $y^t_{p_t}$ to fetch page p_t at time t. So the total cost incurred by the algorithm is simply $\text{cost}_{\mathcal{A}}(\sigma) = \sum_t y^t_{p_t}$. We first bound this cost for time steps when the requested page p_t is at least partially in the cache, i.e., $y^t_{p_t} < 1$. Recall by Lemmas 5 and 6, the algorithm does not undergo a phase transition in this time step.

▶ **Lemma 13.** *Consider any time step t such that $y^t_{p_t} < 1$ for the currently requested (unmarked) page p_t. Let $\Delta\Psi(t)$ denote the change in the potential function during time step t. Then $y^t_{p_t} \leq \Delta\Psi(t)$.*

Proof. We assume that $y^t_{p_t} \geq \frac{1}{k}$, since otherwise by Lemma 10, we must have $y^t_{p_t} = 0$ and the lemma follows trivially. Since $y^t_{p_t} < 1$, by Lemma 8, either agent i_t is tight or we have $y^t_q = y^t_{p_t}$ for every unmarked page q owned by any non-tight agent i that was non-isolated at the start of this phase. In either case, the pages that get evicted to make space for p_t have their initial y values at least $y^t_{p_t} \geq 1/k$. The potential function Ψ changes in this step due to two factors: (i) Ψ drops as page p_t stops contributing to the potential as soon as it gets marked; and (ii) Ψ increases as the y-value of (fractionally) evicted pages increases in this step.

Let $h \triangleq y^t_{p_t}$. At the beginning to time t, page p_t contributed exactly $\phi(h) = 2h\ln(1+kh)$ to the potential; This contribution is lost as soon as p_t gets marked. To prove the lemma, it suffices to show that the rate of increase in the potential function (without including p_t's contribution) is at least $1 + 2\ln(1+kh)$ throughout the eviction of an h amount of unmarked pages belonging to non-tight agents: the 1 term in total pays for the fetch-cost of h and the $2\ln(1+kh)$ term in total pays for the $2h\ln(1+kh)$ loss in potential. This directly follows from Lemma 11 from the fact that the y-values of pages that are fractionally evicted in this timestep were already at least $h \geq 1/k$. Here, we also use the monotonicity of the function $h' \mapsto \ln(1+kh')$. ◀

We still need to bound the cost incurred by the algorithm when the incoming request is to a page that is fully outside the cache. Note that the algorithm incurs exactly unit cost for all such time steps. The following lemma shows that the total cost incurred by the algorithm can be bounded by the drop in potential function at the end of a phase and by a term that depends only on the change in the potential function while processing a request to a page fully outside the cache.

▶ **Lemma 14.** *For any global phase r_0, let $\Delta\Psi(r_0)$ denote the change in the potential function at the end of phase r_0 (line 30 in Algorithm 1). Let R_0 denote the total number of global phases and T denote the time at the end of phase R_0. Then we have the following upper bound on the cost incurred by $\mathcal{A}$ for processing the first T page requests:*

$$\text{cost}_{\mathcal{A}}(\sigma) \leq 2mk\ln(1+k) + \sum_{t\in[T]:y^t_{p_t}=1} (1-\Delta\Psi(t)) - \sum_{r_0=1}^{R_0} \Delta\Psi(r_0)$$

Proof. We have:

$$\begin{aligned}
\text{cost}_{\mathcal{A}}(\sigma) &= \sum_{t\in[T]} y^t_{p_t} = \sum_{t\in[T]:y^t_{p_t}<1} y^t_{p_t} + |\{t\in[T] : y^t_{p_t}=1\}| \\
&\leq \sum_{t:y^t_{p_t}<1} \Delta\Psi(t) + |\{t : y^t_{p_t}=1\}| && \text{(Using Lemma 13)} \\
&= \Psi(T) - \Psi(0) - \sum_{t:y^t_{p_t}=1} \Delta\Psi(t) - \sum_{r_0=1}^{R_0} \Delta\Psi(r_0) + |\{t : y^t_{p_t}=1\}|.
\end{aligned}$$

The lemma follows since $\Psi(T) \leq 2mk\ln(1+k)$ and $\Psi(0)=0$. The bound on $\Psi(T)$ is because we have m agents each with $|P(i,r_i-1)| \leq k$, and $\phi(1) = 2\ln(1+k)$. ◀

So, it is enough to bound the total cost and drop in potential for time steps when the requested page is fully outside the cache and also to bound the drop in potential when the phase changes.

Proof of Theorem 12. Consider any time step t such that the currently requested page p_t is fully outside the cache, i.e. $y^t_{p_t}=1$. We differentiate such requests into two cases depending on whether the page p_t is in the set $P(i_t, r_{i_t}-1)$ at the time or not. In other words, we do a case analysis on p_t being clean or pseudo-clean. (Recall that only unmarked pages in $P(i_t, r_{i_t}-1)$ contribute to the potential).

Case 1: $p_t \notin P(i_t, r_{i_t}-1)$, i.e, p_t is clean. Since page $p_t \notin U(i,t)$, it does not contribute to the potential before (or after) the request has been served. Consider any page q that is evicted (fractionally) by the algorithm in this step. By Lemma 4, before the eviction, we have $y_q = 0$ or $y_q \geq 1/k$. In either case, by Lemma 11, we have $\Delta\phi(y_q) \geq \Delta y_q$ where Δy_q denotes the change in y-value of page q in this step. Since we have $\sum_q \Delta y_q = y^t_{p_t} = 1$, we have $\Delta\Psi(t) = \sum_q \Delta\phi(y_q) \geq 1$.

Case 2: $p_t \in P(i_t, r_{i_t}-1)$, i.e., p_t is pseudo-clean. By the same reasoning as above, we have $\sum_{q\neq p_t} \Delta\phi(y_q) \geq 1$. However, in this case, page p_t also contributed exactly $2\ln(1+k)$ to the potential at the beginning of the time step. So we have $\Delta\Psi(t) = \sum_{q\neq p_t} \Delta\phi(y_q) - 2\ln(1+k) \geq 1 - 2\ln(1+k)$.

Combining the two cases we get:

$$\sum_{t:y^t_{p_t}=1} (1-\Delta\Psi(t)) \leq 2\ln(1+k)\cdot|\{t : y_{p_t}=1 \text{ and } p_t \in P(i_t, r_{i_t}-1)\}| \tag{3}$$

Consider the end of some phase r_0 and let i be a non-isolated agent. Let r_i denote the current local phase of agent i that must also end along with the global phase r_0. Consider any unmarked page q in $U(i,t)$. As the phase r_0 is ending, page q must be fully evicted and thus contributes $\phi(1)$ to the potential. Once phase r_0 ends and phase r_0+1 begins,

page q no longer contributes to the potential. Note that the set of such unmarked pages is exactly $P(i, r_i - 1) \setminus P(i, r_i)$. Hence, the change in potential at the end of (global) phase r_0 is given by:

$$\Delta\Psi(r_0) = -2\ln(1+k) \cdot \sum_{i \notin \mathcal{I}(r_0)} |P(i, r_i - 1) \setminus P(i, r_i)|$$

Since an agent only changes its local phase when it is non-isolated at the end of a global phase, we have:

$$\sum_{r_0=1}^{R_0} \Delta\Psi(r_0) = -2\ln(1+k) \cdot \sum_{i \in [m]} \sum_{r_i=1}^{R_i} |P(i, r_i - 1) \setminus P(i, r_i)|. \tag{4}$$

The theorem now follows from Lemma 14. ◀

3.4 A Lower Bound on OPT through Dual Fitting

In this section, we give a novel LP-based lower bound on the cost of any offline algorithm for caching with reserves via dual-fitting. This lower bound analysis is new even for the classical unweighted paging setting. Crucially, the lower bound derived here perfectly matches the two terms used to bound the cost of the fractional algorithm $\mathcal{A}$ in Theorem 12, thereby completing the proof of our main result (Theorem 1).

We now describe the linear relaxation of the caching with reserves problem and its dual program. The following notation will be useful. For any page $q \in \mathcal{P}$, let $t_{q,1} < t_{q,2} < \ldots$ denote the time steps when q is requested in the online sequence. For an integer $a \geq 0$, define $I(q, a) = \{t_{q,a} + 1, \ldots, t_{q,a+1} - 1\}$ to be the time interval between the ath and $(a+1)$th requests for q. We define $t_{q,0} \triangleq 0$ for all pages. Let $a(q, t)$ denote the number of requests to page q that have been seen until time t (inclusive). Hence, by definition, for any time t and page $q \in \mathcal{P} \setminus \{p_t\}$, we have $t \in I(q, a(q, t))$. The primal LP has variables $y(q, a) \in [0, 1]$ which denote the portion of page q that is evicted between its ath and $(a+1)$th requests, i.e., $1 - y(q, a)$ portion of q is held in the cache during the time-interval $I(q, a)$. For convenience, we define $n \triangleq |\mathcal{P}|$ and $n_i \triangleq |\mathcal{P}(i)|$ for any $i \in [m]$. The first and second set of primal constraints encode the cache size constraint and the agent-level reserve constraints for all times. The dual LP has variables $\alpha(t)$ and $\beta(t, i)$ corresponding to these primal constraints. We also have dual variables $\gamma(q, a)$ corresponding to the primal constraint encoding $y(q, a) \leq 1$. Besides nonnegativity, the dual has a single constraint for each interval $I(q, a)$. The primal and dual LPs are stated below. We emphasize that we use these linear programs purely for analysis and the algorithm itself does not need to solve any linear program.

Primal LP

$$\min \quad \sum_{q \in \mathcal{P}} \sum_{a \geq 1} y(q, a)$$

subject to:

$$\sum_{q \in \mathcal{P}, q \neq p_t} y(q, a(q, t)) \geq n - k \qquad \forall t \tag{5}$$

$$\sum_{q \in \mathcal{P}(i), q \neq p_t} y(q, a(q, t)) \leq n_i - k_i \qquad \forall t, \forall i \tag{6}$$

$$y(q, a) \leq 1 \qquad \forall q, \forall a \tag{7}$$

$$y \geq 0 \tag{8}$$

Dual LP

$$\max \sum_t (n-k)\alpha(t) - \sum_{t,i} (n_i - k_i)\beta(t, i) - \sum_{q,a} \gamma(q, a)$$

subject to:

$$\sum_{t \in I(q,a)} \big(\alpha(t) - \beta(t, ag(q))\big) - \gamma(q, a) \leq 1 \ \forall q, \forall a \tag{9}$$

$$\alpha, \beta, \gamma \geq 0 \tag{10}$$

Consider time T that marks the end of a global phase R_0 for some integer R_0. Let $\mathrm{OPT} = \mathrm{cost}_{\mathrm{OPT}}(\sigma)$ denote the total cost incurred by an optimal offline algorithm. By weak LP duality, the objective function of the Dual LP yields a lower bound on OPT for any feasible dual solution. We now construct an explicit dual solution (α, β, γ) whose objective value is roughly equal to the total number of clean and pseudo-clean pages seen by the algorithm. See Section 3.1 to recall relevant notation and terminology. The dual solution is updated at the end of each (global) phase in two stages. Updates in the first stage, denoted $\mathsf{update}(r_0, 1)$, are simple and account for stale pages belonging to non-isolated agents that got evicted in the most recent local phase for that agent. Updates in the second stage, denoted $\mathsf{update}(r_0, 2)$, are more involved and account for the pseudo-clean pages of agents who lost their isolated status in the current phase. The dual solution that we maintain will always be approximately feasible up to $O(1)$ factors, so the objective value of this dual solution serves as a lower bound on $\mathrm{OPT}(T)$ within a constant factor. We remark that the assumption that T marks the end of a phase is without loss of generality since it can lead to at most an additive $O(k)$ loss in the lower bound. Formally, we show the following.

▶ **Theorem 15.** *Let T denote the timepoint when global phase R_0 ends, and let $(R_i)_{i\in[m]}$ denote the corresponding local phase counters. Let (α, β, γ) denote the dual solution that is constructed by the end of time T, i.e., the solution that arises from a sequential application of dual updates in the order $\mathsf{update}(1,1), \mathsf{update}(1,2), \mathsf{update}(2,1), \mathsf{update}(2,2), \ldots, \mathsf{update}(R_0,1)$, and $\mathsf{update}(R_0,2)$. We have:*

(a) *The dual solution is approximately feasible: for any i-page q and an integer $a \geq 0$, $\sum_{t\in I(q,a)}(\alpha(t) - \beta(t,i)) - \gamma(q,a) \leq 5$ holds.*

(b) *The dual objective value of (α, β, γ) is:*

$$\begin{aligned}\mathrm{dual}(R_0) &\triangleq \sum_{t=1}^{T}(n-k)\alpha(t) - \sum_{t=1}^{T}\sum_{i\in[m]}(n_i - k_i)\beta(t,i) - \sum_{q\in\mathcal{P}}\sum_{a=1}^{a(q,T)}\gamma(q,a)\\ &= \sum_{i\in[m]}\sum_{r_i=1}^{R_i}|P(i,r_i-1)\setminus P(i,r_i)| + \sum_{r_0=1}^{R_0}\sum_{i\in\mathcal{I}(r_0-1)\setminus\mathcal{I}(r_0)}(|P(i,r_i-1)\cup P(i,r_i)| - k_i).\end{aligned}$$

We first show how Theorem 15 implies that our fractional algorithm $\mathcal{A}$ is $O(\log k)$-competitive.

Proof of Theorem 1. In Theorem 12 we proved the following upper bound on the cost incurred by $\mathcal{A}$ for processing the first T page requests:

$$\mathrm{cost}_{\mathcal{A}}(\sigma) \leq 2\ln(1+k)\cdot\Big(mk + \sum_{t=1}^{T}\mathbb{1}_{p_t \text{ is pseudo-clean}} + \sum_{i\in[m]}\sum_{r_i=1}^{R_i}|P(i,r_i-1)\setminus P(i,r_i)|\Big).$$

Clearly, the second nontrivial term in the above cost-expression matches the first term in the expression for $\mathrm{dual}(R_0)$. Now consider an arbitrary global phase $r_0 \in \{1,\ldots,R_0\}$ and a timestep t in this phase. By definition, a pseudo-clean page p_t is necessarily stale, i.e., $p_t \in P(i_t, r_{i_t} - 1)$ holds, and it must be that agent i_t was isolated at the start of phase r_0 but is non-isolated by time t. Therefore, $i_t \in \mathcal{I}(r_0 - 1) \setminus \mathcal{I}(r_0)$ and the following holds:

$$|P(i,r_i-1)\cup P(i,r_i)| - k_i \geq |P(i,r_i)| - k_i \geq |\{t \in \text{phase } r_0 : p_t \text{ is pseudo-clean}\}|.$$

In the above, the final inequality is because among all pages in $P(i,r_i)$ (w.r.t. the order in which they were marked by $\mathcal{A}$), the first k_i pages are not pseudo-clean. Thus, the first nontrivial term in the cost-expression for $\mathcal{A}$ can be bounded by the second term in $\mathrm{dual}(R_0)$.

Overall, we have shown that $\mathrm{cost}_{\mathcal{A}}(\sigma) \leq 2\ln(1+k)\cdot\big(mk + \mathrm{dual}(R_0)\big)$ holds. Since the dual solution is $O(1)$-feasible, we get that $\mathcal{A}$ is $O(\log k)$-competitive. ◀

We now furnish the details of our dual updates. Initially, all our dual variables $\{\alpha(t)\}, \{\beta(i,t)\}, \{\gamma(q,a)\}$ with $t \in [T], i \in [m], q \in \mathcal{P}, a \in [a(q,T)]$ are set to zero. We assume that the dual updates are applied in the sequence given in Theorem 15. That is, the set of updates in $\{\mathsf{update}(r_0, s)\}_{r_0 \in [R_0], s \in \{1,2\}}$ are applied in increasing order of r_0 and within each phase first stage updates are applied first. With a slight abuse of notation, let $\text{dual}(r_0, s)$ denote the objective value of the dual solution right after updates until $\mathsf{update}(r_0, s)$ (inclusive) have been applied where $r_0 \in [R_0], s \in \{1, 2\}$. Note that $\text{dual}(R_0) = \text{dual}(R_0, 2)$. We also define $\text{dual}(0, 1) = \text{dual}(0, 2) := 0$. Throughout our updates, we ensure that the dual objective value never decreases, i.e., $0 \leq \text{dual}(1,1) \leq \text{dual}(1,2) \leq \cdots \leq \text{dual}(R_0, 1) \leq \text{dual}(R_0, 2)$ holds. We remark that β variables may decrease and this only happens in the second stage; However, the α and γ variables never decrease.

In Section 3.4, we describe the first stage of updates and show that the gain in the dual objective corresponds to the first term in Theorem 15(b). In Section 3.4, we describe the second stage of updates and show that the gain in the dual objective corresponds to the second term in Theorem 15(b). Lastly, in Section 3.4, we show that the dual solution that we maintain is always feasible up to constant factors and thus complete the proof of Theorem 15.

First Stage of Dual Updates

Fix a phase $r_0 \in [R_0]$ and consider the set $\mathcal{I}(r_0) \subsetneq [m]$ of agents that are designated as isolated at the end of phase r_0. Let $C(r_0)$ denote the set of timesteps t (in this phase) when the following two conditions hold: (a) $y^t_{p_t} = 1$ in the fractional algorithm $\mathcal{A}$ just before p_t is requested; and (b) i_t is not isolated at time t. Define $\ell^{(r_0)} \triangleq |C(r_0)|$. It is not hard to see that the following is an equivalent expression for $\ell^{(r_0)}$.

$$\ell^{(r_0)} := \sum_{i \notin \mathcal{I}(r_0-1) \cup \mathcal{I}(r_0)} |P(i, r_i) \setminus P(i, r_i - 1)| + \sum_{i \in \mathcal{I}(r_0-1) \setminus \mathcal{I}(r_0)} (|P(i, r_i)| - k_i). \tag{11}$$

Observe that for agents who are non-isolated both at the start and end of phase r_0, $\ell^{(r_0)}$ counts all their clean pages. However, for agents who were isolated at the start of this phase but are no longer isolated by the end, $\ell^{(r_0)}$ only counts clean and pseudo-clean pages that are requested *after* the agent has become non-isolated. Roughly speaking, the motivation for the definition of $\ell^{(r_0)}$ comes from the intuition that an offline algorithm should incur, on an average, a cost of $\Omega(\ell^{(r_0)})$ to serve page requests in phase r_0.

Description of $\mathsf{update}(r_0, 1)$. For each time $t \in C(r_0)$, we separately apply the following updates. First, we increase $\alpha(t)$ by $1/\ell^{(r_0)}$. Next, we increase $\beta(t, i)$ by $1/\ell^{(r_0)}$ for every agent $i \in \mathcal{I}(r_0)$. Last, for each agent $i \notin \mathcal{I}(r_0)$, we increase $\gamma(q, a(q,t))$ by $1/\ell^{(r_0)}$ for every i-page $q \in \mathcal{P}(i) \setminus (P(i, r_i - 1) \cup P(i, r_i))$.

It will be clear from the description of our updates that the α and β variables that were modified in $\mathsf{update}(r_0, 1)$ were previously at 0. However, no such guarantee holds for the affected γ variables. We also remark that the same $\gamma(q, a)$ variable can be increased more than once during $\mathsf{update}(r_0, 1)$; this happens when there are multiple times $t \in C(r_0)$ with the same $a(q, t)$ value. In fact, since the $\gamma(q, a)$ variables arise from intervals $I(q, a)$ that can possibly span across multiple phases, it is possible that the same γ variable is increased by different $1/\ell^{(r_0)}$ amounts across different $\mathsf{update}(r_0, 1)$ steps.

For convenience, let $t \in$ phase r_0 be a shorthand for all timepoints in phase r_0. The following result will be useful to us.

▶ **Lemma 16.** *Let (α, β, γ) denote the dual solution that is obtained right after* update$(r_0, 1)$ *has been applied. We have: (a) $\sum_{t \in phase\ r_0} \alpha(t) = 1$; and (b) $\sum_{t \in phase\ r_0} \beta(t,i) = 1$ for any agent $i \in \mathcal{I}(r_0)$.*

Proof. Follows directly from our choice of $\ell^{(r_0)} = |C(r_0)|$. ◀

Our key technical result in this section is that the gain in the dual objective value that comes from update$(r_0, 1)$ is equal to the number of stale pages owned by non-isolated agents that were not requested in their most recent local phases. For convenience, we use the prefix Δ to refer to changes that occured during update$(r_0, 1)$.

▶ **Lemma 17.** *We have* $\Delta\text{dual}(r_0, 1) = \sum_{i \notin \mathcal{I}(r_0)} |P(i, r_i - 1) \setminus P(i, r_i)|$, *where* $\Delta\text{dual}(r_0, 1) \triangleq \text{dual}(r_0, 1) - \text{dual}(r_0 - 1, 2)$ *is the change in the dual objective after* update$(r_0, 1)$.

Proof. Since the only affected $\alpha(t)$ and $\beta(t,i)$ variables have are those with $t \in C(r_0)$ and they are all increased by exactly $1/|C(r_0)|$, we get:

$$\begin{aligned}
\Delta\text{dual}(r_0, 1) &= \sum_t (n-k)\Delta\alpha(t) - \sum_{t,i} (n_i - k_i)\Delta\beta(t,i) - \sum_{q,a} \Delta\gamma(q,a) \\
&= (n-k) - \sum_{i \in \mathcal{I}(r_0)} (n_i - k_i) - \sum_{q,a} \Delta\gamma(q,a) \\
&= \Big(\sum_{i \notin \mathcal{I}(r_0)} n_i \Big) - k + \Big(\sum_{i \in \mathcal{I}(r_0)} k_i \Big) - \sum_{q,a} \Delta\gamma(q,a)
\end{aligned}$$

Now observe that for every $t \in C(r_0)$ and $i \notin \mathcal{I}(r_0)$, the update$(r_0, 1)$ step increases the $\gamma(q,a)$ variable corresponding to exactly $n_i - |P(i, r_i - 1) \cup P(i, r_i)|$ unique i-pages, each by an amount $1/\ell^{(r_0)}$. So we have $\sum_{q,a} \Delta\gamma(q,a) = (1/\ell^{(r_0)}) \cdot \sum_{t \in C(r_0)} \sum_{i \notin \mathcal{I}(r_0)} (n_i - |P(i, r_i - 1) \cup P(i, r_i)|) = \sum_{i \notin \mathcal{I}(r_0)} (n_i - |P(i, r_i - 1) \cup P(i, r_i)|)$. Substituting back into the equation above, we get:

$$\begin{aligned}
\Delta\text{dual}(r_0, 1) &= \Big(\sum_{i \notin \mathcal{I}(r_0)} n_i \Big) - k + \Big(\sum_{i \in \mathcal{I}(r_0)} k_i \Big) - \sum_{i \notin \mathcal{I}(r_0)} (n_i - |P(i, r_i - 1) \cup P(i, r_i)|) \\
&= \Big(-k + \sum_{i \in \mathcal{I}(r_0)} k_i + \sum_{i \notin \mathcal{I}(r_0)} |P(i, r_i)| \Big) + \sum_{i \notin \mathcal{I}(r_0)} |P(i, r_i - 1) \setminus P(i, r_i)|
\end{aligned}$$

The lemma follows from observing that the above group of terms within the parentheses is 0: this is because the cache (of size k) at the end of phase r_0 consists exactly k_i (fractional) pages for isolated agents $i \in \mathcal{I}(r_0)$ and exactly $|P(i, r_i)|$ (integral) pages for non-isolated agents $i \notin \mathcal{I}(r_0)$. ◀

Second Stage of Dual Updates

We now describe the second stage of dual updates that are carried out at the end of each phase $r_0 \in [R_0]$. Unlike the first stage, where we only increased the α and β variables of time steps in phase r_0, in the second stage we decrease the β variables of time steps in the previous phase $r_0 - 1$.

Description of update$(r_0, 2)$. These dual updates correspond to agents that were isolated at the end of phase $r_0 - 1$ but are no longer isolated at the end of phase r_0. Consider an agent $i \in \mathcal{I}(r_0 - 1) \setminus \mathcal{I}(r_0)$. For every time t in phase $r_0 - 1$ with $\beta(t,i) > 0$ (i.e., $t \in C(r_0 - 1)$), we do the following: we increase $\gamma(q, a(q,t))$ by $\beta(t,i)$ for all i-pages $q \in \mathcal{P}(i) \setminus \big(P(i, r_i - 1) \cup P(i, r_i)\big)$ followed by resetting $\beta(t,i)$ to 0.

For clarity, we note the following: (i) resetting $\beta(t,i)$ to zero is the only dual update when a variable is *decreased*; (ii) the $\beta(t,i)$ updates are applied to timepoints in phase r_0-1 (i.e., the previous phase); and (iii) the $\gamma(q,a(q,t))$ variables that we updated above were unchanged while applying $\mathsf{update}(r_0-1,1)$ at the end of phase r_0-1 because their owner i was designated as isolated at that time. The reason for decreasing the $\beta(t,i)$ variables is that it leads to an increase in the dual objective, which will be needed to pay for costs associated with pseudo-clean pages. We formalize this in the following lemma.

▶ **Lemma 18.** *We have* $\Delta\mathrm{dual}(r_0,2)=\sum_{i\in\mathcal{I}(r_0-1)\setminus\mathcal{I}(r_0)}\left(|P(i,r_i-1)\cup P(i,r_i)|-k_i\right)$ *where* $\Delta\mathrm{dual}(r_0,2)\triangleq\mathrm{dual}(r_0,2)-\mathrm{dual}(r_0,1)$ *is the change in the dual objective after* $\mathsf{update}(r_0,2)$.

Proof. Fix an agent $i\in\mathcal{I}(r_0-1)\setminus\mathcal{I}(r_0)$. In Lemma 16 we showed that after $\mathsf{update}(r_0-1,1)$, $\sum_{t\in\text{phase }r_0-1}\beta(t,i)=1$ and $\beta(t,i)\in\{0,1/\ell^{(r_0-1)}\}$. Consider any time t in phase r_0-1 with $\beta(t,i)>0$. By the definition of $\mathsf{update}(r_0,2)$, we decrease $\beta(t,i)$ by $1/\ell^{(r_0-1)}$ while increasing $\gamma(q,a(q,t))$ by the same amount for all pages $q\in\mathcal{P}(i)\setminus\big(P(i,r_i-1)\cup P(i,r_i)\big)$. Recalling the coefficients in the dual objective function, we see that the updates corresponding to agent i increases the dual objective by exactly:

$$(n_i-k_i)-|\mathcal{P}(i)\setminus(P(i,r_i)\cup P(i,r_i-1))|=|(P(i,r_i)\cup P(i,r_i-1))|-k_i.$$ ◀

Approximate Dual Feasibility

We finish this section by showing that the dual solution is always approximately feasible.

▶ **Lemma 19.** *Let* (α,β,γ) *denote the dual solution that is obtained right after* $\mathsf{update}(r_0,s)$ *has been applied for some* $r_0\in[R_0]$ *and* $s\in\{0,1\}$. *For any* i*-page* q *and an integer* $a\geq 1$ *satisfying* $a\leq a(q,T)$, *we have* $\sum_{t\in I(q,a)}(\alpha(t)-\beta(t,i))-\gamma(q,a)\leq 5$.

Proof. First of all, for the purposes of this proof, the specific values of r_0 and s are irrelevant, so we ignore them. Fix some i-page q and an integer a satisfying $a\leq a(q,T)$. Recall that $I(q,a)=\{t_{q,a}+1,\ldots,t_{q,a+1}-1\}$, where $t_{q,a'}$ denotes the time when q is requested for the a'th time; We redefine $t_{q,a+1}$ to be $T+1$ if $t_{q,a+1}>T$ holds.

The lemma holds trivially if $I(q,a)$ is empty, so we assume otherwise. Let $r_0^b,r_0^e\in[R_0]$ denote the global phases that contain timesteps $t_{q,a}+1$ and $t_{q,a+1}-1$, respectively. Clearly, $r_0^b\leq r_0^e$. Another easy case of the lemma is when $r_0^e\leq r_0^b+1$ holds. The desired conclusion follows easily because all the dual variables are nonnegative and the sum of all $\alpha(t)$ variables in any phase is at most 1 (by Lemma 16). Formally,

$$\sum_{t\in I(q,a)}\big(\alpha(t)-\beta(t,i)\big)-\gamma(q,a)\leq\sum_{t\in\text{phase }r_0^b}\alpha(t)+\sum_{t\in\text{phase }r_0^e}\alpha(t)\leq 2.$$

Now suppose that $r_0^b+2\leq r_0^e$ holds. Define $Z:=\{r_0^b+1,\ldots,r_0^e-1\}$. Repeating the above calculation, we get:

$$\sum_{t\in I(q,a)}(\alpha(t)-\beta(t,i))-\gamma(q,a)\leq 2+\left\{\sum_{r_0\in Z}\sum_{t\in\text{phase }r_0}\big(\alpha(t)-\beta(t,i)\big)\right\}-\gamma(q,a),$$

so the crux of the lemma is to show that the sum of $\delta(t)\triangleq\alpha(t)-\beta(t,i)$ over timepoints spanning phases in Z is not much larger than $\gamma(q,a)$. For a phase $r_0\in Z$, we overload the notation $\delta(r_0)$ to mean $\sum_{t\in\text{phase }r_0}\delta(t)$. Note that by nonnegativity of β variables and Lemma 17, $\delta(r_0)\leq 1$ for every $r_0\in Z$. We do a case analysis on phase $r_0\in Z$ to get a better handle on the changes that happens during our dual update procedures.

(a) Suppose that $i \in \mathcal{I}(r_0) \cap \mathcal{I}(r_0+1)$ holds. Since i is isolated by the end of phase r_0, we know that any increase in $\alpha(t)$ (as part of $\mathsf{update}(r_0, 1)$) for some $t \in C(r_0)$ is accompanied with the same increase in $\beta(t,i)$. Since $i \in \mathcal{I}(r_0+1)$ holds, $\mathsf{update}(r_0+1, 2)$ does not decrease/reset any of the $\{\beta(t,i)\}_{t \in \text{phase } r_0}$ variables to 0. Thus, $\delta(r_0) = 0$ holds. Note that there can be an arbitrary number of phases r_0 that fall under this case, but this is not a problem for us since $\delta(r_0) = 0$.

(b) Suppose that $i \in \mathcal{I}(r_0) \setminus \mathcal{I}(r_0+1)$ and $q \in P(i, r_i - 1) \cup P(i, r_i)$ hold. We rely on the trivial bound $\delta(r_0) \leq 1$ for this case. Since i is isolated by the end of phase r_0 but is non-isolated by the end of phase r_0+1, the local phase counter r_i goes up by 1 at the end of phase r_0+1, and subsequently the $P(i,\cdot)$ set gets updated with some new collection of marked i-pages. By definition of $I(q,a)$, there are no page-requests for q during any of the phases in Z. Thus, there can be at most 2 local phase increments for agent i before q gets dropped from the $P(i,\cdot)$ set; By the design of $\mathcal{A}$, page q cannot enter any of the future $P(i, r_i)$ until the next time it is requested, which does not happen during any of the phases in Z.

(c) Suppose that $i \in \mathcal{I}(r_0) \setminus \mathcal{I}(r_0+1)$ and $q \notin P(i, r_i - 1) \cup P(i, r_i)$ hold. Similar to case (a) above, we know that any increase in $\alpha(t)$ (as part of $\mathsf{update}(r_0, 1)$) for some $t \in C(r_0)$ is accompanied with the same increase in $\beta(t,i)$. Now, although $\mathsf{update}(r_0+1, 2)$ decreases/resets all the $\{\beta(t,i)\}_{t \in C(r_0)}$ variables to 0, it also increases $\gamma(q,a)$ by the same amount since $q \notin P(i, r_i - 1) \cup P(i, r_i)$. Thus, $\sum_{t \in \text{phase } r_0} \alpha(t)$ equals the increase in $\gamma(q,a)$ due to $\mathsf{update}(r_0+1, 2)$. So, the difference is essentially 0.

(d) Suppose $i \notin \mathcal{I}(r_0)$ and $q \in P(i, r_i - 1) \cup P(i, r_i)$ hold. We rely on the trivial bound $\delta(r_0) \leq 1$ for this case. Since i is non-isolated by the end of phase r_0, the local phase counter r_i goes up by 1 at the end of phase r_0. Repeating the argument from case (c), there can be at most 1 more local phase increment for agent i before q gets dropped from the $P(i,\cdot)$ set for the rest of the phases in Z.

(e) Suppose $i \notin \mathcal{I}(r_0)$ and $q \notin P(i, r_i - 1) \cup P(i, r_i)$ hold. Since i is non-isolated by the end of phase r_0 and q is not in $P(i, r_i - 1) \cup P(i, r_i)$, we know that any increase in $\alpha(t)$ (as part of $\mathsf{update}(r_0, 1)$) for some $t \in C(r_0)$ is accompanied with the same increase in $\gamma(q,a)$. Thus, $\sum_{t \in \text{phase } r_0} \alpha(t)$ equals the increase in $\gamma(q,a)$ due to $\mathsf{update}(r_0, 1)$. So, the difference is essentially 0.

From the above case analysis, it follows that $\{\sum_{r_0 \in Z} \sum_{t \in \text{phase } r_0} \big(\alpha(t) - \beta(t,i)\big)\} - \gamma(q,a)$ is bounded by the number of phases $r_0 \in Z$ for which case (b) or (d) hold. Since we argued that there can be at most 3 such occurences, $\sum_{t \in I(q,a)} (\alpha(t) - \beta(t,i)) - \gamma(q,a) \leq 2 + 3 = 5$ holds. ◀

We now prove the main theorem in this section by combining the above lemmas.

Proof of Theorem 15. The first part of the theorem follows from Lemma 19. The second part follows directly from Lemmas 17 and 18 since we have $\text{dual}(R_0) = \sum_{r_0=1}^{R_0} \big(\Delta\text{dual}(r_0, 1) + \Delta\text{dual}(r_0, 2)\big)$ ◀

4 Rounding

In this section we show how to convert the fractional Algorithm 1 into a randomized integral online algorithm for *Caching with Reserves*, each step of which runs in polynomial time.

The algorithm maintains a uniform distribution on $N = k^3$ valid cache states. In each step, these states are updated based on the actions of the fractional algorithm. The randomized algorithm selects one of these states uniformly at random in the beginning, and then follows it throughout the run.

Initially, all N cache states in the distribution are the same as the initial cache state in Algorithm 1. Given the fractional algorithm values x_p^t after each page request, the distribution is updated in two steps. First, we produce a discretized version of these fractions, $\tilde{x}_p^t$, which are also a feasible fractional solution. This is based on the technique in [2]. Second, we update the N cache states so that all of them remain valid, and for each page p, exactly $N \cdot \tilde{x}_p^t$ of the states contain p. This is based on the technique in [10]. We note that the rounding procedure can be done online, as it does not need the knowledge of any future page requests.

4.1 Discretization Procedure

In this subsection, we explain how to perform the first step: discretizing the fractional algorithm's values x_p^t into $\tilde{x}_p^t$ which are multiples of $\frac{1}{N}$. Our procedure is quite simple: we iterate over the pages in any order π that arranges all pages belonging to the same agent consecutively (i.e., order the agents arbitrarily and order each agent's pages arbitrarily, but do not interleave pages from different agents). Then for $i \in [|\mathcal{P}|]$, set:

$$\tilde{x}_{\pi(i)}^t \triangleq \left\lfloor \sum_{j=1}^{i} x_{\pi(j)}^t \right\rfloor_{1/N} - \left\lfloor \sum_{j=1}^{i-1} x_{\pi(j)}^t \right\rfloor_{1/N}$$

where $\lfloor a \rfloor_b$ denotes rounding a down to the nearest multiple of b; formally: $\lfloor a \rfloor_b \triangleq b \lfloor a/b \rfloor$.

▶ **Lemma 20.** *Discretization satisfies the following guarantees:*

1. $\tilde{x}_p^t$ *is a multiple of* $1/N$
2. $\left|\tilde{x}_p^t - x_p^t\right| < 1/N$
3. *for each agent* i, $\left|\sum_{p\in\mathcal{P}(i)} \tilde{x}_p^t - \sum_{p\in\mathcal{P}(i)} x_p^t\right| < 1/N$
4. *if* $x_p^t \in \{0,1\}$, *then* $\tilde{x}_p^t = x_p^t$

Due to space constraints, the proof of the above lemma is deferred to the full version [11].

▶ **Corollary 21.** *If* $\{x_p^t\}$ *satisfy total cache capacity* ($\sum_{p\in\mathcal{P}} x_p^t \le k$) *and reserve requirements* ($\sum_{p\in\mathcal{P}(i)} x_p^t \ge k_i$), *then so do* $\{\tilde{x}_p^t\}$.

Proof. The total cache capacity constraint continues to hold due to a telescoping argument:

$$\begin{aligned}\sum_{p\in\mathcal{P}} \tilde{x}_p^t &= \sum_{i\in[|\mathcal{P}|]} \tilde{x}_{\pi(i)}^t = \sum_{i\in[|\mathcal{P}|]} \left[\left\lfloor \sum_{j=1}^{i} x_{\pi(j)}^t \right\rfloor_{1/N} - \left\lfloor \sum_{j=1}^{i-1} x_{\pi(j)}^t \right\rfloor_{1/N} \right] \\ &= \left\lfloor \sum_{j=1}^{|\mathcal{P}|} x_{\pi(j)}^t \right\rfloor_{1/N} \le \sum_{j=1}^{|\mathcal{P}|} x_{\pi(j)}^t \le k\end{aligned}$$

Next, we will prove that reserve cache sizes are satisfied. For the sake of contradiction, suppose that for some agent i, $\sum_{p\in\mathcal{P}(i)} \tilde{x}_p^t < k_i$. Since the right-hand side of this inequality is an integer and therefore a multiple of $1/N$, the left-hand side, which is also a multiple of $1/N$ due to being a sum of multiples of $1/N$ (by Lemma 20's first guarantee), must be at least a full multiple of $1/N$ less than the right-hand side: $\sum_{p\in\mathcal{P}(i)} \tilde{x}_p^t \le k_i - 1/N$. But this contradicts Lemma 20's third guarantee, $\left|\sum_{p\in\mathcal{P}(i)} \tilde{x}_p^t - \sum_{p\in\mathcal{P}(i)} x_p^t\right| < 1/N$. Therefore for all agents i, $\sum_{p\in\mathcal{P}(i)} \tilde{x}_p^t \ge k_i$, completing the proof. ◀

▶ **Corollary 22.** $\sum_p \left|\tilde{x}_p^t - x_p^t\right| \le k^2/N$

Proof. Without loss of generality, there are at most k agents since we can combine all agents that do not have any reserve. Each agent i has at most k fractional pages by the algorithm (the i-pages that were in cache when i's local phase began). The x value of each fractional page is distorted by at most $1/N$ by Lemma 20's second guarantee, while not being distorted for non-fractional pages by the fourth guarantee. This completes the proof. ◀

▶ **Lemma 23.** *Let x_p^t and x_p^{t+1} be the amounts of each page p in cache in the fractional algorithm for two consecutive time steps, and $\tilde{x}_p^t$ and $\tilde{x}_p^{t+1}$ be the corresponding discretized values. Then the cost of cache update from $\tilde{x}^t$ to $\tilde{x}^{t+1}$ (call it $\tilde{c}$) is at most twice the cost of cache update from x^t to x^{t+1} (call it c).*

Proof. Lemma 10 implies that either $c = 0$ (i.e., the requested page was already in cache and there is no change to the cache state), or $c \ge 1/k$. In the first case, there is no change to the discretized cache state either, so $\tilde{c} = 0$. So we focus on the second case. By triangle inequality, for any page p,

$$|\tilde{x}_p^t - \tilde{x}_p^{t+1}| \le |\tilde{x}_p^t - x_p^t| + |x_p^t - x_p^{t+1}| + |x_p^{t+1} - \tilde{x}_p^{t+1}|.$$

We note that since cost is incurred for adding pages to cache, and both the original fractional solution and the discretized one add as much page mass to cache as they evict, $2c = \sum_p |x_p^t - x_p^{t+1}|$, and similarly for $\tilde{c}$. Summing the above inequality over p, we get

$$2\tilde{c} = \sum_p |\tilde{x}_p^t - \tilde{x}_p^{t+1}| \le \sum_p |x_p^t - x_p^{t+1}| + 2k^2/N = 2c + 2/k \le 4c,$$

where we used $\sum_p (|\tilde{x}_p^t - x_p^t| + |x_p^{t+1} - \tilde{x}_p^{t+1}|) \le 2k^2/N$ by Corollary 22, then $N = k^3$, then $c \ge 1/k$. ◀

4.2 Updating the Distribution of Cache States

In this subsection, we explain how to perform the second step: updating the N cache states. We would like (i) all cache states to be valid, (ii) exactly $N \cdot \tilde{x}_p^t$ (integral due to our discretization step) of the states to contain page p, and (iii) to not use too many evictions.

Formally, let $\mathcal{X}$ be a set of N cache states with k pages each, which corresponds to the discretized values $\tilde{x}_p^t$ for time step t. Given the discretized values $\tilde{x}_p^{t+1}$ for time step $t+1$, we show how to transform $\mathcal{X}$ into $\mathcal{X}'$, in which each page p appears in exactly $N \cdot \tilde{x}_p^{t+1}$ cache states and such that each cache state satisfies all the reserve requirements.

Let P be a multiset of pages whose fraction in the cache increased from time t to $t+1$, with each page p appearing $\max(0, (\tilde{x}_p^{t+1} - \tilde{x}_p^t)N)$ times. Let Q be an analagous multiset for decreases, with each page appearing $\max(0, (\tilde{x}_p^t - \tilde{x}_p^{t+1})N)$ times. Since the total amount of pages in the cache is unchanged, $|P| = |Q|$. We find a matching between pages in P and Q and use it to transform $\mathcal{X}$ into $\mathcal{X}'$ gradually, one pair at a time. The matching is constructed as follows. First, any pages from P and Q that belong to the same agent are matched up. Then, the remaining pages in P and Q are matched up arbitrarily.

▶ **Lemma 24.** *Let $(p_1, q_1), (p_2, q_2), \ldots$ be the matching between P and Q described above. Then for any j, the fractional solution that adds $1/N$ fraction of pages $p_1, \ldots, p_j$ to $\tilde{x}^t$ and removes $1/N$ fraction of pages $q_1, \ldots, q_j$ from it satisfies all the reserve requirements.*

We defer the proof of the above lemma to the full version [11].

We now show how to modify $\mathcal{X}$ with the next pair (p, q) from the matching. This follows the procedure in [10], with the difference that we work on a limited number of N sets, and the amount of increase in p and decrease in q is fixed at $1/N$.

Let $\mathcal{X}$ be the current set of cache states (possibly modified by the previous page pairs). If there is a cache state $S \in \mathcal{X}$ such that $p \notin S$ and $q \in S$, add p to S and remove q from S. Otherwise, find cache states $S \in \mathcal{X}$ and $T \in \mathcal{X}$ with $p \notin S$ and $q \in T$, add p to S and remove q from T. Next, move some page $r \in S \setminus T$ from S to T to adjust the set sizes back to k.

At this point, each page is in the correct number of cache states. However, reserve requirements could be violated by one page for $ag(q)$ or $ag(r)$ in the cache states from which the corresponding pages were removed. In such a case, suppose the requirement is violated for agent i in a cache state $V \in \mathcal{X}$. Since, by Lemma 24, each reserve requirement is satisfied on average, there must be another set $W \in \mathcal{X}$ which has strictly more than k_i pages belonging to agent i. We move one such page from W to V. Now V has $k + 1$ pages, so there must be an agent j which has more than k_j pages in V. We move one of j's pages from V to W to restore the sizes. This completes the update, resulting in new valid sets corresponding to the fractions $\tilde{x}^{t+1}$.

We conclude by bounding the cost of update to $\mathcal{X}$, and thus the expected cost of the randomized algorithm, relative to the cost of the fractional algorithm.

▶ **Lemma 25.** *The cost of update to $\mathcal{X}$ is at most 6 times the cost of fractional cache update from $\tilde{x}^t$ to $\tilde{x}^{t+1}$.*

Proof. Each pair (p, q) in the matching corresponds to a cost of $1/N$ incurred by the discretized fractional solution. In the updates to sets in $\mathcal{X}$, each time a page is removed from one of the cache states incurs a cost of $1/N$ to the randomized algorithm. At most, the following six removals are done: remove q from T; remove r from S; two pages each are swapped to fix the reserve requirements for $ag(q)$ and $ag(r)$. ◀

The proof of Theorem 2 follows by combining Lemmas 23 and 25.

Abstract

In this paper, we consider a transformation of k disjoint paths in a graph. For a graph and a pair of k disjoint paths $\mathcal{P}$ and $\mathcal{Q}$ connecting the same set of terminal pairs, we aim to determine whether $\mathcal{P}$ can be transformed to $\mathcal{Q}$ by repeatedly replacing one path with another path so that the intermediates are also k disjoint paths. The problem is called Disjoint Paths Reconfiguration. We first show that Disjoint Paths Reconfiguration is PSPACE-complete even when $k = 2$. On the other hand, we prove that, when the graph is embedded on a plane and all paths in $\mathcal{P}$ and $\mathcal{Q}$ connect the boundaries of two faces, Disjoint Paths Reconfiguration can be solved in polynomial time. The algorithm is based on a topological characterization for rerouting curves on a plane using the algebraic intersection number. We also consider a transformation of disjoint s-t paths as a variant. We show that the disjoint s-t paths reconfiguration problem in planar graphs can be determined in polynomial time, while the problem is PSPACE-complete in general.

1 Introduction

1.1 Disjoint Paths and Reconfiguration

The *disjoint paths problem* is a classical and important problem in algorithmic graph theory and combinatorial optimization. In the problem, the input consists of a graph $G = (V, E)$ and $2k$ distinct vertices $s_1, \ldots, s_k, t_1, \ldots, t_k$, called *terminals*, and the task is to find k vertex-disjoint paths $P_1, \ldots, P_k$ such that P_i connects s_i and t_i for $i = 1, \ldots, k$ if they exist. A tuple $\mathcal{P} = (P_1, \ldots, P_k)$ of paths satisfying this condition is called a *linkage*. The disjoint paths problem has attracted attention since the 1970s because of its practical applications to transportation networks, network routing [46], and VLSI-layout [16, 29]. When the number k of terminal pairs is part of the input, the disjoint paths problem was shown to be NP-hard by Karp [25], and it remains NP-hard even for planar graphs [30]. For the case when the graph is undirected and k is a fixed constant, Robertson and Seymour [42] gave a polynomial-time algorithm based on the graph minor theory, which is one of the biggest achievements in this area. Although the setting of the disjoint paths problem is quite simple and easy to understand, a deep theory in discrete mathematics is required to solve the problem, which is a reason why this problem has attracted attention in the theoretical study of algorithms.

In this paper, we consider a transformation of linkages in a graph. Roughly, in a transformation, we pick up one path among the k paths in a linkage and replace it with another path to obtain a new linkage. To give a formal definition, suppose that G is a graph and $s_1, \ldots, s_k, t_1, \ldots, t_k$ are distinct terminals. For two linkages $\mathcal{P} = (P_1, \ldots, P_k)$ and $\mathcal{Q} = (Q_1, \ldots, Q_k)$, we say that $\mathcal{P}$ is *adjacent* to $\mathcal{Q}$ if there exists $i \in \{1, \ldots, k\}$ such that $P_j = Q_j$ for $j \in \{1, \ldots, k\} \setminus \{i\}$ and $P_i \neq Q_i$. We say that a sequence $\langle \mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_\ell \rangle$ of linkages is a *reconfiguration sequence* from $\mathcal{P}_1$ to $\mathcal{P}_\ell$ if $\mathcal{P}_i$ and $\mathcal{P}_{i+1}$ are adjacent for $i = 1, \ldots, \ell - 1$. If such a sequence exists, we say that $\mathcal{P}_1$ is *reconfigurable* to $\mathcal{P}_\ell$. In this paper, we focus on the following reconfiguration problem, which we call Disjoint Paths Reconfiguration.

> Disjoint Paths Reconfiguration
> **Input.** A graph $G = (V, E)$, distinct terminals $s_1, \ldots, s_k, t_1, \ldots, t_k$, and two linkages $\mathcal{P}$ and $\mathcal{Q}$.
> **Question.** Is $\mathcal{P}$ reconfigurable to $\mathcal{Q}$?

The problem can be regarded as the problem of deciding the reachability between linkages via rerouting paths. Such a problem falls in the area of *combinatorial reconfiguration*; see Section 1.3 for prior work on combinatorial reconfiguration. Note that Disjoint Paths Reconfiguration is a decision problem that just returns "YES" or "NO" and does not necessarily find a reconfiguration sequence when the answer is YES[1].

Although our study is motivated by a theoretical interest in the literature on combinatorial reconfiguration, the problem can model a rerouting problem in a telecommunication network as follows. Suppose that a linkage represents routing in a telecommunication network, and we want to modify linkage $\mathcal{P}$ to another linkage $\mathcal{Q}$ which is better than $\mathcal{P}$ in some sense. If we can change only one path in a step in the network for some technical reasons, and we have to keep a linkage in the modification process, then this situation is modeled as Disjoint Paths Reconfiguration.

[1] Our positive results in this paper hold also for the problem of finding a reconfiguration sequence.

We also study internally vertex-disjoint s-t paths instead of disjoint paths. In the *disjoint s-t paths problem*, for a graph and two terminals s and t, we seek for k internally vertex-disjoint paths connecting s and t. It is well-known that the disjoint s-t paths problem can be solved in polynomial time. The study of disjoint s-t paths originated from Menger's min-max theorem [33] and the max-flow algorithm by Ford and Fulkerson [14]. Faster algorithms for finding maximum disjoint s-t paths or a maximum s-t flow have been actively studied in particular for planar graphs; see e.g. [12, 24, 26, 51].

In the same way as Disjoint Paths Reconfiguration, we consider a reconfiguration of internally vertex-disjoint s-t paths. Let $G = (V, E)$ be a graph with two distinct terminals s and t. We say that a set $\mathcal{P} = \{P_1, \ldots, P_k\}$ of k paths in G is an *s-t linkage* if $P_1, \ldots, P_k$ are internally vertex-disjoint s-t paths. Note that $\mathcal{P}$ is not a tuple but a set, that is, we ignore the ordering of the paths in $\mathcal{P}$. We say that s-t linkages $\mathcal{P}$ and $\mathcal{Q}$ are *adjacent* if $\mathcal{Q} = (\mathcal{P} \setminus P) \cup \{Q\}$ for some s-t paths P and Q with $P \neq Q$. We define the reconfigurability of s-t linkages in the same way as linkages. We consider the following problem.

Disjoint s-t Paths Reconfiguration
Input. A graph $G = (V, E)$, distinct terminals s and t, and two s-t linkages $\mathcal{P}$ and $\mathcal{Q}$.
Question. Is $\mathcal{P}$ reconfigurable to $\mathcal{Q}$?

1.2 Our Contributions

Since finding disjoint s-t paths is an easy combinatorial optimization problem, we may wonder whether Disjoint s-t Paths Reconfiguration is also tractable. In this paper, we show that Disjoint s-t Paths Reconfiguration is PSPACE-hard even when $k = 2$.

▶ **Theorem 1.** *The Disjoint s-t Paths Reconfiguration is* PSPACE*-complete even when $k = 2$ and the maximum degree of G is four.*

Note that Disjoint s-t Paths Reconfiguration can be easily reduced to Disjoint Paths Reconfiguration by splitting each of s and t into k terminals. Thus, this theorem implies the PSPACE-hardness of Disjoint Paths Reconfiguration with $k = 2$.

In this paper, we mainly focus on the problems in planar graphs. To better understand Disjoint Paths Reconfiguration in planar graphs, we show a topological necessary condition.

Topological conditions play important roles in the disjoint paths problem. If there exist disjoint paths connecting terminal pairs in a graph embedded on a surface Σ, then there must exist disjoint curves on Σ connecting them. For example, when terminals s_1, s_2, t_1 and t_2 lie on the outer face F in a plane graph G in this order, there exist no disjoint curves connecting the terminal pairs in the disk $\Sigma = \mathbb{R}^2 \setminus F$, and hence we can conclude that G contains no disjoint paths. Such a topological condition is used to design polynomial-time algorithms for the disjoint paths problem with $k = 2$ [44, 45, 49], and to deal with the problem on a disk or a cylinder [40]. When Σ is a plane (or a sphere), we can always connect terminal pairs by disjoint curves on Σ, and hence nothing is derived from the above argument. Indeed, Robertson and Seymour [41] showed that if the input graph is embedded on a surface and the terminals are mutually "far apart," then desired disjoint paths always exist.

In contrast, as we will show below in Theorem 2, there exists a topological necessary condition for the reconfigurability of disjoint paths. Thus, even when the terminals are mutually far apart, the reconfiguration of disjoint paths is not always possible. This shows a difference between the disjoint paths problem and Disjoint Paths Reconfiguration.

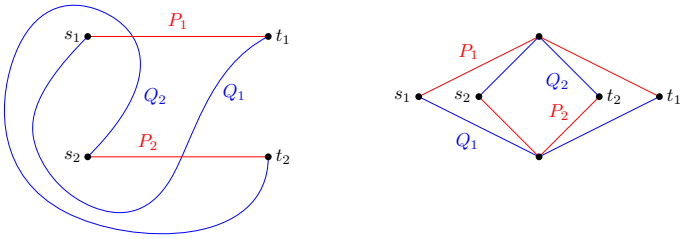

Figure 1 (Left) An example on the plane where (P_1, P_2) is not reconfigurable to (Q_1, Q_2). (Right) An example in a graph where the condition in Theorem 2 holds but (P_1, P_2) is not reconfigurable to (Q_1, Q_2).

To formally discuss the topological necessary condition, we consider the reconfiguration of curves on a surface. Suppose that Σ is a surface and let $s_1, \ldots, s_k, t_1, \ldots, t_k$ be distinct points on Σ. By abuse of notation, we say that $\mathcal{P} = (P_1, \ldots, P_k)$ is a *linkage* if it is a collection of disjoint simple curves on Σ such that P_i connects s_i and t_i. We also define the adjacency and reconfiguration sequences for linkages on Σ in the same way as linkages in a graph. Then, the reconfigurability between two linkages on a plane can be characterized with a word w_j associated to Q_j which is an element of the free group[2] F_k generated by $x_1, \ldots, x_k$ as follows; see Section 3 for the definition of w_j.

▶ **Theorem 2.** *Let $\mathcal{P} = (P_1, \ldots, P_k)$ and $\mathcal{Q} = (Q_1, \ldots, Q_k)$ be linkages on a plane (or a sphere). Then, $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$ if and only if $w_j \in \langle x_j \rangle$ for any $j \in \{1, \ldots, k\}$, where $\langle x_j \rangle$ denotes the subgroup generated by x_j.*

See Figure 1 (left) for an example. It is worth noting that, if $k = 2$ and Σ is a connected orientable closed surface of genus $g \geq 1$, then such a topological necessary condition does not exist, i.e., the reconfiguration is always possible; see the full version [20].

For a graph embedded on a plane, we can identify paths and curves. Then, Theorem 2 gives a topological necessary condition for Disjoint Paths Reconfiguration in planar graphs. However, the converse does not necessarily hold: even when the condition in Theorem 2 holds, an instance of Disjoint Paths Reconfiguration may have no reconfiguration sequence. See Figure 1 (right) for a simple example. The polynomial solvability of Disjoint Paths Reconfiguration in planar graphs is open even for the case of $k = 2$.

With the aid of the topological necessary condition, we design polynomial-time algorithms for special cases, in which all the terminals are on a single face (called *one-face instances*), or $s_1, \ldots, s_k$ are on some face and $t_1, \ldots, t_k$ are on another face (called *two-face instances*). Note that one/two-face instances have attracted attention in the disjoint paths problem [40, 47, 48], in the multicommodity flow problem [18, 35, 36], and in the shortest disjoint paths problem [8, 9, 11, 28]. We show that any one-face instance of Disjoint Paths Reconfiguration has a reconfiguration sequence (Proposition 13). Moreover, we prove a topological characterization for two-face instances of Disjoint Paths Reconfiguration with a certain condition (Theorem 14), which leads to a polynomial-time algorithm in this case.

▶ **Theorem 3.** *When the instances are restricted to two-face instances, Disjoint Paths Reconfiguration can be solved in polynomial time.*

[2] Each element of the free group can be expressed as a word consisting of $x_1, x_1^{-1}, \ldots, x_k, x_k^{-1}$ in which x_i and x_i^{-1} are not adjacent.

Based on this theorem, we give a polynomial-time algorithm for Disjoint s-t Paths Reconfiguration in planar graphs.

▶ **Theorem 4.** *There is a polynomial-time algorithm for Disjoint s-t Paths Reconfiguration in planar graphs.*

Note that the number k of paths in Theorems 3 and 4 can be part of the input.

It is well known that G has an s-t linkage of size k if and only if G has no s-t separator of size $k-1$ (Menger's theorem). The characterization for two-face instances (Theorem 14) implies the following theorem, which is interesting in the sense that one extra s-t connectivity is sufficient to guarantee the existence of a reconfiguration sequence.

▶ **Theorem 5.** *Let $G=(V,E)$ be a planar graph with distinct vertices s and t, and let $\mathcal{P}$ and $\mathcal{Q}$ be s-t linkages of size k. If there is no s-t separator of size k, then $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$.*

As mentioned above, the polynomial solvability of Disjoint Paths Reconfiguration in planar graphs is open even for the case of $k=2$. On the other hand, when k is not bounded, Disjoint Paths Reconfiguration is PSPACE-complete as the next theorem shows.

▶ **Theorem 6.** *The Disjoint Paths Reconfiguration is PSPACE-complete when the graph G is planar and of bounded bandwidth.*

Here, we recall the definition of the bandwidth of a graph. Let $G=(V,E)$ be an undirected graph. Consider an injective map $\pi\colon V\to\mathbb{Z}$. Then, the *bandwidth* of π is defined as $\max\{|\pi(u)-\pi(v)| \mid \{u,v\}\in E\}$. The *bandwidth* of G is defined as the minimum bandwidth of all injective maps $\pi\colon V\to\mathbb{Z}$.

1.3 Related Work

There are a lot of studies on the disjoint paths problem and its variant. For the case of $k=2$, polynomial-time algorithms were presented in [44, 45, 49], while the directed variant was shown to be NP-hard [15]. In the early stages of the study of the disjoint paths problem, for the case when G is embedded on a plane and all the terminals are on one face or two faces, polynomial-time algorithms were given in [40, 47, 48]. For fixed k, Robertson and Seymour [41] gave a polynomial time algorithm for the disjoint paths problem on a plane or a fixed surface. By extending this result, for the case when the graph is undirected and k is a fixed constant, Robertson and Seymour [42] gave a polynomial-time algorithm based on the graph minor theory, which is one of the biggest achievements in this area. For the planar case, faster algorithms were presented in [1, 38, 39]. The directed variant of the problem can be solved in polynomial time if the input digraph is planar and k is a fixed constant; an XP algorithm was given by Schrijver [43] and an FPT algorithm was given by Cygan et al. [10] for the parameter k.

Combinatorial reconfiguration is an emerging field in discrete mathematics and theoretical computer science. In typical problems of combinatorial reconfiguration, we consider two discrete structures and ask whether one can be transformed to the other by a sequence of local changes. See surveys of Nishimura [34] and van den Heuvel [50]. Refer to [22] for a general solver.

Path reconfiguration problems have been studied in this framework. The first problem is the shortest path reconfiguration, introduced by Kaminski et al. [23]. In this problem, we are given an undirected graph with two designated vertices s, t and two s-t shortest paths P and

Q. Then, we want to decide whether P can be transformed to Q by a sequence of one-vertex changes in such a way that all the intermediate s-t paths remain the shortest. Bonsma [6] proved that the shortest path reconfiguration is PSPACE-complete, but polynomial-time solvable when the input graph is chordal or claw-free. Bonsma [7] further proved that the problem is polynomial-time solvable for planar graphs. Wrochna [52] proved that the problem is PSPACE-complete even for graphs of bounded bandwidth. Gajjar et al. [17] proved that the problem is polynomial-time solvable for circle graphs, circular-arc graphs, permutation graphs, and hypercubes. They also considered a variant where a change can involve k successive vertices; in this variant, they proved that the problem is PSPACE-complete even for line graphs. Properties of the adjacency relation in the shortest path reconfiguration have also been studied [4, 5].

Another path reconfiguration problem has been introduced by Amiri et al. [3] who were motivated by a problem in software-defined networks. In their setup, we are given a directed graph with edge capacity and two designated vertices s, t. We are also given k pairs of s-t paths (P_i, Q_i), $i = 1, 2, \ldots, k$, where the number of paths among $P_1, P_2, \ldots, P_k$ (and among $Q_1, Q_2, \ldots, Q_k$ respectively) traversing an edge is at most the capacity of the edge. The problem is to determine whether one set of paths can be transformed into the other set of paths by a sequence of the following type of changes: specify one vertex v and then switch the usable outgoing edges at v from those in the P_i to those in the Q_i. In each of the intermediate situations, there must be a unique path through usable edges in $P_i \cup Q_i$ for each i. See [3] for the precise problem specification. Amiri et al. [3] proved that the problem is NP-hard even when $k = 2$. For directed acyclic graphs, they also proved that the problem is NP-hard (for unbounded k) but fixed-parameter tractable with respect to k. A subsequent work [2] studied an optimization variant in which the number of steps is to be minimized when a set of "disjoint" changes can be performed simultaneously.

Matching reconfiguration in bipartite graphs can be seen as a certain type of disjoint paths reconfiguration problems. In matching reconfiguration, we are given two matchings (with extra properties) and want to determine whether one matching can be transformed to the other matching by a sequence of local changes. There are several choices for local changes. One of the most studied local change rules is the token jumping rule, where we remove one edge and add one edge at the same time. Ito et al. [19] proved that the matching reconfiguration (under the token jumping rule) can be solved in polynomial time.[3]

To see a connection of matching reconfiguration with disjoint paths reconfiguration, consider the matching reconfiguration problem in bipartite graphs G under the token jumping rule, where we are given two matchings M, M' of G. Then, we add two extra vertices s, t to G, and for each edge $e \in M$ (and M') we construct a unique s-t path of length three that passes through e. This way, we obtain two s-t linkages $\mathcal{P}$ and $\mathcal{P}'$ from M and M', respectively. It is easy to observe that $\mathcal{P}$ can be reconfigured to $\mathcal{P}'$ in Disjoint s-t Paths Reconfiguration if and only if M can be reconfigured to M' in the matching reconfiguration problem in G.

1.4 Organization

In Section 2, we introduce some notation and basic concepts in topology. Section 3 deals with rerouting disjoint curves, giving the proof of Theorem 2. In Sections 4 and 5, we prove Theorems 3, 4, and 5. Hardness results (Theorems 1 and 6) are proven in the full version [20].

[3] The theorem by Ito et al. [19] only gave a polynomial-time algorithm for a different local change, the so-called token addition and removal rule. However, their result can easily be adapted to the token jumping rule, too. See [21].

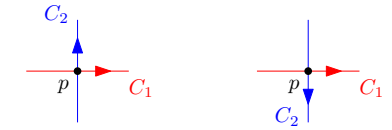

Figure 2 Local intersection numbers of curves C_1 and C_2 at p.

2 Preliminaries

For a positive integer k, let $[k] = \{1, 2, \ldots, k\}$.

Let $G = (V, E)$ be a graph. For a subgraph H of G, the vertex set of H is denoted by $V(H)$. Similarly, for a path P, let $V(P)$ denote the set of vertices in P. For $X \subseteq V$, let $N(X) = \{v \in V \setminus X \mid \{u, v\} \in E \text{ for some } u \in X\}$. For a vertex set $U \subseteq V$, let $G \setminus U$ denote the graph obtained from G by removing all the vertices in U and the incident edges. For a path P in G, we denote $G \setminus V(P)$ by $G \setminus P$ to simplify the notation. For disjoint vertex sets $X, Y \subseteq V$, we say that a vertex subset $U \subseteq V \setminus (X \cup Y)$ *separates* X and Y if $G \setminus U$ contains no path between X and Y. For distinct vertices $s, t \in V$, $U \subseteq V \setminus \{s, t\}$ is called an *s-t separator* if U separates $\{s\}$ and $\{t\}$.

For Disjoint Paths Reconfiguration (resp. Disjoint s-t Paths Reconfiguration), an instance is denoted by a triplet $(G, \mathcal{P}, \mathcal{Q})$, where G is a graph and $\mathcal{P}$ and $\mathcal{Q}$ are linkages (resp. s-t linkages). Note that we omit the terminals because they are determined by $\mathcal{P}$ and $\mathcal{Q}$. Since any instance has a trivial reconfiguration sequence when $k = 1$, we may assume that $k \geq 2$. For linkages (resp. s-t linkages) $\mathcal{P}$ and $\mathcal{Q}$, we denote $\mathcal{P} \leftrightarrow \mathcal{Q}$ if $\mathcal{P}$ and $\mathcal{Q}$ are adjacent. Recall that $\mathcal{P} = (P_1, \ldots, P_k)$ is *adjacent* to $\mathcal{Q} = (Q_1, \ldots, Q_k)$ if there exists $i \in [k]$ such that $P_j = Q_j$ for $j \in [k] \setminus \{i\}$ and $P_i \neq Q_i$.

For a graph G embedded on a surface Σ, each connected region of $\Sigma \setminus G$ is called a *face* of G. For a face F, its boundary is denoted by ∂F. When a graph G is embedded on a surface Σ, a path in G is sometimes identified with the corresponding curve in Σ. A graph embedded on a plane is called a *plane graph*. A graph is said to be *planar* if it has a planar embedding.

The following notion is well-known in topology. See [13, Section 1.2.3] for instance.

▶ **Definition 7.** *Let C_1 and C_2 be piecewise smooth oriented curves on an oriented surface and let $p \in C_1 \cap C_2$ be a transverse double point*[4]*. The* local intersection number *$\varepsilon_p(C_1, C_2)$ of C_1 and C_2 at p is defined by $\varepsilon_p(C_1, C_2) = 1$ if C_1 crosses C_2 from left to right and $\varepsilon_p(C_1, C_2) = -1$ if C_1 crosses C_2 from right to left (see Figure 2). When $\partial C_1 \cap C_2 = C_1 \cap \partial C_2 = \emptyset$, the* algebraic intersection number *$\mu(C_1, C_2) \in \mathbb{Z}$ is defined to be the sum of $\varepsilon_p(C_1, C_2)$ over all $p \in C_1 \cap C_2$ (after a small perturbation if necessary). Note that ∂C_i denotes the set of endpoints of C_i.*

When a graph is embedded on an oriented surface, paths in the graph are piecewise smooth curves, and hence we can define the algebraic intersection number for a pair of paths (see Figure 3).

[4] Intuitively, a "transverse double point" means that at the intersection two curves are not tangent with each other and no three segments of curves do not intersect simultaneously.

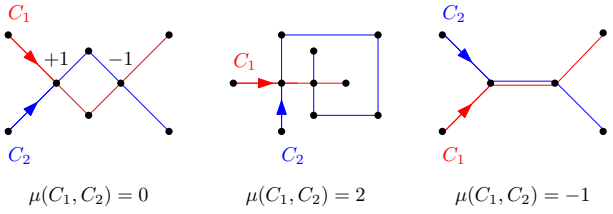

Figure 3 Algebraic intersection numbers of paths C_1 and C_2 on a graph.

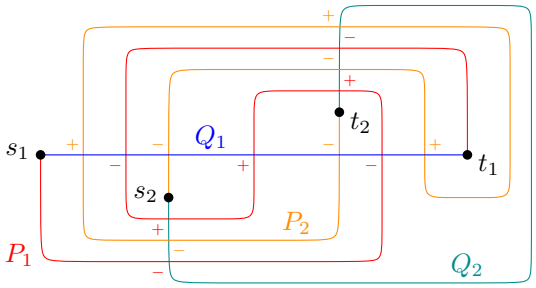

Figure 4 An example of linkages with $w_1 = x_2x_1^{-1}x_2^{-1}x_1x_2^{-1}x_1^{-1}x_2$ and $w_2 = x_1x_2^{-1}x_1^{-1}x_2x_1^{-1}x_2^{-1}x_1$.

3 Curves on a Plane

In this section, we consider the reconfiguration of curves on a plane and prove Theorem 2. Suppose that we are given distinct points $s_1, \dots, s_k, t_1, \dots, t_k$ on a plane and linkages $\mathcal{P}$ and $\mathcal{Q}$ that consist of curves on the plane connecting s_i and t_i.

Throughout this section, all intersections of curves are assumed to be transverse double points. Fix $j \in [k]$ and let $\bigcup_{i\in[k]} P_i \cap Q_j = \{s_j, p_1, \dots, p_n, t_j\}$, where the $n+2$ points are aligned on Q_j in this order. We now define $w_j \in F_k$ by

$$w_j = \prod_{\ell\in[n]} x_{i_\ell}^{\varepsilon_{p_\ell}(P_{i_\ell}, Q_j)},$$

where $i_\ell \in [k]$ satisfies $p_\ell \in P_{i_\ell} \cap Q_j$. Recall that F_k denotes the free group generated by $x_1, \dots, x_k$. We give an example in Figure 4.

▶ Remark 8. Let $\mathrm{ab}\colon F_k \to \mathbb{Z}^k$ denote the abelianization, that is, the ℓth entry of $\mathrm{ab}(w)$ is the sum of the exponents of x_ℓ's in w. For distinct $i, j \in [k]$, the ith entry of $\mathrm{ab}(w_j)$ is equal to the algebraic intersection number $\mu(P_i, Q_j) \in \mathbb{Z}$ of P_i and Q_j. Thus, $w_j \in \langle x_j \rangle$ implies that $\mu(P_i, Q_j) = 0$ for any $i \in [k] \setminus \{j\}$.

In the following two lemmas, we observe the behavior of w_j under certain moves of curves. For $j \in [k]$, let w'_j denote the word defined by a linkage $\mathcal{P}'$ and the curve Q_j.

▶ **Lemma 9.** *Let $i \in [k]$ and let $\mathcal{P}' = (P'_1, \dots, P'_k)$ be a linkage such that $P'_\ell = P_\ell$ if $\ell \neq i$, and P'_i is isotopic[5] to P_i relative to $\{s_i, t_i\}$ in $\mathbb{R}^2 \setminus \bigcup_{\ell\neq i} P_\ell$. Then, $w'_j = w_j$ for $j \in [k] \setminus \{i\}$, and $w'_i = x_i^{e_1} w_i x_i^{e_2}$ for some $e_1, e_2 \in \mathbb{Z}$.*

[5] Intuitively, this means P'_i can be obtained from P_i by a continuous deformation in the plane that fixes the endpoints s_i and t_i and avoids passing any point in $\bigcup_{\ell\neq i} P_\ell$.

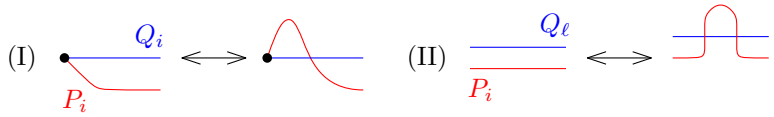

Figure 5 Local pictures of isotopies of P_i.

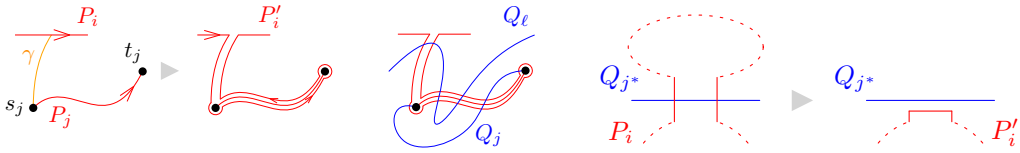

Figure 6 (Left) A move of P_i along γ. (Right) Intersections of P_i' and $\bigcup_\ell Q_\ell$.

Figure 7 A reconfiguration of P_i to P_i'.

Proof. By the definition of an isotopy (see [13, Section 1.2.5]), P_i' is obtained from P_i by a finite sequence of the moves illustrated in Figure 5. By (I), one intersection of P_i and Q_i is created or eliminated, and thus (I) changes w_i to $w_i x_i^{\pm 1}$ or $x_i^{\pm 1} w_i$. In (II), two intersections of P_i and Q_ℓ are created or eliminated for some $\ell \in [k]$. Since $x_i^{\pm 1} x_i^{\mp 1} = 1$, w_j is unchanged under (II) for any $j \in [k]$. ◀

Recall here that $\langle x_\ell \rangle$ denotes the subgroup of F_k generated by x_ℓ.

▶ **Lemma 10.** *Let γ be a simple curve connecting P_i and s_j $(i \neq j)$ whose interior is disjoint from $\bigcup_{\ell \in [k]} P_\ell$, and define P_i' as illustrated in Figure 6. Let $\mathcal{P}'$ be the linkage obtained from $\mathcal{P}$ by replacing P_i with P_i'. For $\ell \in [k]$, if $w_\ell \in \langle x_\ell \rangle$, then $w_\ell' = w_\ell$.*

Proof. Define a group homomorphism $f_{ij} \colon F_k \to F_k$ by $f_{ij}(x_\ell) = x_\ell$ if $\ell \neq j$, and $f_{ij}(x_j) = x_i x_j x_i^{-1}$. Then, one can check that $w_\ell' = f_{ij}(w_\ell)$ if $\ell \neq j$, and $w_j' = x_i^{-1} f_{ij}(w_j) x_i$ (see Figure 6). Since $w_\ell = x_\ell^{e_\ell}$ for some $e_\ell \in \mathbb{Z}$ by the assumption, we have $w_\ell' = w_\ell$ if $\ell \neq j$. Also, one has

$$w_j' = x_i^{-1} f_{ij}(w_j) x_i = x_i^{-1} (x_i x_j x_i^{-1})^{e_j} x_i = w_j.$$

This completes the proof. ◀

As a consequence of Lemmas 9 and 10, we obtain the following key lemma.

▶ **Lemma 11.** *Suppose that $\mathcal{P}$ is reconfigurable to $\mathcal{P}'$. For $j \in [k]$, if $w_j \in \langle x_j \rangle$, then $w_j' \in \langle x_j \rangle$.*

Proof. It suffices to consider the case when there is $i \in [k]$ such that $P_\ell' = P_\ell$ if $\ell \neq i$, and $P_i' \neq P_i$. Since P_i is isotopic to P_i' (relative to $\{s_i, t_i\}$) in $\mathbb{R}^2$, the curve P_i' is obtained from P_i by the moves in Lemmas 9 and 10. Therefore, these lemmas imply that if $w_j \in \langle x_j \rangle$ then $w_j' \in \langle x_j \rangle$. ◀

With this key lemma, we can prove Theorem 2 stating that $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$ if and only if $w_j \in \langle x_j \rangle$ for any $j \in [k]$.

Proof of Theorem 2. First suppose that $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$, namely $\mathcal{P}$ is reconfigurable to $\mathcal{P}'$ such that $P_i' \cap Q_i = \{s_i, t_i\}$ and $P_i' \cap Q_j = \emptyset$ for $j \in [k] \setminus \{i\}$. Then, $w_j' = 1$ for any $j \in [k]$. Since $\mathcal{P}'$ is reconfigurable to $\mathcal{P}$, Lemma 11 implies that $w_j \in \langle x_j \rangle$ for any $j \in [k]$.

The converse is shown by induction on the number, say n, of intersections of $\mathcal{P}$ and $\mathcal{Q}$ except their endpoints. The case $n = 0$ is obvious. Let us consider the case $n \geq 1$. If $P_i \cap Q_j = \emptyset$ for any pair of distinct $i, j \in [k]$, then the reconfiguration is obviously

possible. Otherwise, there exists $x_i x_i^{-1}$ or $x_i^{-1} x_i$ in the product of the definition of w_{j^*} for some $i, j^* \in [k]$ (possibly $i = j^*$). This means that P_i can be reconfigured to a curve P_i' as illustrated in Figure 7. This process eliminates at least two intersections and we have $w_j' \in \langle x_j \rangle$ for any $j \in [k]$ by Lemma 11. Thus, the induction hypothesis concludes that $\mathcal{P}'$ is reconfigurable to $\mathcal{Q}$. ◀

By Theorem 2 and Remark 8, we obtain the following corollary.

▶ **Corollary 12.** *Let $\mathcal{P} = (P_1, \ldots, P_k)$ and $\mathcal{Q} = (Q_1, \ldots, Q_k)$ be linkages on a plane (or a sphere). If $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$, then $\mu(P_i, Q_j) = 0$ for any distinct $i, j \in [k]$.*

It is worth mentioning that the converse is not necessarily true as illustrated in Figure 4. This means that a "non-commutative" tool such as the free group F_k is essential to describe the complexity of the reconfiguration of curves on a plane.

4 Algorithms for Planar Graphs

In this section, we consider the reconfiguration in planar graphs and prove Theorems 3, 4, and 5. We deal with one-face instances and two-face instances of Disjoint Paths Reconfiguration in Section 4.1. Then, we discuss Disjoint s-t Paths Reconfiguration in Section 4.2. A proof of a key theorem (Theorem 14) is postponed to Section 5.

4.1 One-Face Instance and Two-Face Instance

We say that an instance $(G, \mathcal{P}, \mathcal{Q})$ of Disjoint Paths Reconfiguration is a *one-face instance* if G is a plane graph and all the terminals are on the boundary of some face. We show that $\mathcal{P}$ is always reconfigurable to $\mathcal{Q}$ in a one-face instance, whose proof is given in the full version [20].

▶ **Proposition 13.** *For any one-face instance $(G, \mathcal{P}, \mathcal{Q})$ of Disjoint Paths Reconfiguration, $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$.*

Let $k \geq 2$. We say that an instance $(G, \mathcal{P}, \mathcal{Q})$ of Disjoint Paths Reconfiguration is a *two-face instance* if $G = (V, E)$ is a plane graph, $s_1, \ldots, s_k$ are on the boundary of some face S, and $t_1, \ldots, t_k$ are on the boundary of another face T. The objective of this subsection is to present a polynomial-time algorithm for two-face instances.

It suffices to consider the case when the graph is 2-connected since otherwise we can easily reduce to the 2-connected case. Hence, we may assume that the boundary of each face forms a cycle. For ease of explanation, without loss of generality, we assume that G is embedded on $\mathbb{R}^2$ so that S is an inner face and T is the outer face. Furthermore, we may assume that $s_1, \ldots, s_k$ lie on the boundary of S clockwise in this order and $t_1, \ldots, t_k$ lie on the boundary of T clockwise in this order, because there is a linkage.

A vertex set $U \subseteq V$ is called a *terminal separator* if U separates $\{s_1, \ldots, s_k\}$ and $\{t_1, \ldots, t_k\}$. For two curves (or paths) P and Q between ∂S and ∂T that share no endpoints, define $\mu(P, Q)$ as in Definition 7. That is, $\mu(P, Q)$ is the number of times P crosses Q from left to right minus the number of times P crosses Q from right to left, where we suppose that P and Q are oriented from ∂S to ∂T. Since $\mu(P_i, Q_j)$ takes the same value for distinct $i, j \in [k]$ (see the full version [20] for details), this value is denoted by $\mu(\mathcal{P}, \mathcal{Q})$. Roughly, $\mu(\mathcal{P}, \mathcal{Q})$ indicates the difference in the numbers of rotations around S of the linkages.

The existence of a linkage shows that the graph has no terminal separator of size less than k. If the graph has no terminal separator of size k, then we can characterize the reconfigurability by using $\mu(\mathcal{P}, \mathcal{Q})$. The following is a key theorem in our algorithm, whose proof is given in Section 5.

▶ **Theorem 14.** *Let $k \geq 2$. Suppose that a two-face instance $(G, \mathcal{P}, \mathcal{Q})$ of* Disjoint Paths Reconfiguration *has no terminal separator of size k. Then, $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$ if and only if $\mu(\mathcal{P}, \mathcal{Q}) = 0$.*

By using this theorem, we can design a polynomial-time algorithm for two-face instances of Disjoint Paths Reconfiguration and prove Theorem 3.

Proof of Theorem 3. Suppose that we are given a two-face instance $I = (G, \mathcal{P}, \mathcal{Q})$ of Disjoint Paths Reconfiguration.

We first test whether I has a terminal separator of size k, which can be done in polynomial time by a standard minimum cut algorithm. If there is no terminal separator of size k, then Theorem 14 shows that we can easily solve Disjoint Paths Reconfiguration by checking whether $\mu(\mathcal{P}, \mathcal{Q}) = 0$ or not.

Suppose that we obtain a terminal separator U of size k. Then, we obtain subgraphs G_1 and G_2 of G such that $G = G_1 \cup G_2$, $V(G_1) \cap V(G_2) = U$, $\{s_1, \ldots, s_k\} \subseteq V(G_1)$, and $\{t_1, \ldots, t_k\} \subseteq V(G_2)$. We test whether $V(P_i) \cap U = V(Q_i) \cap U$ holds for any $i \in [k]$ or not, where we note that each of $V(P_i) \cap U$ and $V(Q_i) \cap U$ consists of a single vertex. If this does not hold, then we can immediately conclude that $\mathcal{P}$ is not reconfigurable to $\mathcal{Q}$, because $V(P_i) \cap U$ does not change in the reconfiguration. If $V(P_i) \cap U = V(Q_i) \cap U$ for $i \in [k]$, then we consider the instance $I_i = (G_i, \mathcal{P}_i, \mathcal{Q}_i)$ for $i = 1, 2$, where $\mathcal{P}_i$ and $\mathcal{Q}_i$ are the restrictions of $\mathcal{P}$ and $\mathcal{Q}$ to G_i. That is, I_i is the restriction of I to G_i. Then, we see that $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$ if and only if $\mathcal{P}_i$ is reconfigurable to $\mathcal{Q}_i$ for $i = 1, 2$. Since I_1 and I_2 are one-face or two-face instances, by solving them recursively, we can solve the original instance I in polynomial time. ◀

4.2 Reconfiguration of s-t Paths

In this subsection, for Disjoint s-t Paths Reconfiguration in planar graphs, we show results that are analogous to Theorems 14 and 3, which have been already stated in Section 1.2.

▶ **Theorem 5.** *Let $G = (V, E)$ be a planar graph with distinct vertices s and t, and let $\mathcal{P}$ and $\mathcal{Q}$ be s-t linkages of size k. If there is no s-t separator of size k, then $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$.*

Proof. Suppose that G, s, t, $\mathcal{P}$, and $\mathcal{Q}$ are as in the statement, and assume that there is no s-t separator of size k. We fix an embedding of G on the plane. If there is an edge connecting s and t, then s and t are on the boundary of some face, and hence $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$ in the same way as Proposition 13. Thus, it suffices to consider the case when there is no edge connecting s and t.

We now construct an instance of Disjoint Paths Reconfiguration by replacing s and t with large "grids" as follows. Let $e_1, e_2, \ldots, e_\ell$ be the edges incident to s clockwise in this order. Note that $\ell \geq k + 1$ holds, because G has no s-t separator of size k. For $i \in [\ell]$, we subdivide e_i by introducing p new vertices $v_i^1, v_i^2, \ldots, v_i^p$ such that they are aligned in this order and v_i^1 is closest to s, where p is a sufficiently large integer (e.g., $p \geq |V|^2$). For $i \in [\ell]$ and for $j \in [p]$, we introduce a new edge connecting v_i^j and v_{i+1}^j, where $v_{\ell+1}^j = v_1^j$. Define $s_i = v_i^1$ for $i \in [k]$ and remove s. Then, the graph is embedded on the plane and $s_1, \ldots, s_k$ are on the boundary of some face clockwise in this order; see Figure 8. By applying a similar procedure to t, we modify the graph around t and define $t_1, \ldots, t_k$ that are on the boundary of some face counter-clockwise in this order. Let G' be the obtained graph. Observe that G' contains no terminal separator of size k, because G has no s-t separator of size k.

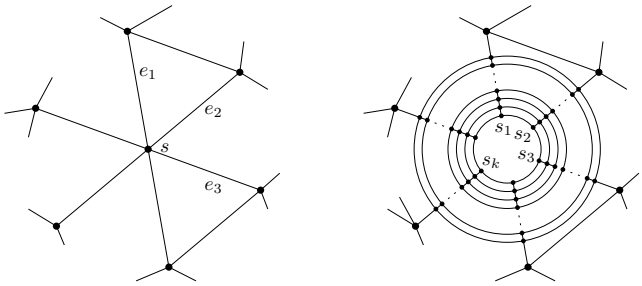

Figure 8 (Left) Original graph G. (Right) Modification around s.

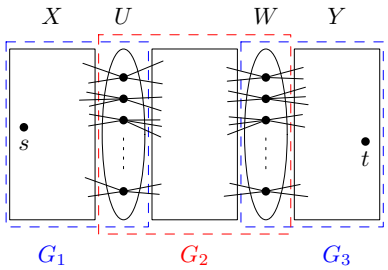

Figure 9 Construction of G_1, G_2, and G_3.

By rerouting the given s-t linkages $\mathcal{P}$ and $\mathcal{Q}$ around s and t, we obtain linkages $\mathcal{P}'$ and $\mathcal{Q}'$ from $\{s_1, \dots, s_k\}$ to $\{t_1, \dots, t_k\}$ in G'. Note that the restrictions of $\mathcal{P}$ and $\mathcal{Q}$ to $G \setminus \{s, t\}$ coincide with those of $\mathcal{P}'$ and $\mathcal{Q}'$, respectively. Then, we can take $\mathcal{P}'$ and $\mathcal{Q}'$ so that $|\mu(\mathcal{P}', \mathcal{Q}')| \leq |V|$. Furthermore, using at most $|V|$ concentric cycles around s and t, we can reroute the linkages so that the value $\mu(\mathcal{P}', \mathcal{Q}')$ decreases or increases by one. Therefore, using $p \geq |V|^2$ concentric cycles, we can reroute $\mathcal{P}'$ and $\mathcal{Q}'$ so that $\mu(\mathcal{P}', \mathcal{Q}')$ becomes zero.

By Theorem 14, $\mathcal{P}'$ is reconfigurable to $\mathcal{Q}'$ in G' (in terms of Disjoint Paths Reconfiguration). Then, the reconfiguration sequence from $\mathcal{P}'$ to $\mathcal{Q}'$ corresponds to that from $\mathcal{P}$ to $\mathcal{Q}$ in G (in terms of Disjoint s-t Paths Reconfiguration). Therefore, $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$ in G. ◀

▶ **Theorem 4.** *There is a polynomial-time algorithm for Disjoint s-t Paths Reconfiguration in planar graphs.*

Proof. Suppose that we are given a planar graph $G = (V, E)$ with $s, t \in V$ and s-t linkages $\mathcal{P} = \{P_1, \dots, P_k\}$ and $\mathcal{Q} = \{Q_1, \dots, Q_k\}$ in G. We first test whether G has an s-t separator of size k. If there is no such a separator, then we can immediately conclude that $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$ by Theorem 5.

Suppose that G has an s-t separator of size k. Let X be the inclusionwise minimal vertex set subject to $s \in X$ and $N(X)$ is an s-t separator of size k. Note that such X is uniquely determined by the submodularity of $|N(X)|$ and it can be computed in polynomial time by a standard minimum cut algorithm. Similarly, let Y be the unique inclusionwise minimal vertex set subject to $t \in Y$ and $N(Y)$ is an s-t separator of size k. Let $U = N(X)$, $W = N(Y)$, $G_1 = G[X \cup U]$, $G_2 = G \setminus (X \cup Y)$, and $G_3 = G[Y \cup W]$; see Figure 9. Since $V(P_i) \cap U$ and $V(P_i) \cap W$ do not change in the reconfiguration, we can consider the reconfiguration in G_1, G_2, and G_3, separately.

We first consider the reconfiguration in G_1. Observe that each path in $\mathcal{P}$ contains exactly one vertex in U, and the restriction of $\mathcal{P}$ to G_1 consists of k paths from s to U that are vertex-disjoint except at s. The same for $\mathcal{Q}$. By the minimality of X, G_1 contains no vertex set of size k that separates $\{s\}$ and U. Therefore, by the same argument as Theorem 5, the restriction of $\mathcal{P}$ to G_1 is reconfigurable to that of $\mathcal{Q}$.

If $U \cap W \neq \emptyset$, then $G \setminus X$ contains no vertex set of size k that separates U and $\{t\}$ by the minimality of Y. In such a case, by applying the same argument as above, the restriction of $\mathcal{P}$ to $G \setminus X$ is reconfigurable to that of $\mathcal{Q}$. By combining the reconfiguration in G_1 and that in $G \setminus X$, we obtain a reconfiguration sequence from $\mathcal{P}$ to $\mathcal{Q}$.

Therefore, it suffices to consider the case when $U \cap W = \emptyset$. In the same way as G_1, we see that the restriction of $\mathcal{P}$ to G_3 is reconfigurable to that of $\mathcal{Q}$. This shows that the reconfigurability from $\mathcal{P}$ to $\mathcal{Q}$ in G is equivalent to that in G_2. By changing the indices if necessary, we may assume that $P_i \cap U = Q_i \cap U$ for $i \in [k]$. If $P_i \cap W \neq Q_i \cap W$ for some $i \in [k]$, then we can conclude that $\mathcal{P}$ is not reconfigurable to $\mathcal{Q}$. Otherwise, let $\mathcal{P}'$ and $\mathcal{Q}'$ be the restrictions of $\mathcal{P}$ and $\mathcal{Q}$ to G_2, respectively. Since $(G_2, \mathcal{P}', \mathcal{Q}')$ is a one-face or two-face instance of Disjoint Paths Reconfiguration, we can solve it in polynomial time by Proposition 13 and Theorem 3. Therefore, we can test the reconfigurability from $\mathcal{P}$ to $\mathcal{Q}$ in polynomial time; ◀

5 Proof of Theorem 14

The necessity ("only if" part) in Theorem 14 is immediately derived from Corollary 12.

In what follows in this section, we show the sufficiency ("if" part) in Theorem 14, which is one of the main technical contributions of this paper. Assume that $\mu(\mathcal{P}, \mathcal{Q}) = 0$ and there is no terminal separator of size k. The objective is to show that $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$. Our proof is constructive, and based on topological arguments. A similar technique is used in [27, 32, 31, 37].

5.1 Preliminaries for the Proof

Let C be a simple curve connecting the boundaries of S and T such that C contains no vertex in G, C intersects the boundaries of S and T only at its endpoints, and $\mu(P_i, C) = 0$ for $i \in [k]$. Note that such C always exists, because the last condition is satisfied if C is disjoint from $\mathcal{P}$. Note also that $\mu(Q_i, C) = 0$ holds for $i \in [k]$, because $\mu(\mathcal{P}, \mathcal{Q}) = 0$.

Since T is the outer face, $\mathbb{R}^2 \setminus (S \cup T)$ forms an annulus (or a cylinder).[6] Thus, by cutting it along C, we obtain a rectangle whose boundary consists of ∂S, ∂T, and two copies of C. We take infinite copies of this rectangle and glue them together to obtain an infinitely long strip R. That is, for $j \in \mathbb{Z}$, let C^j be a copy of C, let R^j be a copy of the rectangle whose boundary contains C^j and C^{j+1}, and define $R = \bigcup_{j \in \mathbb{Z}} R^j$; see Figure 10. By taking C appropriately, we may assume that the copies of $s_1, \ldots, s_k$ lie on the boundary of R^j in this order so that s_1 is closest to C^j and s_k is closest to C^{j+1}. The same for $t_1, \ldots, t_k$. Note that R is called the *universal cover* of $\mathbb{R}^2 \setminus (S \cup T)$ in the terminology of topology.

Since G is embedded on $\mathbb{R}^2 \setminus (S \cup T)$, this operation naturally defines an infinite periodic graph $\hat{G} = (\hat{V}, \hat{E})$ on R that consists of copies of G. A path in $\hat{G}$ is identified with the corresponding curve in R. For $v \in V$ and $j \in \mathbb{Z}$, let $v^j \in \hat{V}$ denote the unique vertex in R^j

[6] More precisely, the annulus is degenerated when $\partial S \cap \partial T \neq \emptyset$, but the same argument works even for this case.

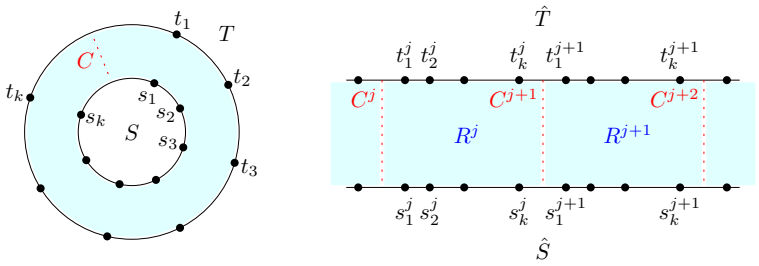

Figure 10 (Left) Curve C in $\mathbb{R}^2 \setminus (S \cup T)$. (Right) Construction of R.

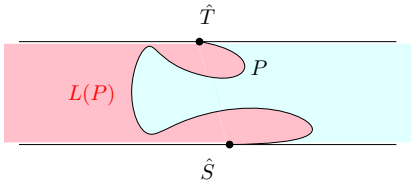

Figure 11 Definition of $L(P)$.

that corresponds to v. Since $\mu(P_i, C) = 0$ for $i \in [k]$, each path in $\hat{G}$ corresponding to P_i is from s_i^j to t_i^j for some $j \in \mathbb{Z}$, and we denote such a path by P_i^j. We define Q_i^j in the same way. Since $\mathcal{P}$ and $\mathcal{Q}$ are linkages in G, $\{P_i^j \mid i \in [k],\ j \in \mathbb{Z}\}$ and $\{Q_i^j \mid i \in [k],\ j \in \mathbb{Z}\}$ are sets of vertex-disjoint paths in $\hat{G}$.

A path in $\hat{G}$ connecting the boundary of R corresponding to ∂S and that corresponding to ∂T is called an $\hat{S}$-$\hat{T}$ *path*. For an $\hat{S}$-$\hat{T}$ path P, let $L(P)$ be the region of $R \setminus P$ that is on the "left-hand side" of P. Formally, let r be a point in R^j for sufficiently small j, and define $L(P)$ as the set of points $x \in R \setminus P$ such that any curve in R between r and x crosses P an even number of times; see Figure 11. For two $\hat{S}$-$\hat{T}$ paths P and Q, we denote $P \preceq Q$ if $L(P) \subseteq L(Q)$, and denote $P \prec Q$ if $L(P) \subsetneq L(Q)$. For two linkages $\mathcal{P} = (P_1, \ldots, P_k)$ and $\mathcal{Q} = (Q_1, \ldots, Q_k)$ in G with $\mu(P_i, C) = \mu(Q_i, C) = 0$ for $i \in [k]$, we denote $\mathcal{P} \preceq \mathcal{Q}$ if $P_i^j \preceq Q_i^j$ for any $i \in [k]$ and $j \in \mathbb{Z}$, and denote $\mathcal{P} \prec \mathcal{Q}$ if $\mathcal{P} \preceq \mathcal{Q}$ and $\mathcal{P} \neq \mathcal{Q}$.

5.2 Case When $\mathcal{P} \preceq \mathcal{Q}$

In this subsection, we consider the case when $\mathcal{P} \preceq \mathcal{Q}$, and the general case will be dealt with in Section 5.3. To show that $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$, we show the following lemma.

▶ **Lemma 15.** *If $\mathcal{P} \prec \mathcal{Q}$, then there exists a linkage $\mathcal{P}'$ such that $\mathcal{P} \leftrightarrow \mathcal{P}'$ and $\mathcal{P} \prec \mathcal{P}' \preceq \mathcal{Q}$.*

Proof. Let $\hat{W} := \{\hat{v} \in \hat{V} \mid \hat{v} \in P_i^j \setminus Q_i^j \text{ for some } i \in [k] \text{ and } j \in \mathbb{Z}\}$ and let W be the subset of V corresponding to $\hat{W}$. If $W = \emptyset$, then take an index $i \in [k]$ such that $P_i \neq Q_i$ and let $\mathcal{P}' = (P_1', \ldots, P_k')$ be the set of paths obtained from $\mathcal{P}$ by replacing P_i with Q_i. Since $\mathcal{Q}$ is a linkage and all the vertices in P_h' are contained in Q_h for $h \in [k]$, $\mathcal{P}'$ is a desired linkage. Thus, it suffices to consider the case when $W \neq \emptyset$.

Let $u \in W$. Let $\hat{u} \in \hat{W}$ be a vertex corresponding to u and let $i \in [k]$ and $j \in \mathbb{Z}$ be the indices such that $\hat{u} \in P_i^j \setminus Q_i^j$. Since $\hat{u} \in P_i^j \setminus Q_i^j$ implies $\hat{u} \in L(Q_i^j) \setminus L(P_i^j)$, there exists a face $\hat{F}$ of $\hat{G}$ such that $\partial \hat{F}$ contains an edge of P_i^j incident to $\hat{u}$ and $\hat{F} \subseteq L(Q_i^j) \setminus L(P_i^j)$. Define $(P_i^j)'$ as the s_i^j-t_i^j path in $\hat{G}$ with maximal $L((P_i^j)')$ subject to $(P_i^j)' \subseteq P_i^j \cup \partial \hat{F}$; see Figure 12. Note that such a path is uniquely determined, it satisfies $P_i^j \prec (P_i^j)' \preceq Q_i^j$, and it can be found in polynomial time.

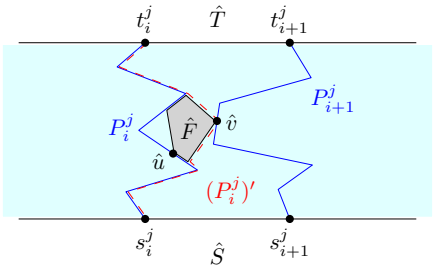

Figure 12 The blue thick paths are P_i^j and P_{i+1}^j, and the red dashed path is $(P_i^j)'$. There exists a vertex $\hat{v} \in \partial\hat{F} \cap P_{i+1}^j$.

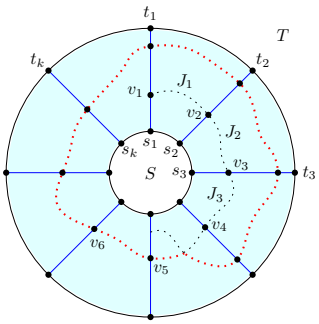

Figure 13 Each blue path represents P_i. The dotted curve is part of J and the red dotted thick curve is C^*.

Let P_i' be the s_i-t_i path in G that corresponds to $(P_i^j)'$. If P_i' is disjoint from P_h for any $h \in [k] \setminus \{i\}$, then we can obtain a desired linkage $\mathcal{P}'$ from $\mathcal{P}$ by replacing P_i with P_i'. Otherwise, P_i' intersects P_h for some $h \in [k] \setminus \{i\}$. This together with $P_i^j \prec (P_i^j)'$ shows that $(P_i^j)'$ intersects P_{i+1}^j, where P_{k+1}^j means P_1^{j+1}. Since P_i^j and P_{i+1}^j are vertex-disjoint, the intersection of $(P_i^j)'$ and P_{i+1}^j is contained in $\partial\hat{F}$, which implies that $\partial\hat{F} \cap P_{i+1}^j$ contains a vertex $\hat{v} \in \hat{V}$; see Figure 12 again. Since $\hat{F} \subseteq L(Q_i^j)$, we obtain $\hat{v} \in L(Q_i^j) \cup Q_i^j \subseteq L(Q_{i+1}^j)$, and hence $\hat{v} \notin Q_{i+1}^j$. Let v and F be the vertex and the face of G that correspond to $\hat{v}$ and $\hat{F}$, respectively. Then, $\hat{v} \in P_{i+1}^j \setminus Q_{i+1}^j$ implies that $\hat{v} \in \hat{W}$ and $v \in W$. Note that there exists a curve in F from u to v.

By the above argument, for any $u \in W$, we can obtain

- **(i)** a desired linkage $\mathcal{P}'$, or
- **(ii)** a vertex $v \in W$ on P_{i+1} and a curve from u to v contained in some face of G, where i is the index with $u \in V(P_i)$.

Therefore, it suffices to show that we obtain the outcome (i) for some $u \in W$. To derive a contradiction, assume to the contrary that we obtain the outcome (ii) for any $u \in W$.

By using the outcome (ii) repeatedly and by shifting the indices of P_i if necessary, we obtain v_i and J_i for $i = 1, 2, \ldots$ such that $v_i \in W$ is on P_i (where the index is modulo k) and J_i is a curve from v_i to v_{i+1} contained in some face. We consider the curve J obtained by concatenating $J_1, J_2, \ldots$ in this order. Since $|W|$ is finite, this curve visits the same point more than once, and hence it contains a simple closed curve C^*. Since C^* is simple and visits vertices on $P_i, P_{i+1}, \ldots$ in this order, C^* surrounds S exactly once in the clockwise direction; see Figure 13. In particular, C^* contains exactly one vertex on P_i for each $i \in [k]$. Let U be the set of vertices in V contained in C^*. Then, $|U| = k$ and $G \setminus U$ has no path between $\{s_1, \ldots, s_k\}$ and $\{t_1, \ldots, t_k\}$ by the choice of C^*. Furthermore, U contains no terminals, because $U \subseteq W$ and W contains no terminals. Therefore, U is a terminal separator of size k, which contradicts the assumption. ◀

As long as $\mathcal{P} \neq \mathcal{Q}$, we apply this lemma and replace $\mathcal{P}$ with $\mathcal{P}'$, repeatedly. Then, this procedure terminates when $\mathcal{P} = \mathcal{Q}$, and gives a reconfiguration sequence from $\mathcal{P}$ to $\mathcal{Q}$. This completes the proof for the case when $\mathcal{P} \preceq \mathcal{Q}$.

We now give a remark on the length of the reconfiguration sequence. For $\hat{S}$-$\hat{T}$ paths P and Q with the same endpoints, we see that $L(Q) \setminus L(P)$ contains $O(|V|^2)$ faces of $\hat{G}$. Therefore, in the reconfiguration sequence from $\mathcal{P}$ to $\mathcal{Q}$ obtained above, each path in $\mathcal{P}$ is replaced with another path $O(|V|^2)$ times, which shows that the number of applications of Lemma 15 is $O(k|V|^2)$ in total.

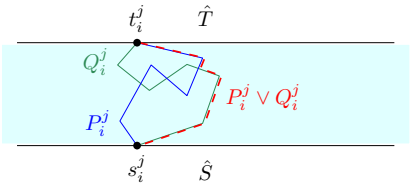

Figure 14 Construction of $P_i^j \vee Q_i^j$.

5.3 General Case

In this subsection, we consider the case when $\mathcal{P} \preceq \mathcal{Q}$ does not necessarily hold. For $i \in [k]$ and $j \in \mathbb{Z}$, define $P_i^j \vee Q_i^j$ as the s_i^j-t_i^j path in $\hat{G}$ with maximal $L(P_i^j \vee Q_i^j)$ subject to $P_i^j \vee Q_i^j \subseteq P_i^j \cup Q_i^j$; see Figure 14. Note that such a path is uniquely determined, $P_i^j \preceq P_i^j \vee Q_i^j$, and $Q_i^j \preceq P_i^j \vee Q_i^j$. Since $\hat{G}$ is periodic, for any $j \in \mathbb{Z}$, $P_i^j \vee Q_i^j$ corresponds to a common s_i-t_i walk $P_i \vee Q_i$ in G. Actually, $\mathcal{P} \vee \mathcal{Q} := (P_1 \vee Q_1, \dots, P_k \vee Q_k)$ is a linkage in G.

▶ **Lemma 16.** *$\mathcal{P} \vee \mathcal{Q}$ is a linkage in G.*

Proof. We first show that $P_i \vee Q_i$ is a path for each $i \in [k]$. Assume to the contrary that $P_i \vee Q_i$ visits a vertex $v \in V$ more than once. Then, for $j \in \mathbb{Z}$, there exist $j_1, j_2 \in \mathbb{Z}$ with $j_1 < j_2$ such that $P_i^j \vee Q_i^j$ contains both v^{j_1} and v^{j_2}. Since the path $P_i^j \vee Q_i^j$ is contained in the subgraph $P_i^j \cup Q_i^j$, without loss of generality, we may assume that P_i^j contains v^{j_2}. This shows that $v^{j_1} \in L(P_i^j) \subseteq L(P_i^j \vee Q_i^j)$, which contradicts that v^{j_1} is contained in $P_i^j \vee Q_i^j$.

We next show that $P_1 \vee Q_1, \dots, P_k \vee Q_k$ are pairwise vertex-disjoint. Assume to the contrary that $P_i \vee Q_i$ and $P_{i'} \vee Q_{i'}$ contain a common vertex $v \in V$ for distinct $i, i' \in [k]$. Since $\hat{G}$ is periodic, there exist $j, j' \in \mathbb{Z}$ such that $P_i^j \vee Q_i^j$ and $P_{i'}^{j'} \vee Q_{i'}^{j'}$ contain v^0 (i.e., the copy of v in R^0). We may assume that (j, i) is smaller than (j', i') in the lexicographical ordering, that is, either $j < j'$ holds or $j = j'$ and $i < i'$ hold. Since $P_i^j \vee Q_i^j \subseteq P_i^j \cup Q_i^j$, we may also assume that $v^0 \in P_i^j$ by changing the roles of P_i^j and Q_i^j if necessary. Then, we obtain $v^0 \in P_i^j \subseteq L(P_{i'}^{j'}) \subseteq L(P_{i'}^{j'} \vee Q_{i'}^{j'})$, which contradicts that v^0 is contained in $P_{i'}^{j'} \vee Q_{i'}^{j'}$. ◀

We also see that $\mu(P_i \vee Q_i, C) = 0$ for $i \in [k]$ by definition, and hence $\mu(\mathcal{P}, \mathcal{P} \vee \mathcal{Q}) = 0$. Since $\mathcal{P} \preceq \mathcal{P} \vee \mathcal{Q}$ and $\mu(\mathcal{P}, \mathcal{P} \vee \mathcal{Q}) = 0$, $\mathcal{P}$ is reconfigurable to $\mathcal{P} \vee \mathcal{Q}$ as described in Section 5.2. Similarly, $\mathcal{Q}$ is reconfigurable to $\mathcal{P} \vee \mathcal{Q}$, which implies that $\mathcal{P} \vee \mathcal{Q}$ is reconfigurable to $\mathcal{Q}$. By combining them, we see that $\mathcal{P}$ is reconfigurable to $\mathcal{Q}$, which completes the proof of the sufficiency in Theorem 14.

Note that the reconfiguration sequence from $\mathcal{P}$ to $\mathcal{Q}$ can be constructed in polynomial time by the discussion in Section 5.2.

6 Concluding Remarks

Although Disjoint Paths Reconfiguration and Disjoint s-t Paths Reconfiguration are decision problems, the proofs for our positive results (Theorems 3, 4, 5, and 14) show that we can find a reconfiguration sequence in polynomial time if it exists.

We leave several open problems for future research. We proved that Disjoint Paths Reconfiguration can be solved in polynomial time when the problem is restricted to the two-face instances. On the other hand, we do not know whether Disjoint Paths Reconfiguration in planar graphs can be solved in polynomial time for fixed k, and even when $k = 2$, if we drop the requirement that inputs are two-face instances.

We did not try to minimize the number of reconfiguration steps when a reconfiguration sequence exists. It is an open problem whether a shortest reconfiguration sequence can be found in polynomial time for Disjoint Paths Reconfiguration restricted to planar two-face instances.

A natural extension of our studies is to consider a higher-genus surface. As a preliminary result, in the full version [20], we give a proof (sketch) to show that when the number k of curves is two, the reconfiguration is *always* possible for any connected orientable closed surface Σ_g of genus $g \geq 1$. Note that this result does not refer to graphs embedded on Σ_g, but only refers to the case when curves can pass through any points on the surface. It is not clear what we can say for Disjoint Paths Reconfiguration for graphs embedded on Σ_g, $g \geq 1$.

Abstract

We prove that the computation of a combinatorial shortest path between two vertices of a graph associahedron, introduced by Carr and Devadoss, is NP-hard. This resolves an open problem raised by Cardinal. A graph associahedron is a generalization of the well-known associahedron. The associahedron is obtained as the graph associahedron of a path. It is a tantalizing and important open problem in theoretical computer science whether the computation of a combinatorial shortest path between two vertices of the associahedron can be done in polynomial time, which is identical to the computation of the flip distance between two triangulations of a convex polygon, and the rotation distance between two rooted binary trees. Our result shows that a certain generalized approach to tackling this open problem is not promising. As a corollary of our theorem, we prove that the computation of a combinatorial shortest path between two vertices of a polymatroid base polytope cannot be done in polynomial time unless P = NP. Since a combinatorial shortest path on the matroid base polytope can be computed in polynomial time, our result reveals an unexpected contrast between matroids and polymatroids.

1 Introduction

Graph associahedra were introduced by Carr and Devadoss [8]. These polytopes generalize associahedra. In an associahedron, each vertex corresponds to a binary tree over a set of n elements, and each edge corresponds to a rotation operation between two binary trees. For the historical account of associahedra, see the introduction of the paper by Ceballos, Santos, and Ziegler [9].

A binary tree can be obtained from a labeled path. Let $V = \{1, 2, \ldots, n\}$ be the set of vertices of the path, and $E = \{\{i, i+1\} \mid 1 \leq i \leq n-1\}$ be the set of edges of the path. To construct a labeled binary tree, we choose an arbitrary vertex from the path. Let it be $i \in V$. Then, the removal of i from the path results in at most two connected components: the left subpath and the right subpath, which may be empty. Then, in the corresponding binary tree, we set i as a root, and append recursively a binary tree of the left subpath as a left subtree and a binary tree of the right subpath as a right subtree. Note that in this construction, each node of the binary tree is labeled by a vertex of the path.

In the construction of graph associahedra, we follow the same idea. Since we are only interested in the graph structure of graph associahedra in this work, we only describe their vertices and edges. To define a graph associahedron, we first fix a connected undirected graph $G = (V, E)$.[1] Then, in the G-associahedron, the vertices correspond to the so-called elimination trees of G, and the edges correspond to swap operations between two elimination trees. The following description follows that of Cardinal, Merino, and Mütze [5].

An *elimination tree* of a connected undirected graph $G = (V, E)$ is a rooted tree defined as follows. It has V as the vertex set and is composed of a root $v \in V$ that has as children elimination trees for each connected component of $G - v$ (Figure 1). A swap from an elimination tree T to another elimination tree T' of G is defined as follows. Let v be a non-root vertex of T, and let u be the parent of v in T. Denote by H the subgraph of G induced by the subtree rooted at v in T. Then, the swap of u with v transforms T to T' as follows. (1) The tree T' has v as the parent of u, and T' has v as a child of the parent of u in T. (2) The subtrees rooted at u in T remain subtrees rooted at u in T'. (3) A subtree S rooted at v in T remains a subtree rooted at v in T', unless the vertices of S belong to the same connected component of $H - v$ as u, in which case S becomes a subtree rooted at u in T'. The G-associahedron for a claw G is given in Figure 2. Note that a swap operation is reversible.

In this paper, among graph properties of graph associahedra, we concentrate on the computation of a combinatorial shortest path (i.e., the graph-theoretic distance) between two vertices of the polytope, which we call the combinatorial shortest path problem on graph associahedra. In this problem, we are given a graph G and two elimination trees T, T' of G, and want to compute the shortest length of a graph-theoretic path from T to T' on the G-associahedron. In the literature, we only find the studies in the case where G is a complete graph or (a generalization of) a star. When G is a complete graph, the G-associahedron is called a permutahedron, and each of its vertices corresponds to a permutation. Since an edge corresponds to an adjacent transposition, the graph-theoretic distance between two vertices is equal to the number of inversions between the corresponding permutations. This can be computed in polynomial time. When G is a star, the G-associahedron is called stellohedron [26]. Recently, Cardinal, Pournin, and Valencia-Pabon [7] gave a polynomial-

[1] A graph associahedron can also be defined for disconnected graphs, but in this paper, we concentrate on connected graphs.

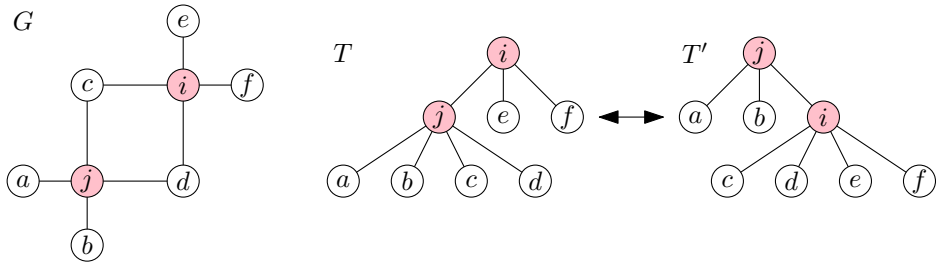

Figure 1 An example of elimination trees. Two trees T and T' are elimination trees of the graph G. The tree T' is obtained from T by the swap of i with j. The example is borrowed from Cardinal, Merino, and Mütze [5].

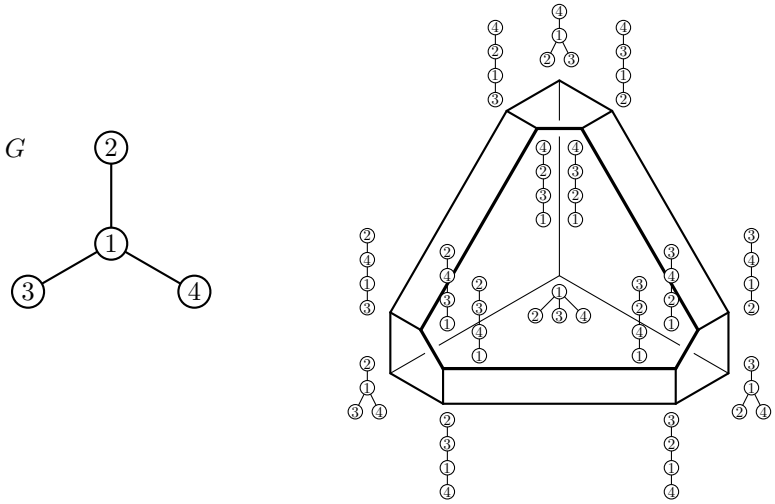

Figure 2 An example of a graph associahedron. Each vertex of the polytope corresponds to an elimination tree of the graph G.

time algorithm to compute a combinatorial shortest path on stellohedra, and they generalize the algorithm when G is a complete split graph (i.e., a graph obtained from a star by replacing the center vertex with a clique).

On the other hand, it is a tantalizing open problem whether a combinatorial shortest path can be computed in polynomial time when G is a path. In this case, the graph-theoretic distance corresponds to the rotation distance between two binary trees. By Catalan correspondences, this is equivalent to the flip distance between two triangulations of a convex polygon. A possible strategy to resolve this open problem is to generalize the problem and solve the generalized problem. In our case, a generalization is achieved by considering graph associahedra for general graphs.

Our main result states that the combinatorial shortest path problem on G-associahedra is NP-hard when G is also given as part of the input. This implies that the strategy mentioned above is bound to fail.

First, we formally state the problem Combinatorial Shortest Path on Graph Associahedra as follows.

Combinatorial Shortest Path on Graph Associahedra
Input: A graph G and two elimination trees $T_{\mathrm{ini}}, T_{\mathrm{tar}}$ of G
Output: The distance between T_{ini} and T_{tar} on the graph of the G-associahedron

Our first theorem states the NP-hardness of Combinatorial Shortest Path on Graph Associahedra. This solves an open problem raised by Cardinal (see [3, Section 4.2]).

▶ **Theorem 1.** *Combinatorial Shortest Path on Graph Associahedra is* NP*-hard.*

Theorem 1 yields the following corollary, which is related to polymatroids introduced by Edmonds [13]. A pair (U, ρ) of a finite set U and a function $\rho\colon 2^U \to \mathbb{R}$ is called a *polymatroid* if ρ satisfies the following conditions: (P1) $\rho(\emptyset) = 0$; (P2) if $X \subseteq Y \subseteq U$, then $\rho(X) \leq \rho(Y)$; (P3) if $X, Y \subseteq U$, then $\rho(X \cup Y) + \rho(X \cap Y) \leq \rho(X) + \rho(Y)$. The function ρ is called the *rank function* of the polymatroid (U, ρ).

For a polymatroid (U, ρ), we define the *base polytope* of (U, ρ) as

$$\mathbf{B}(\rho) := \{x \in \mathbb{R}^U \mid x(X) \leq \rho(X)\,(\forall\, X \subseteq U),\, x(U) = \rho(U)\},$$

where we define $x(X) := \sum_{u \in X} x(u)$ for each subset $X \subseteq U$. Then, $\mathbf{B}(\rho)$ is a polytope because $0 \leq \rho(U) - \rho(U \setminus \{u\}) = x(U) - \rho(U \setminus \{u\}) \leq x(u) \leq \rho(\{u\})$ for every element $e \in E$.

A polymatroid is seen as a polyhedral generalization of a matroid. For example, the greedy algorithm for matroids can be treated as an algorithm to maximize a linear function over the base polytope of a matroid,[2] and the algorithm is readily generalized to the base polytope of a polymatroid. A lot of combinatorial properties of the base polytopes of matroids also hold for the base polytopes of polymatroids. Since it is known that a combinatorial shortest path on the base polytope of a matroid can be computed in polynomial time [18], we are interested in generalizing this result to polymatroids, which leads to the following problem definition.

Combinatorial Shortest Path on Polymatroids
Input: An oracle access to a polymatroid (U, ρ) and two extreme points $x_{\mathrm{ini}}, x_{\mathrm{tar}}$ of the base polytope $\mathbf{B}(\rho)$
Output: The distance between x_{ini} and x_{tar} on $\mathbf{B}(\rho)$

We note that a polymatroid (U, ρ) is given as an oracle access that returns the value $\rho(X)$ for any set $X \subseteq U$. The running time of an algorithm is also measured in terms of the number of oracle calls. This is a standard assumption when we deal with polymatroids [16] since if we would input the function ρ as a table of the values $\rho(X)$ for all $X \subseteq U$, then it would already take at least $2^{|U|}$ space. We also note that the adjacency of two extreme points of the base polytope of a polymatroid can be tested in polynomial time [31].

The next theorem states that this problem is hard, which is proved as a corollary of Theorem 1, and reveals an unexpected contrast between matroids and polymatroids.

▶ **Theorem 2.** *There exists no polynomial-time algorithm for Combinatorial Shortest Path on Polymatroid unless* P = NP*.*

Our proof relies on the fact that graph associahedra can be realized as the base polytopes of some polymatroids [26]. However, we need careful treatment since in the reduction we require the rank function of our polymatroid to be evaluated in polynomial time. To this end, we give an explicit inequality description of the realization of a graph associahedron due to Devadoss [12],[3] which is indeed the base polytope of a polymatroid.

[2] This can further be seen as a generalization of Kruskal's algorithm for the minimum spanning tree problem.

[3] We note here that the original definition of a graph associahedron by Carr and Devadoss [8] does not give explicit vertex coordinates of the polytope. Therefore, we rely on the realization by Devadoss [12] who gave the explicit vertex coordinates.

Related Work

Paths on polytopes have been studied thoroughly. One of the initial motivations for this research direction is to design and understand path-following algorithms for linear optimization such as simplex methods. In his chapter of *Handbook of Discrete and Computational Geometry* [17], Kalai stated as an open problem "Find an efficient routing algorithm for convex polytopes." Here, a routing algorithm means one that finds a short path from a given initial vertex to a given target vertex.

Paths on graph associahedra have been receiving much attention. The diameter is perhaps the most frequently studied quantity, which is defined as the maximum distance between two vertices of the polytope. A famous result by Sleator, Tarjan, and Thurston [30] states that the diameter of the $(n-1)$-dimensional associahedron (i.e., a graph associahedron of an n-vertex path) is at most $2n-6$ when $n \geq 11$ and this bound is tight for all sufficiently large n. This bound is refined by Pournin [27], who proved that the diameter of the $(n-1)$-dimensional associahedron is exactly $2n-6$ when $n \geq 11$.

For a general n-vertex graph G, Manneville and Pilaud [24] proved that the diameter of G-associahedron is at most $\binom{n}{2}$ and at least $\max\{m, 2n-20\}$, when m is the number of edges of G. The upper bound is attained by the case where G is a complete graph (i.e., the G-associahedron is a permutahedron). When G is an n-vertex star (i.e., $K_{1,n-1}$), $n \geq 6$, Manneville and Pilaud [24] showed that the diameter is $2n-2$. When G is a cycle (i.e., the polytope is a cyclohedron), Pournin [28] gave the asymptotically exact diameter. When G is a tree, Manneville and Pilaud [24] gave the upper bound $O(n \log n)$ while Cardinal, Langerman, and Pérez-Lantero [4] gave an example of trees for which the diameter is $\Omega(n \log n)$ (such an example is chosen as a complete binary tree). Cardinal, Pournin, and Valencia-Pabon [6] proved that the diameter is $\Theta(m)$ for m-edge trivially perfect graphs, and gave upper and lower bounds for the diameter in terms of treewidths, pathwidths, and treedepths of graphs. Berendsohn [2] proved that the diameter is $\Theta(n+mH)$ for a caterpillar with n spine vertices, m leg vertices, and the Shannon entropy H of the so-called leg distribution.

To the authors' knowledge, the complexity of computing the diameter of graph associahedra has not been investigated. When polytopes are not restricted to graph associahedra, a few hardness results have been known. Frieze and Teng [15] proved that computing the diameter of a polytope, given by inequalities, is weakly NP-hard. Sanità [29] proved that computing the diameter of the fractional matching polytope of a given graph is strongly NP-hard. Kaibel and Pfetsch [19] raised an open problem about the complexity of computing the diameter of simple polytopes.

The computation of a combinatorial shortest path on a G-associahedron has also been studied. It is a long-standing open problem whether a combinatorial shortest path in an associahedron (i.e., a G-associahedron when G is a path) can be computed in polynomial time. Polynomial-time algorithms are only known when G is a complete graph (folklore), a star, or a complete split graph (Cardinal, Pournin, and Valencia-Pabon [7]). When G is a path, a polynomial-time approximation algorithm of factor two [11] and fixed-parameter algorithms when the distance is a parameter [10, 20, 21, 23] are known.

Since a combinatorial shortest path on an associahedron is equivalent to a shortest flip sequence of triangulations of a convex polygon, the computation of a shortest flip sequence of triangulations has been studied in more general setups. For triangulations of point sets, the problem is NP-hard [22] and even APX-hard [25]. For triangulations of simple polygons, the problem is also NP-hard [1].

Elimination trees have appeared in a lot of branches of mathematics and computer science. For a good summary, see Cardinal, Merino, and Mütze [5].

Technique Overview

To prove the hardness of the combinatorial shortest path problem on graph associahedra, we first consider a "weighted" version of the combinatorial shortest path problem on graph associahedra, which is newly introduced in this paper for our reduction. In this problem, each vertex of a given graph has a positive weight, and the swap of two vertices incurs the weight that is defined as the product of the weights of these two vertices. The weight of a swap sequence is defined as the sum of weights of swaps in the sequence. As our intermediate theorem, we prove that this weighted version is strongly NP-hard.

To this end, we reduce the NP-hard problem of finding a balanced minimum s-t cut in a graph [14] to the weighted version of the combinatorial shortest path problem on graph associahedra. In the balanced minimum s-t cut problem, we want to determine whether there exists a minimum s-t cut of a given graph G that is a bisection of the vertex set. In the reduction, we construct a vertex-weighted graph H from G and two elimination trees T_{ini}, T_{tar} of H. The weighted graph H is constructed by replacing s and t by large cliques, subdividing each edge, and duplicating each vertex; the weights are assigned so that the subdivision vertices receive small weights, and duplicated vertices and vertices in large cliques receive large weights. Elimination trees T_{ini} and T_{tar} are constructed so that swapping two vertices of large weights is forbidden and identifying a few vertices of small weights (that corresponds to a balanced minimum s-t cut of G) gives a shortest path.

In the second step, we reduce the weighted version to the original unweighted version of the problem. To this end, a vertex of weight w is replicated by a clique of size w. We want to make sure that a swap of the vertices u, v of weights $w(u), w(v)$, respectively in the weighted instance is mapped to consecutive $w(u) \cdot w(v)$ swaps of the vertices of cliques that correspond to u and v in the constructed unweighted instance. This is proved via the useful operation of projections combined with the averaging argument.

2 Preliminaries

For a positive integer k, let $[k]$ denote $\{1, 2, \ldots, k\}$.

For a graph $G = (V, E)$ and two elimination trees T_{ini} and T_{tar} of G, we say that a sequence $\mathbf{T} = \langle T_0, T_1, \ldots, T_\ell \rangle$ of elimination trees of G is a *reconfiguration sequence from* T_{ini} *to* T_{tar} if $T_0 = T_{\mathrm{ini}}$, $T_\ell = T_{\mathrm{tar}}$, and T_i is obtained from T_{i-1} by applying a single swap operation for $i \in [\ell]$. We sometimes regard $\mathbf{T}$ as a sequence of swap operations if no confusion may arise. The length of $\mathbf{T}$ is defined as the number ℓ of swaps in $\mathbf{T}$, which we denote length($\mathbf{T}$). Then, Combinatorial Shortest Path on Graph Associahedra is the problem of finding a reconfiguration sequence $\mathbf{T}$ from T_{ini} to T_{tar} that minimizes length($\mathbf{T}$).

When $u \in V$ is a child of $v \in V$ in an elimination tree T, an operation swapping u and v is represented by $\mathbf{swap}(u, v)$. Note that we distinguish $\mathbf{swap}(u, v)$ and $\mathbf{swap}(v, u)$. For an elimination tree T and for a vertex $v \in V(T)$, let $\mathbf{anc}_T(v)$ (resp. $\mathbf{des}_T(v)$) denote the set of all ancestors (descendants) of v in T. Note that $u \in \mathbf{anc}_T(v)$ if and only if $v \in \mathbf{des}_T(u)$. Note also that neither $\mathbf{anc}_T(v)$ nor $\mathbf{des}_T(v)$ contains v. We say that distinct vertices u and v are *comparable* in T if $u \in \mathbf{anc}_T(v)$ or $v \in \mathbf{anc}_T(u)$. Otherwise, they are called *incomparable* in T. A linear ordering $\prec$ on V defines an elimination tree T uniquely so that $u \in \mathbf{anc}_T(v)$ implies $u \prec v$.

Let $G = (V, E)$ be an undirected graph. For $X \subseteq V$, let $\delta_G(X)$ denote the set of edges between X and $V \setminus X$. For $s, t \in V$, we say that $X \subseteq V$ is an *s-t cut* if $s \in X$ and $t \notin X$. An edge set $F \subseteq E$ is called an *s-t cut set* if $F = \delta_G(X)$ for some s-t cut $X \subseteq V$. A *minimum s-t cut* is an s-t cut X minimizing $|\delta_G(X)|$. For $X \subseteq V$, let $G[X]$ denote the subgraph induced by X and let $E[X]$ denote its edge set.

3 Hardness of the Weighted Problem

We consider a weighted variant of Combinatorial Shortest Path on Graph Associahedra, which we call Weighted Combinatorial Shortest Path on Graph Associahedra. In the problem, we are given a graph $G = (V, E)$, two elimination trees T_{ini} and T_{tar}, and a weight function $w\colon V \to \mathbb{Z}_{>0}$. For $u, v \in V$, the *weight* of $\mathbf{swap}(u, v)$ is defined as $w(u) \cdot w(v)$. This value is sometimes denoted by $w(\mathbf{swap}(u, v))$. The *weighted length* (or simply the *weight*) of a reconfiguration sequence $\mathbf{T}$ is defined as the total weight of swaps in $\mathbf{T}$, which we denote by $\mathrm{length}_w(\mathbf{T})$. The objective of Weighted Combinatorial Shortest Path on Graph Associahedra is to find a reconfiguration sequence $\mathbf{T}$ from T_{ini} to T_{tar} that minimizes $\mathrm{length}_w(\mathbf{T})$.

In this section, we show that the weighted variant is strongly NP-hard.

▶ **Theorem 3.** *Weighted Combinatorial Shortest Path on Graph Associahedra is strongly* NP*-hard, that is, it is* NP*-hard even when the input size is* $\sum_{v \in V} w(v)$.

3.1 Reduction

To show Theorem 3, we reduce Balanced Minimum s-t Cut to Weighted Combinatorial Shortest Path on Graph Associahedra. In Balanced Minimum s-t Cut, the input consists of a connected graph $G = (V, E)$ with $s, t \in V$, and the objective is to determine whether G contains a minimum s-t cut X with $|X| = |V \setminus X|$. Without loss of generality, we may assume that $|V|$ is even. Let $V = \{s, t, v_1, v_2, \ldots, v_{2n}\}$ and $E = \{e_1, \ldots, e_m\}$, where $|V| = 2n + 2$ and $|E| = m$. It is known that Balanced Minimum s-t Cut is NP-hard [14]. For an instance of Balanced Minimum s-t Cut, we construct an instance of Weighted Combinatorial Shortest Path on Graph Associahedra as follows.

Let N be a sufficiently large integer (e.g., $N = 10n^3m$). We first subdivide each edge $e \in E$ by introducing a new vertex u_e. Then, for each $v \in V$, we introduce a copy v' of v. We replace s with a clique $\{s_1, \ldots, s_{N^3}\}$ of size N^3 and replace t with another clique $\{t_1, \ldots, t_{N^3}\}$ of size N^3. Let H be the obtained graph. Formally, the graph $H = (V(H), E(H))$ is defined as follows:

$$
\begin{aligned}
V(H) &= (V \setminus \{s, t\}) \cup \{v' \mid v \in V\} \cup \{u_e \mid e \in E\} \cup \{s_1, \ldots, s_{N^3}\} \cup \{t_1, \ldots, t_{N^3}\},\\
E(H) &= \{\{v, u_e\} \mid v \in V \setminus \{s, t\},\ e \in \delta_G(v)\} \cup \{\{v', u_e\} \mid v \in V,\ e \in \delta_G(v)\}\\
&\quad \cup \{\{s_i, s_j\} \mid i, j \in [N^3],\ i \neq j\} \cup \{\{t_i, t_j\} \mid i, j \in [N^3],\ i \neq j\}\\
&\quad \cup \{\{s_i, u_e\} \mid i \in [N^3],\ e \in \delta_G(s)\} \cup \{\{t_i, u_e\} \mid i \in [N^3],\ e \in \delta_G(t)\}.
\end{aligned}
$$

Define $w\colon V(H) \to \mathbb{Z}_{>0}$ as follows:

$$
\begin{aligned}
w(v) &= N && (v \in V \setminus \{s, t\}),\\
w(v') &= N^8 && (v \in V),\\
w(u_e) &= 1 && (e \in E),\\
w(s_i) &= w(t_i) = N^4 && (i \in [N^3]).
\end{aligned}
$$

The initial elimination tree T_{ini} is defined by the following linear ordering:

$$
\begin{aligned}
&v_1 \prec \cdots \prec v_{2n} \prec s_1 \prec t_1 \prec s_2 \prec t_2 \prec \cdots \prec s_{N^3} \prec t_{N^3}\\
&\quad \prec u_{e_1} \prec \cdots \prec u_{e_m} \prec v'_1 \prec \cdots \prec v'_{2n} \prec s' \prec t'.
\end{aligned}
$$

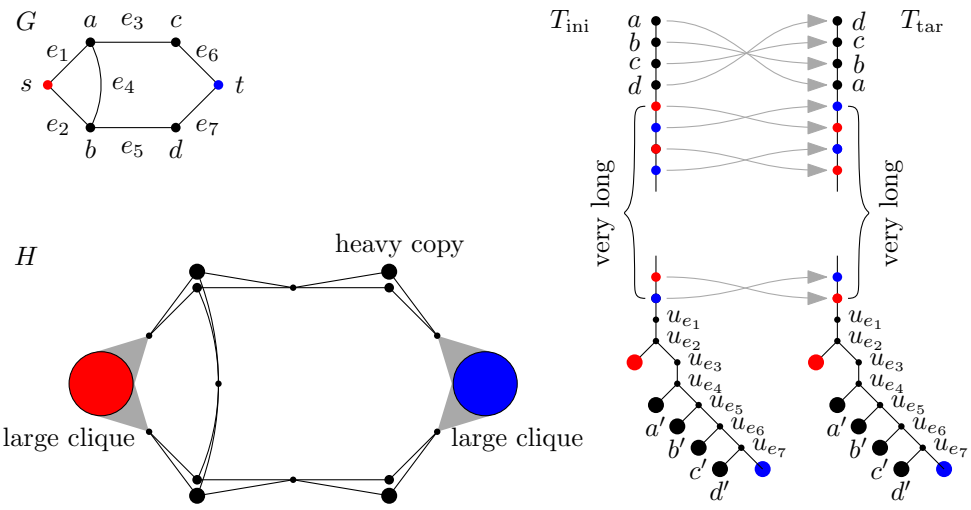

Figure 3 Reduction for Theorem 3.

Note that, in T_{ini}, the vertices $v_1, \ldots, v_{2n}, s_1, t_1, s_2, t_2, \ldots, s_{N^3}, t_{N^3}$ are aligned on a path, while the other elements are not necessarily aligned sequentially. The target elimination tree T_{tar} is the elimination tree defined by the following linear ordering:

$$v_{2n} \prec \cdots \prec v_1 \prec t_1 \prec s_1 \prec t_2 \prec s_2 \prec \cdots \prec t_{N^3} \prec s_{N^3} \\ \prec u_{e_1} \prec \cdots \prec u_{e_m} \prec v'_1 \prec \cdots \prec v'_{2n} \prec s' \prec t'.$$

We consider an instance $(H, w, T_{\mathrm{ini}}, T_{\mathrm{tar}})$ of Weighted Combinatorial Shortest Path on Graph Associahedra. In this instance, we reverse the ordering of the first $2n$ elements and reverse the ordering of s_i and t_i for each i. See Figure 3 for an illustration.

To prove Theorem 1, it suffices to show the following proposition.

▶ **Proposition 4.** *Let λ be the minimum size of an s-t cut set in G. There is a reconfiguration sequence from T_{ini} to T_{tar} of weight less than $4\lambda N^7 + (n^2 - n + 1)N^2$ if and only if G has a minimum s-t cut X with $|X| = |V \setminus X|$.*

3.2 Proof of Proposition 4

Sufficiency ("if" part)

Suppose that G has a minimum s-t cut X with $|X| = |V \setminus X| = n + 1$. Let $U = \{u_e \mid e \in \delta_G(X)\}$. Note that $|U| = |\delta_G(X)| = \lambda$. Starting from T_{ini}, we swap an element in U and its parent repeatedly so that we obtain an elimination tree T_1 in which each element in U is an ancestor of $V(H) \setminus U$. See Figure 4. The total weight of swaps from T_{ini} to T_1 is at most $|U|(2nN + 2N^7 + m)$. Since $G - \delta_G(X)$ consists of two connected components, so does $H - U$. Thus, $T_1 - U$ consists of two elimination trees T_s and T_t such that T_s contains $(X \setminus \{s\}) \cup \{s_1, \ldots, s_{N^3}\} \cup \{u_e \mid e \in E[X]\} \cup \{v' \mid v \in X\}$ and T_t contains $((V \setminus X) \setminus \{t\}) \cup \{t_1, \ldots, t_{N^3}\} \cup \{u_e \mid e \in E[V \setminus X]\} \cup \{v' \mid v \in V \setminus X\}$.

In T_s, by swapping u and v for every pair of $u, v \in X \setminus \{s\}$, we obtain an elimination tree in which v_i is an ancestor of v_j for $v_i, v_j \in X \setminus \{s\}$ with $i > j$. The total weight of these swaps is $\binom{|X|-1}{2} \cdot N^2$. Similarly, by applying swaps with weight $\binom{|V \setminus X|-1}{2} \cdot N^2$ to T_t, we obtain an elimination tree in which v_i is an ancestor of v_j for $v_i, v_j \in (V \setminus X) \setminus \{t\}$ with $i > j$. Let T_2 be the elimination tree obtained from T_1 by applying these operations.

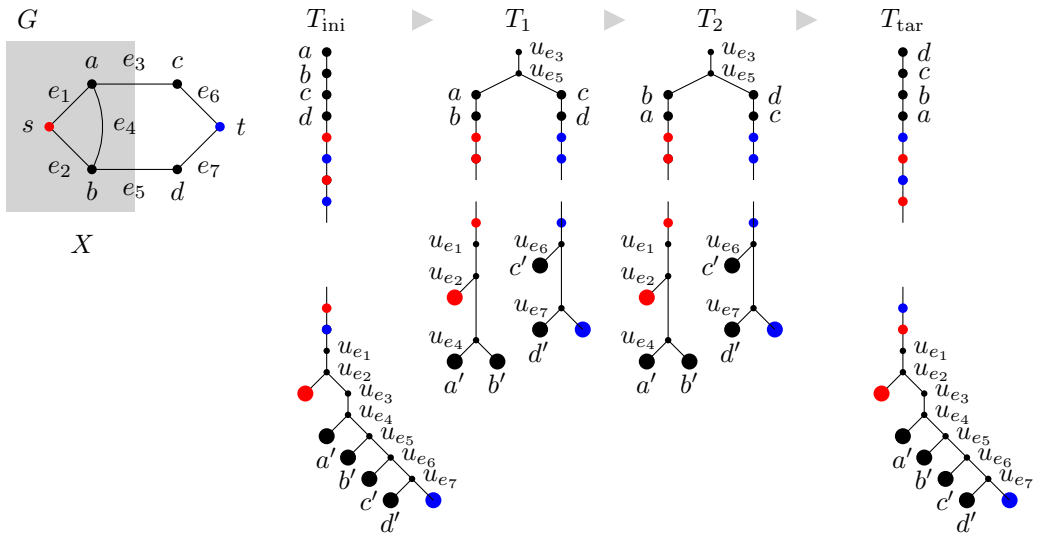

Figure 4 A reconfiguration sequence from T_{ini} to T_{tar}.

Starting from T_2, we swap an element in U and its child repeatedly so that we obtain an elimination tree T_{tar}. This can be done by applying swaps whose total weight is at most $|U|(2nN + 2N^7 + m)$.

Therefore, the total weight of the above swaps from T_{ini} to T_{tar} is at most

$$\begin{aligned} &2|U|(2nN + 2N^7 + m) + \binom{|X| - 1}{2} \cdot N^2 + \binom{|V \setminus X| - 1}{2} \cdot N^2 \\ &\quad = 4\lambda N^7 + n(n-1)N^2 + 4\lambda nN + 2\lambda m \\ &\quad < 4\lambda N^7 + (n^2 - n + 1)N^2, \end{aligned}$$

where we note that $|U| = \lambda$ and $|X| = |V \setminus X| = n + 1$. This shows the sufficiency.

Necessity ("only if" part)

Let $\mathbf{T}$ be a reconfiguration sequence from T_{ini} to T_{tar} whose weight is less than $4\lambda N^7 + (n^2 - n + 1)N^2$. Since this weight is less than N^8, we observe the following.

▶ **Observation 5.** *For $v \in V$, vertex v' is not swapped with other vertices in $\mathbf{T}$. For $i, j \in [N^3]$, none of $\mathbf{swap}(s_i, s_j)$, $\mathbf{swap}(t_i, t_j)$, $\mathbf{swap}(s_i, t_j)$, and $\mathbf{swap}(t_i, s_j)$ is applied in $\mathbf{T}$.*

By Observation 5, we cannot swap s_1 and t_1 directly, and hence $\mathbf{T}$ contains an elimination tree T^* in which s_1 and t_1 are incomparable. Then, there exists a vertex set $V^* \subseteq V(H)$ such that s_1 and t_1 are contained in different connected components of $H - V^*$, and each vertex in V^* is an ancestor of s_1 and t_1 in T^*. By Observation 5 again, V^* does not contain v' for $v \in V$, that is, $V^* \subseteq V \cup \{u_e \mid e \in E\}$. Note that removing $V^* \cap V$ does not affect the connectedness of H since each vertex $v \in V^* \cap V$ has its copy v' in H. Let

$$F := \{e \in E \mid u_e \in V^*\}.$$

Then, s and t are contained in different connected components of $G - F$, i.e., F contains an s-t cut set in G.

Since removing V does not affect the connectedness of H, we also observe the following.

▶ **Observation 6.** *Let T and T' be elimination trees in $\mathbf{T}$ and let $e_1, e_2 \in E$ be distinct edges. If $u_{e_1} \in \mathbf{anc}_T(u_{e_2})$ and $u_{e_2} \in \mathbf{anc}_{T'}(u_{e_1})$, then $\mathbf{swap}(u_{e_3}, u_{e_4})$ is applied for some $e_3, e_4 \in E$ (possibly $\{e_1, e_2\} \cap \{e_3, e_4\} \neq \emptyset$) between T and T'.*

We divide $\mathbf{T}$ into two reconfiguration sequences $\mathbf{T}_1$ and $\mathbf{T}_2$, where $\mathbf{T}_1$ is from T_{ini} to T^* and $\mathbf{T}_2$ is from T^* to T_{tar}. By symmetry, we may assume that

$$\mathrm{length}_w(\mathbf{T}_1) \leq \frac{\mathrm{length}_w(\mathbf{T})}{2} < 2\lambda N^7 + N^3.$$

For $i \in [N^3]$, define

$$L_i = \{e \in E \mid \mathbf{swap}(u_e, s_i) \text{ is applied in } \mathbf{T}_1\},$$
$$R_i = \{e \in E \mid \mathbf{swap}(u_e, t_i) \text{ is applied in } \mathbf{T}_1\}.$$

For $i \in [N^3]$, let $\mathbf{swap}(L_i)$ denote the set of all swaps $\mathbf{swap}(u_e, s_i)$ in $\mathbf{T}_1$ with $e \in L_i$. Similarly, let $\mathbf{swap}(R_i)$ denote the set of all swaps $\mathbf{swap}(u_e, t_i)$ in $\mathbf{T}_1$ with $e \in R_i$.

▷ Claim 7. For $i \in [N^3]$, we have the following:
- if an edge $e \in E$ is contained in the connected component of $G - L_i$ containing s, then $u_e \in \mathbf{des}_T(s_i)$ for any elimination tree T in $\mathbf{T}_1$, and
- if an edge $e \in E$ is contained in the connected component of $G - R_i$ containing t, then $u_e \in \mathbf{des}_T(t_i)$ for any elimination tree T in $\mathbf{T}_1$.

Proof. For each edge $e \in E$ in the connected component of $G - L_i$ containing s, vertices s_i and u_e are contained in the same connected component in $H - \{u_f \mid f \in L_i\}$. Since $u_e \in \mathbf{des}_{T_{\mathrm{ini}}}(s_i)$ holds and $\mathbf{swap}(u_e, s_i)$ is not applied in $\mathbf{T}_1$ as $e \notin L_i$, we have that $u_e \in \mathbf{des}_T(s_i)$ for any elimination tree T in $\mathbf{T}_1$. The same argument works for the second statement. ◁

To simplify the notation, let $L_0 = R_0 = F$. For $i \in [N^3] \cup \{0\}$, let $X_i \subseteq V$ be the vertex set of the connected component of $G - L_i$ containing s. Similarly, let $Y_i \subseteq V$ be the vertex set of the connected component of $G - R_i$ containing t.

▷ Claim 8. For $i, j \in [N^3] \cup \{0\}$ with $j > i$, we have the following:
(i) $(E[X_j] \setminus L_j) \cap L_i = \emptyset$, and
(ii) $(E[Y_j] \setminus R_j) \cap R_i = \emptyset$.

Proof. To show (i), assume to the contrary that there exists $e \in (E[X_j] \setminus L_j) \cap L_i$ for some $j > i$. Note that $j \in [N^3]$. Since $e \in E[X_j] \setminus L_j$, Claim 7 shows that $u_e \in \mathbf{des}_T(s_j)$ for any elimination tree T in $\mathbf{T}_1$. If $i \geq 1$, then since $u_e \in \mathbf{des}_T(s_j)$ and $s_i \in \mathbf{anc}_T(s_j)$, we see that u_e and s_i are not adjacent in T. This implies that $\mathbf{swap}(u_e, s_i)$ is not applied in $\mathbf{T}_1$, which contradicts $e \in L_i$. If $i = 0$, then $e \in L_0 = F$ implies that $u_e \in \mathbf{anc}_{T^*}(s_1) \subseteq \mathbf{anc}_{T^*}(s_j)$, which contradicts $u_e \in \mathbf{des}_T(s_j)$ for any T. The same argument works for (ii). ◁

▷ Claim 9. $X_0 \supseteq X_1 \supseteq X_2 \supseteq \cdots \supseteq X_{N^3}$ and $Y_0 \supseteq Y_1 \supseteq Y_2 \supseteq \cdots \supseteq Y_{N^3}$.

Proof. Let $i, j \in [N^3] \cup \{0\}$ be indices with $j > i$. Since $(E[X_j] \setminus L_j) \cap L_i = \emptyset$ by Claim 8 (i), all vertices in X_j are contained in the same connected component of $G - L_i$. Since both X_i and X_j contain s, we obtain $X_j \subseteq X_i$. This shows that $X_0 \supseteq X_1 \supseteq X_2 \supseteq \cdots \supseteq X_{N^3}$. Similarly, we obtain $Y_0 \supseteq Y_1 \supseteq Y_2 \supseteq \cdots \supseteq Y_{N^3}$. ◁

▷ Claim 10. For $i \in [N^3]$, we have $|L_i| = |R_i| = \lambda$, $L_i = \delta_G(X_i)$, and $R_i = \delta_G(Y_i)$.

Proof. Since F contains an s-t cut set, it holds that $X_0 \subseteq V \setminus \{t\}$. For $i \geq 1$, since $s \in X_i \subseteq X_0 \subseteq V \setminus \{t\}$ by Claim 9, we see that $\delta_G(X_i)$ is an s-t cut set contained in L_i. Similarly, R_i contains an s-t cut set in G. Therefore, we obtain $|L_i|, |R_i| \geq \lambda$ for any $i \in [N^3]$. By considering the weight of $\mathbf{T}_1$, we obtain

$$\begin{aligned} 2\lambda N^7 + N^3 &> \mathrm{length}_w(\mathbf{T}_1) \\ &\geq \sum_{i=1}^{N^3} (w(s_i)|L_i| + w(t_i)|R_i|) \\ &= 2\lambda N^7 + N^4 \sum_{i=1}^{N^3} ((|L_i| - \lambda) + (|R_i| - \lambda)), \end{aligned}$$

which shows that $|L_i| = |R_i| = \lambda$ for any $i \in [N^3]$. Therefore, each of L_i and R_i is a minimum s-t cut set in G, and hence $L_i = \delta_G(X_i)$ and $R_i = \delta_G(Y_i)$ hold. ◁

Since the total weight of $\mathbf{swap}(L_i)$ and $\mathbf{swap}(R_i)$ is at least $2\lambda N^7$ by this claim, we see that u_e and s_i (resp. t_i) are swapped exactly once in $\mathbf{T}_1$ for $e \in L_i$ (resp. $e \in R_i$) and for $i \in [N^3]$. For $i \in [N^3]$, let T_i (resp. T'_i) be the elimination tree that appears in $\mathbf{T}_1$ after all the swaps in $\mathbf{swap}(L_i)$ (resp. $\mathbf{swap}(R_i)$) are just applied.

▷ Claim 11. Elimination trees $T'_{N^3}, T_{N^3}, T'_{N^3-1}, T_{N^3-1}, \ldots, T'_1, T_1$ appear in this order in $\mathbf{T}_1$.

Proof. We first show that T_i appears after T'_i for $i \in [N^3]$. Let $e \in R_i$ be the edge such that $\mathbf{swap}(u_e, t_i)$ is applied just before obtaining T'_i. Ler $f \in L_i \setminus (R_i \setminus \{e\})$, where the existence of such f is guaranteed by $|L_i| = |R_i|$. Since R_i is a minimum s-t cut set by Claim 10, we see that $G - (R_i \setminus \{e\})$ is connected. Then, for any elimination tree T before T'_i, we have $u_{e'} \in \mathbf{des}_T(t_i)$ for any $e' \in E \setminus (R_i \setminus \{e\})$. In particular, $u_f \in \mathbf{des}_T(t_i)$. Since $s_i \in \mathbf{anc}_T(t_i)$, we see that u_f and s_i are not adjacent in T. This shows that we cannot apply $\mathbf{swap}(u_f, s_i)$ before T'_i. Therefore, T_i appears after T'_i in $\mathbf{T}_1$.

By the same argument, we can show that T'_i appears after T_{i+1} for $i \in [N^3 - 1]$. Therefore, T'_{N^3}, T_{N^3}, T'_{N^3-1}, $T_{N^3-1}, \ldots, T'_1$, T_1 appear in this order. ◁

▷ Claim 12. For $i \in [N^3]$, we have the following:

- $u_e \in \mathbf{anc}_{T_i}(u_{e'})$ for any $e \in L_i$ and $e' \in E \setminus L_i$, and
- $u_e \in \mathbf{anc}_{T'_i}(u_{e'})$ for any $e \in R_i$ and $e' \in E \setminus R_i$.

Proof. Let T be an elimination tree in $\mathbf{T}_1$ just before T_i. Then, there exists an edge $f \in L_i$ such that T_i is obtained from T by applying $\mathbf{swap}(u_f, s_i)$. Since $G - (L_i \setminus \{f\})$ is connected by Claim 10, we have $u_e \in \mathbf{anc}_T(s_i)$ for $e \in L_i \setminus \{f\}$ and $u_{e'} \in \mathbf{des}_T(s_i)$ for $e' \in E \setminus (L_i \setminus \{f\})$. Therefore, after applying $\mathbf{swap}(u_f, s_i)$, we obtain $u_e \in \mathbf{anc}_{T_i}(f)$ for $e \in L_i \setminus \{f\}$ and $u_{e'} \in \mathbf{des}_{T_i}(f)$ for $e' \in E \setminus L_i$. This shows that $u_e \in \mathbf{anc}_{T_i}(u_{e'})$ for any $e \in L_i$ and $e' \in E \setminus L_i$. By the same argument, we obtain $u_e \in \mathbf{anc}_{T'_i}(u_{e'})$ for any $e \in R_i$ and $e' \in E \setminus R_i$. ◁

▷ Claim 13. $X_1 = V \setminus Y_1$.

Proof. Observe that X_0 and Y_0 are disjoint since $F = L_0 = R_0$ contains an s-t cut set in G. Since $X_1 \subseteq X_0$ and $Y_1 \subseteq Y_0$ by Claim 9, we see that X_1 and Y_1 are disjoint. To derive a contradiction, assume that $X_1 \neq V \setminus Y_1$, that is, X_1 and Y_1 are disjoint sets with $X_1 \cup Y_1 \subsetneq V$. Then, by Claim 9, we obtain $X_i \neq V \setminus Y_i$ for any $i \in [N^3]$. This shows that $L_i \neq R_i$ for any $i \in [N^3]$. Since $|L_i| = |R_i| = \lambda$, there exist $f_i \in L_i \setminus R_i$ and $f'_i \in R_i \setminus L_i$. By Claim 12, we

obtain $u_{f_i} \in \mathbf{anc}_{T_i}(u_{f'_i})$ and $u_{f'_i} \in \mathbf{anc}_{T'_i}(u_{f_i})$. By Observation 6, $\mathbf{swap}(u_e, u_{e'})$ is applied for some $e, e' \in E$ between T'_i and T_i. Since such a swap is required for each $i \in [N^3]$, by Claim 11, we have to swap pairs in $\{u_e \mid e \in E\}$ at least N^3 times in $\mathbf{T}_1$. Therefore, we obtain

$$\mathrm{length}_w(\mathbf{T}_1) \geq \sum_{i=1}^{N^3} (w(s_i)|L_i| + w(t_i)|R_i|) + N^3 = 2\lambda N^7 + N^3,$$

which contradicts $\mathrm{length}_w(\mathbf{T}_1) < 2\lambda N^7 + N^3$. ◁

▷ Claim 14. $F = \delta_G(X_1) = \delta_G(Y_1)$.

Proof. Claims 10 and 13 show that $L_1 = R_1 = \delta_G(X_1) = \delta_G(Y_1)$. This together with Claim 8 shows that $F \cap E[X_1] = F \cap E[Y_1] = \emptyset$. Since F contains an s-t cut set in G, we obtain $F = \delta_G(X_1) = \delta_G(Y_1)$. ◁

▷ Claim 15. Let T be an elimination tree in $\mathbf{T}_1$. If two vertices $u, v \in V \setminus \{s, t\}$ are contained in the same connected component in $G - F$, then u and v are comparable in T.

Proof. By Claim 14, $G - F$ consists of two connected components $G[X_1]$ and $G[Y_1]$. We first consider the case when $u, v \in X_1 \setminus \{s\}$. By Claims 7 and 14, we obtain $u_e \in \mathbf{des}_T(s_1)$ for any $e \in E[X_1]$. Furthermore, since $\mathrm{length}_w(\mathbf{T}_1) < 2\lambda N^7 + N^3$ holds and the total weight of $\mathbf{swap}(L_i)$ and $\mathbf{swap}(R_i)$ is $2\lambda N^7$, neither $\mathbf{swap}(s_1, u)$ nor $\mathbf{swap}(s_1, v)$ is applied in $\mathbf{T}_1$, because $w(s_1)w(u) = w(s_1)w(v) = N^5$. Therefore, we obtain $u \in \mathbf{anc}_T(s_1)$ and $v \in \mathbf{anc}_T(s_1)$, which shows that u and v are comparable in T. The same argument works when $u, v \in Y_1 \setminus \{t\}$. ◁

Since the weight of $\mathbf{T}_1$ is at least $\sum_{i=1}^{N^3}(w(s_i)|L_i| + w(t_i)|R_i|) = 2\lambda N^7$, we obtain

$$\mathrm{length}_w(\mathbf{T}_2) = \mathrm{length}_w(\mathbf{T}) - \mathrm{length}_w(\mathbf{T}_1) < 2\lambda N^7 + N^3.$$

Hence, the above argument (Claims 7–15) can be applied also to the reverse sequence of $\mathbf{T}_2$. In particular, Claim 15 holds even if $\mathbf{T}_1$ is replaced with $\mathbf{T}_2$. Therefore, if two vertices $u, v \in V \setminus \{s, t\}$ are contained in the same connected component in $G - F$, then u and v are comparable in any elimination tree in $\mathbf{T}$. For such a pair of vertices u and v, the only way to reverse the ordering of u and v is to apply $\mathbf{swap}(u, v)$ or $\mathbf{swap}(v, u)$.

Recall that $G - F$ consists of two connected components $G[X_1]$ and $G[Y_1]$ by Claim 14. Since the ordering of $v_1, \ldots, v_{2n}$ are reversed from T_{ini} to T_{tar}, we see that $\mathbf{swap}(u, v)$ or $\mathbf{swap}(v, u)$ has to be applied in $\mathbf{T}$ if $u, v \in X_1 \setminus \{s\}$ or $u, v \in Y_1 \setminus \{t\} = (V \setminus X_1) \setminus \{t\}$. Furthermore, we have to swap some elements in $\{u_e \mid e \in E\}$ and $\{s_1, t_1, \ldots, s_{N^3}, t_{N^3}\}$ in $\mathbf{T}_2$, whose total weight is at least $2\lambda N^7$ in the same way as $\mathbf{T}_1$. With these observations, we evaluate the weight of $\mathbf{T}$ as follows, where we denote $k = |X_1|$ to simplify the notation:

$$\begin{aligned}
\mathrm{length}_w(\mathbf{T}) &\geq 2\lambda N^7 + 2\lambda N^7 + \binom{|X_1| - 1}{2} \cdot N^2 + \binom{|V \setminus X_1| - 1}{2} \cdot N^2 \\
&= 4\lambda N^7 + \frac{(k-1)(k-2)}{2} N^2 + \frac{(2n-k+1)(2n-k)}{2} N^2 \\
&= 4\lambda N^7 + (k^2 - 2(n+1)k + 2n^2 + n + 1)N^2 \\
&= 4\lambda N^7 + (n^2 - n)N^2 + (k - n - 1)^2 N^2.
\end{aligned}$$

This together with $\mathrm{length}_w(\mathbf{T}) < 4\lambda N^7 + (n^2 - n + 1)N^2$ shows that $(k - n - 1)^2 < 1$, and hence $k = n + 1$ by the integrality of k and n.

Therefore, we obtain $|X_1| = k = n + 1$ and $|Y_1| = |V \setminus X_1| = n + 1$. Since $|\delta_G(X_1)| = |L_1| = \lambda$, this shows that X_1 is a desired s-t cut in G.

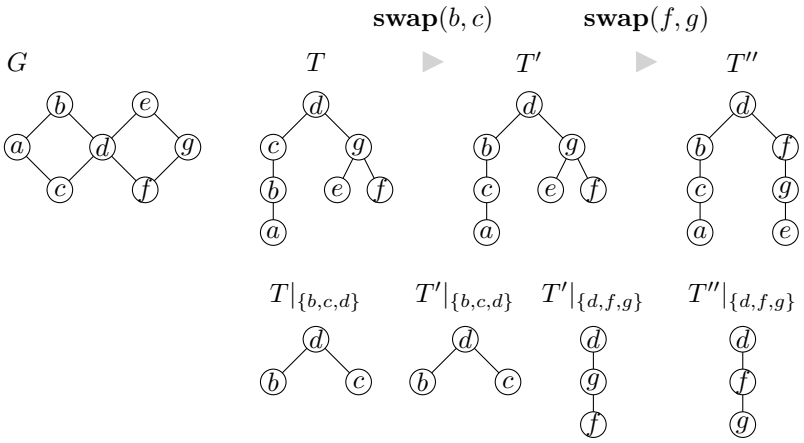

Figure 5 An example of projections. Note that $T|_{\{b,c,d\}} = T'|_{\{b,c,d\}}$ since b and c are incomparable in $T|_{\{b,c,d\}}$, and $T''|_{\{d,f,g\}}$ is obtained from $T'|_{\{d,f,g\}}$ by swapping f and g since f and g are adjacent in $T'|_{\{d,f,g\}}$.

4 Hardness of the Unweighted Problem (Proof of Theorem 1)

To show Theorem 1, we reduce Weighted Combinatorial Shortest Path on Graph Associahedra to Combinatorial Shortest Path on Graph Associahedra. An operation called *projection* (e.g. [6]) plays an important role in our validity proof.

4.1 Useful Operation: Projection

Let $G = (V, E)$ be a graph and let T be an elimination tree associated with G. For $U \subseteq V$ such that $G[U]$ is connected, let $T|_U$ be the elimination tree associated with $G[U]$ that preserves the ordering in T. That is, $u \in \mathbf{anc}_{T|_U}(v)$ if and only if $u \in \mathbf{anc}_T(v)$ and u are v are connected in $G[U] - \mathbf{anc}_T(u)$ for $u, v \in U$. Note that such $T|_U$ is uniquely determined. We call $T|_U$ the *projection* of T to U. See Figure 5 for illustration.

▶ **Lemma 16.** *Let $U \subseteq V$ be a vertex set such that $G[U]$ is connected. Let T and T' be elimination trees associated with G such that T' is obtained from T by applying* $\mathbf{swap}(u, v)$*, where $u, v \in V$.*

1. *If $\{u, v\} \subseteq U$, then either $T'|_U = T|_U$ or $T'|_U$ is obtained from $T|_U$ by applying* $\mathbf{swap}(u, v)$*.*
2. *Otherwise, $T'|_U = T|_U$.*

Proof. Since all the vertices in $V \setminus U$ are removed when we construct $T|_U$, $\mathbf{swap}(u, v)$ affects $T|_U$ only if $\{u, v\} \subseteq U$, which proves the second item. For the first item, suppose that $\{u, v\} \subseteq U$. Then, u and v are adjacent or incomparable in $T|_U$. If they are adjacent, then $T'|_U$ is obtained from $T|_U$ by applying $\mathbf{swap}(u, v)$. If they are incomparable, then $T'|_U = T|_U$. ◀

4.2 Reduction

Suppose we are given a graph $G = (V, E)$, two elimination trees T_{ini} and T_{tar}, and a weight function $w\colon V \to \mathbb{Z}_{>0}$, which form an instance of Weighted combinatorial Shortest Path on Graph Associahedra. Then, we replace each vertex $v \in V$ with a clique of size $w(v)$. Formally, consider a graph $G' = (V', E')$ such that $V' = \{v_i \mid v \in V,\ i \in \{1, \ldots, w(v)\}\}$,

and $\{u_i, v_j\} \in E'$ if $\{u, v\} \in E$ or $u = v$. Let T'_{ini} (resp. T'_{tar}) be the elimination tree obtained from T_{ini} (resp. T_{tar}) by replacing a vertex $v \in V$ with a path $v_1, v_2, \ldots, v_{w(v)}$. That is, for distinct $u, v \in V$, there is an arc (u, v) in T_{ini} (resp. T_{tar}) if and only if $(u_{w(u)}, v_1)$ is an arc of T'_{ini} (resp. T'_{tar}). Note that the obtained elimination tree is associated with G'. This defines an instance of Combinatorial Shortest on Graph Associahedra.

4.3 Validity

In what follows, we show that the obtained instance of Combinatorial Shortest Path on Graph Associahedra has a reconfiguration sequence of length at most ℓ if and only if the original instance of Weighted Combinatorial Shortest Path on Graph Associahedra has a reconfiguration sequence $\mathbf{T}$ with $\mathrm{length}_w(\mathbf{T}) \leq \ell$.

Sufficiency ("if" part)

Suppose that the original instance of Weighted Combinatorial Shortest Path on Graph Associahedra has a reconfiguration sequence $\mathbf{T}$ from T_{ini} to T_{tar}. Then, we construct a reconfiguration sequence $\mathbf{T}'$ from T'_{ini} to T'_{tar} by replacing each swap $\mathbf{swap}(u, v)$ in $\mathbf{T}$ with $w(u) \cdot w(v)$ swaps $\{\mathbf{swap}(u_i, v_j) \mid i \in [w(u)],\ j \in [w(v)]\}$. This gives a reconfiguration sequence from T'_{ini} to T'_{tar} whose length is $\mathrm{length}_w(\mathbf{T})$, which shows the sufficiency.

Necessity ("only if" part)

Suppose that the obtained instance of Combinatorial Shortest Path on Graph Associahedra has a reconfiguration sequence $\mathbf{T}'$ from T'_{ini} to T'_{tar} of length at most ℓ. For any $v \in V$, since $v_1, \ldots, v_{w(v)}$ form a clique, they are comparable in any elimination tree in $\mathbf{T}'$. Furthermore, since $v_1, \ldots, v_{w(v)}$ are aligned in this order in both T'_{ini} and T'_{tar}, we may assume that $\mathbf{swap}(v_i, v_j)$ is not applied in $\mathbf{T}'$ for any $i, j \in [w(v)]$.

Let Φ be the set of all maps $\phi\colon V \to \mathbb{Z}$ such that $\phi(v) \in \{1, \ldots, w(v)\}$ for any $v \in V$. Note that $|\Phi| = \prod_{v \in V} w(v)$. For $\phi \in \Phi$, define $U_\phi = \{v_{\phi(v)} \mid v \in V\}$. Note that $G'[U_\phi]$ is isomorphic to G, and hence it is connected. By projecting each elimination tree in $\mathbf{T}'$ to U_ϕ, we obtain a sequence of elimination trees. Lemma 16 shows that this forms a reconfiguration sequence, say $\mathbf{T}_\phi$, if we remove duplications when the same elimination tree appears consecutively. Since $G'[U_\phi]$ is isormorphic to G, by idenfitying $v_{\phi(v)}$ with v for each $v \in V$, we can regard $\mathbf{T}_\phi$ as a recofiguration sequence from T_{ini} to T_{tar}. That is, $\mathbf{T}_\phi$ is regarded as a feasible solution of the original instance of Weighted Combinatorial Shortest Path on Graph Associahedra.

In what follows, we consider reconfiguration sequences $\{\mathbf{T}_\phi \mid \phi \in \Phi\}$ and show that a desired sequence exists among them. Suppose that $\mathbf{swap}(u_i, v_j)$ is applied in $\mathbf{T}'$, where $u, v \in V$, $i \in [w(u)]$, and $j \in [w(v)]$. Then, Lemma 16 shows that the corresponding swap operation $\mathbf{swap}(u_i, v_j)$, which is identified with $\mathbf{swap}(u, v)$, is applied in $\mathbf{T}_\phi$ only if $\phi(u) = i$ and $\phi(v) = j$. Thus, such a swap is applied in at most $|\{\phi \in \Phi \mid \phi(u) = i,\ \phi(v) = j\}| = |\Phi|/(w(u) \cdot w(v))$ sequences in $\{\mathbf{T}_\phi \mid \phi \in \Phi\}$. Therefore, we obtain

$$\begin{aligned}
\sum_{\phi \in \Phi} \mathrm{length}_w(\mathbf{T}_\phi) &= \sum_{\phi \in \Phi} \sum_{\mathbf{swap}(u,v) \in \mathbf{T}_\phi} w(\mathbf{swap}(u, v)) \\
&\leq \sum_{\mathbf{swap}(u_i, v_j) \in \mathbf{T}'} w(\mathbf{swap}(u, v)) \cdot \frac{|\Phi|}{w(u) \cdot w(v)} \\
&= \mathrm{length}(\mathbf{T}') \cdot |\Phi| \leq \ell \cdot |\Phi|,
\end{aligned}$$

where each reconfiguration sequence is regarded as a multiset of swaps. Therefore,

$$\min_{\phi\in\Phi}(\mathrm{length}_w(\mathbf{T}_\phi)) \leq \frac{1}{|\Phi|}\sum_{\phi\in\Phi}\mathrm{length}_w(\mathbf{T}_\phi) \leq \ell.$$

Hence, there exists $\phi \in \Phi$ such that $\mathbf{T}_\phi$ is a desired sequence. This shows the necessity.

Therefore, the weighted problem can be reduced to the unweighted problem, and hence Theorem 3 implies Theorem 1.

5 Hardness for Polymatroids (Proof of Theorem 2)

In this section, we give a proof sketch of Theorem 2.

We reduce Combinatorial Shortest Path on Graph Associahedra to Combinatorial Shortest Path on Polymatroids. Assume that we are given an instance $G = (V, E)$, T_{ini}, and T_{tar} of Combinatorial Shortest Path on Graph Associahedra. To this end, we construct a polymatroid (V, f) satisfying the following conditions.

1. $\mathbf{B}(f)$ is a realization of the G-associahedron.
2. For each subset $X \subseteq V$, we can evaluate the value $f(X)$ in time bounded by a polynomial in the size of G.
3. We can find the extreme points $x_{\mathrm{ini}}, x_{\mathrm{tar}}$ of $\mathbf{B}(f)$ corresponding to $T_{\mathrm{ini}}, T_{\mathrm{tar}}$, respectively, in time bounded by a polynomial in the size of G.

We first argue that the conditions above suffice for our proof. Suppose the existence of a polymatroid (V, f) with the properties above. Then, we may construct a polynomial-time algorithm for Combinatorial Shortest Path on Graph Associahedra with a fictitious polynomial-time algorithm for Combinatorial Shortest Path on Polymatroids as follows. Let $(G, T_{\mathrm{ini}}, T_{\mathrm{tar}})$ be an instance of Combinatorial Shortest Path on Graph Associahedra. From Properties 1 and 3, we can construct an instance $((V, f), x_{\mathrm{ini}}, x_{\mathrm{tar}})$ of Combinatorial Shortest Path on Polymatroids in polynomial time. By the fictitious polynomial-time algorithm, we can solve the instance in time bounded by a polynomial in $|V|$ and the number of oracle calls to f. By Property 2, this running time is bounded by a polynomial in $|V|$. Thus, we find a solution to $(G, T_{\mathrm{ini}}, T_{\mathrm{tar}})$ in polynomial time, and the proof is completed.

In our construction of such a polymatroid (V, f), we use the realization of the G-associahedron by Devadoss [12], which can be described as follows. Let T be an elimination tree of G. For each vertex $v \in V$, we define $T(v)$ as the vertex set of the subtree of T rooted at v. Then, we define the vector $x^T \in \mathbb{R}^V$ by choosing the coordinate $x^T(v)$ at every vertex of v from the leaves to the root according to the following rule.

- If v is a leaf of T, then we define $x^T(v) := 0$.
- If v is not a leaf of T, then we define $x^T(v)$ so that

$$\sum_{u\in T(v)} x^T(u) = 3^{|T(v)|-2}.$$

Define $\mathcal{E} := \{x^T \mid T \text{ is an elimination tree of } G\}$. Then, Devadoss [12] proved that the convex hull of $\mathcal{E}$ is a realization of the G-associahedron, and for each elimination tree T of G, the point x^T is an extreme point of the G-associahedron.

In our proof, we define the function $f\colon 2^V \to \mathbb{R}$ by

$$f(X) := 3^{|V|-2} - \sum_{C \in \mathcal{C}^*(X)} 3^{|C|-2}$$

for each subset $X \subseteq V$, where $\mathcal{C}^*(X)$ is the family of connected components of $G - X$ with at least two vertices.

Properties 2 and 3 above are immediate: it is not difficult to see that we can evaluate the values of the function f in time bounded by a polynomial in the size of G; we can construct x_{ini} and x_{tar} from T_{ini} and T_{tar}, respectively, as $x_{\mathrm{ini}} = x^{T_{\mathrm{ini}}}$ and $x_{\mathrm{tar}} = x^{T_{\mathrm{tar}}}$. In the full version, we prove that (V, f) is a polymatroid and $\mathbf{B}(f)$ coincides with the convex hull of $\mathcal{E}$. This completes the reduction. Therefore, Theorem 2 follows from Theorem 1.

6 Conclusion

We prove that the combinatorial shortest path computation is hard on graph associahedra and base polytopes of polymatroids. This evaporates our hope for resolving an open problem to obtain a polynomial-time algorithm for finding a shortest flip sequence between two triangulations of convex polygons and the rotation distance between two binary trees by generalizing the setting to graph associahedra. However, that open problem is still open, and we should pursue another way of attacking it.

Searching for Regularity in Bounded Functions

Abstract

Given a function f on $\mathbb{F}_2^n$, we study the following problem. What is the largest affine subspace $\mathcal{U}$ such that when restricted to $\mathcal{U}$, all the non-trivial Fourier coefficients of f are very small?

For the natural class of bounded Fourier degree d functions $f : \mathbb{F}_2^n \to [-1, 1]$, we show that there exists an affine subspace of dimension at least $\widetilde{\Omega}(n^{1/d!}k^{-2})$, wherein all of f's nontrivial Fourier coefficients become smaller than 2^{-k}. To complement this result, we show the existence of degree d functions with coefficients larger than $2^{-d \log n}$ when restricted to any affine subspace of dimension larger than $\Omega(dn^{1/(d-1)})$. In addition, we give explicit examples of functions with analogous but weaker properties.

Along the way, we provide multiple characterizations of the Fourier coefficients of functions restricted to subspaces of $\mathbb{F}_2^n$ that may be useful in other contexts. Finally, we highlight applications and connections of our results to parity kill number and affine dispersers.

1 Introduction

The search for structure within large objects is an old one that lies at the heart of Ramsey theory. For example, a famous corollary of Ramsey's theorem is that any graph on n vertices must contain a clique or an independent set of size $\Omega(\log n)$. Another example is Roth's[1] theorem [19] on 3-term arithmetic progressions, which essentially says that *every* subset of $\{1, \ldots, n\}$ of density $\delta > \Omega(1/\log\log n)$ must contain a 3-term arithmetic progression.[2]

Szemerédi's Regularity Lemma is also a well known example of this phenomenon. Roughly speaking, it states that any graph G can be partitioned into $k := M(\delta)$ parts $V_1, \ldots, V_k$, wherein most pairs of parts (V_i, V_j) are δ-regular. In this setting, the δ-regularity of (V_i, V_j) roughly corresponds to saying that the bipartite graph induced across V_i and V_j appears as though its edges were sampled randomly. This powerful statement has found applications

[1] The related Hales-Jewett theorem [10] is also a classic result in Ramsey theory.
[2] See also the recent quantitative improvement due to Kelley and Meka [13] which gives the same result for all subsets of density at least $\Omega(2^{-\log^{1/11}(n)})$.

in both pure mathematics (e.g., Szemerédi's [23] generalization of Roth's result to k-term arithmetic progressions) and theoretical computer science (to test triangle-freeness in dense graphs [20, 1, 22]).

Similar to the definition of regular partitions in Szemerédi's Regularity Lemma, one can also define a notion of regularity for functions. In particular, for functions $f : \mathbb{F}_2^n \to \mathbb{R}$, we follow Green [9] and O'Donnell [17] and define a function to be δ-*regular* if all its nontrivial Fourier coefficients are at most δ in magnitude.[3] This definition can be viewed as a pseudorandomness condition; in particular, a randomly chosen Boolean function $f : \mathbb{F}_2^n \to \{\pm 1\}$ is δ-regular with very high probability, even for $\delta = 2^{-\Omega(n)}$.[4]

The prior works surrounding graph regularity [23, 7, 22] and function regularity [9, 12] have been concerned with obtaining δ-regular *partitions*, which, roughly speaking, are partitions of the object at hand into (mostly) pseudorandom parts. Often, these results have quite poor dependencies on the parameter δ so as not to be practical for any reasonably small value of δ (see Proposition 3 and Proposition 4 for detailed statements). Motivated by this, and by applications in theoretical computer science, we relax our requirement and look to find just *one* δ-regular part. Namely, we seek to understand the following quantity:

$$\mathsf{r}(f, \delta) := \min\{\operatorname{codim}(\mathcal{U}) : \mathcal{U} \text{ is an affine subspace such that } f_{\mathcal{U}} \text{ is } \delta\text{-regular}\},$$

where here and throughout this work $f_{\mathcal{U}} : \mathcal{U} \to \mathbb{R}$ denotes the restriction of f to inputs coming from $\mathcal{U}$.

Before stating our main results as well as prior work, we make a few remarks about the quantity $\mathsf{r}(f, \delta)$. In the special case when $\delta = 0$, the quantity $\mathsf{r}(f, 0)$ has been previously studied in the literature, under the name of *parity kill number* [18]. This is the smallest number of parities that need to be fixed in order to make f constant. The value $\mathsf{r}(f, 0)$ is also a measure associated with affine dispersers, objects that have received significant attention in the study of pseudorandomness, see e.g. [21, 14, 5, 6, 3]. An affine disperser of dimension k is a coloring of $\mathbb{F}_2^n$ such that no affine subspace of dimension k is monochromatic. If we view an affine disperser as a function $f : \mathbb{F}_2^n \to \{0, 1, \ldots, C\}$, then its dimension is just $n - \mathsf{r}(f, 0) + 1$.

Now, we briefly discuss the bounds on $\mathsf{r}(f, \delta)$ most relevant to our work. For a general function $f : \mathbb{F}_2^n \to [-1, 1]$, it is known that $\mathsf{r}(f, \delta) \leq 1/\delta$; this follows from a well-known density-increment argument, see [15] (for a short proof of this, see Proposition 5). One might ask if $\mathsf{r}(f, \delta)$ is small when we assume f is structured, and a natural example of such functions is the class of functions with low Fourier degree. For general degree d functions $f : \mathbb{F}_2^n \to [-1, 1]$, the best bound on $\mathsf{r}(f, \delta)$ until this work was just the above mentioned bound of $1/\delta$. However, for the class of degree d Boolean functions, we know that $\mathsf{r}(f, \delta) \leq \mathsf{r}(f, 0) = O(d^3)$; this follows from the polynomial relationship between Fourier degree and decision tree depth, see [16], and [2, 4] for surveys. We emphasize that this result relies crucially on Booleanity (and is independent of δ), and one can ask if the more general class of degree d functions bounded in the interval $[-1, 1]$ also have small $\mathsf{r}(f, \delta)$ values. Our main result answers exactly this question, and provides an upper bound for $\mathsf{r}(f, \delta)$ in this setting.

▶ **Theorem 1.** *For any $\delta \in (0, 1)$ and any degree d function $f : \mathbb{F}_2^n \to [-1, 1]$, we have* $\mathsf{r}(f, \delta) \leq n - \Omega\left(n^{1/d!}(\log(n/\delta))^{-2}\right)$.

[3] For a formal definition, see Definition 11, and for more background on Fourier analysis, see Section 2.
[4] See for example [17], Exercise 1.7 and Proposition 6.1.

Note that the general bound $\mathsf{r}(f,\delta) \leq 1/\delta$ that we mentioned earlier, is only meaningful when $\delta > 1/n$, however, our theorem allows for δ to be much smaller. The regime of small δ is particularly interesting from the perspective of pseudorandomness. Indeed, in a qualitative sense, we see that by decreasing δ, we are asking for affine subspaces where the restricted function looks increasingly like a random function. Using Theorem 1 together with our connection between $\mathsf{r}(f,0)$ and the dimension of affine disperse, we obtain the following corollary which says that low degree polynomials cannot serve as good affine dispersers.

▶ **Corollary 2.** *If $f : \mathbb{F}_2^n \to \{0,\dots,C\}$ has Fourier degree d, then f cannot be an affine disperser of dimension k for any $k \geq \Omega\left(n^{1/d!}(d+\log(nC))^{-2}\right)$.*

Lower Bounds on $\mathsf{r}(f,\delta)$. To complement Theorem 1, we present in Table 1 several examples of functions (bounded as well as Boolean) for which $\mathsf{r}(f,\delta)$ is large. For each row in the table, we exhibit a class of functions (whose degree and range is as specified), such that for any $\delta' \leq \delta$, *no* affine subspace of dimension larger than $n - \mathsf{r}(f,\delta)$ is δ'-regular.

Table 1 Table of functions with large $\mathsf{r}(f,\delta)$ values.

$\delta \leq$	$\mathsf{r}(f,\delta) \geq$	$\deg(f)$	range(f)	Ref.
$1/n$	$n/2-1$	1	$[-1,1]$	Lemma 26
$\binom{n}{d}^{-1}$	$n - 2dn^{1/(d-1)}$	d	$[-1,1]$	Lemma 27
$\Theta(n^{-1/2})$	$\Theta(\sqrt{n})$	n	$\{\pm 1\}$	Lemma 32
$\frac{1}{2}\cdot n^{-d}$ (for $d \leq \frac{\log n}{\log\log n+1}$)	$n - 2dn^{1/(d-1)}$	$\Omega(n)$	$\{\pm 1\}$	Corollary 30
$1/2^{2^k+1}$ (for integer k)	$\Omega\left((\log\frac{1}{\delta})^{\log_2(3)}\right)$	2^k	$\{\pm 1\}$	Lemma 31

Observe that Lemma 27 provides a somewhat of a converse to Theorem 1. However there is a noticeable gap between the two results, and we conjecture that Lemma 27 is closer to being tight, and that Theorem 1 could be improved. We also note that Lemma 27 and Corollary 30 are not explicit – it would be interesting to find more explicit examples.

1.1 Related Work

To the best of our knowledge, $\mathsf{r}(f,\delta)$ has not been explicitly studied before. However, it is closely related to well-studied notions of function regularity as well as the concepts of parity kill number and affine dispersers. In this section, we give a detailed description of both these connections.

Parity Kill Number and Affine Dispersers. As we have already mentioned, $\mathsf{r}(f,0)$ has been studied under the name of *parity kill number*, denoted $C^{\oplus}_{\min}[f]$ (see [18]). Parity kill number can be considered as a further generalization of the *minimum certificate complexity* of f, denoted $C_{\min}[f]$, which is the minimum number of bits one must fix in order to make f constant. In particular, for any $\delta \geq 0$, we have $\mathsf{r}(f,\delta) \leq \mathsf{r}(f,0) \leq C_{\min}[f]$. The minimum certificate complexity is one of several natural complexity measures that have been well studied for Boolean functions $f : \mathbb{F}_2^n \to \{\pm 1\}$ (see [4, 2] for surveys).

As we have already alluded to, the quantity $\mathsf{r}(f,0)$ is also closely related to efficacy of $f : \mathbb{F}_2^n \to \{0,\dots,C\}$ as an affine disperser. In the case of $C = 1$, Cohen and Tal [6] rule out $\mathbb{F}_2$-polynomials of degree d as affine dispersers by showing that any such function satisfies $\mathsf{r}(f,0) \leq n - \Omega(d \cdot n^{1/(d-1)})$. This result resembles our Corollary 2; however, the two results are incomparable for two reasons. First, degree d functions over $\mathbb{F}_2$ can have very large

Fourier degree; moreover, the corresponding result of [6] applies to functions whose range is $\mathbb{F}_2$, while ours applies to functions that take values in the set $\{0, \ldots, C\}$, which can have a much larger size. Furthermore, for $f : \mathbb{F}_2^n \to \{0, \ldots, C\}$, a standard argument (analogous to the one in [16]) shows that $\mathsf{r}(f, 0) \leq O(Cd^3)$, where d here is the Fourier degree. However, this does not address the case where $C = \Omega(n)$, which is when Corollary 2 becomes useful.

Pseudorandom Partitions. As we have mentioned, much prior work on function regularity has been focused on finding pseudorandom partitions of $\mathbb{F}_2^n$. To the best of our knowledge, the earliest result in this direction is due to Green [9]; below, the notation $\mathrm{twr}(x)$ refers to an exponential tower of 2's $2^{2^{\cdot^{\cdot^{\cdot}}}}$ of height x.

▶ **Proposition 3** (Theorem 2.1 in [9]). *For any $f : \mathbb{F}_2^n \to \{0, 1\}$ and $\delta > 0$, there exists a subspace $\mathcal{V}$ of co-dimension $M(\delta) \leq \mathrm{twr}(\lceil 1/\delta^3 \rceil)$ such that for all but a δ-fraction of the affine subspaces $\mathcal{U} = \alpha + \mathcal{V}$, $f_{\mathcal{U}}$ is δ-regular.*

In the same paper, Green showed that $M(\delta) \geq \mathrm{twr}(\Omega(\log(1/\delta)))$ was necessary. Subsequently, Hosseini et al. [12] exhibited a better counterexample showing co-dimension $M(\delta) \geq \mathrm{twr}(\lceil 1/16\delta \rceil)$ is required.

In the above upper and lower bound of [9, 12], the partition of $\mathbb{F}_2^n$ is of a specific form – namely, it is every affine shift of a given subspace. Given this observation, one can ask if there is a partition of $\mathbb{F}_2^n$ into affine subspaces of smaller co-dimension so that in most parts f is δ-regular. As the next proposition, due to Girish et al. [8] shows, this is indeed the case.

▶ **Proposition 4** (Proposition A.1 in [8]). *For any $f : \mathbb{F}_2^n \to [0, 1]$ and $\delta > 0$, there exists a partition Π of $\mathbb{F}_2^n$, where every $\pi \in \Pi$ is an affine subspace of co-dimension at most $\frac{1}{\delta^3}$ such that for all but a δ-fraction of the parts, f_π is δ-regular.*

The proof of Proposition 4 is based on a simple algorithm that greedily fixes the parities corresponding to the largest Fourier coefficients; it is included in Appendix A.1 for completeness.

Although, both these results partition $\mathbb{F}_2^n$ into several affine subspaces where f is δ-regular, they are only meaningful when δ is relatively large. Indeed, Proposition 3 is trivial when $\delta < (\log^*(n))^{-1/3}$, and Proposition 4 when $\delta < n^{-1/3}$. As we mentioned earlier, if we relax our requirement to finding just one affine subspace, there is a simple upper bound on $\mathsf{r}(f, \delta)$ based on a density-increment argument, which goes back to the works of Roth [19] and Meshulam [15].

▶ **Proposition 5** (Folklore). *For any $f : \mathbb{F}_2^n \to [-1, 1]$, we have $\mathsf{r}(f, \delta) \leq \frac{1}{\delta}$.*

We provide a proof of Proposition 5 in Appendix A.1 for completeness.

1.2 Techniques

Upper bound on $\mathsf{r}(f, \delta)$. We give a brief proof sketch of Theorem 1. The proof proceeds by induction over the Fourier degree. The base case corresponds to degree one functions. Our intuition is derived from the following fact. If we have any k real numbers $a_1, \ldots, a_k$ such that the sum of any subset of them has magnitude at most one, then by the pigeonhole principle, there is a non-empty subset $S \subseteq [k]$, and a signing of the numbers in S so that the signed sum has magnitude at most $2^{-\Omega(k)}$. In the degree one case, we partition $\{1, \ldots, n\}$ into consecutive disjoint intervals of size $k = O(\log 1/\delta)$. We apply the above intuition to the k Fourier coefficients in each interval, to obtain signed sums that have small magnitude.

Then, by appropriately choosing an affine subspace, $\mathcal{U}$ of dimension $\Omega(n/\log(1/\delta))$, we show that these signed sums are exactly the Fourier coefficients of the function restricted to $\mathcal{U}$ (see Proposition 13 for a more general statement). We give a more detailed description of how this works in Section 3.

At a high level, we reduce the problem for degree d functions to degree $d-1$ by restricting to an affine subspace of dimension $\widetilde{\Omega}\left(n^{1/d}\right)$, where the function is degree d and all Fourier coefficients at the d-th level are extremely small $\ll \delta/n^d$. For a detailed statement, see Lemma 19. When we use the inductive hypothesis for $d-1$, the last constraint ensures that the degree d coefficients cannot increase the new coefficients by more than $O(\delta)$, even if they combine in the most constructive way possible.

Lemma 19 is also obtained by repeatedly applying the pigeonhole principle. However, the key issue now is that several Fourier coefficients could be affected when we apply a restriction, unlike the degree one case. To avoid this, we apply restrictions iteratively so that each one preserves the small Fourier coefficients from past iterations while still ensuring that *several* new Fourier coefficients are also small. The cost of this procedure is that, in each step, we must apply the pigeonhole principle over larger and larger subsets of coordinates.

Lower Bounds. Here, we give a very high level overview of our lower bounds on $\mathsf{r}(f,\delta)$. The basic idea is to consider functions f with the property that their Fourier spectrum is concentrated on a small number of Fourier coefficients. It turns out (see Proposition 13) that when we restrict to an affine subspace, say $\mathcal{U}$, the Fourier coefficients of $f_{\mathcal{U}}$ are simply signed sums of the Fourier coefficients of f. By our choice of f, if the restricted function was δ-regular, then the large coefficients of f involved in the signed sums somehow cancelled each other out. We show that by choosing the vectors corresponding to the large Fourier coefficients in f appropriately, such a cancellation would imply that the co-dimension of $\mathcal{U}$ must be large. For more detailed sketches of the entries in Table 1, see Appendix A.2.

2 Preliminaries

Notation. $\mathbb{1}\{\cdot\}$ denotes an indicator function that takes the value 1 if the clause is satisfied and 0 otherwise. For a set $J \subseteq [n]$, we use $\mathsf{span}(J)$ to denote the subspace spanned by the standard basis vectors corresponding to the elements in J. We refer to the L_1 norm of $\gamma \in \mathbb{F}_2^n$ by $\|\gamma\|_1$. Given a subset $S \subseteq \mathbb{F}_2^n$, we denote $S^{=t} := S \cap \{u : \|u\|_1 = t\}$. Further, we define the degree of a function $f : \mathbb{F}_2^n \to \mathbb{R}$ to be $\max\{\|\gamma\|_1 : \widehat{f}(\gamma) \neq 0\}$. We frequently interpret a linear transformation $M : \mathbb{F}_2^n \to \mathbb{F}_2^n$ as a matrix and refer to the linear map obtained by taking the transpose of the matrix as M^{T}. At several points, we consider the compositions of functions with linear maps. For a function f and a map $M : \mathbb{F}_2^n \to \mathbb{F}_2^n$, we denote by $f \circ M$ the composition of the functions f with M. In particular, $f \circ M(x) = f(M(x))$.

Probability. The following basic facts from probability theory are useful for us.

▶ **Fact 6** (Hoeffding, [11]). *Suppose $X_1, \ldots, X_n$ are such that $a \leq X_i \leq b$ for all i. Let $M = \frac{X_1 + \ldots X_n}{n}$. Then,*

$$\Pr\Big[|M_n - \mathbf{E}M_n| \geq t\Big] \leq 2\exp\left(\frac{-2t^2 n}{|b-a|}\right).$$

▶ **Definition 7** (Statistical Distance). *Let X and Y be two random variables taking values in a set $\mathcal{S}$. Then we define the statistical distance between X and Y as*

$$|X - Y| := \max_{\mathcal{T} \subseteq \mathcal{S}} \Big| \Pr[X \in \mathcal{T}] - \Pr[Y \in \mathcal{T}] \Big| = \frac{1}{2} \sum_{s \in \mathcal{S}} \Big| \Pr[X = s] - \Pr[Y = s] \Big|.$$

Linear Algebra. We recap two concepts from linear algebra, namely, orthogonal subspaces and direct sum, since they become useful for studying the Fourier spectrum of functions defined over subspaces of $\mathbb{F}_2^n$. For a subspace $\mathcal{A}$ of $\mathbb{F}_2^n$, we denote the **orthogonal subspace** of $\mathcal{A}$ as $\mathcal{A}^\perp = \{\gamma \in \mathbb{F}_2^n : \langle \gamma, \gamma' \rangle = 0, \, \forall \, \gamma' \in \mathcal{A}\}$. We denote by $\dim(\mathcal{A})$, the dimension of $\mathcal{A}$ and $\operatorname{codim}(\mathcal{A}) = n - \dim(\mathcal{A})$.

We now define the notion of the direct sum of two subspaces.

▶ **Definition 8** (Independence, Direct Sum). *Two subspaces $\mathcal{A}, \mathcal{B}$ are* independent *if $a + b \neq 0$ for any non-trivial choice of $a \in \mathcal{A}$ and $b \in \mathcal{B}$. In addition, if $\{a + b : a \in \mathcal{A} \text{ and } b \in \mathcal{B}\} = \mathbb{F}_2^n$, we say that $\mathbb{F}_2^n$ is a* direct sum *of $\mathcal{A}$ and $\mathcal{B}$, written as $\mathcal{A} \oplus \mathcal{B} = \mathbb{F}_2^n$.*[5]

If $\mathcal{A} \oplus \mathcal{B} = \mathbb{F}_2^n$, then $\dim(\mathcal{A}) + \dim(\mathcal{B}) = n$. It is also well known that $\dim(\mathcal{A}^\perp) + \dim(\mathcal{A}) = n$. Note, however, that $\mathcal{A}^\perp$ and $\mathcal{A}$ need not be independent,[6] and often in fact must not be.

▶ **Fact 9.** *Let $\mathcal{A}, \mathcal{B}$ be independent subspaces of $\mathbb{F}_2^n$. Then for all distinct $b, b' \in \mathcal{B}$, the affine subspaces $b + \mathcal{A}$ and $b' + \mathcal{A}$ are mutually disjoint.*

Proof. If $b + a = b' + a'$, then a non-trivial sum of a vector from each $\mathcal{A}$ and $\mathcal{B}$ equals zero, contradicting the fact that $\mathcal{A} \oplus \mathcal{B} = \mathbb{F}_2^n$. ◀

Fourier Analysis. For $f : \mathbb{F}_2^n \to \mathbb{R}$, we can write f in the Fourier representation as

$$f(x) = \sum_{\gamma \in \mathbb{F}_2^n} \widehat{f}(\gamma) \chi_\gamma(x),$$

where $\chi_\gamma(x) := (-1)^{\langle \gamma, x \rangle}$ and $\widehat{f}(\gamma) = \mathbf{E}_x[f(x)\chi_\gamma(x)]$. We say f has degree d if $\max_{\gamma : \widehat{f}(\gamma) \neq 0} \|\gamma\|_1 = d$, and we refer to the degree d part of f by $f^{=d}(x) := \sum_{\|\gamma\|_1 = d} \widehat{f}(\gamma)\chi_\gamma(x)$. For more on this topic, see [17], which uses notation consistent with ours.

Restrictions. We are ultimately concerned with understanding the Fourier coefficients of a function when it is restricted to some affine subspace of $\mathbb{F}_2^n$. In the special case where the coordinates in a set $J \subseteq [n]$ are fixed using the vector $b \in \mathbb{F}_2^J$, we denote the restriction of f thus obtained as the function $f_{J \leftarrow b} : \mathsf{span}(\overline{J}) \to \mathbb{R}$, which can be written as $f_{J \leftarrow b}(x) = f(x + b)$. Next, we recall the formula of the Fourier coefficients of the restricted function. Note that $\{\chi_\gamma(x) := (-1)^{\langle \gamma, x \rangle} : \gamma \in \mathsf{span}(\overline{J})\}$ is a Fourier basis of the restricted function.

▶ **Fact 10** (Fourier Coefficients of Restricted Functions (see [17], Proposition 3.21)). *For every $\gamma \in \mathsf{span}(\overline{J})$ and $b \in \mathsf{span}(J)$,*

$$\widehat{f_{J \leftarrow b}}(\gamma) = \sum_{\beta \in \mathsf{span}(J)} \widehat{f}(\beta + \gamma)\chi_\beta(b).$$

---

[5] Such a subspace $\mathcal{B}$ is sometimes called a **complement** of $\mathcal{A}$. However, this term can be confused with the orthogonal subspace/complement, so we avoid using this terminology.

[6] this might be unexpected at first for those used to working over the reals, but it is essentially because the inner product over $\mathbb{F}_2$ allows self-orthogonal vectors in $\mathbb{F}_2^n$.

2.1 Fourier Analysis on Subspaces

We move to the general setting of restricting functions to arbitrary affine subspaces.[7] Let $\mathcal{U} = \mathcal{V} + \alpha$ be an affine subspace of $\mathbb{F}_2^n$. By the restriction of f to $\mathcal{U}$, we mean the function $f_{\mathcal{U}} : \mathcal{V} \to \mathbb{R}$ defined as $f_{\mathcal{U}}(x) = f(x + \alpha)$.

For the remainder of this section (and paper), let $\mathcal{W}$ be such that $\mathcal{W} \oplus \mathcal{V}^\perp = \mathbb{F}_2^n$. For each element $\gamma \in \mathcal{W}$, consider the function $\chi_\gamma : \mathcal{V} \to \{\pm 1\}$ as $\chi_\gamma(x) = (-1)^{\langle \gamma, x \rangle}$. It is easy to verify that $\{\chi_\gamma : \gamma \in \mathcal{W}\}$ form an orthonormal basis of real-valued functions defined over $\mathcal{V}$ under the inner product given by $\langle p, q \rangle = \mathbf{E}_{x \in \mathcal{V}}[p(x)q(x)]$. We can therefore uniquely associate each vector $\gamma \in \mathcal{W}$ with the function χ_γ, and for $\mathcal{U} = \alpha + \mathcal{V}$, we can write

$$f_{\mathcal{U}}(x) = \sum_{\gamma \in \mathcal{W}} \widehat{f_{\mathcal{U}}}(\gamma)(-1)^{\langle \gamma, x \rangle}. \tag{1}$$

We now state the formal definition of δ-regularity.

▶ **Definition 11** (δ-regularity). *Let $\mathcal{V}$ be a subspace of $\mathbb{F}_2^n$ and $g : \mathcal{V} \to \mathbb{R}$. For $\delta \geq 0$, we say g is δ-regular if $\max_{\gamma \neq 0} |\widehat{g}(\gamma)| \leq \delta$.*

In this section, we present three separate formulas (Fact 12, Proposition 13 and Proposition 16) for the Fourier coefficients of $f_{\mathcal{U}}$, each of which is useful in different contexts. With the exception of Fact 12, which is direct, the proofs of the statements in this section can be found in Appendix B.

First, using the above observations, we have the following simple formula for the Fourier coefficients of $f_{\alpha+\mathcal{V}}$, which follows from the orthogonality of the χ_γ we have defined.

▶ **Fact 12.** *Let $\mathcal{V}, \mathcal{W}$ be subspaces such that $\mathcal{W} \oplus \mathcal{V}^\perp = \mathbb{F}_2^n$ and $\mathcal{U} = \alpha + \mathcal{V}$. For any $\gamma \in \mathcal{W}$, we have that*

$$\widehat{f_{\mathcal{U}}}(\gamma) = \mathbf{E}_{x \in \mathcal{V}}[f(x + \alpha) \cdot (-1)^{\langle \gamma, x \rangle}] = (-1)^{\langle \gamma, \alpha \rangle} \mathbf{E}_{x \in \mathcal{U}}[f(x) \cdot (-1)^{\langle \gamma, x \rangle}].$$

Fact 12 represents a simple and analogous formula for Fourier coefficients of functions restricted to affine subspaces. It also highlights that the magnitude of the Fourier coefficients of a restricted function are unaffected by the choice for shift α as long it corresponds to the same affine subspace.

Our next formula, which shows how the Fourier coefficients of $f_{\mathcal{U}}$ can be written in terms of the Fourier coefficients of f, is an easy consequence of Fact 12.

▶ **Proposition 13.** *Let $\mathcal{V}, \mathcal{W}$ be subspaces such that $\mathcal{W} \oplus \mathcal{V}^\perp = \mathbb{F}_2^n$ and $\mathcal{U} = \alpha + \mathcal{V}$. For any $\gamma \in \mathcal{W}$, we have*

$$\widehat{f_{\mathcal{U}}}(\gamma) = \sum_{\beta \in \gamma + \mathcal{V}^\perp} \widehat{f}(\beta) \cdot (-1)^{\langle \beta, \alpha \rangle}.$$

For a proof of Proposition 13 as well as proofs for the rest of the statements in this section, see Appendix B. We note that Proposition 13 gives a formula analogous to Fact 10 for restrictions to general affine subspaces. This fact will be useful to construct functions and argue that they never become δ-regular when restricted to any sufficiently large subspace. Before we give our final formula, we highlight one particular choice of $\mathcal{W}$ such that $\mathcal{W} \oplus \mathcal{V}^\perp = \mathbb{F}_2^n$.

[7] For an arbitrary subspace $\mathcal{V}$, there is no canonical mapping between vectors and characters when $\mathcal{V} \neq \mathbb{F}_2^n$, and we cannot simply define the vectors χ_γ, for each $\gamma \in \mathcal{V}$, as we did in the case of $\mathbb{F}_2^n$ to be the characters of $\mathcal{V}$.

▶ **Definition 14** (M mapping $\mathcal{V}$ to $\mathsf{span}(J)$)**.** *Given a k-dimensional subspace $\mathcal{V}$, let $B = \{\beta_1, \ldots, \beta_n\}$ be a basis for $\mathbb{F}_2^n$ such that $\mathcal{V} = \mathsf{span}(\{\beta_1, \ldots, \beta_k\}$. For any subset $J \subseteq [n]$ of size k, let $M : \mathbb{F}_2^n \to \mathbb{F}_2^n$ be an invertible linear map such that $\{M\beta_i : i \in [k]\} = \{e_j : j \in J\}$.*

▶ **Proposition 15** (Choice of $\mathcal{W}$)**.** *Let $\mathcal{V}$, M and J be defined as in Definition 14. The subspaces $\mathcal{W} = \{M^{\mathsf{T}}\gamma : \gamma \in \mathsf{span}(J)\}$ and $\mathcal{V}^{\perp}$ are independent, and $\mathcal{W} \oplus \mathcal{V}^{\perp} = \mathbb{F}_2^n$.*

Finally, we show that the Fourier coefficients of a function restricted to an affine subspace are the same as the Fourier coefficients of the function $f \circ M$ under a suitable (normal) restriction and for a particular choice of M.

▶ **Proposition 16.** *Let $\mathcal{V}$, M and J be defined as in Definition 14 and $\mathcal{U} = \alpha + \mathcal{V}$. For any $\gamma \in \mathsf{span}(J)$, we have $\left|\widehat{f_{\mathcal{U}}}(M^{\mathsf{T}}\gamma)\right| = \left|\widehat{h_{\mathcal{U}'}}(\gamma)\right|$, where $h = f \circ M^{-1}$ and $\mathcal{U}' = \{Mu : u \in \mathcal{U}\} = M\alpha + \mathsf{span}(J)$ is a standard restriction.*

Proposition 16 implies the following important corollary.

▶ **Corollary 17.** *There exists an affine subspace $\mathcal{U}$ of dimension k such that $f_{\mathcal{U}}$ is δ-regular if and only if there exists an invertible linear map $M : \mathbb{F}_2^n \to \mathbb{F}_2^n$, a set $J \subseteq [n]$ of size k, and a fixing of coordinates outside J given by $b \in \mathbb{F}_2^{\overline{J}}$ such that the function $h_{\overline{J} \leftarrow b}$ is δ-regular, where $h = f \circ M$.*

We use Corollary 17 crucially in the proof of Theorem 1, wherein we construct M and b such that $f \circ M_{\overline{[k]} \leftarrow b}$ has small Fourier coefficients. In the proof of this theorem we must understand the Fourier coefficients of $f \circ M$ in terms of the Fourier coefficients of f. The following fact gives an identity relating the Fourier coefficients of the two functions. For completeness, we include the proof in Appendix B.

▶ **Fact 18** ([17], Exercise 3.1)**.** *Let M be an invertible linear transformation, and consider the function $g = f \circ M^{-1} : \mathbb{F}_2^n \to \mathbb{R}$. Then we have that $\widehat{g}(\gamma) = \widehat{f}(M^{\mathsf{T}}\gamma)$.*

3 Upper Bound on $\mathsf{r}(f, \delta)$

Now we prove our main theorem, restated here for convenience.

▶ **Theorem 1.** *For any $\delta \in (0, 1)$ and any degree d function $f : \mathbb{F}_2^n \to [-1, 1]$, we have $\mathsf{r}(f, \delta) \leq n - \Omega\left(n^{1/d!}(\log(n/\delta))^{-2}\right)$.*

First, we gain some intuition from degree one functions.

Base Case/Toy Example. Suppose f is a Fourier degree one function. In this case our function has the form

$$f(x) = \widehat{f}(0) + \sum_i \widehat{f}(e_i)(-1)^{x_i}.$$

For a parameter $t \geq 1$ and a subset $S \subseteq [t]$, consider the sum $g_S = \widehat{f}(0) + \sum_{i \in S} \widehat{f}(e_i)$. Note that $g_S = \mathbf{E}[f(x) | x_i = 0 \ \forall i \in S] \in [-1, 1]$. The pigeonhole principle implies that for $t = \Omega(\log 1/\delta)$ there must exist two distinct sets S, S' such that the difference $|g_S - g_{S'}| \leq \delta$. We can further write $g_S - g_{S'} = \sum_{i \in S \triangle S'} \widehat{f}(e_i)(-1)^{|\{i\} \cap S'|}$.

We now use the set $S \triangle S'$ and the signs to construct an affine subspace where at least one Fourier coefficient will have small magnitude. Assume without loss of generality that $1 \in S \setminus S'$ and $S \triangle S' = [t']$ for some $t' \leq t$. Consider restricting f to the affine subspace $\mathcal{U}$

defined by the linear equations $x_1 + x_i = b_i$ for each $i \in \{2, \dots, t'\}$, where $b_i = |\{i\} \cap S'|$. We can reason about the Fourier spectrum of $f_{\mathcal{U}}$ by plugging in $x_i = b_i + x_1$. Under this restriction, we see that the Fourier coefficients of $e_{t'+1}, \dots, e_n$ stay the same, and the new Fourier coefficient of e_1 is exactly equal to

$$\widehat{f}(e_1) + \sum_{i=2}^{t'} \widehat{f}(e_i)(-1)^{b_i} = g_S - g_{S'},$$

which we observed has magnitude at most δ. Repeatedly applying this argument roughly $n(\log(1/\delta))^{-1}$ times for the remaining standard basis vectors and fixing remaining coordinates arbitrarily, we obtain an affine subspace of dimension at least $\Omega\left(\frac{n}{\log(1/\delta)}\right)$.

Theorem 1 is proved via induction using the following lemma.

▶ **Lemma 19.** *For $\tau \in (0,1)$ and any degree d function $f : \mathbb{F}_2^n \to [-1,1]$, there exists an invertible linear map $M : \mathbb{F}_2^n \to \mathbb{F}_2^n$, a set $J \subseteq [n]$ with size at least $\frac{d}{4e}\left(\frac{n}{\log 5/\tau}\right)^{1/d}$, and $b \in \mathsf{span}(\overline{J})$ such that $h = f \circ M$ satisfies*

$$\left|\widehat{h_{\overline{J}\leftarrow b}}(\gamma)\right| \leq \begin{cases} \tau & \text{if } \|\gamma\|_1 = d, \\ 0 & \text{for all } \|\gamma\|_1 > d. \end{cases}$$

We now prove Theorem 1 using Lemma 19.

Proof. The proof proceeds by induction over the degree. Our inductive hypothesis is that for any $\delta > 0$ and any degree d function f, there exists an invertible linear map M, a set $I \subseteq [n]$, and $b \in \mathsf{span}(\overline{I})$ such that the following two items hold:

1. $h_{\overline{I}\leftarrow b}$ is δ-regular, where $h = f \circ M$, and
2. for $C_d = \sum_{i=1}^{d} (i!)^{-1}$, we have

$$|I| \geq \frac{n^{1/d!}}{(8e)^{C_{d-1}} \left(\log(n/\delta)\right)^{C_d}}.$$

Note that $C_d \leq e - 1 < 2$ for all $d \geq 1$. The existence of the desired affine subspace is then given by Corollary 17, and its dimension is equal to $|I| \geq \Omega\left(n^{1/d!} \left(\log(n/\delta)\right)^{-2}\right)$.

The base case corresponds to the degree being one. Let us apply Lemma 19 for degree one with $\tau = \delta$ and denote $g = f \circ M$, where M is the linear map M promised by the lemma. Additionally, we have a set J of size at least $\frac{n}{4e \log 5/\delta} \geq \Omega\left(\frac{n}{\log n/\delta}\right)$, and $b \in \mathsf{span}(\overline{J})$ such that

$$\left|\widehat{g_{\overline{J}\leftarrow b}}(\gamma)\right| \leq \begin{cases} \tau & \text{if } \|\gamma\|_1 = 1, \\ 0 & \text{for all } \|\gamma\|_1 > 1. \end{cases} \implies \left|\widehat{g_{\overline{J}\leftarrow b}}(\gamma)\right| \leq \delta, \text{ for all } \gamma \neq 0.$$

Assuming both items hold for some degree $d-1$, we show them for degree d. Applying Lemma 19 with degree d and $\tau = n^{-d}\delta/3$, we denote $p := (f \circ M)_{\overline{J}\leftarrow b}$, where M, J and b are as promised by the lemma. Note that, by Lemma 19, p has degree at most d, and for any γ with $\|\gamma\|_1 = d$, we have, $|\widehat{p}(\gamma)| \leq \delta/(3n^d)$. Consider the functions $p^{<d}$ and $p^{=d}$, which are the degree at most $d-1$ part of p and the degree d part of p, respectively. We note that $\frac{p^{<d}}{(1+\delta/3)}$ is bounded in the interval $[-1,1]$ because for any x,

$$\left|p^{<d}(x)\right| \leq |p(x)| + \left|p^{=d}(x)\right| \leq 1 + \sum_{\gamma : \|\gamma\|_1 = d} |\widehat{p}(\gamma)| \leq 1 + \frac{\delta}{3}.$$

Applying the inductive hypothesis[8] to $\frac{p^{<d}}{1+\delta/3}$ for the choice of $\delta/3$, we get a linear map M', a set $I \subseteq J$, and $b' \in \mathsf{span}(J \setminus I)$ such that $\left(\frac{q}{1+\delta/3}\right)_{J\setminus I \leftarrow b'}$ is $\delta/3$-regular, where $q := p^{<d} \circ M'$. Therefore, for any $\gamma \neq 0$, we have $\left|\widehat{q_{J\setminus I\leftarrow b'}}(\gamma)\right| \leq \left(1+\frac{\delta}{3}\right)\frac{\delta}{3} < \frac{2\delta}{3}$. Denoting $p' := p \circ M'$ and $r := p^{=d} \circ M'$, we have for any $\gamma \neq 0$ that

$$\left|\widehat{p'_{J\setminus I\leftarrow b'}}(\gamma)\right| \leq \left|\widehat{q_{J\setminus I\leftarrow b'}}(\gamma)\right| + \left|\widehat{r_{J\setminus I\leftarrow b'}}(\gamma)\right| < 2\delta/3 + \sum_{\beta:\|\beta\|_1=d} |\widehat{g}(\beta)| \leq \delta.$$

This shows that ${p'}_{J\setminus I\leftarrow b'}$ is δ-regular. Moreover, if we extend M' to act as the identity map on the coordinates in $\overline{J}$, we can write

$$\begin{aligned}{p'}_{J\setminus I\leftarrow b'}(x) = (p\circ M')_{J\setminus I\leftarrow b'}(x) &= p(M'(x+b')) \\ &= (f\circ M)_{J\leftarrow b}(M'(x+b')) = f(MM'(x+b'+b)),\end{aligned}$$

which implies that item 1 of the inductive hypothesis is satisfied by applying the linear map MM' and restricting to the set I by fixing the coordinates outside according to $b+b'$.

We now show that the size of I satisfies item 2 above. Note that Lemma 19 promises that $|J| \geq \frac{d}{4e}\left(\frac{n}{\log(15n^d/\delta)}\right)^{1/d}$. Moreover, we have

$$\log(15n^d/\delta) \leq d\log n/\delta + \log 15 \leq 4d\log n/\delta,$$

where the last inequality follows for sufficiently large n. Therefore, $|J| \geq \frac{1}{8e}\left(\frac{n}{\log(n/\delta)}\right)^{1/d}$. Moreover, we assume without loss of generality that $3|J| \leq n$ because, if not, we can arbitrarily fix coordinates in J until it is, which does not affect the crucial property that all remaining degree d Fourier coefficients have small magnitude. Using the bounds on $|J|$ and applying item 2 of the inductive hypothesis for degree $d-1$, we get

$$\begin{aligned}|I| \geq \frac{|J|^{1/(d-1)!}}{(8e)^{C_{d-2}}\left(\log(3|J|/\delta)\right)^{C_{d-1}}} &\geq \frac{n^{1/d!}}{(8e)^{C_{d-1}}\log(n/\delta)^{1/d!}\left(\log(3|J|/\delta)\right)^{C_{d-1}}} \\ &\geq \frac{n^{1/d!}}{(8e)^{C_{d-1}}\left(\log(n/\delta)\right)^{C_d}}.\end{aligned}$$

This shows item 2 of the inductive hypothesis as desired. ◀

To prove Lemma 19, we need the following claim, which ultimately lets us bound Fourier coefficients in certain affine subspaces.

▷ Claim 20 (Pigeonhole Principle). Let $f : \mathbb{F}_2^n \to [-1,1]$ be degree d. For every $K \subseteq [n]$ of size k such that $n-k \geq \binom{k}{d-1}\log(5/\tau)$, there exists $S \subseteq [n]\setminus K$ and $z \in \{\pm 1\}^S$ such that

1. $\forall \gamma \in \mathsf{span}(K)$ with $\|\gamma\|_1 = d-1$, we have $\left|\sum_{j\in S}\widehat{f}(\gamma+e_j)\cdot z_j\right| \leq \tau$, and
2. $1 < |S| \leq \binom{k}{d-1}\log(5/\tau)$.

Proof. Consider any subset of $T \subseteq \overline{K}$ of size $\binom{k}{d-1}\log(5/\tau)$. For any $U \subseteq T$, consider the sum

$$a_U(\gamma) := \widehat{f}(\gamma) + \sum_{j\in U}\widehat{f}(\gamma+e_j).$$

[8] Technically, $\frac{p^{<d}}{1+\delta/3} : \mathsf{span}(J) \to [-1,1]$. However, we can abuse notation slightly and consider it as a function from $\mathbb{F}_2^J$ to $[-1,1]$ in order to apply the inductive hypothesis.

We must have that $a_U(\gamma) \in [-1,1]$ since it is exactly equal to the Fourier coefficient corresponding to γ if we restricted everything in U to be one. This follows because f is degree d.

Now, divide the interval $[-1,1]$ into $2/\tau$ intervals of length τ. For a fixed $U \subseteq T$ of even size, consider putting the values of $a_U(\gamma)$ for all $\gamma \in \mathsf{span}(K)^{=d-1}$ into a vector v_U of length $\binom{k}{d-1}$. First, note that the number of even subsets of T is at least $2^{\binom{k}{d-1}\log(5/\tau)-1} > (2/\tau)^{\binom{k}{d-1}}$. Moreover, the number of possible interval vectors is at most $(2/\tau)^{\binom{k}{d-1}}$. Therefore, by the pigeonhole principle, there must be two distinct sets $U, U' \subseteq T$ such that $\|v_U - v_{U'}\|_\infty \leq \tau$.

Thus, we have that

$$\|v_U - v_{U'}\|_\infty \leq \tau \iff \sum_{i \in U \triangle U'} (-1)^{|\{i\}\cap U'|} \widehat{f}(\gamma + e_i) \leq \tau \quad \forall\, \gamma \in \mathsf{span}(K)^{=d-1}.$$

Since U, U' have even size and are not equal, $U \triangle U'$ has even size as well, so we can set our $S = U \triangle U' \subseteq T$ and $z_i = (-1)^{|\{i\}\cap U'|}$, and the claim follows. ◁

We can now prove Lemma 19.

Proof of Lemma 19. We build the map M, the set J, and the vector b iteratively. Throughout the iterations, we seek to maintain a set K of coordinates for which (under a suitable linear transformation M) every Fourier coefficient corresponding to a vector of weight d in $\mathsf{span}(K)$ has magnitude at most τ. We build K one coordinate at a time by repeatedly invoking Claim 20 and arguing that the quantities guaranteed to be small by Claim 20 are exactly the (new) Fourier coefficients. When we can no longer add more coordinates to K, we fix any remaining coordinates (outside of K that are still alive), and we are left with a function, over only the coordinates in K, that has the desired property.

Note that we can start with K being an arbitrary subset of size $d-1$ (w.l.o.g. let it be $[d-1]$) since any such subset has no Fourier coefficients of degree d. Therefore, we can assume without loss of generality that $\tau \geq 5 \cdot 2^{-n/(4e)^d}$, since otherwise $\frac{d}{4e}\left(\frac{n}{\log(5/\tau)}\right)^{1/d} < d$ and the lemma becomes trivial. In each iteration, we maintain the following invariant for M, J and b. In iteration i, there exists some $K \subseteq J$ of size $d+i-1$ such that the function $g = (f \circ M)_{\overline{J} \leftarrow b}$ satisfies

$$|\widehat{g}(\gamma)| \leq \begin{cases} \tau & \text{if } \gamma \in \mathsf{span}(K) \text{ and } \|\gamma\|_1 = d, \\ 0 & \text{for all } \|\gamma\|_1 > d. \end{cases}$$

Assume without loss of generality that $J = [j]$ for some $j \leq n$ and $K = [d+i-1] \subseteq J$. Since g has degree d, we can apply Claim 20 to g and obtain a subset $S \subseteq J \setminus K$ of size at most $\binom{d+i-1}{d-1}(\log(5/\tau)$ and a sign vector $z \in \{\pm 1\}^S$ so that

$$\left|\sum_{j \in S} \widehat{g}(\gamma + e_j) \cdot z_j\right| \leq \tau, \qquad \text{for all } \gamma \in \mathsf{span}([d+i-1]) \text{ such that } \|\gamma\|_1 = d-1. \tag{2}$$

We can also assume that $d+i \in S$ and $z_{d+i} = 1$. Now consider the invertible linear transformation $M_i : \mathbb{F}_2^n \to \mathbb{F}_2^n$ that maps e_{d+i} to $\sum_{j \in S} e_j$ and behaves as the identity map on the remaining standard basis vectors. Further, denote $J_i := S \setminus \{d+i\}$ and let $b_i \in \mathsf{span}(J_i)$, where $(b_i)_j := (1 - z_j)/2$ for each $j \in J_i$. Intuitively, applying the linear transformation M_i and then fixing the coordinates in J_i to b_i corresponds to restricting the affine subspace described by the equations $x_j + x_{d+i} = (1 - z_j)/2$ for all $j \in J_i$.

After this iteration, we show that if we set $M' \leftarrow MM_i$, $J' \leftarrow J \setminus J_i$ and $b' \leftarrow b + b_i$, the invariant holds with $K' \leftarrow K \cup \{d+i\}$. For these choices, we have

$$\begin{aligned}(f \circ M')_{\overline{J'} \leftarrow b'}(x) = f \circ M(M_i(x + b')) &= f \circ M(M_i(x + b_i + b)) \\ &= f \circ M(M_i(x + b_i) + b) \\ &= g \circ M_i(x + b_i) = (g \circ M_i)_{J_i \leftarrow b_i}(x),\end{aligned}$$

and it therefore suffices to show that $(g \circ M_i)_{J_i \leftarrow b_i}$ – denoted by h henceforth, for shorthand – is degree d and $\left|\widehat{h}(\gamma)\right| \leq \tau$ for all $\gamma \in \mathsf{span}([d+i])$ with $\|\gamma\|_1 = d$. We start by analyzing the Fourier coefficients of h, for which by Fact 10 we have

$$\widehat{h}(\gamma) = \sum_{\beta \in \mathsf{span}(J_i)} \widehat{g \circ M_i}(\gamma + \beta)(-1)^{\langle \beta, b_i \rangle}. \tag{3}$$

Next, we observe the following relation between the Fourier coefficients of $g \circ M_i$ and those of g, which we use to simplify Equation (3). Denoting $v := \sum_{j \in J_i} e_j$, we claim that, for any γ,

$$\widehat{g \circ M_i}(\gamma) = \widehat{g}(\gamma + e_{d+i}\langle \gamma, v \rangle). \tag{4}$$

Before proving Equation (4), we use it to prove that h has the desired properties. Note that since g is degree d, Equation (4) implies that if $\widehat{g \circ M_i}(\gamma) \neq 0$, then $\|\gamma + e_{d+i}\langle \gamma, v \rangle\|_1 \leq d$, which in turn implies that $\|\gamma\|_1 \leq d+1$. This immediately tells us that $g \circ M_i$ has degree at most $d+1$; therefore, h also has degree at most $d+1$ since the degree cannot increase under restrictions. Now, for any γ, Equation (3) reduces to

$$\begin{aligned}\widehat{h}(\gamma) &= \sum_{\substack{\beta \in \mathsf{span}(J_i), \\ \|\beta\|_1 \leq d+1-\|\gamma\|_1}} \widehat{g \circ M_i}(\gamma + \beta)(-1)^{\langle \beta, b_i \rangle} \\ &= \widehat{g \circ M_i}(\gamma) + \sum_{\substack{\beta \in \mathsf{span}(J_i), \\ 0 < \|\beta\|_1 \leq d+1-\|\gamma\|_1}} \widehat{g \circ M_i}(\gamma + \beta)(-1)^{\langle \beta, b_i \rangle} \\ &= \widehat{g}(\gamma + e_{d+i}\langle \gamma, v \rangle) + \sum_{\substack{\beta \in \mathsf{span}(J_i), \\ 0 < \|\beta\|_1 \leq d+1-\|\gamma\|_1}} \widehat{g}(\gamma + \beta + e_{d+i}\langle \gamma + \beta, v \rangle)(-1)^{\langle \beta, b_i \rangle}, \end{aligned} \tag{5}$$

where, in the first equality, we used the fact that if $\|\beta\|_1 > d+1-\|\gamma\|_1$, then $\|\beta+\gamma\|_1 > d+1$ and the corresponding Fourier coefficient in $g \circ M_i$ is just zero, and in the last equality, we used Equation (4). Moreover, for any $\gamma \in \mathsf{span}(J \setminus J_i)$, we have $\langle \gamma, v \rangle = 0$, which means that $\widehat{g}(\gamma + e_{d+i}\langle \gamma, v \rangle) = \widehat{g}(\gamma)$. We can now conclude that h has degree at most d. Indeed, if $\|\gamma\|_1 \geq d+1$, then Equation (5) implies that $\widehat{h}(\gamma) = \widehat{g}(\gamma) = 0$ since g has degree at most d.

Next, we show that for any $\gamma \in \mathsf{span}([d+i])$ with $\|\gamma\|_1 = d$, it must be that $|\widehat{h}(\gamma)| \leq \tau$. Applying Equation (5) for such γ, we note that

$$\begin{aligned}\widehat{h}(\gamma) &= \widehat{g}(\gamma) + \sum_{j \in J_i} \widehat{g}(\gamma + e_j + e_{d+i}\langle \gamma + e_j, v \rangle)(-1)^{\langle e_j, b_i \rangle} \\ &= \widehat{g}(\gamma) + \sum_{j \in J_i} \widehat{g}(\gamma + e_j + e_{d+i}) z_j.\end{aligned}$$

We now consider two cases. First, when $\gamma_{d+i} = 0$, the above equation implies that $\widehat{h}(\gamma) = \widehat{g}(\gamma)$ since $\|\gamma + e_{d+i} + e_j\|_1 = d+2$ for every $j \in J_i$, and g has degree at most d. Therefore, in

this case, $\left|\widehat{h}(\gamma)\right| = |\widehat{g}(\gamma)| \leq \tau$ by the inductive hypothesis. Otherwise, $\gamma_{d+i} = 1$, and now using both Equation (2) and the fact that $\gamma + e_{d+i} \in \mathsf{span}(\{e_1, \ldots, e_{d+i-1}\})$, we conclude that $\left|\widehat{h}(\gamma)\right| = \left|\sum_{j \in S} \widehat{g}((\gamma + e_{d+i}) + e_j) z_j\right| \leq \tau$.

It remains to show Equation (4). We start by observing that $M_i = M_i^{-1}$, which can be verified by noting that $M_i^{-1} e_{d+i} = M_i^{-1}(e_{d+i} + v + v) = e_{d+i} + v$ and M_i^{-1} acts as the identity map on the remaining standard basis vectors. From Fact 18, we know that $\widehat{g \circ M_i}(\gamma) = \widehat{g \circ M_i^{-1}}(\gamma) = \widehat{g}(M_i^{\mathsf{T}}\gamma)$. Since the rows of M_i^{T} are the same as the columns of M_i, we have

$$(M_i^{\mathsf{T}}\gamma)_j = \begin{cases} \langle v + e_{d+i}, \gamma \rangle & \text{if } j = d+i, \\ \gamma_j & \text{otherwise.} \end{cases}$$

Therefore, we can write $M_i^{\mathsf{T}}\gamma = \sum_{j \neq d+i} \gamma_j e_j + e_{d+i}\langle v + e_{d+i}, \gamma \rangle = \gamma + e_{d+i}\langle v, \gamma \rangle$, as claimed.

We conclude the argument by calculating how many times we can repeat the above procedure. Note that, in the i-th iteration, we fixed at most $\binom{d+i-1}{d-1} \log 5/\tau - 1$ coordinates and we added exactly one coordinate to K. We can thus continue this process until iteration t for the largest value of t such that

$$\log(5/\tau) \cdot \left(\sum_{i=1}^{t} \binom{d+i-1}{d-1} \right) \leq n - d + 1.$$

Simplifying the binomial sum, we get

$$\begin{aligned} \sum_{i=1}^{t} \binom{d+i-1}{d-1} = \sum_{i=1}^{t} \binom{d+i-1}{i} &= \sum_{i=1}^{t} \binom{d+i-1}{i} + \binom{d}{0} - 1 \\ &= \binom{d+t}{t} - 1 < \left(\frac{e(d+t)}{d} \right)^d, \end{aligned}$$

where the last equality follows by repeatedly using the identity $\binom{a}{i} + \binom{a}{i-1} = \binom{a+1}{i}$. Thus, we can set $t = \frac{d}{e}\left(\frac{n-d+1}{\log 5/\tau}\right)^{1/d} - d$. Adding in the initial $d-1$ coordinates, at the end of the t iterations, we can bound $|K|$ as,

$$\begin{aligned} |K| &= \frac{d}{e}\left(\frac{n-d+1}{\log 5/\tau}\right)^{1/d} - d + d - 1 \\ &\geq \frac{d}{e}\left(\frac{n}{\log 5/\tau}\left(1 - \frac{d-1}{n}\right)\right)^{1/d} - 1 \\ &\geq \frac{d}{e}\left(\frac{n}{\log 5/\tau} \cdot \frac{1}{d}\right)^{1/d} - 1 \\ &\geq \frac{d}{2e}\left(\frac{n}{\log 5/\tau}\right)^{1/d} - 1 && (d^{1/d} \leq 2 \quad \forall d \geq 1) \\ &= \frac{d}{4e}\left(\frac{n}{\log 5/\tau}\right)^{1/d} + \frac{d}{4e}\left(\frac{n}{\log 5/\tau}\right)^{1/d} - 1 \\ &\geq \frac{d}{4e}\left(\frac{n}{\log 5/\tau}\right)^{1/d} + d - 1 && (\text{since } \tau \geq 5 \cdot 2^{-n/(4e)^d}) \\ &\geq \frac{d}{4e}\left(\frac{n}{\log 5/\tau}\right)^{1/d}. && (d \geq 1) \end{aligned}$$

At the end of t iterations, we can fix any coordinates outside the set K arbitrarily to ensure that the only non-zero Fourier coefficients with L_1 norm d in the resulting function must correspond to vectors in $\mathsf{span}(K)$, which do not change under the restriction. ◀

4 Applications

We now present an application of Theorem 1 that shows a tradeoff between the dimension of a disperser and its Fourier degree, and a connection to extractors, as well. First, we introduce a definition that generalizes Boolean functions and helps us reason about the Fourier spectrum of dispersers.

▶ **Definition 21.** *We say a function $f : \mathbb{F}_2^n \to \mathbb{R}$ is G-granular if for every $x \in \mathbb{F}_2^n$, we have that $f(x)$ is an integer multiple of G.*

▷ Claim 22. If a degree d function $f : \mathbb{F}_2^n \to \mathbb{R}$ is G-granular, then for every $\gamma \in \mathbb{F}_2^n$, we have that $\widehat{f}(\gamma)$ is an integer multiple of $2^{-d} \cdot G$.

We defer the proof of Claim 22 to the full version. Assuming the claim, we now show that low degree granular functions cannot have a large parity kill number. As a consequence, we get that low-degree affine dispersers cannot have small dimension (Corollary 2).

▶ **Lemma 23.** *Every degree d function $f : \mathbb{F}_2^n \to [-1, 1]$ that is G-granular satisfies*

$$C^{\oplus}_{\min}[f] \leq n - \Omega\left(n^{1/d!}(d + \log n/G)^{-2}\right).$$

Proof. If f is G-granular and degree d, then from Claim 22 we know that all its Fourier coefficients must be integer multiples of $2^{-d} \cdot G$. Moreover, a Fourier coefficient of f in any affine subspace is simply a signed sum of the Fourier coefficients of f and therefore it must also be an integer multiple of $2^{-d} \cdot G$. This shows that if f is δ-regular in some affine subspace $\mathcal{U}$ with $\delta < 2^{-d} \cdot G$, then $f_{\mathcal{U}}$ must be constant. The lemma follows by using Theorem 1 for $\delta = 2^{-d-1} \cdot G$. ◀

Proof of Corollary 2. Using f, we can construct a degree d function $h : \mathbb{F}_2^n \to [-1, 1]$ as $h(x) = 1 - \frac{2f(x)}{C}$. Noting that h is $2/C$-granular and using the above lemma, it follows that

$$C^{\oplus}_{\min}[f] = C^{\oplus}_{\min}[h] \leq n - \Omega\left(n^{1/d!}(d + \log(nC))^{-2}\right),$$

which shows that there is some affine subspace of dimension at least $\Omega\left(n^{1/d!}(2d + \log(nC))^{-2}\right)$ where f is constant. ◀

▶ Remark 24. Affine dispersers can be viewed as a relaxation of affine extractors, objects that have been well studied in the pseudorandomness literature. In a similar vein, we observe a connection between the notion of δ-regularity and affine extractors. In particular, we note that affine extractors can be viewed as functions that are δ-regular in *all* affine subspaces of sufficiently large dimension. We detail this connection in the full version of this work.

5 Lower Bounds on $\mathsf{r}(f, \delta)$

In this section, we prove lower bounds on $\mathsf{r}(f, \delta)$. With the exception of Lemma 26, we defer the proofs of all the statements to the appendices. We start with lower bounds for functions f that are bounded in the interval $[-1, 1]$; in the subsequent section, we give lower bounds for Boolean functions. For detailed sketches of all the results in this section, see Appendix A.2.

5.1 Bounded Functions

We begin with a simple bound on the number of standard basis vectors in low-dimensional affine subspaces, which is crucial in the analysis of the lower bounds.

▶ **Observation 25.** *For a subspace $\mathcal{V} \subseteq \mathbb{F}_2^n$ of co-dimension C, and $\mathcal{W}$ such that $\mathcal{W} \oplus \mathcal{V}^\perp = \mathbb{F}_2^n$, there exists a set $S \subseteq \mathcal{W}$ of size at least $n - C$ such that for every $u \in S$,*

$$|\left(u + \mathcal{V}^\perp\right)^{=1}| \geq 1.$$

Moreover, there exists a subset $S_1 \subseteq S$ of size at least $n - 2C$ whose corresponding shifts contain exactly *one standard basis vector.*

The proof of Observation 25 can be found in Appendix C. Using this observation, we provide an example of a degree one function f that witnesses large values for $\mathsf{r}(f, \delta)$.

▶ **Lemma 26.** *There is a degree one function $f : \mathbb{F}_2^n \to [-1, 1]$ for which $\mathsf{r}(f, \delta) \geq n/2$, for all $\delta < 1/n$.*

Proof. The counterexample is given by the function $f(x) = \frac{1}{n} \cdot \sum_i (-1)^{e_i \cdot x}$. Let $\mathcal{V}$ be a subspace of $\mathbb{F}_2^n$ of co-dimension C, and suppose we restrict the function to the affine subspace $\mathcal{U} = \alpha + \mathcal{V}$. By Observation 25, if $C \leq n/2 - 1$, there exists at least two vectors $\gamma, \gamma' \in \mathcal{W}$ (where $\mathcal{W}$ is such that $\mathcal{W} \oplus \mathcal{V}^\perp = \mathbb{F}_2^n$) such that $|(\gamma + \mathcal{V}^\perp)^{=1}| = |(\gamma' + \mathcal{V}^\perp)^{=1}| = 1$. Assume without loss of generality that $\gamma \neq 0$. Then, by Proposition 13, we have that

$$|\widehat{f_{\mathcal{U}}}(\gamma)| = \Big| \sum_{\eta \in u + \mathcal{V}^\perp} \widehat{f}(\eta)(-1)^{\langle \eta, \alpha \rangle} \Big| = \frac{1}{n} > \delta,$$

which follows by observing that exactly one of the summands in the last sum corresponds to a weight one vector and is non-zero. Therefore, $\mathsf{r}(f, \delta) \geq n/2$. ◀

We next show that Lemma 26 can be generalized to degree d bounded functions.

▶ **Lemma 27.** *For $d > 2$ and $\delta < \binom{n}{d}^{-1}$, there exists a degree d function $f : \mathbb{F}_2^n \to [-1, 1]$ for which $\mathsf{r}(f, \delta) \geq n - 2dn^{1/(d-1)}$.*

The proof of Lemma 27 can also be found in Appendix C. We note that unlike the degree one case, the functions achieving the lower bound in the above lemma are not explicit. Additionally, when $d = 2$, we see that Lemma 27 is trivial; it would be interesting to obtain a tighter result in this case.

5.2 Boolean Functions

This section has two parts. The first gives non-explicit lower bounds on $\mathsf{r}(f, \delta)$ for Boolean functions, and the second gives explicit lower bounds.

5.2.1 Non-explicit Lower Bounds on $\mathsf{r}(f, \delta)$

We can turn our lower bounds on $\mathsf{r}(f, \delta)$ for bounded functions into (non-explicit) lower bounds for Boolean functions. To do so, we use the following simple but powerful lemma of [12], which states that given a bounded function with a large $\mathsf{r}(f, \delta)$, there must exist some Boolean function g with similarly a large $\mathsf{r}(g, 2\delta)$.

▶ **Proposition 28** ([12], Claim 1.2). *Let $\tau > 0$ and $f : \mathbb{F}_2^n \to [-1, 1]$. There exists a Boolean function $g : \mathbb{F}_2^n \to \{\pm 1\}$ satisfying, for every affine subspace $\mathcal{U}$ such that $|\mathcal{U}| \geq \frac{4n^2}{\tau^2}$ and any $\gamma \in \mathbb{F}_2^n$, that $\left|\widehat{f_{\mathcal{U}}}(\gamma) - \widehat{g_{\mathcal{U}}}(\gamma)\right| \leq \tau$.*

Using Proposition 28, we have the following lemma.

▶ **Lemma 29.** *For all $d \geq 3$ and $\delta < \frac{1}{2} \cdot \binom{n}{d}^{-1}$, there exists a Boolean function f with*

$$\mathsf{r}(f, \delta) \geq n - \max\left\{2d \cdot n^{1/(d-1)}, \log\left(16n^2/\delta^2\right)\right\}.$$

Proof. By Lemma 27, there exists a bounded f that is not δ-regular in any affine subspace of dimension at least $2dn^{1/(d-1)}$ for all $\delta < \binom{n}{d}^{-1}$. Proposition 28 tells us that there exists a Boolean function g whose Fourier coefficients agree up to an additive error $\delta/2$ with the Fourier coefficients of f on all affine subspaces of dimension at least $\log\left(16n^2/\delta^2\right)$. Therefore, if f is not δ-regular on all of these affine subspaces, then g is also not $\delta/2$-regular on any of these subspaces. ◀

We can plug some parameters into Lemma 29 and achieve the following more parsable corollary.

▶ **Corollary 30.** *For every $3 \leq d \leq \frac{\log n}{\log\log n + 1}$ and $\delta = \frac{1}{2} \cdot n^{-d}$, there exists a Boolean function f with $\mathsf{r}(f, \delta) \geq n - 2d \cdot n^{1/(d-1)}$.*

We include the proofs of Proposition 28 and Corollary 30 in Appendix C.

5.2.2 Explicit Lower Bounds on $\mathsf{r}(f, \delta)$

We now turn to lower bounds on $\mathsf{r}(f, \delta)$ given by explicit Boolean functions. Our first example comes from analyzing certain Boolean functions studied by [18] that provide lower bounds for $\mathsf{r}(f, 0)$.

▶ **Lemma 31** (Related to Corollary 1.1 in [18]). *For each $\delta > 0$, there exists an explicit Boolean function $f : \mathbb{F}_2^n \to \{0, 1\}$ with $\mathsf{r}(f, \delta) = \Omega\left((\log \frac{1}{\delta})^{\log_2(3)}\right)$.*

Our second example is the majority function; we show that the majority function, denoted by MAJ_n, has a large $\mathsf{r}(f, \delta)$ value when $\delta = O(1/\sqrt{n})$. This in particular rules out the possibility of proving a bound of the form $\mathsf{r}(f, \delta) \leq \mathsf{poly}(\log(1/\delta))$ for Boolean f.

▶ **Lemma 32.** *There is an absolute constant $C > 0$, such that for all sufficiently large n, $\mathsf{r}(\mathsf{MAJ}_n, \delta) \geq \Omega(n^{1/2})$ for any $\delta \leq C/\sqrt{n}$.*

The proofs of Lemma 31 and Lemma 32 can be found in the full version of this work.

A Section 1 Omissions

A.1 Omitted Proofs

In this section we provide the proofs of Proposition 4 and Proposition 5. We first begin with a corollary of Proposition 13 which will be useful in the analysis of the claims.

▶ **Corollary 33.** *If $\mathcal{V}$ has dimension $n-1$ and $\mathcal{V}^{\perp} = \mathsf{span}(\{\gamma\})$, we have that $\widehat{f_{\alpha+\mathcal{V}}}(0) = \widehat{f}(0) \pm \widehat{f}(\gamma)$. Moreover, there exists a choice of α such that $|\widehat{f_{\alpha+\mathcal{V}}}(0)| = |\widehat{f}(0)| + |\widehat{f}(\gamma)|$.*

Proof. By Proposition 13, we have

$$\widehat{f_{\alpha+\mathcal{V}}}(0) = (-1)^{\langle 0,\alpha\rangle}\widehat{f}(0) + (-1)^{\langle \gamma,\alpha\rangle}\widehat{f}(\gamma) = \widehat{f}(0) + (-1)^{\langle \gamma,\alpha\rangle}\widehat{f}(\gamma).$$

This immediately implies both parts of the corollary. ◀

Proof of Proposition 4. Given some $f : \mathbb{F}_2^n \to [-1,1]$, consider the following simple procedure:

- While at least δ fraction of $\pi \in \Pi$ have some γ_π such that $|\widehat{f_\pi}(\gamma_\pi)| > \delta$, further partition each π into $\pi \cap \{x : \langle \gamma_\pi, x\rangle = 0\}$ and $\pi \cap \{x : \langle \gamma_\pi, x\rangle = 1\}$.

We would like to show that we cannot perform the above partitioning action more that $\frac{1}{\delta^3}$ times. Towards this end, define the potential function $\Phi(\Pi) := \mathbf{E}_{\pi\in\Pi}\widehat{f_\pi}(0)^2 = \mathbf{E}_{\pi\in\Pi}[(\mathbf{E}f_\pi)^2] \in [0,1]$. Whenever we partition further, by Corollary 33 each $|\widehat{f_\pi}(0)|$ is updated to either $|\widehat{f_\pi}(0) + \widehat{f_\pi}(\gamma_\pi)|$ or $|\widehat{f_\pi}(0) - \widehat{f_\pi}(\gamma_\pi)|$. Therefore, the contribution of π to Φ in one step of the partitioning process is

$$\frac{1}{2}\left((\widehat{f_\pi}(0) + \widehat{f_\pi}(\gamma_\pi))^2 + (\widehat{f_\pi}(0) - \widehat{f_\pi}(\gamma_\pi))^2\right) - \widehat{f_\pi}(0)^2 = \widehat{f_\pi}(\gamma_\pi)^2.$$

Since we assume at least δ fraction of $\pi \in \Pi$ had some γ_π such that $|\widehat{f_\pi}(\gamma_\pi)| > \delta$, at each step of the refinement Φ must increase by at least δ^3, completing the proof. ◀

Proof of Proposition 5. Suppose without loss of generality, $\mathbf{E}f \geq 0$. Start with the trivial subspace, $\pi_0 = \mathbb{F}_2^n$. While there exists γ such that $|\widehat{f_{\pi_t}}(\gamma)| > \delta$, by Corollary 33 we can fix the parity corresponding to γ in such a way that ensures that $|\widehat{f_{\pi_{t+1}}}(0)| = \left|\widehat{f_{\pi_t}}(0) + |\widehat{f_{\pi_t}}(\gamma)|\right| > \widehat{f_{\pi_t}}(\gamma) + \delta$. Since $\widehat{f_\pi}(0) \leq 1$ for all π, this process can happen at most $\frac{1}{\delta}$ times. ◀

A.2 Omitted Sketches

We give the main ideas behind the lower bounds in Table 1.

Sketch of Lemma 26. The proof of this claim is based on the homogeneous degree-one function $f(x) = \frac{1}{n}\sum_i (-1)^{x_i}$. Its key idea comes from Observation 25, which we use to show that if the dimension of $\operatorname{codim}(\mathcal{V}) < n/2$, then at least one shift of $\mathcal{V}^\perp$ must contain *exactly* one standard basis vector. By the preceding discussion, this implies that $f_{\alpha+\mathcal{V}}$ has a non-trivial Fourier coefficient with magnitude exactly $1/n > \delta$.

We remark that Lemma 26 is tight. The function f is symmetric, and for any such function, we can fix $n/2$ parities to obtain an affine subspace where every vector has weight $n/2$, which in turn fixes the function.

Sketch of Lemma 27 and Corollary 30. To achieve Lemma 27, one might expect to extend the above argument to the homogeneous degree d function $f(x) = \binom{n}{d}^{-1}\sum_{\gamma:\|\gamma\|_1=d}(-1)^{\langle\gamma,x\rangle}$. Unfortunately, this function is symmetric, and we have $r(f,0) \leq n/2$. We therefore consider a random homogeneous degree d function $f_{\mathbf{z}}(x) = \binom{n}{d}^{-1}\sum_{\gamma:\|\gamma\|_1=d}\mathbf{z}_\gamma\cdot(-1)^{\langle\gamma,x\rangle}$, where each $\mathbf{z}_\gamma$ is a random sign. A simple argument, again utilizing Observation 25, shows that there must be at least $\binom{k}{d}$ affine subspaces of $\mathcal{V}^\perp$ with at least one vector of weight d. By our earlier reasoning, each of those subspaces must in fact contain at least two vectors of weight d so that the restricted function would have a non-trivial Fourier coefficient with magnitude $\binom{n}{d}^{-1} > \delta$. Moreover, the probability (over the signs $\mathbf{z}_\gamma$'s) that each of the $\binom{k}{d}$ signed sums cancels is at most $2^{-\binom{k}{d}}$, and a union bound over all the possible affine subspaces of dimension $k = \Theta(dn^{1/(d-1)})$ completes the argument.

If we restrict our attention to Boolean functions, we might hope to obtain strong upper bounds for $\mathsf{r}(f,\delta)$; however, Corollary 30 rules this out. The proof of this claim is based on a simple lemma of [12] (Proposition 28), which uses the probabilistic method to convert a bounded function that is not δ-regular in large affine subspaces to a Boolean function with the same property. Applying this lemma to the lower bound from Lemma 27 achieves the result.

Sketch of Lemma 32. This lower bound is based on the majority function. Its key idea is that there exists a non-trivial affine subspace of $\mathcal{V}^{\perp}$ containing *exactly* one weight-1 vector and relatively few vectors of higher weight (see the full version of the work for details on this). Then, we use properties of the Fourier spectrum of the majority function to show that the signed sum of the Fourier coefficients of majority corresponding to vectors in this affine subspace, is on the order of $\left|\widehat{f}(e_1)\right| = \Omega(n^{-1/2})$. Specifically, we argue that even if the coefficients coming from higher weight vectors in the aforementioned sum combined in the most constructive way possible, they cannot combine to more than $\left|\widehat{f}(e_1)\right|/2$. We also note that Lemma 32 is tight up to constant factors via Proposition 5. Conversely, Lemma 32 implies that for $\delta \geq n^{-1/2}$, the majority function on $O(1/\delta^2)$ variables is an explicit Boolean function for which $\mathsf{r}(f,\delta) \geq \Omega(1/\delta)$.

Rationale for Lemma 31. The last entry in the table corresponds to Lemma 31 and is based on a simple function f on 4 inputs that is composed with itself k times. We use key properties of the composition of Boolean functions (from [24, 18]) to achieve the bound. The function itself is the same one considered in [18], and we use their main theorem crucially to obtain our lower bound. We present a slightly generalized version of the main theorem of [18], so we include a proof this in the full version of this work.

We make some final comments about the lower bounds from Corollary 30. The Boolean functions that achieve the lower bounds share the property that the magnitudes of their Fourier coefficients are extremely close to their bounded counterparts in Lemma 27. However, even though the bounded functions themselves have low degree, the Boolean functions are very far from being low-degree functions; in fact, *almost all* their Fourier mass comes from the high-degree terms. Notably, these functions are also non-explicit affine dispersers with small dimension, and it would be interesting to find explicit Boolean functions with similar strong lower bounds on the $\mathsf{r}(f,\delta)$.

B Section 2 Omitted Proofs

Proof of Proposition 13. Using Fact 12, we can write

$$\begin{aligned}\widehat{f_{\mathcal{U}}}(\gamma) = \mathbf{E}_{x\in\mathcal{V}}[f(x+\alpha)\cdot(-1)^{\langle\gamma,x\rangle}] &= \mathbf{E}_{x\in\mathcal{V}}\sum_{\beta}\widehat{f}(\beta)(-1)^{\langle\beta,x+\alpha\rangle}(-1)^{\langle\gamma,x\rangle}\\ &= \sum_{\beta}\widehat{f}(\beta)(-1)^{\langle\beta,\alpha\rangle}\mathbf{E}_{x\in\mathcal{V}}[(-1)^{\langle\beta+\gamma,x\rangle}]\\ &= \sum_{\beta\in\gamma+\mathcal{V}^{\perp}}\widehat{f}(\beta)(-1)^{\langle\beta,\alpha\rangle},\end{aligned}$$

where the last equality follows by observing that $\mathbf{E}_{x\in\mathcal{V}}\left[(-1)^{\langle\gamma+\beta,x\rangle}\right] = 1$ if $\beta\in\gamma+\mathcal{V}^{\perp}$, and zero otherwise. ◀

Proof of Proposition 15. We first show that $\mathcal{W}$ and $\mathcal{V}^\perp$ are independent. Suppose that $M^\mathsf{T}\gamma + u = 0$, where $\gamma \in \mathsf{span}(J)$ and $u \in \mathcal{V}^\perp$. For any $v \in \mathcal{V}$ such that $v \neq 0$, we have

$$0 = \langle v, M^\mathsf{T}\gamma + u\rangle = \langle v, M^\mathsf{T}\gamma\rangle = \langle Mv, \gamma\rangle,$$

which is impossible unless $\gamma = 0$ since this implies $Mv \in \mathsf{span}(J)^\perp = \mathsf{span}(\overline{J})$ and $Mv \neq 0$. This in turn implies that $u = 0$ and therefore that $\mathcal{W}$ and $\mathcal{V}^\perp$ are independent. The claim follows by noting that $\dim(\mathcal{W} \oplus \mathcal{V}^\perp) = \dim(\mathcal{W}) + \dim(\mathcal{V}^\perp) = k + n - k = n$. ◀

Proof of Proposition 16. Repeatedly using Fact 12, we have that

$$\begin{aligned}\left|\widehat{f_{\mathcal{U}}}(M^\mathsf{T}\gamma)\right| = \left|\mathbf{E}_{x\in\mathcal{U}}\left[f(x)(-1)^{\langle M^\mathsf{T}\gamma, x\rangle}\right]\right| &= \left|\mathbf{E}_{x\in\mathcal{U}}\left[f(x)(-1)^{\langle \gamma, Mx\rangle}\right]\right| \\ &= \left|\mathbf{E}_{z\in\mathcal{U}'}\left[f(M^{-1}z)(-1)^{\langle \gamma, z\rangle}\right]\right| = \left|\widehat{g_{\mathcal{U}'}}(\gamma)\right|.\end{aligned}$$ ◀

Proof of Fact 18. We have that

$$\begin{aligned}\widehat{g}(\gamma) = \mathbf{E}_x[g(x)\chi_\gamma(x)] &= \mathbf{E}[f(Mx)\chi_\gamma(x)] \\ &= \mathbf{E}_y[f(y)\chi_\gamma(M^{-1}y)] \\ &= \mathbf{E}_y[f(y)\chi_{M^{-\mathsf{T}}\gamma}(y)] = \widehat{f}(M^{-\mathsf{T}}\gamma),\end{aligned}$$

where we have used the fact that $\chi_\gamma(M^{-1}y) = (-1)^{\langle \gamma, M^{-1}y\rangle} = (-1)^{\langle M^{-\mathsf{T}}\gamma, y\rangle}$. ◀

C Proofs from Section 5

C.1 Proofs from Section 5.1

Proof of Observation 25. Let $S = \{u : u \in \mathcal{W} \text{ and } |(u+\mathcal{V}^\perp)^{=1}| \geq 1\}$. Since every standard basis vector can be expressed as $u+v$ for some $u \in S$ and $v \in \mathcal{V}^\perp$, we have that $\dim(\mathsf{span}(S \cup \mathcal{V}^\perp)) = n$. However, we also know that $\dim(\mathsf{span}(S \cup \mathcal{V}^\perp)) \leq |S| + C$, and rearranging we get $|S| \geq n - C$. Next, let $S_1 = \{u \in S : |(u + \mathcal{V}^\perp)^{=1}| = 1\}$. By Fact 9, for any $u, u' \in S$, we have $u + \mathcal{V}^\perp \neq u' + \mathcal{V}^\perp$. Therefore,

$$n = \sum_{u\in S} |(u+\mathcal{V}^\perp)^{=1}| = \sum_{u\in S_1} |(u+\mathcal{V}^\perp)^{=1}| + \sum_{u\in S\setminus S_1} |(u+\mathcal{V}^\perp)^{=1}| \geq |S_1| + 2(|S| - |S_1|),$$

and rearranging, we get $|S_1| \geq 2|S| - n \geq n - 2C$. ◀

Fully Dynamic Shortest Paths and Reachability in Sparse Digraphs

Abstract

We study the exact fully dynamic shortest paths problem. For real-weighted directed graphs, we show a deterministic fully dynamic data structure with $\widetilde{O}(mn^{4/5})$ worst-case update time processing arbitrary s,t-distance queries in $\widetilde{O}(n^{4/5})$ time. This constitutes the first non-trivial update/query tradeoff for this problem in the regime of *sparse weighted* directed graphs.

Moreover, we give a Monte Carlo randomized fully dynamic *reachability* data structure processing single-edge updates in $\widetilde{O}(n\sqrt{m})$ worst-case time and queries in $O(\sqrt{m})$ time. For sparse digraphs, such a tradeoff has only been previously described with amortized update time [Roditty and Zwick, SIAM J. Comp. 2008].

1 Introduction

Computing all-pairs shortest paths (APSP) is among the most fundamental algorithmic problems on directed graphs. This classical problem is often generalized into a data structure "oracle" variant: given a graph G, preprocess G so that efficient point-to-point distance or shortest paths queries are supported. Computing APSP can be viewed as an extreme solution to the oracle variant; if one precomputes the answers to all the n^2 possible queries in $\widetilde{O}(nm)$ time, the queries can be answered in constant time. The other extreme solution is to not preprocess G at all and run near-linear-time Dijkstra's algorithm upon each query. Interestingly, for general directed weighted graphs, no other tradeoffs for the exact oracle variant of static APSP beyond these trivial ones are known.

In this paper, we consider the exact APSP problem, and its easier relative *all-pairs reachability* (or, in other words, *transitive closure*), in the *fully dynamic* setting, where the input graph G evolves by both edge insertions and deletions.

1.1 Prior work

There has been extensive previous work on APSP and transitive closure in the fully dynamic setting. Notably, Demetrescu and Italiano [16] showed that APSP in a real-weighted digraph can be maintained deterministically in $\widetilde{O}(n^2)$ amortized time per vertex update

(changing all edges incident to a single vertex). Thorup [36] later slightly improved and simplified their result. These data structures maintain an explicit distance matrix and the corresponding collection of shortest paths, and thus allow querying distances and shortest paths in optimal time. Similar amortized bounds have been earlier obtained for transitive closure [17, 30, 32] albeit using different combinatorial techniques. Polynomially worse (but nevertheless subcubic) *worst-case* update bounds for real-weighted fully dynamic APSP are also known: randomized $\widetilde{O}(n^{2+2/3})$ [2, 24] and slightly worse deterministic $\widetilde{O}(n^{2+41/61})$ [13].

For dense *unweighted* digraphs, non-trivial fully dynamic data structures for all-pairs reachability and APSP can be obtained using algebraic techniques. Via a reduction to dynamic matrix inverse, Sankowski [35] obtained $O(n^2)$ *worst-case* update bound for explicitly maintaining the transitive closure, and also gave update/query tradeoffs. In particular, he showed a reachability data structure with subquadratic $O(n^{1.529})$ update time and sublinear $O(n^{0.529})$ query time. Using the same general algebraic framework, van den Brand, Nanongkai, and Saranurak [40] showed $O(n^{1.407})$ worst-case update bound for *st*-reachability (that is, fixed single-pair reachability), whereas van den Brand, Forster, and Nazari [38] gave an $O(n^{1.704})$ worst-case update bound for maintaining exact *st*-distance in unweighted digraphs.[1] That framework, however, inherently leads to Monte Carlo randomized solutions and does not generally allow reporting (shortest) paths within the stated query bounds.[2]

Interestingly, neither the known fully dynamic APSP data structures for *real-weighted* digraphs (or even for integer weights between 1 and n) nor the algebraic data structures tailored to dense graphs yield any improvement over the extreme recompute-from-scratch approaches for *sparse* graphs with $m = \widetilde{O}(n)$. This is especially unfortunate as such graphs are ubiquitous in real-world applications. Indeed, for $m = \widetilde{O}(n)$, recomputing APSP from scratch takes $\widetilde{O}(n^2)$ worst-case update time and $O(1)$ query time (which matches the amortized bound in [17, 36]), whereas naively running Dijkstra's algorithm upon query costs $\widetilde{O}(n)$ time (which already improves upon the update bound of the algebraic *st*-distance data structure of [38]). The only non-trivial fully dynamic APSP data structure in the sparse regime has been described by Roditty and Zwick [34]. Their randomized data structure has $\widetilde{O}(m\sqrt{n})$ amortized update time and $O(n^{3/4})$ query time. Unfortunately, it works only for *unweighted digraphs*. To the best of our knowledge, no non-trivial update/query tradeoffs for fully dynamic APSP in sparse weighted digraphs have been described to date. A step towards this direction has been made by Karczmarz [27] who showed that some *fixed* – in a crucial way – m distance pairs can be maintained in $\widetilde{O}(mn^{2/3})$ worst-case time per update.

For the simpler fully dynamic reachability problem, the $O(n^{1.529})$ update time and $O(n^{0.529})$ query time algebraic tradeoff of [35] is already non-trivial for all graph densities. However, specifically for sparse graphs, a deterministic and combinatorial tradeoff of Roditty and Zwick [33] is more efficient; they showed a data structure with $O(m\sqrt{n})$ amortized update time and $O(\sqrt{n})$ query time. Moreover, the data structure of [35] requires fast matrix multiplication algorithms [3, 21] and these are considered impractical. That being said, the downside of [33] is that the update bound holds only in the amortized sense.

[1] The single-pair data structures [40, 38] can be easily extended to support arbitrary-pair queries. Then, the query time matches the update time.

[2] As shown quite recently, reporting (shortest) paths in subquadratic time can be possible via a combination of algebraic and combinatorial techniques [8, 28]. However, this comes with a polynomial time overhead.

1.2 Our results

Dynamic shortest paths. Most importantly, we show the first fully dynamic APSP data structure with non-trivial update and query bounds for *sparse weighted* digraphs.

▶ **Theorem 1.** *Let G be a real-weighted directed graph. There exists a deterministic data structure maintaining G under fully dynamic vertex updates and answering arbitrary s,t-distance queries with $\widetilde{O}(mn^{4/5})$ worst-case update time and $\widetilde{O}(n^{4/5})$ query time and using $\widetilde{O}(n^2)$ space. The queries are supported only when G has no negative cycles. After answering a distance query, some corresponding shortest path $P = s \to t$ can be reported in $O(|P|)$ time.*

Compared to the data structure of Roditty and Zwick [34] for the unweighted case, our obtained update/query bounds are polynomially higher. However, our data structure has some very significant advantages. It is deterministic, handles real-edge-weighted graphs (possibly with negative edge weights and negative cycles), and the update time bounds holds in the worst case, as opposed to only in the amortized sense in [34]. Moreover, if path reporting is required, then the bounds in [34] hold only against an oblivious adversary. We also remark that a slightly more efficient variant of Theorem 1, with $\widetilde{O}(mn^{3/4})$ worst-case update time and $\widetilde{O}(n^{3/4})$ query time, can be obtained for the unweighted case.

The near-quadratic space requirement in Theorem 1 is clearly undesirable in the sparse setting, but also applies to all the other known fully dynamic reachability and shortest paths data structures. Moreover, this phenomenon is not specific to the dynamic setting. To the best of our knowledge, even for the *static* transitive closure problem, it is not known whether one can preprocess a general sparse directed graph into a data structure of size $O(n^{2-\epsilon})$ supporting arbitrary reachability queries in $O(n^{1-\epsilon})$ time.[3]

Dynamic reachability. For fully dynamic all-pairs reachability in sparse digraphs, we show that the amortized update bound of Roditty and Zwick [33] can also hold in the worst case.

▶ **Theorem 2.** *Let G be a directed graph. Let $t \in [1, \sqrt{m}]$. There exist a Monte Carlo randomized data structure maintaining G subject to fully dynamic single-edge updates with $\widetilde{O}(mn/t)$ worst-case update time and supporting arbitrary-pair reachability queries in $O(t)$ time. The answers produced are correct with high probability[4].*

Note that for $t = \sqrt{m}$, Theorem 2 yields $O(n^{2-\epsilon})$ update time and $O(n^{1-\epsilon})$ for some $\epsilon > 0$ for all but dense graphs. The data structure of Roditty and Zwick [33], on the other hand, has amortized update time at least $\Theta(m\sqrt{n})$, which is $o(n^2)$ only if $m = o(n^{3/2})$. However, the downsides of Theorem 2 compared to [33] are: supporting more restricted single edge (as opposed to vertex-) updates, using randomization, and not being able to report the underlying path efficiently.

Our data structure should also be compared with the $O(n^{1.529})/O(n^{0.529})$ worst-case update/query bounds obtained in [35]. Theorem 2 gives polynomially better bounds for very sparse graphs, with $m = O(n^{1.057})$. Moreover, although it is also algebraic in nature, it does not rely on fast matrix multiplication [3, 21], thus avoiding this potential practical efficiency bottleneck.

[3] Such a tradeoff is possible, for example, if the graph has a sublinear *minimum path cover*, see, e.g., [31].
[4] That is, with probability at least $1 - 1/n^c$, where the constant $c \geq 1$ can be set arbitrarily. We will also use the standard abbreviation w.h.p.

1.3 Technical overview

Shortest paths. In order to obtain a basic randomized variant of Theorem 1, we combine ideas from the known data structures for fully dynamic APSP with subcubic worst-case update bound [2, 24, 27]. These data structures all build upon hitting set arguments (dating back to the work of Ullman and Yannakakis [37]) yielding a sublinear $\widetilde{O}(n/h)$-sized set of vertices of the graph that lie on the shortest paths whose number of edges (*hops*) is at least $h = \operatorname{poly} n$. With this in hand, the main challenge is to recompute pairwise *small-hop* shortest paths, i.e., those with at most h hops, under edge deletions. As usual, edge insertions are rather easy to handle since the potential new paths created by insertions necessarily pass through the inserted edges' endpoints.

For efficient recomputation of small-hop paths, our data structure once in a while chooses a collection Π of n^2 pairwise $\leq h$-hop paths in G, and a set $C \subseteq V$ of *congested vertices* of truly sublinear (in n) size, so that the chosen paths are at least as short as shortest $\leq h$-hop paths in $G - C$ (i.e., the graph G with edges incident to the vertices C removed). The congested vertices are picked in such a way that no individual vertex $v \in V$ appears on the chosen paths too often. As a result, the number of precomputed paths destroyed by a vertex deletion that have to be restored is bounded. This idea is due to Probst Gutenberg and Wulff-Nilsen [24]. However, as opposed to [24], we cannot afford to recompute shortest $\leq h$-hop paths upon update in a hierarchical way which is inherently quadratic in n (albeit advantageous in the case of dense graphs). Instead, recomputation upon deletions is performed using a Dijkstra-like procedure (as in [2]), crucially with the sparsity-aware enhancements of [27] (such as the degree-weighted congestion scheme). These techniques, combined with the standard random hitting set argument [37] are enough to get the stated bounds, albeit Monte Carlo randomized.

Derandomization. Randomization above is only required for the sake of the hitting set argument. Curiously, we do not (and do not know how to) exploit the often-used property that a random hitting set, once sampled, is valid through multiple versions of the evolving graph as long as the adversary is oblivious to the hitting set. Therefore, we may as well sample the hitting set from scratch after each update. This is as opposed to [2, 27], where avoiding that leads to polynomially better bounds. If a fresh hitting set can be used upon each update, the standard derandomization method is to use a folklore greedy algorithm (see Lemma 8) for constructing a minimum hitting set that is $O(\log n)$-approximate, first used in the context of static and dynamic APSP algorithms in [30, 42]. The greedy algorithm runs in linear time in the input size. For constructing a hitting set of explicitly given pairwise $\leq h$-hop paths, this gives an $O(n^2 h)$ time bound per update. This is enough for deterministic variants of [2] and [42]. However, the incurred cost is prohibitive in the sparse case.

Derandomization of our data structure without a polynomial slowdown turns out to be non-trivial and requires some new tools. First, when precomputing $\leq h$-hop paths Π, we construct a hitting set H_0 of those paths in Π that have $\Theta(h)$ hops. When G is subject to deletions, H_0 hits the precomputed paths in Π that are not destroyed as a result of deletions. Hence, in order to lift H_0 into a hitting set after an update, it is enough to extend it so that it hits all the restored paths. If we wanted to run the greedy algorithm on the restored paths, the data structure would suffer from a factor-h polynomial slowdown. This is because the representation of the restored paths (constructed using Dijkstra's algorithm) can be computed more efficiently that their total hop-length and encoded using a collection of shortest paths trees $\mathcal{Z}$. The goal can be thus achieved by finding a hitting set of all $\Theta(h)$-hop root-leaf paths in $\mathcal{Z}$. King [30] gave a variant of the aforementioned deterministic greedy

algorithm precisely for this task. The algorithm of [30] runs in $O(\min(Nh, |\mathcal{Z}|n))$ time, where N denotes the total size of trees in $\mathcal{Z}$. While this is optimal when $\mathcal{Z}$ contains $\Theta(n)$ trees of size $\Theta(n)$ (as required in [30]), for small enough N and large enough $|\mathcal{Z}|$, this is not better than the standard greedy algorithm which could also solve the task in $O(Nh)$ time.

We deal with this problem by designing a novel near-optimal deterministic algorithm computing an $\widetilde{O}(n/h)$-sized hitting set of h-hop root-leaf path in a collection of trees that runs in $O(N \log^2 N)$ time independent of h (see Theorem 9). We believe that this algorithm might be of independent interest. The main idea here is to simulate the greedy algorithm only approximately, which enables taking advantage of dynamic tree data structures [4].

Reachability and sparse matrix inverse. Our improved worst-case bounds for fully dynamic reachability in sparse digraphs are obtained via a small change in the subquadratic update-sublinear query tradeoff of [35] based on dynamic matrix inverse. That algorithm once in a while explicitly recomputes the inverse of a certain matrix associated with the graph using fast rectangular matrix multiplication. That inverse encodes the transitive closure of the graph G. We observe that for sparse graphs, it is beneficial to recompute the inverse in a more naive way, entirely from scratch. This is because for large enough finite fields (with more than n^2 elements), it is in fact possible to compute the inverse of a sparse matrix with $m = \widetilde{\Theta}(n)$ non-zero elements in near-optimal $\widetilde{O}(mn)$ time without fast Strassen-style matrix multiplication algorithms (see Theorem 13). This is a relatively easy consequence of the classical work of Kaltofen and Pan [26], and has been, to the best of our knowledge, overlooked and not explicitly stated before. Sparse matrix inversion has been recently viewed (see, e.g., [12, 18]) mainly through the lens of *black-box matrix computations*, i.e., parameterized by the cost $\phi(n)$ of multiplying the input matrix (or its transpose) by a vector. For sparse matrices, we clearly have $\phi(n) = \widetilde{O}(n)$, but the best described bound for sparse matrix inversion in finite fields in that literature seems to be $O(n^{2.214})$ [12]. However, $\phi(n) = \widetilde{O}(n)$ holds for sparse matrices even in a less general so-called *straight-line program* computation model (also called the *algebraic circuit* model) which allows employing powerful tools such as the Baur-Strassen theorem [7].

1.4 Further related work

Exact all-pairs shortest paths in unweighted graphs have been studied also in partially dynamic settings: incremental [5] and decremental [6, 19]. Fully dynamic data structures are also known for $(1+\epsilon)$-approximate distances in weighted directed graphs [9, 39]. A significant research effort has been devoted to finding fully- and partially dynamic (approximate) all-pairs shortest paths data structures for *undirected* graphs, e.g., [10, 14, 15, 20, 38].

Dynamic reachability and shortest paths problems have also been studied from the perspective of conditional lower bounds [1, 23, 25, 34, 40].

2 Preliminaries

We work with directed graphs $G = (V, E)$. We denote by $w_G(e) \in \mathbb{R}$ the weight of an edge $uv = e \in E$. The graph G is called *unweighted* if $w_G(e) = 1$ for all $e \in E$. If the graph whose edge we refer to is clear from the context, we may sometimes skip the subscript and write $w(e)$. For simplicity, we do not allow parallel directed edges between the same endpoints of G, as those with non-minimum weights can be effectively ignored in reachability and shortest paths problems we study. As a result, we sometimes write $w_G(uv)$ or $w(uv)$.

For $u, v \in V$, an $u \to v$ path P in G is formally a sequence of vertices $v_1 \dots v_k \in V$, where $k \geq 1$, $u = v_1$, $v = v_k$, such that $v_i v_{i+1} \in E$ for all $i = 1, \dots, k-1$. The hop-length $|P|$ of P equals $k-1$. The length $\ell(P)$ of P is defined as $\sum_{i=1}^{k-1} w_G(v_i v_{i+1})$. P is a *simple path* if $|V(P)| = |E(P)| + 1$. We sometimes view P as a subgraph of G with vertices $\{v_1, \dots, v_k\}$ and edges (hops) $\{v_1 v_2, \dots, v_{k-1} v_k\}$.

For any $k \geq 0$, $\delta_G^k(s,t)$ is the minimum length of an $s \to t$ path in G with at most k hops. A *shortest k-hop-bounded $s \to t$ path* in G is an $s \to t$ path with length $\delta_G^k(s,t)$ and at most k hops. We define the s,t-distance $\delta_G(s,t)$ as $\inf_{k \geq 0} \delta_G^k(s,t)$. For $s, t \in V$, we say that t is *reachable* from s in G if there exists an $s \to t$ path in G, that is, $\delta_G(s,t) < \infty$. If $\delta_G(s,t)$ is finite, there exists a simple $s \to t$ path of length $\delta_G(s,t)$. Then, we call any $s \to t$ path of length $\delta_G(s,t)$ a *shortest s,t-path*.

If G contains no negative cycles, then $\delta_G(s,t) = \delta_G^{n-1}(s,t)$ for all $s, t \in V$. Moreover, in such a case there exists a *feasible price function* $p : V \to \mathbb{R}$ such that reduced weight $w_p(e) := w(e) + p(u) - p(v) \geq 0$ for all $uv = e \in E$. For any path $s \to t = P \subseteq G$, the reduced length $\ell_p(P)$ (i.e., length wrt. weights w_p) is non-negative and differs from the original length $\ell(P)$ by the value $p(s) - p(t)$ which does not depend on the shape of P.

For any $S \subseteq V$, we denote by $G - S$ the subgraph of G on V obtained from G by removing all edges incident to vertices S.

We sometimes talk about rooted out-trees T with all edges directed from a parent to a child. In such a tree T with root s, a *root path* $T[s \to t]$ is the unique path from the root to the vertex t of T. A subtree of T rooted in some of its vertices v is denoted by $T[v]$.

3 Fully dynamic shortest paths data structure

This section is devoted to proving the main theorem of this paper.

▶ **Theorem 1.** *Let G be a real-weighted directed graph. There exists a deterministic data structure maintaining G under fully dynamic vertex updates and answering arbitrary s,t-distance queries with $\widetilde{O}(mn^{4/5})$ worst-case update time and $\widetilde{O}(n^{4/5})$ query time and using $\widetilde{O}(n^2)$ space. The queries are supported only when G has no negative cycles. After answering a distance query, some corresponding shortest path $P = s \to t$ can be reported in $O(|P|)$ time.*

First, let us assume that all the edge weights are non-negative. Let us also make a simplifying assumption that any shortest k-hop-bounded $s \to t$ path in G always has a minimum possible number of hops and is simple. If there are no negative cycles, this is easy to guarantee by replacing each edge weight $w(e)$ in G with a pair $(w(e), 1)$, adding weights coordinate-wise, and comparing them lexicographically. We discuss how to extend the data structure to also handle negative edge weights and negative cycles later in Section 3.7.

We will first present a simple Monte Carlo randomized data structure, and show how to make it deterministic with no asymptotic time penalty (wrt. $\widetilde{O}(\cdot)$ notation) in Section 3.5.

Some further variants of the data structure are sketched in the Appendix. A variant for unweighted digraphs is given in Section A.1. In the weighted case, one can also achieve polynomially faster update at the cost of polynomially slower query and randomization. For details, see Section A.2.

The data structure operates in phases of Δ vertex updates. At the beginning of each phase, we apply a rather costly preprocessing described in the next subsection.

3.1 Preprocessing at the beginning of a phase

The preprocessing follows the general approach of [24] adjusted with some ideas from [27].

Let $h \in [2, n]$, and let τ be a *congestion threshold*, to be set later. We compute a certain collection of paths Π in G containing, for every pair $s, t \in V$, at most one $s \to t$ path $\pi_{s,t}$, satisfying $|\pi_{s,t}| = O(h)$, and a subset $C \subseteq V$ of *congested vertices*.

First of all, the collection Π and the set C satisfy:

$$\delta^h_G(s,t) \leq \ell(\pi_{s,t}) \leq \delta^h_{G-C}(s,t), \text{ for all } s,t \in V. \tag{1}$$

Above, we abuse the notation a bit and set $\ell(\pi_{s,t}) := \infty$ if there is no path $\pi_{s,t}$ in Π. Moreover, for any $v \in V$, let us define:

$$\Pi(v) := \{\pi_{s,t} \in \Pi : v \in V(\pi_{s,t})\},$$
$$\alpha(v) := \sum_{\pi_{s,t} \in \Pi(v)} \deg(t).$$

Crucially, Π additionally satisfies:

$$\alpha(v) \leq \tau, \text{ for all } v \in V. \tag{2}$$

▶ **Lemma 3.** *Let $h \in [1, n]$. For any $\tau \geq 2m$, in $O(nmh)$ time one can compute the congested set $C \subseteq V$ and a set of paths Π satisfying conditions (1) and (2) so that $|C| = O(nmh/\tau)$.*

Proof. We start with empty sets C and Π. Note that (2) is satisfied initially since all values $\alpha(\cdot)$ are zero. We will gradually add new paths to Π while maintaining (2) and ensuring that (1) holds for more and more pairs s, t. While introducing new paths to Π, we will also maintain the values $\alpha(v)$ (as defined above) for all $v \in V$.

We process source vertices $s \in V$ one by one, in arbitrary order. For each such s, we first move to C all the vertices $v \in V \setminus C$ with $\alpha(v) > \tau/2$. Next, we compute, for all $t \in V$, a shortest h-hop-bounded path $\pi_{s,t} = s \to t$ in $G - C$ (if such a path exists). For a fixed s, all the paths $\pi_{s,t}$ can be computed in $O(mh)$ time using a variant of Bellman-Ford algorithm. We add the newly computed paths to Π. Afterwards, (1) clearly holds for s and all $t \in V$. Moreover, (1) also holds for all $\pi_{s',t'} \in \Pi$ that have been added for a source s' processed earlier than s. Indeed, extending the set C only weakens the upper bound in (1). The values $\alpha(v)$ can be updated easily in $O(nh)$ time. Observe that for any $v \in V \setminus C$, $\alpha(v)$ grows by at most $\sum_{t \in V} \deg(t) = m$ when processing s. As a result, after processing s, we have $\alpha(v) \leq \tau/2 + m \leq \tau/2 + \tau/2 = \tau$ and hence (2) is satisfied. At the same time, since we use paths from $G - C$, for any $y \in C$, $\alpha(y)$ does not increase and thus we still have $\alpha(y) \leq \tau$.

Finally, note that for any $\pi_{s,t}$ added to Π, since $|\pi_{s,t}| \leq h$, $\alpha(v)$ grows by $\deg(t)$ for at most h distinct vertices v. As a result, we have $\sum_{v \in V} \alpha(v) \leq \sum_{t \in V} \deg(t) \cdot \left(\sum_{s \in V} h\right) \leq m \cdot nh$. But for each $y \in C$, we have $\alpha(y) > \tau/2$, so there is at most $2nmh/\tau$ such vertices y. ◀

Applying Lemma 3 constitutes the only preprocessing that we apply at the beginning of a phase in the Monte Carlo randomized variant. The computed paths Π are stored explicitly and thus the used space might be $\Theta(n^2 h)$. Note that with the help of additional $O\left(\sum_{\pi_{s,t} \in \Pi} |\pi_{s,t}|\right) = O(n^2 h)$ vertex-path pointers, we can report the elements of any $\Pi(v)$, $v \in V$, in constant time per element. We will discuss how to improve the space to $\widetilde{O}(n^2)$ using a trick due to Probst Gutenberg and Wulff-Nilsen [24] in Section 3.6.

3.2 Update

When a phase proceeds, let D be the set of at most Δ *affected* vertices in the current phase, that is, D contains every v such that a vertex update around v has been issued in this phase.

In the query procedure, we will separately consider paths going through $C \cup D$, and those lying entirely in $G - (C \cup D)$. To handle the former, upon each update we simply compute single-source shortest-path trees from and to each $s \in C \cup D$ in the current graph G. This takes $\widetilde{O}(|C \cup D|m)$ worst-case time using Dijkstra's algorithm.

As a matter of fact, we will not quite compute shortest paths in $G - (C \cup D)$, but instead, we will find paths in $G - D$ that are not longer than the distances between their corresponding endpoints in $G - (C \cup D)$. This is acceptable since $G - D \subseteq G$.

To prepare for queries about the paths in $G - (C \cup D)$, we do the following. We will separately handle *short* $\leq h$-hop shortest paths, and *long* $> h$-hop shortest paths.

Short paths. Denote by G_0 the graph at the beginning of the phase. Recall that we use G to refer to the current graph. Clearly, we have $G - D \subseteq G_0$. Fix some $s \in V$. First of all, note that if for some $t \in V$, $V(\pi_{s,t}) \cap D = \emptyset$, then $\pi_{s,t} \subseteq G - D$, so by (1):

$$\delta_{G-D}(s,t) \leq \ell(\pi_{s,t}) \leq \delta^h_{G_0-C}(s,t) \leq \delta^h_{G-(C\cup D)}(s,t).$$

The paths $\pi_{s,t}$ going through D are not preserved in $G - (C \cup D)$ and thus we cannot use them. We replace them with other paths $\pi'_{s,t}$ constructed using the following lemma.

▶ **Lemma 4.** *For $s \in V$, let Q_s contain all t such that $V(\pi_{s,t}) \cap D \neq \emptyset$. In $\widetilde{O}\left(\sum_{t\in Q_s} \deg(t)\right)$ time we can compute a representation of paths $\pi'_{s,t} \subseteq G - D$ (where $t \in Q_s$), each with possibly $\Theta(n)$ hops, satisfying:*

$$\delta_{G-D}(s,t) \leq \ell(\pi'_{s,t}) \leq \delta^h_{G-(C\cup D)}(s,t).$$

The representation is a tree T_s rooted at s such that:

(1) *some edges $sv \in E(T_s)$ represent paths $\pi_{s,v} \subseteq G - D$ from Π and have corresponding weights $\ell(\pi_{s,v})$,*

(2) *all other edges of T_s come from $E(G - D)$,*

(3) *for all $t \in Q_s$, $\pi'_{s,t}$ equals $T_s[s \to t]$ with possibly the first edge sw of that path uncompressed into the corresponding path $\pi_{s,w} \in \Pi$.*

Proof. Let Y be an edge-induced directed graph obtained as follows. For all $t \in Q_s$, and every of at most $\deg(t)$ edges $vt \in E(G - D)$, we add to Y the following:

- the edge vt itself (with the same weight),
- if $V(\pi_{s,v}) \cap D = \emptyset$, an edge sv of weight $\ell(\pi_{s,v})$ corresponding to the path $\pi_{s,v} \in \Pi$.

The algorithm is to simply compute a shortest paths tree T_s from s in Y in $\widetilde{O}(|E(Y)|) = \widetilde{O}\left(\sum_{t\in Q_s} \deg(t)\right)$ time using Dijkstra's algorithm. Clearly, any path $T_s[s \to t]$ corresponds to an $s \to t$ path in $G - D$. It is thus sufficient to prove that for all $t \in Q_s$, we have $\ell(T_s[s \to t]) \leq \delta^h_{G-(C\cup D)}(s,t)$.

If t is unreachable in $G - (C \cup D)$ from s using a path with at most h hops, there is nothing to prove. Otherwise, let a simple path P be a shortest h-hop-bounded $s \to t$ path in $G - (C \cup D)$. Let p be the last vertex on P such that $V(\pi_{s,p}) \cap D = \emptyset$, that is, $p \notin Q_s$. Note that p exists since $\delta^h_{G-C}(s,v) \neq \infty$ for all $v \in V(P)$ (which implies $\pi_{s,v} \in \Pi$) and $p \neq t$. Let P' be the $s \to p$ subpath of P. Let $e_1, \ldots, e_k \in E(G - (C \cup D))$ be the edges following p on P. Here, p is the tail of e_1. By the definition of Y and p, we have $e_i \in E(Y)$ for all $i = 1, \ldots, k$ since the head of each e_i is in Q_s. Moreover, there is an edge sp of weight $\ell(\pi_{s,p})$ in Y. Now, since $\pi_{s,p}$ is a path in $G - D$ of length at most $\delta^h_{G_0-C}(s,p)$, whereas the path $P' \subseteq G - (C \cup D) = G_0 - (C \cup D)$ has less than h hops, we obtain $\ell(\pi_{s,p}) \leq \ell(P')$ and hence:

$$\ell(T_s[s \to t]) = \delta_Y(s,t) \leq \ell(\pi_{s,p}) + \sum_{i=1}^{k} w(e_i) \leq \ell(P') + \sum_{i=1}^{k} w(e_i) = \ell(P) = \delta^h_{G-(C\cup D)}(s,t). \qquad \blacktriangleleft$$

We compute the paths $\pi'_{s,t}$ from Lemma 4 for all $s \in V$, $t \in Q_s$. Recall that $t \in Q_s$ implies that $V(\pi_{s,t}) \cap D \neq \emptyset$ and thus $\pi_{s,t} \in \Pi(d)$ for some $d \in D$. Therefore, the time needed for computing the paths $\pi'_{s,t}$ can be bounded as follows:

$$\widetilde{O}\left(\sum_{s\in V}\sum_{t\in Q_s}\deg(t)\right) = \widetilde{O}\left(\sum_{d\in D}\sum_{\pi_{s,t}\in\Pi(d)}\deg(t)\right) = \widetilde{O}\left(\sum_{d\in D}\alpha(d)\right) = \widetilde{O}(|D|\tau) = \widetilde{O}(\Delta\tau).$$

Note that the sets Q_s can also be constructed within this bound, since they can be read from $\bigcup_{d\in D}\Pi(d)$ which also has size $\widetilde{O}(\Delta\tau)$ and the paths from any $\Pi(v)$ can be reported in $O(1)$ time per path.

For all $s \in V$ and $t \notin Q_s$, let us simply set $\pi'_{s,t} := \pi_{s,t}$ and put $\Pi' = \{\pi'_{s,t} : s,t \in V\}$. To summarize, in $\widetilde{O}(\Delta\tau)$ time we can find, for all $s,t \in V$, a representation of paths $\pi'_{s,t}$ in $G - D$ that are at least as short as the corresponding shortest h-hop-bounded $s \to t$ paths in $G - (C \cup D)$. Storing a representation of the paths $\Pi' \setminus \Pi$ requires $\widetilde{O}(\min(\Delta\tau, n^2))$ additional space since, by the construction of Lemma 4, each of these paths can be encoded using its last edge and a pointer to another path in Π' with less hops.

Long paths. In order to handle long paths, we use the following standard hitting set trick from [37].

▶ **Lemma 5.** *Let $G = (V, E)$ be a directed graph with no negative cycles. For any $s,t \in V$, fix some simple shortest $s \to t$ path $p_{s,t}$ in G. Let $H \subseteq V$ be obtained by sampling, uniformly and independently (also from the choice of paths $p_{s,t}$), $c \cdot (n/h)\log n$ elements of V, where $c \geq 1$ is a constant. Then, with high probability (controlled by the constant c), for all $s,t \in V$, if $|p_{s,t}| \geq h$, then $V(p_{s,t}) \cap H \neq \emptyset$.*

On update, we simply apply Lemma 5 to the graph $G - (C \cup D)$ and an arbitrary choice of pairwise shortest paths therein. This way, with high probability, we obtain an $\widetilde{O}(n/h)$-sized hitting set H of shortest paths in $G - (C \cup D)$ that have at least h hops. Finally, we simply compute shortest paths trees from and to the vertices H in $G - (C \cup D)$ in $\widetilde{O}(|H|m) = \widetilde{O}(mn/h)$ worst-case time using Dijkstra's algorithm.

3.3 Query

To answer a query about s,t distance in the current graph, we simply return:

$$\min\left(\min_{v\in C\cup D}\left\{\delta_G(s,v)+\delta_G(v,t)\right\}, \min_{v\in H}\left\{\delta_{G-(C\cup D)}(s,v)+\delta_{G-(C\cup D)}(v,t)\right\}, \ell(\pi'_{s,t})\right). \quad (3)$$

The first term above is responsible for considering all s,t paths in G going through $C \cup D$. If all shortest s,t paths in G do not pass through $C \cup D$, then the second term captures (with high probability) one of such paths provided that it has at least h hops. Finally, if every shortest s,t path in G does not go through $C \cup D$ and has less than h hops, then $\delta_G(s,t) = \delta_{G-D}(s,t) = \delta^h_{G-(C\cup D)}(s,t)$. Moreover, by Lemma 4, $\pi'_{s,t}$ belongs to $G - D \subseteq G$ and $\delta_G(s,t) = \delta_{G-D}(s,t) \leq \ell(\pi'_{s,t}) \leq \delta^h_{G-(C\cup D)}(s,t) = \delta_G(s,t)$, so indeed $\delta_G(s,t) = \ell(\pi'_{s,t})$.

Finally, note that finding the minimizer in (3) allows for reconstruction of some shortest s,t path P in G in $O(|P|)$ time using the stored data structures.

3.4 Time analysis

The total time spent handling a single update is:

$$\widetilde{O}\left((|D|+|C|+|H|)m+\Delta\tau\right)=\widetilde{O}(m\Delta+nm^2h/\tau+mn/h+\Delta\tau).$$

There is also an $O(mnh)$ preprocessing cost spent every Δ updates which yields an amortized cost of $\widetilde{O}(mnh/\Delta)$ per update. Since $\tau \geq 2m$, the term $m\Delta$ is negligible above.

Balancing the terms mnh/Δ and mn/h yields $\Delta = h^2$. Next, balancing with $\Delta\tau$ yields $\tau = mn/h^3$ under the assumption $h = O(n^{1/3})$. Finally, balancing mn/h and $nm^2h/\tau = mh^4$ yields $h = n^{1/5}$, $\Delta = n^{2/5}$, and $\tau = mn^{2/5}$. For such a choice of parameters, the amortized update time is $\widetilde{O}(mn^{4/5})$. Since the only source of amortization here is a costly preprocessing step happening in a coordinated way every Δ updates, the bounds can be made worst-case using a standard technique, see, e.g., [2, 40].

The query time is $O(|C|+|D|+|H|+1)$. For the obtained parameters, the bound becomes $\widetilde{O}(\Delta+nmh/\tau+n/h)=\widetilde{O}(h^4+n/h)=\widetilde{O}(n^{4/5})$.

▶ Remark 6. In the above analysis, we have silently assumed that the "current" number of edges m does not decrease significantly (say, by more than a constant factor) during a phase due to vertex deletions, so that $m = \Omega(m_0)$ holds at all times, where $m_0 = |E(G_0)|$. Since the preprocessing of Lemma 3 is applied to G_0, for the chosen parameters h, Δ, and $\tau = m_0 n^{2/5}$, the update bound should more precisely be bounded by $\widetilde{O}(\max(m, m_0) \cdot n^{4/5})$. In general, it might happen that m becomes polynomially smaller that m_0 while the phase proceeds, e.g., if $m_0 = O(n\Delta)$. This could make the update bound higher than $\widetilde{O}(mn^{4/5})$.

There is a simple fix to this shortcoming, described in [27]: when a phase starts, it is enough to put aside a set $B \subseteq V$ of Δ vertices with largest degrees in G_0 and preprocess the graph $G_0 - B$ instead. The edges incident to vertices B can be viewed as added during the first Δ "auxiliary" updates in the phase, and effectively included in the affected set D from the beginning of the phase. One can easily prove that this guarantees that $m = \Omega(m_0)$ throughout the phase, where m_0 is now defined as $|E(G_0 - B)|$.

3.5 Derandomization

The only source of randomization so far was sampling a subset of vertices that hits shortest paths in $G - (C \cup D)$ with at least h hops. To derandomize the data structure, we will construct a hitting set H of size $\widetilde{O}(n/h)$ such that H hits all the paths in $\Pi' = \{\pi'_{s,t} : s, t \in V\}$ (constructed during update) with at least h distinct vertices. Recall that the paths Π' have been used to handle short paths so far. We first show that a hitting set H defined this way can serve the same purpose as the randomly sampled hitting set.

▶ **Lemma 7.** *Let $H \subseteq V$ be such that for all $s, t \in V$ satisfying $|V(\pi'_{s,t})| \geq h$, $V(\pi'_{s,t}) \cap H \neq \emptyset$ holds. Let $a, b \in V$ be such that every shortest $a \to b$ path in G has more than h hops and* does not *go through $C \cup D$. Then there exists a shortest $a \to b$ path in G that goes through a vertex of H.*

Proof. Let Q be the shortest $a \to b$ path in G that has the minimum number of hops. By the assumption, $|Q| > h$ and $V(Q) \cap (C \cup D) = \emptyset$. Let $Q = RS$, where $R = a \to c$ is the h-hop prefix of Q. We have $R \subseteq G - (C \cup D)$ and, since Q is a shortest path in G, R is also shortest in G and

$$\ell(R) = \delta_G(a, c) = \delta^h_G(a, c) = \delta^h_{G-(C\cup D)}(a, c).$$

Since $\delta^h_{G-(C\cup D)}(a,c)$ is finite, the path $\pi'_{a,c} \subseteq G - D \subseteq G$ satisfies

$$\delta_G(a,c) \leq \delta_{G-D}(a,c) \leq \ell(\pi'_{a,c}) \leq \delta^h_{G-(C\cup D)}(a,c) = \delta_G(a,c).$$

We conclude that the path $Q' = \pi'_{a,c} \cdot S$ satisfies $\ell(Q') = \ell(Q)$ and thus Q' is also a shortest $a \to b$ path in G. Since G has no negative cycles, one can obtain a *simple* $a \to c$ path $\pi''_{a,c}$ from $\pi'_{a,c}$ by eliminating zero-weight cycles, so that $\ell(\pi''_{a,c}) = \ell(\pi'_{a,c}) = \delta_G(a,c)$ and $V(\pi''_{a,c}) \subseteq V(\pi'_{a,c})$. By the definition of Q, $|V(\pi'_{a,c})| \geq |\pi''_{a,c}| \geq |R| \geq h$, since otherwise Q would not have a minimum number of hops. By the assumption we have $V(\pi'_{a,c}) \cap H \neq \emptyset$, so Q' is a shortest $a \to b$ path in G going through a vertex of H. ◀

Additional preprocessing. When a phase starts, we additionally do the following. Let Π_0 be a set of paths obtained as follows. For all $\pi_{s,t} \in \Pi$, if $|\pi_{s,t}| \geq h/2$, we add $\pi_{s,t}$ to Π_0.

Let us now recall a folklore greedy algorithm (used, e.g., in [42]) for computing a hitting set of a collection of sufficiently large sets over a common ground set, summarized by the following lemma.

▶ **Lemma 8.** *Let X be a ground set of size n and let $\mathcal{Y}$ be a family of subsets of X, each with at least k elements. Then, in $O\left(\sum_{Y\in\mathcal{Y}} |Y|\right)$ time one can deterministically compute a* hitting set *$H \subseteq X$ of size $O(n/k \cdot \log n)$ such that $H \cap Y \neq \emptyset$ for all $Y \in \mathcal{Y}$.*

We skip the proof of Lemma 8 since we later prove a more general result in Theorem 9. Using Lemma 8 we can compute a hitting set $H_0 \subseteq V$ of Π_0 in $O(n^2 h)$ time. H_0 has size $\widetilde{O}(n/h)$.

Computing a hitting set upon update. To compute a hitting set $H \subseteq V \setminus D$ as required by Lemma 7, we perform the following additional steps upon update. Recall that the precomputed set $H_0 \subseteq V$ hits all (simple) paths in $\Pi \cap \Pi'$ with at least $h/2$ hops, and thus also those that have at least h distinct vertices. We will augment H_0 into H so that it also hits all the paths in $\Pi' \setminus \Pi$ with at least h distinct vertices.

Recall from Lemma 4 that for a fixed $s \in V$, all the paths $\pi'_{s,t}$, where $t \in Q_s$, are encoded using a tree T_s. By construction, for each edge e of T_s, we have that the tail of e is s, or the head of e is in Q_s. Consider a subtree $T_s[u]$ rooted at some child u of s in T_s. If the edge su in T_s corresponds to the path $\pi_{s,u}$ with $|\pi_{s,u}| \geq h/2$ then H_0 hits $\pi_{s,u}$. As a result, for all $t \in Q_s \cap V(T_s[u])$, $V(\pi_{s,u}) \subseteq V(\pi'_{s,t})$ and hence if $|V(\pi'_{s,t})| \geq h$ then H_0 hits $V(\pi'_{s,t})$. Otherwise either su is a single edge from $G - D$, or it corresponds to a path $\pi_{s,u}$ with $|\pi_{s,u}| < h/2$. In either of these cases, if some t is at depth less than $h/2 - 1$ in $T_s[u]$, then $|V(\pi'_{s,t})| < h/2 + 1 + (h/2 - 1) = h$, so the path $\pi'_{s,t}$ does not need to be hit by H. Consequently, observe that it is enough for H to hit all the $(h/2-1)$-hop root paths in $T_s[u]$ in order to have $V(\pi'_{s,t}) \cap H \neq \emptyset$ for each $t \in T_s[u]$ with $|V(\pi'_{s,t})| \geq h$.

Let $\mathcal{Z}$ be the collection of all the subtrees $T_s[u]$, where $s \in V$ and $su \in E(T_s)$. It is now enough to compute an $\widetilde{O}(n/h)$-sized hitting set H_1 of each of the $(h/2-1)$-hop root paths in all trees in $\mathcal{Z}$. Then, $H_0 \cup H_1$ will form a desired hitting set H of all the paths in Π' with at least h distinct vertices. To this end, we could use a well-known variant of Lemma 8 due to King [30, Lemma 5.2]. However, the running time of that algorithm cannot be easily bounded with the total size N of $\mathcal{Z}$ (i.e., $N = \sum_{T\in\mathcal{Z}} |T|$) exclusively; its running time is $O\left(N + \sum_{T\in\mathcal{Z}} \min(n \log n, |T|k)\right) = O(\min(Nk, |\mathcal{Z}|n \log n))$ if one desires to hit k-hop root paths. Though, for some important cases, e.g., when $\mathcal{Z}$ contains n trees with $\Theta(n)$ vertices each, the running time is near-linear in N for any k. Unfortunately, this might not be the case in our scenario. Instead, we present a more sophisticated near-linear (independent of k) time algorithm for this task.

▶ **Theorem 9.** *Let V be a vertex set of size n and let $\mathcal{Z}$ be a family of trees on V. Let $N = \sum_{T\in\mathcal{Z}} |T|$. For any $k \in [1, n]$, in $O(N \log^2 n)$ time one can deterministically compute an $O(n/k \cdot \log n)$-sized* hitting set *$H \subseteq V$ of all the k-hop root paths in all the trees in $\mathcal{Z}$.*

Proof. We first iteratively prune the trees in $\mathcal{Z}$ of all the leaves at depths not equal to k: this does not alter the set of subpaths required to be hit. Afterwards, the task is to hit all the root-leaf paths in the collection $\mathcal{Z}$, each of exactly k hops.

Similarly as in [30], we would like to simulate the greedy algorithm behind Lemma 8, that is, repeatedly pick a vertex $v \in V$ hitting the largest number of paths not yet hit, and add it to the constructed set H. However, we cannot afford to follow this approach directly. Instead, when $L \geq 1$ paths are remaining to be hit, and there is $n' \geq k+1$ vertices $V \setminus H$ that have not yet been chosen, we pick a vertex hitting at least $\frac{L(k+1)}{2n'}$ remaining paths. Note that there always exists a vertex hitting at least $\frac{L(k+1)}{n'}$ remaining paths, since otherwise some of the remaining paths would contain a vertex from outside $V \setminus H$, a contradiction. A single step in our approach reduces L to at most $\left(1 - \frac{k+1}{2n'}\right) L$, so $\lceil 2n'/(k+1) \rceil = O(n/k)$ steps reduce L to at most L/e. Hence, since L is an integer, after $O\left(\frac{n}{k} \ln L\right) = O\left(\frac{n}{k} \ln N\right)$ steps L will drop to 0, i.e., all required paths will be hit.

Our strategy can be also rephrased as follows: maintain 2-approximate counters $\{c_v : v \in V\}$ such that the vertex v hits between c_v and $2c_v$ of the remaining paths, and repeatedly pick a vertex z with the maximum value of c_z. By the above discussion, the picked z will always satisfy $c_z \geq L(k+1)/2n'$, as desired. To implement this strategy, we proceed as follows.

For each $T \in \mathcal{Z}$, and $v \in V(T)$, let $d_{v,T}$ be the *exact* number of *previously not hit* root-leaf paths in T that v hits. Note that through the entire collection, v hits $D_v := \sum_{T\in\mathcal{Z}} d_{v,T}$ paths not yet hit. Observe that when a root-leaf path to the leaf l in T is hit for the first time, the value $d_{v,T}$ of all the ancestors v of l gets decreased by one. In fact, the algorithm of [30] can be seen to maintain such values $d_{v,T}$ and D_v explicitly. However, this is too costly for us; we will instead maintain the exact values $d_{v,T}$ only implicitly, in a data structure.

For each $T \in \mathcal{Z}$, we keep $V(T)$ (explicitly) partitioned into subsets $V_{T,0}, \ldots, V_{T,\ell}$, where $\ell = O(\log |V(T)|)$, so that $v \in V_{T,i}$ iff $d_{v,T} \in [2^i, 2^{i+1})$. Throughout the process, the values $d_{v,T}$ will only decrease, so a vertex $v \in V(T)$ can only move $O(\log n)$ times to a subset $V_{T,j}$ with a lower value j. Let us first argue that maintaining such partitions yields the desired 2-approximate counters rather straightforwardly.

For $v \in V$, let us define $c_v = \sum_{T,j:v\in V_{T,j}} 2^j$. Then, we have:

$$D_v = \sum_{T\in\mathcal{Z}} d_{v,T} \geq \sum_{T,j:v\in V_{T,j}} 2^j = c_v = \sum_{T,j:v\in V_{T,j}} 2^j = \frac{1}{2} \sum_{T,j:v\in V_{T,j}} 2^{j+1} > \frac{1}{2} \sum_{T\in\mathcal{Z}} d_{v,T} = \frac{1}{2} D_v.$$

As a result, the counters c_v indeed 2-approximate the values D_v and can be maintained subject to changes in the partitions $V_{T,i}$, for all T, i, in $O\left(\sum_{T\in\mathcal{Z}} |T| \log n\right) = O(N \log n)$ time.

Fix some $T \in \mathcal{Z}$. To maintain the partition $V_{T,0}, \ldots, V_{T,\ell}$, we maintain the values $d_{v,T}$ using ℓ data structures $S_{T,0}, \ldots, S_{T,\ell}$. The data structure $S_{T,i}$ associates (implicitly) the following vertex weights to the individual vertices v of T. If $d_{v,T} \geq 2^i$, then v has weight $d_{v,T}$ in $S_{T,i}$. Otherwise, if $d_{v,T} < 2^i$, then v has weight ∞ in $S_{T,i}$. In particular, $S_{T,0}$ associates the exact values $d_{v,T}$ to the vertices of T.

Fix some $i = 0, \ldots, \ell$. $S_{T,i}$ is implemented using, e.g., a top-tree [4, Theorem 2.4] that allows performing the following operations, both in $O(\log n)$ time[5]:

[5] As a matter of fact, in [4] this is shown for edge weights. However, vertex weights can be simulated easily using edge weights by assigning each vertex its parent edge, and explicitly maintaining the weight of the root.

(1) adding the same $\delta \in \mathbb{R}$ to the weights of vertices on some specified path in the tree, and
(2) querying for a vertex of the tree with minimum weight.

Clearly, $S_{T,i}$ can be initialized at the beginning of the process in $O(|T| \log n)$ time. When a new vertex z is added to H, and $z \in V(T)$, we iterate through all the (previously unvisited) descendants of z to identify the (original) leaves y at depth k such that the root-to-y path in T has not been previously hit. For each such y, we decrease the weights of all the ancestors of y in T (all lying on a single path in T) by 1. This requires a single top-tree operation on $S_{T,i}$. Afterwards, for all $w \in V(T)$ whose value $d_{w,T}$ was at least 2^i before adding z to H, $S_{T,i}$ contains (in an implicit way) the correctly updated exact value $d_{w,T}$. Some of these values in $S_{T,i}$ might drop below 2^i, though. To deal with this, we repeatedly attempt to extract the minimum-valued vertex $x \in V(T)$ from $S_{T,i}$. If the value of x is less than 2^i, we reset the value of x in $S_{T,i}$ to ∞. Otherwise, we stop; at this point all the values in $S_{T,i}$ are at least 2^i; the invariant posed on $S_{T,i}$ is fixed.

The above update procedure is performed for each i. Observe that $v \in V_{T,i}$ iff i is the maximum index such that v has assigned a finite value in $S_{T,i}$. Since for all i we can explicitly track which vertices in $S_{T,i}$ are assigned ∞ while performing updates, the time needed to maintain the partition $V_{T,0}, \ldots, V_{T,\ell}$ can be charged to the cost of maintaining the data structures $S_{T,0}, \ldots, S_{T,\ell}$.

Let us now analyze the time cost of this algorithm. For each $T \in \mathcal{Z}$, we iterate through every vertex of T at most $O(1)$ times. For $i = 0, \ldots, \ell$, at most $O(|V(T)| + |H \cap V(T)|) = O(|V(T)|)$ top-tree operations are performed on $S_{T,i}$. Hence, the cost of maintaining all $S_{T,i}$ for all $i = 0, \ldots, O(\log n)$ is $O(|T| \log^2 n)$. Through all $T \in \mathcal{Z}$, this is $O(N \log^2 n)$.

To implement finding a next vertex $z \in H$ with the largest c_z, one may simply store the counters c_z in a priority queue. Since the counters are updated $O(N \log n)$ times in total, the priority queue operations cost is $O(N \log^2 n)$ as well. ◀

Observe that through all s, the total number of edges in trees added to $\mathcal{Z}$ can be bounded by the number of edges in the (compressed) trees T_s of Lemma 4, and thus also by $\widetilde{O}(\min(\tau\Delta, n^2))$. As a result, by Theorem 9, the desired set H hitting all paths $\pi'_{s,t}$ with at least h distinct vertices can be computed in $\widetilde{O}(\tau\Delta)$ time, using at most quadratic space. This does not increase the running time of the update procedure in the asymptotic sense.

3.6 Reducing the space usage

So far, the space used by the preprocessing phase could only be bounded by $O(n^2 h)$ as we have explicitly stored the $O(n^2)$ preprocessed paths $\pi_{s,t} \in \Pi$, each with $O(h)$ hops.

We do not, however, need to store the paths $\pi_{s,t} \in \Pi$ explicitly. For performing updates and answering distance queries, we only require storing the values $\ell(\pi_{s,t})$, $|\pi_{s,t}|$, and being able to efficiently access the sets $\Pi(v)$, for any $v \in V$. If we want to also support path queries, then constant-time reporting of the subsequent edges of $\pi_{s,t}$ is also needed. Probst Gutenberg and Wulff-Nilsen [24, Section 4.2] showed an elegant way of achieving that in a slightly relaxed way using only $\widetilde{O}(n^2 \log h)$ space.

▶ **Lemma 10** ([24]). *Let $G = (V, E)$ be a real-weighted digraph with no negative cycles. Let $s \in V$ and let $h \in [1, n]$. Using $O(mh)$ time and $O(nh)$ space, one can build an $\widetilde{O}(n)$-space data structure representing a collection $\{\pi_t : t \in V\}$ of (not necessarily simple) $O(h)$-hop paths from s to all other vertices in G such that for any t, $\ell(\pi_t) \le \delta^h_G(s, t)$.*

For any $v \in V$, the data structure allows:

- *accessing $\ell(\pi_v)$ and $|\pi_v|$ in $O(1)$ time,*
- *reporting the set $P_v = \{t \in V : v \in V(\pi_t)\}$ in $\widetilde{O}(|P_v|)$ time,*
- *reporting the edges of π_v in $O(|\pi_v|)$ time.*

Proof sketch. Suppose we compute shortest h-hop-bounded $s \to t$ paths p_t from s to all $t \in V$. This takes $O(mh)$ time, but storing the computed paths explicitly would require $\Theta(nh)$ space. Recall that if G has no negative cycles, then we may wlog. assume that the paths p_t are all simple. As a result, one can deterministically compute an $\widetilde{O}(n/h)$-sized hitting set H of the $\lceil h/3 \rceil$-hop infixes starting at the $(\lceil h/3 \rceil + 2)$-th hop of those of the computed p_t that satisfy $|p_t| \geq \lceil 2h/3 \rceil$. We explicitly store the paths p_y for all $y \in H$ which costs only $\widetilde{O}(|H| \cdot h) = \widetilde{O}(n)$ space.

Let G' be obtained from G be adding shortcut edges $e_y = sy$ of weight $w(e_y) = \ell(p_y)$ for all $y \in H$. Note that for all $v \in V$, $\delta_{G'}^{\lceil 2h/3 \rceil}(s, v) \leq \delta_G^h(s, v) = \ell(p_v)$ and every $\leq \lceil 2h/3 \rceil$-hop path in G' corresponds to a path in G with at most $h + \lceil h/3 \rceil$ hops.

We recursively solve the problem on the graph G' with hop-bound $h' = \lceil 2h/3 \rceil$. Let $\{\pi'_t : t \in V\}$ be the obtained set of paths. For every $t \in V$, we define π_t to be π'_t with possibly the first shortcut edge e_z expanded to the corresponding path p_z. One can easily prove by induction that $|\pi_t| = O(h)$ and $\ell(\pi_t) \leq \delta_G^h(s, t)$. The recursion depth is clearly $O(\log h)$.

Finally, each of the explicitly stored $\widetilde{O}(n/h)$ paths p_t at some level of the recursion can be imagined to point to at most one path of the previous level (corresponding to a shortcut edge) and some $O(h)$ distinct vertices of G. By keeping only the nodes reachable from the paths at the last level of the recursion in this pointer system, and storing reverse pointers, we can report the elements of each P_v so that every element gets reported $O(\log n)$ times. ◀

To reduce the space to $\widetilde{O}(n^2)$, we simply replace the Bellman-Ford like procedure run on $G - C$ in the preprocessing of Lemma 3 with the construction of Lemma 10. The total congestion of all the vertices can increase only by a constant factor then. In Section 3.5 we have assumed that the preprocessed paths $\pi_{s,t}$ were simple when hitting all $\pi_{s,t}$ satisfying $|\pi_{s,t}| \geq h/2$ with H_0. But we can as well assume that H_0 hits all $\pi_{s,t}$ with $|V(\pi_{s,t})| \geq h/2$ instead. Even though the paths represented by the data structure of Lemma 10 might be non-simple, we can compute the sizes $|V(\pi_v)|$ within the same bound easily. Moreover, the algorithm behind Lemma 8 can be implemented so that it requires only $O(n)$ additional space if it is possible to (1) iterate through the elements of individual sets of $\mathcal{Y}$ in $O(1)$ time per element, and (2) report the sets $Y \in \mathcal{Y}$ containing a given $x \in X$ in near-linear time in the number of reported sets. This is precisely what Lemma 10 enables.

3.7 Negative edges and cycles

In this section we briefly describe the modifications to the data structure needed to handle negative edge weights and possibly negative cycles.

First of all, we run in parallel a deterministic fully dynamic negative cycle detection algorithm with $\widetilde{O}(m)$ worst-case update time (see, e.g., [27]). That algorithm also maintains a feasible price function p of the current graph G. With this in hand, whenever G has a negative cycle, we refrain from running the update procedure and forbid issuing queries. Otherwise, p is also a feasible price function of $G - D$, and thus the Dijkstra-based update procedure can simply use p to ensure that all the edge and path lengths accessed are non-negative.

In the basic randomized variant of our data structure we don't need to alter the preprocessing at the beginning of a phase at all. Indeed, our analysis did not require that the paths $\pi'_{s,t}$ are simple or with no negative cycles, and h-hop-bounded shortest paths are well-defined even in presence of negative cycles. In the $O(n^2 h)$-space deterministic variant (Section 3.5), similarly as in Section 3.6, we may compute the hitting set H_0 only for those $\pi_{s,t}$ that satisfy $|V(\pi_{s,t})| \geq h/2$. Recall that if the update procedure is run, then $G - D$ has no negative cycle and hence no path $\pi_{s,t}$ containing a negative cycle survives in $G - D$ anyway.

Finally, the preprocessing algorithm behind Lemma 10 internally uses hitting-set arguments (valid for simple paths) and requires, out-of-the-box, that there are no negative cycles. We now sketch how to deal with negative cycles while using the space-saving Lemma 10.

Whenever the preprocessing in Lemma 10 for source s encounters a path p_t containing a negative cycle, we use it as the desired path π_t, but discard it when computing a hitting set and thus also in the recursive preprocessing in Lemma 10 – effectively making reporting π_t (in any way) during update or query impossible. Similarly, such a path is included as $\pi_{s,t} \in \Pi$ in Lemma 3 only implicitly and marked as *negative*, but nevertheless used for updating the congestion counters $\alpha(\cdot)$ during the preprocessing. Note that during the update procedure, if G has no negative cycles, then for each "negative" path $\pi_{s,t}$, we have $V(\pi_{s,t}) \cap D \neq \emptyset$. The used charging scheme ensures that we can afford reconstructing the path $\pi'_{s,t}$ within the $\widetilde{O}(\tau\Delta)$ bound even though we do not know which vertices of D lie on $\pi_{s,t}$.

4 Algebraic fully dynamic reachability in sparse digraphs

In this section we show how the algebraic approach to dynamic reachability [35] can be applied in the case of sparse graphs, even without resorting to fast matrix multiplication [3, 21].

Assume for simplicity that $m = |E(G)| \geq n$ at all times. We prove the following.

▶ **Theorem 2.** *Let G be a directed graph. Let $t \in [1, \sqrt{m}]$. There exist a Monte Carlo randomized data structure maintaining G subject to fully dynamic single-edge updates with $\widetilde{O}(mn/t)$ worst-case update time and supporting arbitrary-pair reachability queries in $O(t)$ time. The answers produced are correct with high probability.*

Let us first review the approach of [35]. Identify the vertices of $G = (V, E)$ with $\{1, \ldots, n\}$. Assume G has a self-loop at every vertex, i.e., $vv \in E$ for all $v \in V$; self-loops do not change the reachability relation in G. Let $A(G)$ be an adjacency matrix of G, that is, an $n \times n$ matrix with the entry $A(G)_{ij}$ equal to 1 if $ij \in E(G)$, and 0 otherwise.

Let us choose a field $\mathbb{F} = \mathbb{Z}/p\mathbb{Z}$, for a prime number $p = \Theta(n^c)$, where $c \geq 3$ is a constant. Let the matrix $\tilde{A}(G)$ be obtained from $A(G)$ by replacing each 1 with a random element from $\mathbb{F}$. Sankowski [35, Theorem 6] showed the following.

▶ **Theorem 11.** [35] *With high probability (controlled by the constant c), the matrix $\tilde{A}(G)$ is invertible over $\mathbb{F}$ and for all $u, v \in V$, $(\tilde{A}(G)^{-1})_{u,v} \neq 0$ holds if and only if there exists a $u \to v$ path in G.*

Theorem 11 reduces fully dynamic reachability to the *dynamic matrix inverse* problem. Note that a single-edge update to G translates to a single-entry matrix update on $\tilde{A}(G)$, whereas a reachability query corresponds to an element query on the inverse $\tilde{A}(G)^{-1}$.

Sankowski [35] studied update/query tradeoffs for the dynamic matrix inverse problem. One tradeoff, summarized by the following theorem, is of our particular interest.

▶ **Theorem 12.** [35] *Suppose a matrix $A \in \mathbb{F}^{n \times n}$ is subject to single-element updates that keep A non-singular at all times.*

Let $\delta \in (0, 1)$. There exists a data structure maintaining A^{-1} with $\widetilde{O}(n^{\omega(1,\delta,1)-\delta} + n^{1+\delta})$ worst-case update time and supporting element queries on A^{-1} in $O(n^\delta)$ time.

Above, $\omega(1, \delta, 1) \geq 2$ denotes the rectangular matrix multiplication exponent (see [21]), i.e., a value such that one can multiply an $n \times n^\delta$ matrix by an $n^\delta \times n$ matrix in $\widetilde{O}\left(n^{\omega(1,\delta,1)}\right)$ time. Here, the time is measured in field operations. By applying Theorem 12 with $\delta \approx 0.529$ such that $\omega(1, \delta, 1) = 1 + 2\delta$ to the matrix $\tilde{A}(G)$ (whose inverse correctly encodes the

transitive closure of G throughout $\operatorname{poly} n$ updates, w.h.p. against an adaptive adversary), Sankowski [35] obtains a Monte Carlo randomized fully dynamic reachability algorithm with $\widetilde{O}(n^{1.529})$ worst-case update and $O(n^{0.529})$ query time.

To continue, we need to discuss some of the internals of the data structure of Theorem 12 [35, Section 6]. That data structures operates in phases of n^δ updates. At the end of each phase, the inverse A^{-1} is *explicitly* recomputed from (1) the explicitly stored inverse $(A_0)^{-1}$ of the matrix A_0 from the beginning of the phase, and (2) the n^δ updates in the current phase, via rectangular matrix multiplication. This is the sole reason why the term $n^{\omega(1,\delta,1)-\delta}$ appears in the update bound. In particular, at the beginning of each phase, we could also recompute the inverse of the current matrix A *from scratch* in $O(n^\omega)$ time and thus obtain a slightly worse update bound of $\widetilde{O}(n^{\omega-\delta}+n^{1+\delta})$, which in turn leads to the $\widetilde{O}(n^{(\omega+1)/2}) = O(n^{1.687})$ update bound if optimized wrt. δ. The query time is proportional to the phase length n^δ.

Speaking more generally, if we could compute the inverse of the maintained matrix at any time in T time, then by following the approach behind Theorem 12, for any parameter $t \in [1, n]$ (denoting the phase length) we could obtain a data structure with $\widetilde{O}(T/t + nt)$ worst-case update time and $O(t)$ query time. For $T = \Omega(n)$, it only makes sense to use $t \in \left[1, \sqrt{T/n}\right]$, and the update bound then simplifies to $\widetilde{O}(T/t)$. To obtain our fully dynamic reachability algorithm for sparse digraphs, we use this observation combined with the below theorem following from a classical result on solving linear systems in parallel [26].

▶ **Theorem 13.** *Let $A \in \mathbb{F}^{n\times n}$ be a non-singular matrix with $m = \Omega(n)$ non-zero entries. Assume the finite field $\mathbb{F}$ has at least n^{2+c} elements, where $c \geq 1$ is a constant.*

There is a Las Vegas randomized algorithm that computes A^{-1} in $\widetilde{O}(nm)$ time. The success probability is at least $1 - O(n^{-c})$.

Proof sketch. Kaltofen and Pan [26, Theorem 4] show, using techniques of [41], that finding the determinant of A can be reduced, in $\widetilde{O}(n^2)$ time, to solving the following subproblems:

(a) For a given vector $v \in \mathbb{F}^{n\times 1}$, computing vectors $\tilde{A}^i \cdot v$, for $i = 0, \ldots, 2n-1$, where $\tilde{A} = A \cdot H \cdot D$, $H \in \mathbb{F}^{n\times n}$ is a Hankel matrix, and $D \in \mathbb{F}^{n\times n}$ is a diagonal matrix.

(b) For a given vector $v \in \mathbb{F}^{n\times 1}$, computing vectors $T^i \cdot v$ for $i = 0, \ldots, n-1$, where $T \in \mathbb{F}^{n\times n}$ is a Toeplitz matrix.

Then, in [26, Section 4] it is proven that if the determinant algorithm is realized using a randomized algebraic circuit, or, in other words, a straight-line program with no conditional branches, loops, etc., that possibly can divide by zero with low probability, then the Baur-Strassen theorem [7] implies that the matrix inverse can be computed within the same asymptotic bound as the determinant, even in parallel.

The subproblems (a) and (b) for general dense $n \times n$ matrices can be solved within this model in $\widetilde{O}(n^\omega)$ time using a folklore combination of repeated squaring and fast matrix multiplication (see, e.g., [29]). In our case, to obtain a desired $\widetilde{O}(mn)$-time sparse matrix inverse algorithm, it is enough to argue that the subproblems (a) and (b) admit $\widetilde{O}(mn)$ time straight-line program (SLP) solutions for matrices with m non-zero entries.

Consider the subproblem (a), since (b) is very similar. We compute each subsequent vector $\tilde{A}^{i+1} \cdot v$ as $A \cdot (H \cdot (D \cdot (\tilde{A}^i v)))$. Multiplying a vector by a matrix with $m = \Omega(n)$ non-zero entries can clearly be realized in $O(m)$ time using an SLP with no conditional statements. This justifies that multiplications by the matrices A and D can be realized in the required model. It is also well-known that multiplying a vector by a Hankel/Toeplitz matrix reduces to polynomial multiplication (see, e.g., [22]), and thus also can be realized

using an $\widetilde{O}(n)$-gate straight-line program (see, e.g., [11]). This proves that each $\tilde{A}^{i+1}v$ can be obtained from $\tilde{A}^{i}v$ in $\widetilde{O}(m)$ time in the SLP model. This implies the desired $\widetilde{O}(nm)$ SLP time bound for subproblem (a). The theorem follows. ◀

▶ **Corollary 14.** *Suppose a matrix $A \in \mathbb{F}^{n\times n}$ is subject to single-element updates that keep A non-singular at all times and the number of non-zero elements in A is always $O(m)$, where $m \geq n$. Let $t \in [1, \sqrt{m}]$. There exists a data structure maintaining A^{-1} with $\widetilde{O}(mn/t)$ worst-case update time and supporting element queries on A^{-1} in $O(t)$ time.*

The above corollary applied to the matrix $\tilde{A}(G)$ combined with Theorem 11 implies Theorem 2.

A Further variants of the fully dynamic shortest paths data structure

A.1 Unweighted digraphs

Similarly as in the case of previous fully dynamic APSP data structures [2, 24], improved bounds can be obtained if the graph G is unweighted. This is simply because the preprocessing of Lemma 3 can be completed in $O(mn)$ time instead of $O(mnh)$ time. Indeed, in an unweighted graph, the shortest h-hop-bounded s, t path, if exists, coincides with the (globally) shortest s, t path. As a result, the Bellman-Ford-based computation can be replaced with breadth-first search. Similarly, the collection of paths Π can be represented using n BFS trees and thus one can achieve quadratic space without resorting to Lemma 10.

For unweighted graphs, the update bound becomes $\widetilde{O}(m\Delta+mn/\Delta+mn/h+nm^2h/\tau+\Delta\tau)$, whereas the query time remains $\widetilde{O}(\Delta + nmh/\tau + n/h)$. For $\Delta = h = n^{1/4}$ and $\tau = mn^{1/2}$ the update and query time bounds become $\widetilde{O}(mn^{3/4})$ and $\widetilde{O}(n^{3/4})$, respectively.

A.2 A slight tradeoff

In the basic variant of the data structure, it is not clear whether pushing the update time below $\widetilde{O}(n^{4/5})$ is possible even at the cost of increasing the query time. Here, we sketch that a slight tradeoff is indeed possible with another trick of [24, Section 4.1]: to delegate handling paths through the congested set to the data structure of [2, Section 3]. For simplicity, assume again that the edge weights are non-negative. Since that data structure, in turn, is tailored to dense graphs, we instead use the following sparse variant implicit in [27].

▶ **Lemma 15.** [2, 27] *Let $G = (V, E)$ be a directed graph and let $C \subseteq V$. Let $h \in [1, n]$. In $\widetilde{O}(|C|mh)$ time one can build a data structure supporting the following.*

For any query set $D \subseteq V$, update the data structure so that it supports queries computing the length of some $s \to t$ path of length at most $\min_{c\in C}\{\delta^h_{G-D}(s, c) + \delta^h_{G-D}(c, t)\}$ for any $s, t \in V$. The worst-case update time is $\widetilde{O}(|D|mh)$ and the query time is $O(|C|)$.

Proof sketch. For at most $2|C|$ *centers* $c_1, \ldots, c_\ell$, repeatedly find shortest $2h$-hop-bounded paths from/to c_i in $G - \{c_1, \ldots, c_{i-1}\}$. While this computation proceeds, maintain vertex congestions $\alpha(\cdot)$ as in Lemma 3. When choosing the subsequent centers c_i, alternate between picking an unused vertex from C and the most congested vertex of $V \setminus \{c_1, \ldots, c_{i-1}\}$, until all vertices of C are used. This preprocessing costs $O(\ell mh) = O(|C|mh)$ time.

Given the above preprocessing, one can prove that by proceeding as in Lemma 4, in $\widetilde{O}(|D|mh)$ time one can recompute a representation of paths $s \to c_i$ of length at most $\delta^{2h}_{G-(D\cup\{c_1,\ldots,c_{i-1}\})}(s, c_i)$ and analogous paths $c_i \to t$, for all i and $s, t \in V$.

Upon a query (s, t), in $O(\ell) = O(|C|)$ time we can find an $s \to t$ path of length at most $y^* = \min_{i=1}^{\ell}\{y_i\}$, where $y_i := \delta^{2h}_{G-(D\cup\{c_1,\ldots,c_{i-1}\})}(s, c_i) + \delta^{2h}_{G-(D\cup\{c_1,\ldots,c_{i-1}\})}(c_i, t)$. To see that this is enough, let $c^* \in C$ be such that $\delta^h_{G-D}(s, c^*) + \delta^h_{G-D}(c^*, t)$ is minimum. Let j be minimum index such that the corresponding $\leq 2h$-hop path $Q = s \to c^* \to t$ contains the center c_j. Then we have $Q \subseteq G - (D \cup \{c_1, \ldots, c_{j-1}\})$ and thus $y^* \leq y_j \leq \ell(Q)$. ◀

Note that by computing shortest-paths trees from and to a randomly sampled $\widetilde{O}(n/h)$-sized hitting set H we can in fact handle "long" shortest paths in the current graph G, and not only in $G - (C \cup D)$. As a result, we don't need to recompute full shortest paths trees from C – instead, it would be enough to consider short paths in $G - D$ through C upon query. This is what we use Lemma 15 for. Every Δ updates, when a new phase starts, a fresh congested set C is computed. We additionally initialize the data structure of Lemma 15 for the current graph G and the congested set C. This way, that data structure is always off from the current G by at most Δ updates, and thus can be updated in $\widetilde{O}(\Delta mh)$ time. Again, the data structure of Lemma 15 can be reinitialized in such a way that the additional worst-case cost incurred is $\widetilde{O}(|C|mh/\Delta)$. The full worst-case update time becomes:

$$\widetilde{O}(m\Delta + mnh/\Delta + mn/h + \Delta\tau + m^2nh^2/(\tau\Delta) + \Delta hm).$$

Balancing as before, for $\Delta = h^2$ and $\tau = mn/h^3$, we obtain the update bound $\widetilde{O}(mn/h+mh^3)$. Note that this bound is $\Omega(mn^{3/4})$ for any h.

The query bound unfortunately remains $\widetilde{O}(\Delta + |H| + mnh/\tau) = \widetilde{O}(n/h + h^4)$. If we aim at serving $\Theta(n)$ queries per update and the graph is sparse, then we get no improvement over the basic approach. However, for a desired query time of $\widetilde{O}(t)$, where $t \in [n^{4/5}, n]$, we can achieve $\widetilde{O}(mn/t^{1/4})$ worst-case update time this way.

New Additive Emulators

Abstract

For a given (possibly weighted) graph $G = (V, E)$, an additive emulator H is a weighted graph in $V \times V$ that preserves the (all pairs) G-distances up to a small additive stretch. In their breakthrough result, [Abboud and Bodwin, STOC 2016] ruled out the possibility of obtaining $o(n^{4/3})$-size emulator with $n^{o(1)}$ additive stretch. The focus of our paper is in the following question that has been explicitly stated in many of the prior work on this topic:

What is the minimal additive stretch attainable with linear size emulators?

The only known upper bound for this problem is given by an implicit construction of [Pettie, ICALP 2007] that provides a linear-size emulator with $+\widetilde{O}(n^{1/4})$ stretch. No improvement on this problem has been shown since then.

In this work we improve upon the long standing additive stretch of $\widetilde{O}(n^{1/4})$, by presenting constructions of linear-size emulators with $\widetilde{O}(n^{0.222})$ additive stretch. Our constructions improve the state-of-the-art size vs. stretch tradeoff in the entire regime. For example, for every $\epsilon > 1/7$, we provide $+n^{f(\epsilon)}$ emulators of size $\widetilde{O}(n^{1+\epsilon})$, for $f(\epsilon) = 1/5 - 3\epsilon/5$. This should be compared with the current bound of $f(\epsilon) = 1/4 - 3\epsilon/4$ by [Pettie, ICALP 2007].

The new emulators are based on an extended and optimized toolkit for computing weighted additive emulators with sublinear distance error. Our key construction provides a weighted modification of the well-known Thorup and Zwick emulators [SODA 2006]. We believe that this TZ variant might be of independent interest, especially for providing improved stretch for distant pairs.

1 Introduction

Emulators are well-studied compression schemes that approximately encode the distance metric of a (dense) undirected input graph $G = (V, E)$ by a sparse *weighted* graph $H \subseteq V \times V$. This extends the notion of spanners which are required to be subgraphs of G. Along with their spanner cousin, emulators admit a wide range of algorithmic applications, most notably in settings related to graph compression, routing schemes, distributed computing, and all pairs shortest paths approximation. The focus of this paper is in providing improved constructions for *additive emulators* which only allow for additive stretch. For a given unweighted n-vertex graph $G = (V, E)$, a graph $H \subseteq V \times V$ is an $f(d)$-emulator if $\text{dist}_G(u, v) \leq \text{dist}_H(u, v) \leq f(\text{dist}_G(u, v))$ for every $u, v \in V$. An $f(d)$-emulator for $f(d) = d + \beta$ for some fixed β is denoted as *additive* emulator. There has been a long line of work on additive emulators, both from an upper bound and lower bound perspectives, see Table 1.

The first explicit construction for this setting obtained $+4$ emulators of size $O(n^{4/3})$ by Dor, Halperin and Zwick [11]. The question of whether sparser emulators exist for any constant additive stretch has been one of the most major open problems in the area. In their breakthrough result, Abboud and Bodwin [1] refuted this possibility by demonstrating that any emulator with $O(n^{4/3-\epsilon})$ edges might induce a polynomially large additive stretch of $\Omega(n^{\delta(\epsilon)})$, for any ϵ.

On the other side of the size vs. stretch tradeoff, additive emulators of *linear* size have in particular attracted a lot of attention over the years [18, 7, 10, 9, 1, 16, 2, 14, 17]. To this date, the best additive stretch known for linear size emulators is $\widetilde{O}(n^{1/4})$, as shown (implicitly) by an earlier work of Pettie [18]. Bodwin and Vassilevska Williams [10] designed linear-size spanners and emulators with additive stretch of $+\widetilde{O}(\sqrt{n})$ (resp., $+\widetilde{O}(n^{1/3})$). In a follow-up work [9] , they cleverly improved the spanner's stretch to the state-of-the-art bound of $+\widetilde{O}(n^{3/7})$; Unfortunately, their improved spanner constructions do not seem to imply improved bounds for emulators, and Pettie's result [18] remains the state-of-the-art.

In this paper we focus on the following basic graph compression problem which despite all efforts is still fairly open:

▶ **Question 1.1.** What is the minimal additive error that can be achieved with linear space?

This question on its various forms (e.g., spanners, emulators) has been raised in many of the prior work on the topic, see e.g., [10, 3], especially in light of the "4/3 barrier" of [1]. Indeed in their seminal lower bound paper, Abboud and Bodwin [1] explicitly asked:

> *Our work shows that polynomial additive error must be suffered in order to obtain near-linear size compression of graphs. Given this, it is natural to wonder* how much *polynomial error is necessary to obtain compression in this regime.*

While not much progress has been provided on the upper bound side, there has been more movement on the lower bound aspects of the problem. Abboud and Bodwin showed that any linear size emulator must suffer $\Omega(n^{1/22})$ additive stretch, in the worst case. Huang and Pettie [16] improved this bound to $+\Omega(n^{1/18})$. This was further improved by Lu, Wein, Vassilevska Williams, and Xu [17] to $+\Omega(n^{2/29})$. Very recently, Bodwin and Hoppenworth [8] provided an $+\Omega(n^{1/7})$ stretch lower bound for linear spanners, by extending the known obstacle product framework to support also non-layered graphs.

Our new constructions are built upon modifying and extending the existing constructions for emulators with sublinear additive stretch and weighted additive spanners. While these notions have been studied before, our primary conceptual contribution is in demonstrating their usefulness for computing additive emulators of unweighted graphs. We next discuss the prior work on each of these settings.

Sublinear additive stretch. Elkin and Peleg showed that the "4/3 barrier" could be broken if one allows a $(1+\epsilon)$ multiplicative stretch, in addition to a small additive stretch [15]. Thorup and Zwick gave an elegant construction of an $O(kn^{1+1/(2^{k+1}-1)})$-size emulator H with $O(1+\epsilon, O(k/\epsilon)^{k-1})$-type stretch[1]. Their emulator has the remarkable property that its stretch bound holds for every $\epsilon > 0$ *simultaneously*, as its size bound is independent in ϵ. For any distance d, choosing $\epsilon = k/d^{1/k}$ leads to an emulator with a sublinear additive stretch function $f(d) = d + O(d^{1-1/k} + 3^k)$. As noted in [2], an interesting open question is whether one can match this size-stretch tradeoff for spanners.

[1] I.e., for every $u, v \in V$, $\mathrm{dist}_H(u,v) \leq (1+\epsilon)\mathrm{dist}_G(u,v) + O(k/\epsilon)^{k-1}$.

Weighted (near) additive stretch. Elkin, Gitlitz and Neiman [13] provided the first constructions of near-additive spanners for *weighted* graphs. Their algorithm extends the unweighted construction of near-additive spanners (e.g., by [15]) to provide stretch guarantees of $f(d) = (1+\epsilon)d + \beta W$ where W is the maximum edge weight. Ahmed et al. [3] extended the constructions of spanners with purely additive stretch to weighted graphs by an ingenious amortized argument (which plays a role in our constructions, as well). Consequently, they provide $+2W, +4W, +8W$ weighted spanners with $\widetilde{O}(n^{3/2})$, $\widetilde{O}(n^{7/5})$ and $\widetilde{O}(n^{4/3})$ edges, respectively. Elkin, Gitlitz and Neiman [12] improve the latter stretch bound to $(6+o(1))W$, nearly matching the unweighted result for $W = 1$. Note that the above mentioned constructions also provide a *local* stretch guarantee of $+\beta \cdot W_{s,t}$ for every s, t pair, where $W_{s,t}$ is the largest edge weight on an s-t shortest path.

1.1 New Results

We provide a positive progress for Question 1.1 by improving upon the long-standing bound of $+\widetilde{O}(n^{1/4})$ by Pettie [18] to an additive stretch of $+O(n^{0.222-o(1)})$. Our end result is:

▶ **Theorem 1.2.** *Any unweighted n-vertex graph $G = (V, E)$ admit a linear-size emulator with additive stretch $\widetilde{O}(n^{2/9-1/1600-o(1)})$.*

The main novel aspect of this result is in our approach, which draws an interesting connection between weighted additive emulators and unweighted emulators with polynomial additive stretch. The final additive bound $O(n^{0.222-o(1)})$ is obtained by taking a gradual approach, containing two major steps of optimizations.

To illustrate our new algorithmic approach, we start by presenting a very simple construction for recovering the state-of-the-art additive stretch of $+\widetilde{O}(n^{1/4})$. This construction is obtained by using in a black-box manner the recent constructions of *weighted additive*

spanners by Ahmed et al. [4] and Elkin, Gitlitz and Neiman [12] which provides an additive stretch $+\beta W$. While such an additive term might be undesirable in many settings, these constructions play a key role in providing additive emulators for *unweighted* graphs[2].

Improved Stretch vs. Size Bounds via Weighted Additive Emulators. A careful inspection of our $+\widetilde{O}(n^{1/4})$ additive construction reveals that our reduction yields in fact, a specialized *weighted* graph instance with several convenient properties. In particular, we enjoy the fact that our generated weighted graphs are in fact obtained from unweighted graphs, in the sense that the edge weights corresponds to distances, rather than being arbitrary. We then provide a designated construction of weighted additive emulators that takes advantage of these specialized weighted graph instances. This leads to a quite general construction which improves over the known bounds in the entire regime of sparsity, i.e., n to $n^{4/3}$:

▶ **Theorem 1.3.** *For any n-vertex graph $G = (V, E, \omega)$ where $\omega : E \to \{1, \ldots, W\}$ and $0 \leq \epsilon \leq \frac{1}{3}$, there exists a $+\widetilde{O}(W \cdot n^{f(\epsilon)})$ emulator H of size at most $\widetilde{O}(n^{1+\epsilon})$ where:*

$$f(\epsilon) = \begin{cases} (1-3\epsilon)/5 & \text{if } 1/7 \leq \epsilon \leq 1/3; \\ (9-31\epsilon)/40 & \text{if } 3/37 \leq \epsilon \leq 1/7; \\ (3-9\epsilon)/14 & \text{if } 1/15 \leq \epsilon \leq 3/37; \\ (25-87\epsilon)/112 & \text{if } 0 \leq \epsilon \leq 1/15. \end{cases}$$

Setting $\epsilon = 0$, provides a linear-size emulator with additive stretch $n^{25/112} \sim n^{0.223}$.

Discretization of the Thorup-Zwick (TZ) Emulator Construction. Our final emulator result of Theorem 1.2 is based on a rather involved discretization of the TZ emulator construction adapted for weighted graphs. The following (quite technically to state) result serves as the core component of the final linear-size emulator:

▶ **Theorem 1.4.** *For every n-vertex unweighted $G = (V, E)$ a constant integer $k \geq 3$ and integer $D \geq 1$, one can compute an emulator H with additive stretch $O(D^{1-1/(k-1)} \log n)$ for any distance $d = O(D \cdot \log n)$. The size of H is bounded by*

$$\widetilde{O}(n^{1+1/(2^{k+1}-1)} + n^{1+1/(2^k-1)}/(D^{(2^k-2k)/((2^k-1)k(k-1))}).$$

This should be compared with the original TZ construction that provides an additive stretch of $d^{1-1/k}$ using $n^{1+1/(2^{k+1}-1)}$ edges. Theorem 1.4 can also be shown to imply that the stretch function of the TZ emulator is optimal only for a restricted regime of distances. In particular, with a size bound of $\widetilde{O}(n^{1+1/(2^{k+1}-1)})$, one can provide pairs at distances $d \geq n^{k^2/2^k}$ an additive stretch of $O(d^{1-1/(k-1)})$, rather than $O(d^{1-1/k})$ as provided by the TZ bounds, which might be of independent interest.

1.2 Technical Overview

Our $+\widetilde{O}(n^{0.222})$-additive linear-size emulator is obtained in a sequence of two intermediate results, that gradually take advantage of several interesting degrees of freedom in the current constructions of weighted (near) additive emulators. Our technique exhibits several directions

[2] While our constructions utilizes the $+\beta W$ stretch guarantees, it is unclear if the local $+\beta W_{s,t}$ stretch guarantees can be useful in our context, as well.

of optimizations in the emulator framework of Thorup and Zwick [19], which become useful in the context of designing additive emulators with a small polynomial stretch. Note that while all our constructions are implemented in polynomial time, in this paper we put emphasis on the stretch vs. size tradeoff.

Beginner: $+\widetilde{O}(n^{1/4})$ Additive Stretch. As a warmup to our approach, we provide in Sec. 2 a new proof technique to obtain $+\widetilde{O}(n^{1/4})$ emulators of linear size, which simplifies the (implicit) state-of-the-art construction of Pettie [18]. Interestingly, our argument follows immediately by the weighted $+O(W)$ additive spanners of Ahmed et al. [4] and Gitlitz, Elkin, Neiman [12] with $\widetilde{O}(n^{4/3})$ edges, where W is the maximum edge weight of the graph. This provides the starting indication for the potential connection between weighted additive emulators and purely additive emulators for unweighted graphs.

On a high level, the construction works by computing a weighted *net* graph G' for the given (unweighted) graph G, obtained by sampling each G-vertex independently with probability of $\Theta(1/n^{1/4})$. The edges of G' connect every pair of sampled vertices u, v provided that their G-distance is at most $\Theta(n^{1/4}\log n)$. The net edges are weighted by the G-distance between their endpoints. The output emulator is union of two spanners: (i) a $O(\log n)$ multiplicative spanner for G (see Lemma 1.7), and (ii) a $+O(W)$ additive spanner for G' where $W = \Theta(n^{1/4}\log n)$. It is easy to see that the size bound is (near) linear[3]. The stretch argument for nearby pairs u, v at G-distance $O(n^{1/4}\log n)$ follows by the addition of the $O(\log n)$ multiplicative spanner. The argument for distant pairs $\Omega(n^{1/4}\log n)$ follows by using the $+O(W)$ additive spanner for G'.

Intermediate : $+\widetilde{O}(n^{0.223})$ Additive Stretch. The essence of the above mentioned construction is to employ on a weighted additive algorithm on the computed (weighted) net graph G', in a black box manner. Our starting observation, to break the current $+\Theta(n^{1/4})$ barrier, is the following: while G' is indeed a weighted graph, it is obtained from a given *unweighted* base graph G. Therefore it might be possible to treat G' better than any arbitrary input weighted graph. More specifically, by including the TZ emulator for G, one can provide a *sublinear* stretch guarantee for any neighboring pairs in G'. This, in principle, is impossible, for general weighted graphs. Since the sublinear stretch guarantees of the TZ emulators require a superlinear size bound, we cannot employ them directly on G, but rather on a subsampled *net* of G. This sub-sampling immediately converts the unweighted input instance into a weighted instance. We therefore conclude that the key task should be concerned with providing sparse constructions of *weighted additive* emulators. Our core construction computes a superlinear-size emulator for any weighted graph whose weighted stretch and size guarantees depend on the input integer parameters D, k, as follows:

▶ **Theorem 1.5.** *Any n-vertex graph $G = (V, E, \omega)$ with max weight W and integers $k \geq 2, D \geq 1$ admits a $+O(WD)$ emulator of size $\widetilde{O}(n^{1+1/(2^{k+1}-1)} + n^{4/3}/(D^{4/3} + 2/(3k)))$.*

Theorem 1.5 serves as the key technical step in providing the improved additive stretch vs. size bounds in almost the entire regime of parameters (see Theorem 1.3). In particular, by using a suitable pre-sampling of a net graph G' and applying Thm. 1.5 on G', we obtain linear-size emulator with $+\widetilde{O}(n^{25/112})$ stretch. Moreover, for any $\epsilon > 1/7$, Thm. 1.5 allows us to provide an $+n^{f(\epsilon)}$ emulator with $n^{1+\epsilon}$ edges, where $f(\epsilon) = 1/5 - 3\epsilon/5$. This improves the state-of-the-art bounds of $1/4 - 3\epsilon/4$ due to [18].

[3] One can make it linear by reducing the sampling probability an $O(\log n)$ factor.

We prove 1.5 by presenting a three-step algorithm. The first step (which takes care of the short distances) include a weighted variant of the TZ emulators which for integer stretch k provides $f(d)$-emulator with $\widetilde{O}(n^{1+1/(2^{k+1}-1)})$ edges and $f(d) = d + d^{1-1/k}W^{1/k}$ for $d \geq W$ and $f(d) = O(W)$, otherwise. This variant can be obtained by a straightforward adaptation of the TZ construction to the weighted setting. In particular, setting $W = 1$ recovers the TZ bounds (see Thm. 1.8).

The second step is based on the useful tool of *light-initialization* introduced by Ahemd et al. [3] in the context of translating the existing constructions of additive spanners for unweighted graphs into suitable constructions for weighted graphs. For a given weighted graph G and integer parameter t, the t light-initialization is a subgraph H' of G containing the t-lightest (based on edge weight) edges[4] incident to each vertex in G. Ahemd et al. [3] provided a very elegant argument that in essence achieves the same net effect as obtained in the unweighted setting (where one simply adds t arbitrary edges per vertex): Specifically, the key property is that any u-v shortest path P that has misses ℓ edges in H' must contains $\Omega(t\ell)$ vertices that are incident to the vertices of P via the edges of H'. Our algorithm employs the light-initialization tool on sampled net G' of G, for a carefully chosen parameter t. Each G-vertx is sampled into the net G' with probability $\Theta(\log n/D)$. The third and last step further sub-samples the vertices of G' and adds the complete weighted graph on this sample to the output spanner.

The stretch analysis of this scheme has the following structure. First, using the TZ emulators allows us to satisfy the stretch for pairs at distance $O(WD\log n)$ in G. The focus is then on bounding the stretch for a pair of sampled vertices $u, v \in V(G')$. The argument considers a u-v shortest path P in G' and distinguishes between two cases: $|P \setminus H| \leq q$ for some chosen parameter q, and the complementarity case where $|P \setminus H| > q$. For the first case, we use the weighted-TZ spanner of G to obtain a sublinear stretch guarantee for every edge on $P \setminus H$, taking advantage of the fact that each such edge corresponds to a path in the original graph G. The benefit that we get from the sublinear stretch bounds allows us to accumulate it for each of the t missing edges.

To handle the complementary case where $|P \setminus H| > q$, we use H' to claim that the final sampled set V'' contains a pair u'', v'' that are sufficiently close to u and v. The stretch bound is provided by the addition of the edge (u'', v'') to the final emulator.

Advanced: $+\widetilde{O}(n^{0.222})$ Additive Stretch. Our last and most involved improvement performs a *root treatment* to the TZ emulator construction. Instead of using the weighted-TZ variant in a black-box manner on our weighted sampled graph, we provide a discretization variant for this algorithm in which we replace the continuous TZ stretch function by a step function. The latter provides worse bounds for nearby pairs, with the benefit of using fewer edges. More specifically, the construction is parameterized by integers D, k, p and show:

▶ **Theorem 1.6.** *For every n-vertex $G = (V, E, \omega)$ with maximum weight W, a constant integer $k \geq 3$, integer $D \geq 1$ and $p \in (0, 1)$, one can compute an emulator H with additive stretch $O(D^{1-1/(k-1)} \cdot W \log n/p)$ for any distance $d = O(D \cdot W \log n/p)$. The size of H is bounded by*

$$|H| = \widetilde{O}\left(n^{1+\frac{1}{2^{k+1}-1}} + (n \cdot p)^{1+\frac{1}{2^k-1}} / \left((1/p)^{\frac{2^k-2}{(2^k-1)k}} \cdot D^{\frac{2^k-2k}{(2^k-1)k(k-1)}}\right)\right) .$$

[4] Each vertex sorts its incident edges in increasing edge weight, and the t first edges in this ordering are taken.

Our optimized variant of the weighted TZ emulators is fitted to the setting where the given weighted graph provided as input to Theorem 1.6 is in fact a net graph G' that corresponds to some unweighted base graph[5] G. We then aim at exploiting the fact that the edges of G' corresponds to G-paths already in the construction of the weighted TZ emulators. To present our key ideas, we briefly describe the TZ algorithm. For a subset of vertices V' and probability q, let $V'[q]$ be the set of vertices obtained by sampling each vertex $v \in V'$ independently with probability of q.

For a given parameter k, the algorithm computes a hierarchy $V = V_0 \supset V_1 \supset V_2 \supset \ldots \supset V_{k-1}$ of levels, where $V_i = V_{i-1}[q_{i-1}]$ for $q_{i-1} = |V_{i-1}|/n^{1+1/(2^k-1)}$. For every vertex $v \in V_i$, its $(i+1)^{th}$ pivot $p_{i+1}(v)$ is the closest vertex to v in V_{i+1}. The bunch $B_i(v)$ contains all vertices in V_i that are closer to v than its pivot $p_{i+1}(v)$. The algorithm adds to the emulator the edges between each $v \in V_i$ to all vertices in its bunch $B_i(v)$. The weights of the edges are the G-distance of their endpoints. This is done for every $i \in \{1, \ldots, k-2\}$. Finally, all edges in $V_{k-1} \times V_{k-1}$ are added to the emulator.

Our adaptation to weighted net graphs G' (whose edges correspond to paths in a base graph G) computes a hierarchy of $2(k-1)$ levels: $V = V_{1/2} \supseteq V_1 \supseteq V_{3/2} \supseteq V_2 \supseteq \ldots \supseteq V_{k-1/2}$, where $V_{(j+1)/2} \leftarrow V_{j/2}[q_j]$ for every $j \in \{1, \ldots, 2(k-1)\}$. Hence, we have $k-1$ integral levels $V_1, \ldots, V_{k-1}$ and k "half"-levels $V_{1/2}, V_{3/2}, \ldots, V_{k-1/2}$. Intuitively, the "half" levels represent an intermediate step that re-scales the "aggregate" benefit obtained by the existence of the precomputed emulator H_0 that takes care of the short distances in G'. The selection of the sampling probabilities are made in a careful manner that depend on the properties of H_0. Once the hierarchy is computed, we have $k-1$ steps which mimic the TZ algorithm with one main distinction, we add to the emulator edges from the *half*-level $V_{i+1/2}$ to the next *integral*-level V_{i+1}.

That is, for every $i \in \{0, \ldots, k-2\}$ and every $u \in V_{i+0.5}$, the algorithm computes a pivot $p_{i+1}(v)$ (closest vertex in V_{i+1}) and a bunch $B_{i+0.5}(u)$, which consists of all $V_{i+0.5}$ vertices that are closer to u than its pivot $p_{i+1}(u)$. The edges in $\{u\} \times B_{i+0.5}(u)$ are added to the emulator. Finally, in the last half level $k-0.5$, we add all edges in $V_{k-0.5} \times V_{k-0.5}$.

Remark. We note that our approach for computing improved linear emulators of Thm. 1.2 can also be used to improve the general tradeoff provided in Thm. 1.3. The total improvement, however, is limited to a small $o(1)$ additive term, and therefore we make this extra effort only for linear size emulators. We also note that our approach for the latter could be further optimized by considering a large number of recursive sampling steps, but again the net effect on the stretch is negligible (in particular, an additional sampling step might reduce the stretch by an 0.0001 additive term).

Notations. For a possibly weighted graph G, let $\text{dist}_G(u, v)$ be the *length* of a shortest path from u to v. The length of a shortest-path Q is measured by the sum of its weighted edges. Let $|Q|$ be the number of edges on this path. We use $\widetilde{O}(\cdot)$ notation to hide polylogarithmic factors in n. For a set of elements X and $p \in [0, 1]$, let $X[p]$ be the set obtained by sampling each X-element independently with probability p.

For a given (possibly) weighted graph G and integer t, a subgraph $H \subseteq G$ is a *t-spanner* if $\text{dist}_H(u, v) \leq t \cdot \text{dist}_G(u, v)$ for every $u, v \in V$. Our constructions use the following algorithm as a subroutine, mainly for $t = O(\log n)$.

[5] I.e., in our constructions, the graph G provided as input to Theorem 1.6 is in fact a net graph G' of some base graph G.

▶ **Lemma 1.7** ([6]). *For every n-vertex (possibly weighted) graph G and a given integer $k \geq 1$, one can compute a $(2k-1)$-spanner $H \subseteq G$ with $|H| \leq n^{1+1/k}$ edges.*

▶ **Theorem 1.8** ([19]). *For every n-vertex unweighted graph G and a given integer $k \geq 1$, one can compute an emulator H with $\widetilde{O}(n^{1+1/(2^{k+1}-1)})$ edges, such that for every $u, v \in V$, it holds that $\mathrm{dist}_G(u,v) \leq \mathrm{dist}_H(u,v) \leq \mathrm{dist}_G(u,v) + (\mathrm{dist}_G(u,v))^{1-1/k}$.*

Roadmap. In Sec. 2, we present a simple approach to recover the state-of-the-art bound of $+\widetilde{O}(n^{1/4})$ additive emulator. Sec. 3 provides an improved emulator construction for the entire regime, proving Theorem 1.5 and consequently also Thm. 1.3. Finally, in Sec. 4 we provide the proof of the key result, Thm. 1.2.

2 Warmup: $+\widetilde{O}(n^{1/4})$ Linear Emulators

We start by presenting a simple construction of linear size $+\widetilde{O}(n^{1/4})$-emulators, which uses the following theorem for weighted additive spanners by [4] (recently improved by [12]).

▶ **Theorem 2.1** (Theorem 3 in [4]). *Any n-vertex weighted graph $G = (V, E, \omega)$ with max edge weight W admits a $+8W$ additive spanner $H \subseteq G$ with $O(n^{4/3})$ edges.*

Algorithm. The algorithm for computing $+\widetilde{O}(n^{1/4})$-emulator has two steps. The first step computes a $O(\log n)$-multiplicative spanner $H_1 \subseteq G$, which as we show later handles the short distances in G. The second step computes a net graph $G' = (V', E', \omega')$ defined over a sampled subset $V' = V[p]$ for $p = \log n / n^{1/4}$. The edge set E' consists of all pairs in $V' \times V'$ whose distance in G is at most $n^{1/4}$. The weights of the E' are taken to be the G-distances. Formally, $E' = \{(x,y) \in V' \times V' \mid \mathrm{dist}_G(x,y) \leq n^{1/4}\}$, $\omega((x,y)) = \mathrm{dist}_G(x,y), \forall (x,y) \in E'$. Note that, by definition, the maximum weight W' of G' is $O(n^{1/4})$. The algorithm then applies Theorem 2.1 to compute $+8W'$ emulator H_2 for G'. The output emulator is given by $H = H_1 \cup H_2$. This completes the description of the algorithm.

The size analysis is immediate as w.h.p. $|V'| = O(n^{3/4} \log n)$ and thus by Theorem 2.1 $|H_2| = \widetilde{O}(n)$. We now consider the stretch argument. Fix $u, v \in V$. Assume first that $\mathrm{dist}_G(u,v) \leq c \cdot n^{1/4}$ for some constant c. Then, by including the $O(\log n)$-multiplicative spanner H_1, we have that $\mathrm{dist}_H(u,v) = O(n^{1/4} \log n)$, as desired.

Consider the complementary case where $\mathrm{dist}_G(u,v) > c \cdot n^{1/4}$, and let P be a u-v shortest path in G. Let P', P'' be the $n^{1/4}$-length prefix (resp., suffix) of P. By the Chernoff bound, w.h.p., we have that there exists a sampled vertex $u' \in P' \cap V'$ and $v' \in P'' \cap V'$. By the previous argument (for short distances), it remains to show that $\mathrm{dist}_H(u', v') \leq \mathrm{dist}_G(u', v') + O(n^{1/4} \cdot \log n)$.

Observe that since every $n^{1/4}$-length consecutive segment on P contains, w.h.p., a sampled vertex in V', we have that $\mathrm{dist}_{G'}(u', v') = \mathrm{dist}_G(u', v')$. By the properties of H_2, we then have that $\mathrm{dist}_{H_2}(u', v') \leq \mathrm{dist}_{G'}(u', v') + 8W' = \mathrm{dist}_G(u', v') + 8n^{1/4}$. Overall, we have

$$\begin{aligned} \mathrm{dist}_H(u,v) &\leq \mathrm{dist}_{H_1}(u,u') + \mathrm{dist}_{H_2}(u',v') + \mathrm{dist}_{H_1}(v',v) \\ &\leq O(\log n)(\mathrm{dist}_G(u,u') + \mathrm{dist}_G(v',v)) + \mathrm{dist}_G(u',v') + 8n^{1/4} \\ &= \mathrm{dist}_G(u,v) + O(n^{1/4} \cdot \log n) \ . \end{aligned}$$

3 New Weighted Additive Emulators

3.1 The Core Construction

We start by presenting the key construction which for n-vertex weighted graphs provides emulators with $+O(WD)$ stretch and with $O(n^{4/3}/f(D))$ edges, for some monotone increasing function $f(\cdot)$. These emulators serve the basis for improved emulator constructions in wide range of parameters, and in particular computing linear emulators with improved additive stretch $+n^{0.222}$. We show:

▶ **Theorem 3.1.** *There is an algorithm* SuperLinEmulator *that given any n-vertex graph $G=(V,E,\omega)$ with maximum weight W, and integers $k\geq 2, D\geq 1$ computes a $+O(WD)$ emulator H of size $\widetilde{O}\left(n^{1+1/(2^{k+1}-1)}+\frac{n^{4/3}}{D^{4/3+2/(3k)}}\right)$.*

We start by presenting the two main tools used by Algorithm SuperLinEmulator.

Tool I: Weighted Near-Additive Emulator. We used the following adaptation of the Thorup and Zwick emulators to the weighted setting. An adaptation for universal emulators has been recently provided by Elkin, Gitlitz and Neiman [13]. In the full version, we show:

▶ **Lemma 3.2.** *There is an algorithm* WeightedTZEmulator *that for any n-vertex graph $G=(V,E,\omega)$ with maximum weight W, and any fixed integer $k\geq 2$ computes an $+f(d)$ emulator H of size $O(n^{1+1/(2^{k+1}-1)})$, where $f(d)=d+O(d^{1-1/k}\cdot W^{1/k})$ for any distance $d>W$, and $f(d)=d+O(W)$ for $d\leq W$.*

Tool II: Light Initialization. A t-light initialization of a weighted graph $G=(V,E,\omega)$, introduced by Ahmed et al. [4], is a subgraph $H\subseteq G$ obtained by including the t lightest edges incident to each vertex v (or all its edges when $\deg(v)\leq t$). Edge weight ties can be broken arbitrarily; Let Initialization be the algorithm that given the graph G and a parameter t, outputs the t-light initialization subgraph H. We say that v is a t-light neighbor of u if the edge (u,v) is among the t-lightest edges incident on u.

▶ **Theorem 3.3** (Theorem 5 in [4])**.** *Let $G=(V,E,\omega)$ be an undirected weighted graph and let $H=$ Initialization(G,t) for some input integer t. Then, for every shortest path $P_{u,v}$ that is missing ℓ edges in H (i.e., $|P_{u,v}\setminus H|=\ell$), there is a set of vertices $S\subseteq V$ such that (i) $|S|=\Omega(t\cdot\ell)$ and (ii) for every $a\in S$, there is a vertex $b\in P_{u,v}$ satisfying that a is a t-light neighbor of b.*

Tool III: Algorithm Net. Given an n-vertex weighted graph $G=(V,E,\omega)$ with maximum edge weight W and a probability $p\in(0,1)$, the algorithm Net(G,p) outputs a graph $G'=(V',E',\omega')$, denoted as a *net*, defined as follows. Let $V'=V[p]$ be a random sample of V, obtained by sampling each $v\in V$ independently with probability of p. Let $E'=\{(u,v)\in V'\times V' \mid \mathrm{dist}_G(u,v)\leq\Theta(\log n/p)\cdot W\}$ and $\omega'((u,v))=\mathrm{dist}_G(u,v)$ for every $(u,v)\in E'$. We use the following observation in our constructions:

▶ **Observation 3.4.** *Let $G'=(V',E',\omega')$ be the output net graph of Alg.* Net(G,p) *where $G=(V,E,\omega)$ is an n-vertex graph with maximum edge weight W. Then w.h.p., the following holds: (i) $|V'|=O(np\log n)$, (ii) for every $u,v\in V'$, $\mathrm{dist}_{G'}(u,v)=\mathrm{dist}_G(u,v)$, and (iii) the maximum edge weight of G' is bounded by $W'=\Theta(W\log n/p)$.*

Description of Alg. SuperLinEmulator. The algorithm has three main steps, each computes an emulator graph H_1, H_2, H_3 whose union provides the desired emulator. The first emulator H_1 is obtained by computing the weighted-variant of the Thorup-Zwick emulator using Lemma 3.2. As we will see in the analysis, this would provide the desired stretch for short distances. The second emulator H_2 is obtained by computing the t-initialization of some net graph G_2 for $t = n^{1/3}/D^{(1+2/k)/3}$. The net G_2 is defined by sampling a subset of vertices $V_2 = V[p_1]$ for $p_1 = 10 \log n/D$. The edges E_2 of the net G_2 are defined by connecting each pair $(u, v) \in V_2 \times V_2$ provided that $\text{dist}_G(u, v) \leq WD$, every edge (u, v) in G_2 is then weighted by the G-distance between its endpoints. Finally, the last emulator graph H_3 is obtained by adding all the weighted edges between a sampled set $V_3 = V_2[p_2]$ for $p_2 = 10 \log n/(t \cdot D^{1/k})$. The weights are taken to be the G-distances between the endpoints. This completes the algorithmic description.

Algorithm 1 SuperLinEmulator(G, k, D).

Input: Graph $G = (V, E, \omega)$ with maximum edge weight W, integers k, D.
Output: A $+O(W \cdot D)$ emulator H of size $\widetilde{O}\left(n^{1+1/(2^{k+1}-1)} + \frac{n^{4/3}}{D^{4/3+2/(3k)}}\right)$.

1. $H_1 \leftarrow$ WeightedTZEmulator(G, k) (using Lemma 3.2).
2. Let $G_2 = (V_2, E_2, \omega_2) \leftarrow$ Net(G, p_1) for $p_1 = 10 \log n/D$.
3. $H_2 \leftarrow$ Initialization(G_2, t) for $t = n^{1/3}/D^{(1+2/k)/3}$ (using Thm. 3.3).
4. Let $V_3 \leftarrow V_2[p_2]$ for $p_2 = 10 \log n/(t \cdot D^{1/k})$;
5. Set $H_3 \leftarrow (V_3, V_3 \times V_3, \omega_3)$ where $\omega_3((u, v)) = \text{dist}_G(u, v)$ for every $(u, v) \in H_3$.
6. Output $H \leftarrow H_1 \cup H_2 \cup H_3$.

Size analysis. By Lemma 3.2, $|H_1| = O(n^{1+1/(2^{k+1}-1)})$. By the Chernoff bound, w.h.p $|V_2| = n \cdot p_1$ and $|H_2| = t \cdot |V_2| = \widetilde{O}\left(\frac{n^{4/3}}{D^{4/3+2/(3k)}}\right)$. Finally, by the Chernoff bound, w.h.p, $|V_3| = |V_2| \cdot p_2$, and as $|H_3| = |V_3|^2$, we also get that $|H_3| = \widetilde{O}\left(\frac{n^{4/3}}{D^{4/3+2/(3k)}}\right)$.

Stretch analysis. We prove the following somewhat stronger lemma.

▶ **Lemma 3.5.** *Let H' be an emulator for G with maximum edge weight W such that for any u, v pair at G-distance at most WD, it holds that $\text{dist}_{H'}(u, v) \leq \text{dist}_G(u, v) + O(WD^{1-1/k})$. Then, for* every $u, v \in V$*, it holds that $\text{dist}_{H' \cup H_2 \cup H_3}(u, v) \leq \text{dist}_G(u, v) + O(WD)$.*

By Lemma 3.2, we then have that $\text{dist}_{H_1}(u, v) \leq \text{dist}_G(u, v) + O(WD^{1-1/k})$ for every u, v pair at G-distance at most WD, hence by taking $H' = H_1$, the stretch argument holds.

Proof of Lemma 3.5. Fix a pair $u, v \in V$ and first consider the simpler case where $\text{dist}_G(u, v) \leq WD$. By the properties of H', $\text{dist}_{H'}(u, v) \leq O(WD)$. From now on, we assume that $\text{dist}_G(u, v) > WD$. Let $P_{u,v}$ be the u-v shortest path in G, and let u', v' be a sampled vertex in V_2 in the $D/4$-hop prefix (resp., suffix) of the path. By the above, we have that $\text{dist}_G(u, u') \leq WD$ and $\text{dist}_G(v', v) \leq WD$, and therefore H' provides an additive $+O(WD)$ term for each of these distances.

Our next goal is to bound the u'-v' distance in H where $u', v' \in V_2$. It is easy to see that w.h.p., $\text{dist}_{G_2}(u', v') = \text{dist}_G(u', v')$, since each D-hop segment on the $P_{u,v}$ path contains a sampled vertex in V_2. Let P' be a u'-v' shortest path in G_2. We distinguish between two cases depending on the number of edges in $P_2 \setminus H_2$.

Case 1: $|P' \setminus H_2| \leq D^{1/k}$. Each edge (x, y) in $P' \subseteq G_2$ corresponds to an x-y shortest path where $\text{dist}_G(x, y) \leq WD$. Using the H' emulator, we have that for each such edge $(x, y) \in G_2$, $\text{dist}_{H'}(x, y) \leq \text{dist}_G(u, v) + O(D^{1-1/k} \cdot W)$. Since there are at most $D^{1/k}$, the total additive stretch introduced due to these edges is bounded by $O(D^{1/k} \cdot D^{1-1/k} \cdot W) = O(WD)$, as required. This is the critical point where we exploit the fact that the weighted edges of G_2 correspond to short paths in G.

Case 2: $|P' \setminus H_2| > D^{1/k}$. We next turn to consider the case where H_2 misses many edges from P'. Here we will exploit the expansion property guaranteed by the addition of the t-light initialization. Let P_1 (resp., P_2) be a prefix (resp., suffix) of P' for which H_2 misses exactly $D^{1/k}/2$. I.e., $|P_i \setminus H_2| = D^{1/k}/2$ for $i \in \{1, 2\}$. By Theorem 3.3 the following claims holds for every $i \in \{1, 2\}$: There exists a subset $S_i \subseteq V_2$ such that (i) $|S_i| = \Omega(t \cdot D^{1/k})$ and (ii) for every $a \in S_i$, there is a vertex $b_i \in P_i$ such that a is t-light neighbor of b_i. By the value of p_2, we get that w.h.p., there exists $s_i \in S_i \cap V_3$ for every $i \in \{1, 2\}$. Therefore, the emulator H_3 contains the edge (s_1, s_2) with weight $\text{dist}_G(s_1, s_2)$.

Since the maximum edge weight in G_2 is at most $W_2 = WD$, and $(b_i, s_i) \in H_2$, we have that $\text{dist}_H(b_1, s_1) + \text{dist}_H(s_2, b_2) = O(WD)$. By the triangle inequality,

$$\text{dist}_G(s_1, s_2) \leq \text{dist}_G(b_1, b_2) + O(WD) \ . \tag{3.1}$$

Since the segments $P'[u, b_1]$ and $P'[b_2, v]$, each has at most $D^{1/k}$ missing edges in H. Therefore, by applying the argument for Case 1, we have:

$$\text{dist}_H(u, b_i) \leq \text{dist}_G(u, b_i) + O(WD), \text{ for } i \in \{1, 2\} \ . \tag{3.2}$$

We are now ready to complete the stretch argument by showing:

$$\begin{aligned} \text{dist}_H(u', v') &\leq \text{dist}_H(u', b_1) + \text{dist}_H(b_1, s_1) + \text{dist}_H(s_1, s_2) + \text{dist}_H(s_2, b_2) + \text{dist}_H(b_2, v') \\ &\leq \text{dist}_G(u', b_1) + \text{dist}_G(b_1, b_2) + \text{dist}_G(b_2, v') + O(WD) \ , \end{aligned}$$

where the inequalities follow by plugging Eq. (3.1,3.2), and using the fact that as $(s_1, s_2) \in H_3$, by the triangle inequality $\text{dist}_H(s_1, s_2) = \text{dist}_G(s_1, s_2) \leq \text{dist}_G(b_1, b_2) + O(WD)$. ◀

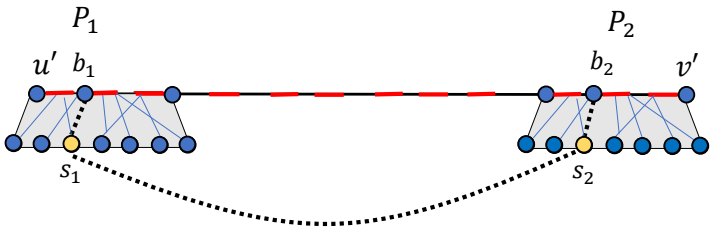

Figure 1 An illustration for the stretch argument of Alg. SuperLinEmulator. Shown is a u'-v' shortest path $P' \subseteq G_2$, the segments P_1, P_2 each containing $D^{1/k}/2$ missing edges w.r.t H_2. By the properties of the t-initialization procedure, each these segments contains a vertex b_1, b_2 with at least one sampled t-light neighbor, s_1, s_2. The added weighted edge (s_1, s_2) establishes the stretch guarantees.

3.2 Improved Additive Emulators

Our improved additive stretch bounds are provided by using Theorem 3.1 with two sparsity bounds determined by $k = 2, 3$. We have:

▶ **Corollary 3.6.** *For any n-vertex graph $G = (V, E)$ with max weight W, there exists a:*
1. *$+O(W \cdot n^{4/35})$ emulator of size $\widetilde{O}(n^{8/7})$, and*
2. *$+O(W \cdot n^{6/35})$ emulator of size $\widetilde{O}(n^{16/15})$.*

Proof. (1) follows by setting $k = 2$ and $D = n^{4/35}$ in Theorem 3.1, and (2) follows by setting $k = 3$ and $D = n^{6/35}$ in Theorem 3.1. ◀

Using these two emulator constructions, we show an improved stretch vs. size tradeoff in almost the entire regime of interest.

Proof of Thm. 1.3 for $0 \leq \epsilon \leq 1/15$ and $3/37 \leq \epsilon \leq 1/7$. We describe Algorithm ImprovedEmulator which given $G = (V, E, \omega)$ and $\epsilon \in [0, 1/15] \cup (3/37, 1/7]$, computes the desired emulator. The algorithm starts by computing a $O(\log n)$ multiplicative spanner H_0, which as always, takes care of the short distances in G. Next, the algorithm computes a net graph G' whose bounds depends on the value of ϵ, as follows. Define:

$$k_\epsilon = \begin{cases} 3, & \text{for } \epsilon \in [0, 1/15], \\ 2, & \text{for } \epsilon \in (3/37, 1/7] \ . \end{cases} \tag{3.3}$$

Let $n_\epsilon = n^{(1-1/2^{k_\epsilon+1})(1+\epsilon)}$ and $q = n/n_\epsilon$. Then, the net graph G' is obtained by applying Alg. $\mathsf{Net}(G, p)$ for $p = 10 \log n/q$. Finally, it applies Alg. SuperLinEmulator with the input G', k_ϵ and $D = (n_\epsilon)^{2k_\epsilon/35}$. This results in the emulator H_1. The output emulator is given by $H = H_0 \cup H_1$.

Algorithm 2 ImprovedEmulator(G, ϵ).

Input: Graph $G = (V, E, \omega)$ with maximum weight W, $\epsilon \in [0, 1/15] \cup (3/37, 1/7]$.
Output: $+\widetilde{O}(W \cdot n^{f(\epsilon)})$ emulator H of size $\widetilde{O}(n^{1+\epsilon})$.
1. $H_0 \leftarrow \mathsf{MultSpanner}(G, O(\log n))$.
2. Let $n_\epsilon = n^{(1-1/2^{k_\epsilon+1})(1+\epsilon)}$ and $q = n/n_\epsilon$ (see Eq. (3.3)).
3. $(G' = (V', E', \omega')) \leftarrow \mathsf{Net}(G, p)$ for $p = 10 \log n/q$.
4. $H_1 \leftarrow \mathsf{SuperLinEmulator}(G', k_\epsilon, D)$ for $D = (n_\epsilon)^{2k_\epsilon/35}$.
5. Output $H_0 \cup H_1$.

Analysis. We start with a stretch argument for a fixed pair $u, v \in V$. First, assume the more interesting case where $u', v' \in V'$. By the properties of H_1, the additive stretch is:

$$\widetilde{O}(D \cdot q \cdot W) = \widetilde{O}(n_\epsilon)^{2k_\epsilon/35} \cdot n^{1/2^{k_\epsilon+1}} \cdot n^{\epsilon(1/2^{k_\epsilon+1}-1)} \cdot W) = \widetilde{O}(W \cdot n^{f(\epsilon)}) \ . \tag{3.4}$$

Next assume that $\mathrm{dist}_G(u, v) \leq W \cdot q$. By adding the multiplicative spanner H_0, we have $\mathrm{dist}_{H_0}(u, v) \leq O(Wq \log n)$. Finally, assume that $\mathrm{dist}_G(u, v) \geq Wq$ and let $u', v' \in V'$ be the closest sampled vertex to u (resp., v) on the u-v shortest path. W.h.p., $\mathrm{dist}_G(u, u'), \mathrm{dist}_G(v, v') \leq Wq$ and therefore, $\mathrm{dist}_{H_0}(u, u'), \mathrm{dist}_{H_0}(v, v') \leq O(Wq \log n)$. Since w.h.p. $\mathrm{dist}_G(u', v') = \mathrm{dist}_{G'}(u', v')$, the stretch argument is completed by Eq. (3.4). The size bound follows by plugging $|H_0| = \widetilde{O}(n)$, and moreover, $|H_1| = \widetilde{O}(n^{1+\epsilon})$ by Corollary 3.6. We are now ready to complete the proof for the missing regimes.

Complete proof of Thm. 1.3. For the range $1/7 \leq \epsilon \leq 1/3$, the proof follows by letting $H = \mathsf{SuperLinEmulator}(G, k = 2, D)$ for $D = n^{(1-3\epsilon)/5}$. For the range $1/15 \leq \epsilon \leq 3/37$, the proof follows by letting $H = \mathsf{SuperLinEmulator}(G, k = 3, D)$ for $D = n^{(3-9\epsilon)/14}$. ◀

4 $+n^{0.222}$ Emulator of Linear Size

4.1 An Optimized Weighted Thorup-Zwick Emulator

In this section, we present an optimized variant of Thorup-Zwick that plays a key role in the construction of our linear additive emulator. We prove the following theorem which in particular implies Thm. 1.4.

▶ **Theorem 4.1.** *For every n-vertex $G = (V, E, \omega)$ with maximum weight W, a constant integer $k \geq 3$, integer $D \geq 1$ and $p \in (0, 1)$, there is an Algorithm* ImprovedTZEmulator *for computing an emulator H with additive stretch $O(D^{1-1/(k-1)} \cdot W \log n/p)$ for any distance $d = O(D \cdot W \log n/p)$. The size of H is bounded by*

$$|H| = \widetilde{O}\left(n^{1+\frac{1}{2^{k+1}-1}} + (n \cdot p)^{1+\frac{1}{2^k-1}} / \left((1/p)^{\frac{2^k-2}{(2^k-1)k}} \cdot D^{\frac{2^k-2k}{(2^k-1)k(k-1)}}\right)\right) .$$

We can also show interesting corollaries of Thm. 4.1 which demonstrate the sub-optimality of the TZ construction for a wide-range of distances. For example, the following holds:

▶ **Corollary 4.2.** *Every n-vertex unweighted graph G and given integer $k \geq 1$ admits an emulator H of size $\widetilde{O}(n^{1+1/(2^{k+1}-1)})$ such that pairs at distances $d \geq n^{k^2/2^k}$ have additive stretch of $O(d^{1-1/(k-1)})$.*

This should be compared with the additive stretch of $O(d^{1-1/k})$ provided by the TZ emulator (which also marks the state-of-the-art bounds). Thus, while the original TZ emulator is optimal for small distances as proven in [2], this optimality holds in a restricted range of distances, especially for non-constant values of k, e.g., $k = O(\log \log n)$. We now turn to prove Thm. 4.1 which constitutes the key technical contribution in the linear emulator construction.

Algorithm ImprovedTZEmulator. The algorithm starts by applying our weighted-variant of the Thorup-Zwick emulator to obtain $H_1 \leftarrow \mathsf{WeightedTZEmulator}(G, k)$, see Lemma 3.2. Next, it computes a net $G' = \mathsf{Net}(G, p)$ obtained by sampling each vertex in V into the net G' independently with probability p. By Obs. 3.4, we have that the maximum edge weight G' is bounded by $W' = \Theta(\log n \cdot W/p)$. In addition, w.h.p. it also holds that the G'-distances equal to the G-distances. The key technically involved step is in the computation of an additional emulator that we denoted by H_2 for G'. This emulator is computed by applying a new variant of the TZ emulator which takes advantageous of the fact that each weighted edge in G' corresponds to some path in a prior graph G, and more specifically, that there is a precomputed emulator (namely, H_1) that handles short distances in G'.

The construction builds a hierarchy $V = V_{1/2} \supseteq V_1 \supseteq V_{3/2} \supseteq V_2 \supseteq \ldots \supseteq V_{k-1/2}$, where $V_{(j+1)/2} \leftarrow V_{j/2}[q_j]$ for every $j \in \{1, \ldots, 2(k-1)\}$. Note that in contrast to the classic TZ emulator construction, our hierarchy has $2k-1$ levels: $k-1$ integral levels $V_1, \ldots, V_{k-1}$ and k "half"-levels $V_{1/2}, V_{3/2}, \ldots, V_{k-1/2}$. Intuitively, the "half" levels represent an intermediate

step that re-scales the extra-benefit obtained by the existence of the emulator H_1 (that takes care of short distances in G'). The definition of the sampling probabilities q_j is somewhat more involved compared to that of the classic construction. To define these probabilities, we need the following function definitions, for every integer $0 \leq i \leq k$:

$$h(i) = 1 - \frac{2^i - 1}{2^k - 1}, \qquad f(i) = \frac{2(2^k-1)i - 2k(2^i-1) - 2^k + 2^i}{(2^k-1)k} \quad \text{and} \quad g(i) = \frac{2^k - 2^i}{(2^k-1)k} \ . \tag{4.1}$$

The probabilities q_j for $j \in \{2i, 2i+1\}$ are chosen in order to satisfy the following, w.h.p., for every $i \in \{1, \ldots, k-1\}$:

$$|V_i| = \widetilde{O}\left(n^{h(i)} \cdot \Delta^{f(i)} \cdot \left(\frac{W'}{W}\right)^{g(i)}\right) \quad \text{and} \quad |V_{i+1/2}| = \widetilde{O}\left(|V_i| / \left(\Delta^{(i-1)/k} \cdot \left(\frac{W'}{W}\right)^{1/k}\right)\right) \ . \tag{4.2}$$

The sampling probabilities $q_{j=2i}$ for every $i \in \{1, \ldots, k-1\}$ have a simple to state expression:

$$q_{2i} = \Theta\left(\frac{\log n}{\Delta^{(i-1)/k} \cdot \left(\frac{W'}{W}\right)^{1/k}}\right) \ . \tag{4.3}$$

Let us give a concrete example for $k = 4$: For ease of notation, let $\widehat{W} = W'/W$.

1. $|V_{0.5}| = n$.
2. $|V_1| = \widetilde{O}\left(n^{14/15} \cdot \Delta^{2/15} \cdot \left(\widehat{W}\right)^{7/30}\right)$.
3. $|V_{1.5}| = \widetilde{O}\left(|V_1|/(\widehat{W})^{1/4}\right) = \widetilde{O}(n^{14/15} \cdot \Delta^{2/15} \cdot \left(\widehat{W}\right)^{7/30-1/4}\right)$.
4. $|V_2| = \widetilde{O}\left(n^{12/15} \cdot \Delta^{6/15} \cdot \left(\widehat{W}\right)^{1/5}\right)$.
5. $|V_{2.5}| = \widetilde{O}\left(|V_2|/(\Delta \cdot \widehat{W})^{1/4}\right) = \widetilde{O}\left(n^{12/15} \cdot \Delta^{6/15-1/4} \cdot \left(\widehat{W}\right)^{1/5-1/4}\right)$.
6. $|V_3| = \widetilde{O}\left(n^{8/15} \cdot \Delta^{13/30} \cdot \left(\widehat{W}\right)^{2/15}\right)$.
7. $|V_{3.5}| = \widetilde{O}\left(|V_3|/(\Delta^2 \cdot \widehat{W})^{1/4}\right) = \widetilde{O}\left(n^{8/15} \cdot \Delta^{13/30-1/2} \cdot \left(\widehat{W}\right)^{2/15-1/4}\right)$.

Given the q_j's probabilities, the algorithm proceeds in a very similar manner to the TZ emulator algorithm, with one main emphasis: There are $k-1$ phases in which we add to the emulator edges from the *half*-level $V_{i+1/2}$ to the next *integral*-level V_{i+1}. That is, no edges are added between V_{i+1} to $V_{i+1.5}$. For every $i \in \{0, \ldots, k-2\}$ and every $u \in V_{i+0.5}$, the algorithm computes a pivot $p_{i+1}(u)$ and a bunch $B_{i+0.5}(u)$, as follows. The pivot $p_{i+1}(u)$ is the closest[6] vertex to u in the next integral-level, V_{i+1}. The bunch $B_{i+0.5}(u)$ consists of all vertices in $V_{i+0.5}$ that are strictly closer to u than its pivot $p_{i+1}(u)$. The edges in $\{u\} \times B_{i+0.5}[u]$ are added to the emulator H_2, weighted by their G'-distances (which by Obs. 3.4(ii) also equal to the G-distances). Finally, all edges between the vertices in the last-half level $V_{k-0.5}$ are also added to H_2. The output emulator is given by $H_1 \cup H_2$.

The analysis is deferred to the full version.

[6] As usual, we can assume that the shortest-paths are unique.

Algorithm 3 ImprovedTZEmulator(G, k, p, D).

Input: Graph $G = (V, E, \omega)$ with maximum weight W and parameters $k \geq 3, D \geq 1$, $p \in (0, 1)$.
Output: $+O(D^{1-1/(k-1)} \cdot W \log n/p)$ emulator H for pairs at distance $d = O(D \cdot W \log n/p)$

1. $H_1 \leftarrow$ WeightedTZEmulator(G, k) (using Lemma 3.2), $H_2 \leftarrow \emptyset$.
2. $(G' = (V', E', \omega')) \leftarrow$ Net(G, p).
3. Set $\Delta = D^{1/(k-1)}$ and $V_{0.5} = V$.
4. For $j \in \{1, \ldots, 2(k-1)\}$ do: $V_{(j+1)/2} \leftarrow V_{j/2}[q_j]$, where q_j is defined based on Eq. (4.2).
5. For $i = 0$ to $k-2$ do:
   - For every $u \in V_{i+0.5}$ do:
     a. $p_{i+1}(u) = CLOSEST(V_{i+1}, u)$.
     b. $B_{i+0.5}(u) \leftarrow \{v \in V_{i+0.5} \mid \text{dist}_{G'}(u, v) < \text{dist}(u, p_{i+1}(u))\}$.
     c. $B_{i+0.5}[u] \leftarrow B_{i+0.5}(u) \cup \{p_{i+1}(u)\}$.
     d. $H_2 \leftarrow H_2 \cup (\{u\} \times B_{i+0.5}[u])$.
6. $H_2 \leftarrow H_2 \cup (V_{k-0.5} \times V_{k-0.5})$.
7. $H = H_1 \cup H_2$.

4.2 Improved Linear Emulators

This section is devoted to the proof of Theorem 1.2. Let ModifiedSuperLinEmulator be the same algorithm as SuperLinEmulator only that we omit the computation of H_1 in Step (1). We next present Algorithm ImprovedLinearEmulator that computes the desired emulators, as follows:

Algorithm 4 ImprovedLinearEmulator.

Input: An *unweighted* graph $G = (V, E)$ on n vertices.
Output: $+\widetilde{O}(n^{2/9-1/1600})$ emulator H of size $\widetilde{O}(n)$.
1. $H_0 \leftarrow$ MultSpanner$(G, k = O(\log n))$.
2. Set $p_1 = 10 \log n/n^{1/32}$, $p_2 = 10 \log n/n^{21/1060}$ and $D = n^{723/4240}$.
3. $(G_1 = (V_1, E_1, \omega_1)) \leftarrow$ Net(G, p_1).
4. $H_1' \leftarrow$ ImprovedTZEmulator$(G_1, k = 4, p_2, D = n^{723/4240})$.
5. $(G_2 = (V_2, E_2, \omega_2)) \leftarrow$ Net(G_1, p_2).
6. $H_2 \leftarrow$ ModifiedSuperLinEmulator$(G_2, k = 3, D)$.
7. Output $H_0 \cup H_1' \cup H_2$.

Algorithm 5 ModifiedSuperLinEmulator(G, k, D).

1. Let $G_2 = (V_2, E_2, \omega_2) \leftarrow$ Net(G, p_1) for $p_1 = 10 \log n/D$.
2. $H_2 \leftarrow$ Initialization(G_2, t) for $t = n^{1/3}/D^{(1+2/k)/3}$ (using Thm. 3.3).
3. Let $V_3 \leftarrow V_2[p_2]$ for $p_2 = 10 \log n/(t \cdot D^{1/k})$;
4. Set $H_3 \leftarrow (V_3, V_3 \times V_3, \omega_3)$ where $\omega_3((u, v)) = \text{dist}_G(u, v)$ for every $(u, v) \in H_3$.
5. Output $H \leftarrow H_2 \cup H_3$.

Size analysis. Clearly, $|H_0| = \widetilde{O}(n)$. By Theorem 4.1, we have that:

$$|H'_1| = \widetilde{O}\left((n \cdot p_1)^{1+\frac{1}{2^{4+1}-1}} + (n \cdot p_1 \cdot p_2)^{1+\frac{1}{2^4-1}} / \left((1/p_2)^{\frac{2^4-2}{(2^4-1)4}} \cdot D^{\frac{2^4-2\cdot 4}{(2^4-1)4(4-1)}}\right)\right) .$$

Therefore, $|H'_1| = \widetilde{O}(n^{(1-1/32-21/1060)(16/15)-(21/1060)\cdot(14/60)-(723/4240)\cdot(8/(15\cdot 4\cdot 3))}) = \widetilde{O}(n^1)$. Finally, by the proof of Thm. 3.1, it holds that $|H_2| = O((|V_2|)^{4/3}/D^{4/3+2/(3k)})$. Therefore,

$$|H_2| = (n \cdot p_1 \cdot p_2)^{4/3}/D^{4/3+2/9} = \widetilde{O}(n^{(1-1/32-21/1060)\cdot(4/3)-(4/3+2/9)\cdot(723/4240)}) = \widetilde{O}(n) .$$

Stretch analysis. Let W_1 (resp. W_2) be the maximum edge weight of G_1 (reps., G_2). By Obs. 3.4, we have that $W_1 = \widetilde{O}(1/p_1)$, $W_2 = \widetilde{O}(W_1 \cdot (1/p_2))$. We show that the additive stretch is $O(W_2 \cdot D) = O(n^{2/9-1/1600})$. By Obs. 3.4, the G_1-distances and G_2-distances, w.h.p., equal to the G-distances.

Case 1: Consider first a vertex pair $u', v' \in V_2$, we shall compute the stretch argument for the pair u', v'. By Lemma 3.5 with $H' = H'_1$ and $W = W_2$ we have that the additive stretch of the pair u', v' is given by:

$$\widetilde{O}(D \cdot W_2) = O(n^{2/9-1/1600}) . \tag{4.4}$$

Case 2: $\mathrm{dist}_G(u, v) \leq W_2$. By adding the multiplicative spanner H_0, $\mathrm{dist}_{H_0}(u, v) \leq O(W_2 \log n)$.

Case 3: $\mathrm{dist}_G(u, v) > W_2$. Let $u', v' \in V_2$ be the closest sampled vertex to u (resp., v) on the u-v shortest path in G. By the Chernoff bound, w.h.p., $\mathrm{dist}_G(u, u'), \mathrm{dist}_G(v, v') \leq W_2$ and therefore, by Case 2, $\mathrm{dist}_{H_0}(u, u'), \mathrm{dist}_{H_0}(v, v') \leq O(W_2 \log n)$. By Obs. 3.4, w.h.p., $\mathrm{dist}_G(u', v') = \mathrm{dist}_{G_2}(u', v')$, and the stretch argument is completed by Eq. (4.4) of Case 1.

Nearly-Linear Time LP Solvers and Rounding Algorithms for Scheduling Problems

Shi Li
State Key Laboratory for Novel Software Technology, Nanjing University, China

Abstract

We study nearly-linear time approximation algorithms for non-preemptive scheduling problems in two settings: the unrelated machine setting, and the identical machine with job precedence constraints setting, under the well-studied objectives such as makespan and weighted completion time. For many problems, we develop nearly-linear time approximation algorithms with approximation ratios matching the current best ones achieved in polynomial time.

Our main technique is linear programming relaxation. For the unrelated machine setting, we formulate mixed packing and covering LP relaxations of nearly-linear size, and solve them approximately using the nearly-linear time solver of Young. For the makespan objective, we develop a rounding algorithm with $(2+\epsilon)$-approximation ratio. For the weighted completion time objective, we prove the LP is as strong as the rectangle LP used by Im and Li, leading to a nearly-linear time $(1.45+\epsilon)$-approximation for the problem.

For problems in the identical machine with precedence constraints setting, the precedence constraints can not be formulated as packing or covering constraints. To achieve the nearly-linear running time, we define a polytope for the constraints, and leverage the multiplicative weight update (MWU) method with an oracle which always returns solutions in the polytope.

1 Introduction

Scheduling theory is an important sub-area of combinatorial optimization, operations research and approximation algorithms. Over the past few decades, advanced techniques have been developed to design approximation algorithms for numerous scheduling problems, among which mathematical relaxation is a prominent one. The algorithms based on the technique follow a two-step framework: solve some linear/convex/semi-definite programming relaxation for the problem to obtain a fractional schedule, and round it into an integral one. The main focus of the algorithm design in the literature has been the best approximation ratios that can be achieved in polynomial time. Many of the LPs used have size much larger than that of the input, and a general convex/semi-definite program requires a large polynomial time to solve, making these algorithms impractical.

To overcome the running time issue, we design approximate LP-based scheduling algorithms that run in *nearly-linear* time. We focus on two well-studied non-preemptive scheduling settings:

1. **Unrelated machine setting.** We are given a set J of n jobs, a set M of m machines, a bipartite graph $G=(M,J,E)$ between M and J, and a processing time $p_{ij}\in\mathbb{Z}_{>0}$ for every $ij\in E$, indicating the time it takes to process job j on machine i. If $ij\notin E$, then

the job j can not be processed on machine i. The output of a problem in this setting is an assignment $\sigma \in M^J$ of jobs to machines so that $\sigma_j j \in E$ for every $j \in J$. This indicates that we process the job j on machine σ_j.

2. **Identical machine with job precedence constraints setting.** In this setting, we are given a set J of n jobs, each job $j \in J$ with a processing time $p_j \in \mathbb{Z}_{\geq 0}$, and the number $m \geq 1$ of identical machines. There are precedence constraints of the form $j \prec j'$, indicating that the job j' can only start after job j completes. The output of a problem in the setting is a completion time vector $(C_j)_{j \in J} \in \mathbb{Z}^J_{\geq 0}$, meaning that a job $j \in J$ is processed during the time interval $(C_j - p_j, C_j]$. We need $C_j \geq p_j$ for every $j \in J$, $C_j \leq C_{j'} - p_{j'}$ for every $j \prec j'$, and every integer $t \geq 1$ is contained in $(C_j - p_j, C_j]$ for at most m jobs $j \in J$.[1]

The main objective function we focus on is *weighted completion time*: We are additionally given a weight $w_j \in \mathbb{Z}_{>0}$ for every job $j \in J$, and the goal of the problem is to minimize $\sum_{j \in J} w_j C_j$, where C_j is the completion time of j on its assigned machine. For the second setting, this is explicitly given by the output. For the first setting, given the assignment $\sigma \in M^J$ of jobs to machines, it is well-known that the Smith's rule[2] gives the optimum order on each machine i. For the first setting, we also consider the objective of minimizing the *makespan*, which is defined as $\max_i \sum_{j \in \sigma^{-1}(i)} p_{ij}$, i.e., the maximum load over all machines.

It is convenient for us to use the classic three-field notation $\alpha|\beta|\gamma$ in [19] to denote scheduling problems studied in this paper.[3] The makespan and weighted completion time minimization problems in the unrelated machine setting are denoted as $R||C_{\max}$ and $R||\sum_j w_j C_j$ respectively. The problem to minimize weighted completion time in the identical machine with job precedence constraint setting is denoted as $P|\text{prec}|\sum_j w_j C_j$. We will also consider special cases of the problem, and give their notations when we discuss them.

There is a rich literature on designing approximation algorithms for these problems. For the unrelated makespan minimization problem, i.e., $R||C_{\max}$, the classic result of Lenstra, Shmoys and Tardos [32] gives a 2-approximation, which remains the state-of-the-art result. The problem is NP-hard to approximate within a factor of better than 1.5. Plotkin, Shmoys and Tardos [39] studied fast approximation algorithms for the problem, as an application of their packing and covering LP solver. They developed a randomized $(2+\epsilon)$-approximation algorithm in time $\tilde{O}_\epsilon(mn)$.[4] So their algorithm is nearly-linear if $|E| = \Theta(mn)$. Much work on the problem has focused on a special setting called the restricted assignment setting [49, 24, 25], where there is an intrinsic size $p_j \in \mathbb{Z}_{>0}$ for every $j \in J$, and for every $ij \in E$ we have $p_{ij} = p_j$.

For the unrelated machine weighted completion time problem, i.e., $R||\sum_j w_j C_j$, many independent rounding algorithms achieve an approximation ratio of 1.5 [42, 47, 43, 35]. Bansal, Svensson and Srinivasan [5] showed that the barrier of 1.5 is inherent for this type of algorithms. To overcome the barrier, they developed a novel dependent rounding scheme

[1] It is a folklore that if the last property is satisfied, we can assign $\{(C_j - p_j], j \in [J]\}$ to m machines so that the intervals assigned to each machine are disjoint.

[2] By this rule, we schedule jobs j assigned to a machine i using non-decreasing order of p_{ij}/w_j.

[3] In the notation, α indicates the machine model, β gives the set of additional constraints, and γ is the objective. $\alpha = R$ and $\alpha = P$ denote the unrelated and identical machine settings respectively, and $\text{prec} \in \beta$ indicates that jobs have precedence constraints. $\gamma = C_{\max}$ and $\gamma = \sum_j w_j C_j$ denote the makespan and weighted completion time objectives respectively.

[4] In this paper, we use $\tilde{O}_\epsilon(\cdot)$ to hide a factor that is poly-logarithmic in the input size of the instance being considered, which will be clear from the context, and polynomial in $1/\epsilon$, where ϵ is a precision parameter. An algorithm is nearly-linear if its running time is $\tilde{O}_\epsilon(\text{input size})$.

and a lifted SDP relaxation for the problem, leading to a $(1.5 - 1/2160000)$-approximation algorithm. The ratio has been improved to $1.5 - 1/6000$ by Li [35], to 1.488 by Im and Shadloo [23] and to the current best ratio of 1.45 by Im and Li [22]. The three subsequent works are based on the rectangle LP relaxation for the problem.

There is a vast literature on the problem of minimizing weighted completion time in the identical machine with job precedence constraints setting, i.e., the problem $P|\text{prec}|\sum_j w_j C_j$. A special case of the problem where there is only one machine (i.e., $m = 1$), denoted as $1|\text{prec}|\sum_j w_j C_j$, is already non-trivial. Hall et al. [20] developed a 2-approximation for the problem, which is the best possible under some stronger version of the unique game conjecture introduced by Bansal and Khot [4]. Another special case that is considered moderately in the literature is when all jobs have unit-size, denoted as $P|\text{prec}, p_j = 1|\sum_j w_j C_j$. Munier, Queyranne and Schulz [37] gave approximation ratios of 3 and 4 for the special case and the general problem $P|\text{prec}|\sum_j w_j C_j$ respectively. The ratios were improved to $1 + \sqrt{2}$ and $2 + 2\ln 2$ by Li [35]. Most algorithms [20, 37, 41, 35] for $P|\text{prec}|\sum_j w_j C_j$ and the two special cases use the following framework: Solve some linear/convex program to obtain an order of the jobs respecting the precedence constraints. For every job in this order, schedule it as early as possible, without violating the precedence and m-machine constraints.

Most of the results we discussed focused on optimizing the approximation ratios with polynomial time algorithms. Albeit being polynomial, the running times in these results are often very large. For LP-based algorithms, this may be caused by two factors. First, the size of an LP might already be large w.r.t the input size. Consider a typical time-indexed LP relaxation in the unrelated machine setting, one need a variable for every triple ijs with $ij \in E$ and s being the starting time. Assuming the number of possible starting times is linear in n, the number of variables in the LP is already $\Theta(n|E|)$; the size of the LP can only be bigger. Second, these algorithms often use a general LP solver, which has a large running time w.r.t the size of the LP. There is a vast literature in recent years on designing exact and approximate general LP solvers. Here we could only include a few representative results. To solve a linear program with $\bar{n}$ variables, $\bar{m}$ constraints and $\bar{N}$ non-zero coefficients up to a precision of ϵ, Lee and Sidford [29] developed an algorithm with running time $\tilde{O}\big((\bar{N} + \bar{m}^2)\sqrt{\bar{m}}\log\frac{1}{\epsilon}\big)$. Lee, Song and Zhang [30] gave an algorithm with running time $\tilde{O}(\bar{n}^\omega \log\frac{1}{\epsilon})$,[5] where $\omega \approx 2.373$ is the current best exponent for matrix multiplication. Brand, Lee, Sidford and Song [8] provided a $\tilde{O}(\bar{m}\bar{n} + \bar{n}^3)$ time randomized algorithm that solves the LP exactly with high probability; the running time is nearly linear if the constraint matrix is dense and tall. However, to solve general linear programs, these running times are at least quadratic, even if the LP has a linear size. Convex or semi-definite programming based algorithms need to solve the CP/SDP using the interior point or ellipsoid methods, which are often time-consuming.

1.1 Our Results

To overcome the above issue, we design approximation algorithms for scheduling problems, that run in *nearly-linear* time, i.e., in time $\tilde{O}_\epsilon(\text{input size})$. So, up to a $\text{poly}(\log n, 1/\epsilon)$-factor, our running times are the best possible. Some of the algorithms we developed have been studied empirically [2]. In the unrelated machine setting, $G = (M, J, E)$ denotes the bipartite graph between M and J, and a nearly-linear time is of order $\tilde{O}_\epsilon(|E|)$. For the identical machine with precedence constraints setting, we use κ to denote the number of precedence

[5] The result requires that the LP does not have redundant constraints.

constraints. A nearly-linear time algorithm runs in time $\tilde{O}_\epsilon(n+\kappa)$. Unlike the polynomial running time scenario, we can not assume $\prec$ is transitive, as it may dramatically increase the number of precedence constraints to quadratic. Moreover, the best known algorithm computing the transitive closure of the precedence constraints takes $O(n\kappa)$ time [40].

For many problems, including $R||C_{\max}, R||\sum_j w_jC_j, 1|\text{prec}|\sum_j w_jC_j$ and $P|\text{prec}, p_j = 1|\sum_j w_jC_j$, our nearly-linear time algorithms achieve the correspondent best known polynomial-time approximation ratios, due to Lenstra, Shmoys and Tardos [32], Im and Li [22], Hall et al. [20], and Li [35] respectively.

▶ **Theorem 1.1.** *For any $\epsilon > 0$, there is a $\tilde{O}_\epsilon(|E|)$-time $(2+\epsilon)$-approximation algorithm for $R||C_{\max}$, i.e., the makespan minimization problem on unrelated machines.*

For the problem $R||\sum_j w_jC_j$, we believe that showing that the rectangle LP can be approximated in nearly-linear time is interesting on its own. So we give two theorems for the problem. Refer to LP(6) for the formal description of the rectangle LP for the problem.

▶ **Theorem 1.2.** *Consider an instance of $R||\sum_j w_jC_j$ and the rectangle LP (6) for the instance. Let $\epsilon > 0$ and $\mathsf{lp}_{(6)}$ be the value of the LP. Then in $\tilde{O}_\epsilon(|E|)$ time, we can construct a solution $\mathbf{z}$ to the LP such that:*

- *$\mathbf{z}$ satisfies all the constraints in the LP, except that the constraint at most one job is processed on any machine at any time may be violated by a factor of $1+\epsilon$. (Formally, Constraint (8) is only satisfied with the right-side replaced by $1+\epsilon$.)*
- *The value of $\mathbf{z}$ to the LP is at most $(1+\epsilon)\mathsf{lp}_{(6)}$.*

In the theorem, our $\mathbf{z}$ will be represented by the list of non-zero coordinates and their values. Then, we show that the rounding algorithm of Im and Li [22] can indeed run in time nearly-linear on the support size of the LP solution. This gives the following theorem.

▶ **Theorem 1.3.** *For any $\epsilon > 0$, there is a $\tilde{O}_\epsilon(|E|)$-time $(1.45+\epsilon)$-approximation algorithm for $R||\sum_j w_jC_j$, i.e., the weighted completion time minimization problem on unrelated machines.*

The following two theorems are for $1|\text{prec}|\sum_j w_jC_j$ and $P|\text{prec}, p_j = 1|\sum_j w_jC_j$.

▶ **Theorem 1.4.** *For any $\epsilon > 0$, there is a $\tilde{O}_\epsilon((n+\kappa)\log p_{\max})$-time $(2+\epsilon)$-approximation algorithm for $1|\text{prec}|\sum_j w_jC_j$, i.e., the weighted completion time problem on a single machine with precedence constraints, where $p_{\max} := \max_{j\in J} p_j$ is the maximum job size.*

So the algorithm runs in nearly-linear time only when $p_{\max}$ is polynomially bounded.

▶ **Theorem 1.5.** *For any $\epsilon > 0$, there is a $\tilde{O}_\epsilon(n+\kappa)$-time $(1+\sqrt{2}+\epsilon)$-approximation algorithm for $P|\text{prec}, p_j = 1|\sum_j w_jC_j$, i.e., the weighted completion time problem on identical machines with unit-size jobs and precedence constraints.*

Along the way of algorithm design for the identical machine with precedence constraints setting, we developed a nearly-linear time $(1+\epsilon)$-approximation algorithm for the single commodity network flow problem in directed acyclic graphs, with bounded supplies and demands on sources and sinks, but infinite capacities on edges.

Recently there has been a lot of progress on solving maximum flow problem on undirected and directed graphs. For undirected graphs, the problem can be approximated within a factor of $1+\epsilon$ in nearly-linear time [26, 38, 45], and solved exactly with a slightly weaker running time of $m^{1+o(1)}$ (this is called *almost-linear* time) [7]. It was open whether an almost-linear

running time can be achieved for solving maximum flow on directed graphs.[6] This was resolved in the affirmative by a recent breakthrough due to Chen et al. [14]: They developed an algorithm that computes exact maximum flows on directed graphs with polynomially bounded integral capacities in $m^{1+o(1)}$ time. Thus, we could use the result as a black-box for our problem, if we allow the running time to be almost-linear. Nevertheless as our theme is to design *nearly-linear* time algorithms, we include in the full version of the paper our approximate maximum-flow algorithm for the special case with this running time. To the best of our knowledge, this was not known before.

For the general precedence-constrained scheduling problem $P|\text{prec}|\sum_j w_j C_j$ (on multiple machines with variant job lengths), we achieve an $O(1)$-approximation algorithm in nearly-linear time. However, the approximation ratio of the algorithm is $6+\epsilon$, which is worse than the best polynomial-time ratio of $2+2\ln 2$ due to Li [35].

▶ **Theorem 1.6.** *For any $\epsilon > 0$, there is a $\tilde{O}_\epsilon((n+\kappa)\log p_{\max})$-time $(6+\epsilon)$-approximation algorithm for $P|\text{prec}|\sum_j w_j C_j$, i.e., the weighted completion time minimization problem on identical machines with precedence constraints, where $p_{\max} := \max_{j\in J} p_j$ is the maximum job size.*

1.2 Our Techniques

All of our algorithms are based on linear programming: We design an LP relaxation of nearly-linear size, solve it in nearly-linear time to obtain a $(1+\epsilon)$-approximate solution, and round the solution into an integral schedule in nearly-linear time.

For $R||C_{\max}$, the natural LP relaxation has $O(|E|)$ size, and the mixed packing and covering form. Thus it can be solved within a factor of $1+\epsilon$ by the algorithm of Young [51] in $\tilde{O}_\epsilon(|E|)$ time. In particular, the algorithm outputs a $(1+\epsilon)$-approximate solution that violates the constraints by a factor of $1\pm\epsilon$, in $O\left(\frac{\bar{N}\log\bar{m}}{\epsilon^2}\right) = \tilde{O}_\epsilon(\bar{N})$ time, where $\bar{m}$ and $\bar{N}$ are the number of constraints and non-zero coefficients in the LP respectively. To round the fractional solution, we apply the grouping technique of [46] for the so called generalized assignment problem, but with a $(1+\epsilon)$-slack. This gives us a bipartite graph $H = (V, J, E_H)$ satisfying $|N_H(J')| \geq (1+\epsilon)|J'|$ for every $J' \subseteq J$, where $N_H(J')$ is the set of neighbors of J' in H. This allows us to find a matching in H that covers J in nearly-linear time, which leads to a $(2+\epsilon)$-approximate solution, matching the current best approximation of 2 in [32]. We remark that the $\tilde{O}_\epsilon(mn)$-running time of [39] comes from both solving the LP, and rounding the LP solution. So even with the nearly-linear time mixed covering and packing LP solver, the algorithm of [39] still requires $\tilde{O}_\epsilon(mn)$ time.

For the problem $R||\sum_j w_j C_j$, we give a nearly-linear size mixed packing and covering LP that (up to a factor of $1+O(\epsilon)$) is equivalent to the rectangle LP used by Li [35], Im and Shadloo [23], Im and Li [22]. In the rectangle LP, there is a variable x_{ijs} indicating if a job j is scheduled on the machine i and has starting time s, and constraints that at most one job is processed at any time on any machine. To reduce the size of the LP to $\tilde{O}_\epsilon(|E|)$, we partition the time horizon into *windows*, with lengths geometrically increasing by a factor of $1+\epsilon$. We distinguish between two types of scheduling intervals: If a job is scheduled within a window on some machine i (we call this an inside-window interval), then we do not need to capture the precise location of the scheduling interval. On the other hand, if the job

[6] By repeatedly solving maximum flow instances on residual graphs, one can convert an approximate maximum flow algorithm on directed graphs to an exact algorithm, without much loss on the running time. So for directed graphs, allowing $(1+\epsilon)$-approximation does not give much advantage.

starts and ends at two different windows (we call the interval an cross-window interval), we will approximately capture its starting and ending times. To do so, we divide each window into $1/\epsilon$ sub-windows, and let the LP variables capture the two sub-windows containing the starting and completion times. In the LP, we require all the cross-window intervals incur a congestion of 1: any point t is covered by at most 1 fraction of cross-window intervals. Then we require the total volume of jobs processed inside each window is at most its length. We show that up to a factor of $1 + O(\epsilon)$, a solution to the LP can be converted to one for the rectangle LP with no large cost. Roughly speaking, the width of window is small compared to its position and so we do not need to know the precise location of an inside-window-interval. For a cross-window-interval, we may incur an error on its length that is about ϵ times the total length of its starting window and ending window. As a sub-window has a small length, and a cross-window-interval covers some window-boundary, the total error incurred will also be small.

We proceed to our techniques for the weighted completion time problems in the identical machine with precedence constraints setting, i.e., the problem $P|\text{prec}|\sum_j w_j C_j$ and its special cases. Due to the precedence constraints, the LP relaxations do not have the mixed packing and covering form anymore. Nevertheless, the multiplicative weight update (MWU) framework can still be applied. We enclose the precedence constraints in a polytope $\mathcal{Q}$. In each iteration of the MWU framework, we guarantee that all these constraints are satisfied, i.e., the vector we obtain is in $\mathcal{Q}$. Other than the precedence constraints, we have $\tilde{O}_\epsilon(\log p_{\max})$ packing inequalities correspondent the m-machine constraint. This is due to that we can round completion times to integer powers of $1 + \epsilon$.

The number of iterations the MWU framework takes is $\tilde{O}_\epsilon(\bar{m})$, where $\bar{m}$ is the number of packing constraints in the LP, without counting the constraints for $\mathcal{Q}$. Fortunately we have $\bar{m} = \tilde{O}_\epsilon(\log p_{\max})$. To obtain the claimed $\tilde{O}_\epsilon((n + \kappa) \log p_{\max})$ time, we need to run each iteration of MWU in nearly-linear time. The bottleneck comes from finding a vector in $\mathcal{Q}$ satisfying one aggregated packing constraint, that maximizes a linear objective with non-negative coefficients.

A key technical contribution of our paper is an oracle for the problem. For an appropriately defined directed acyclic graph $G = (V, E)$, the polytope $\mathcal{Q}$ can be formulated as $\{\mathbf{y} \in [0, 1]^V : y_v \leq y_u, \forall vu \in E\}$. For two given row vectors $\mathbf{a}, \mathbf{b} \in \mathbb{R}^V_{\geq 0}$, the aggregated LP in each iteration of MWU is: $\max \mathbf{ay}$ subject to $\mathbf{y} \in \mathcal{Q}$ and $\mathbf{by} \leq 1$. Using LP duality, the problem is reduced to the special single commodity maximum flow problem we introduced: We have bounded supplies and demands on sources and sinks, but infinite capacities on edges. When allowing a $(1 + \epsilon)$-approximation for the scheduling problem, we need to find a flow whose value is at least the maximum value for the instance with sink capacities scaled by $\frac{1}{1+\epsilon}$. This is done by our nearly-linear time maximum-flow algorithm for the special case.

1.3 Other Related Work

The makespan minimization problem in the identical machine setting with precedence constraints, i.e., the problem $P|\text{prec}|C_{\max}$, is another classic problem in scheduling theory. The seminal work of Graham [18] gives a simple greedy algorithm that achieves a 2-approximation. On the negative side, Lenstra and Rinnooy Kan [31] proved a $(4/3 - \epsilon)$-hardness for the problem. Under the stronger version of the Unique Game Conjecture (UGC) introduced by Bansal and Khot [4], Svensson [48] showed that the problem is hard to approximate within a factor of $2 - \epsilon$ for any $\epsilon > 0$. Much work has focused on the special case where $m = O(1)$ and all jobs have size 1 [33, 17, 34], for which obtaining a PTAS is a long-standing open problem.

The multiplicative weight update (MWU) method for solving linear programs has played an important role in a wide range of applications. Some of its foundational work can be found in a beautiful survey by Arora, Hazan and Kale [3]. There has been a vast literature on solving packing, covering, and mixed packing and covering LPs approximately to a factor of $1+\epsilon$ using iterative methods [44, 39, 36, 50, 16, 28, 27, 51, 1, 13]. In particular, to solve a mixed packing and covering LP with $\bar{n}$ variables, $\bar{m}$ constraints and $\bar{N}$ non-zero coefficients, the algorithm of Young [51] returns $(1+\epsilon)$-approximation deterministically in $O\left(\frac{\bar{N}\ln\bar{m}}{\epsilon^2}\right)$ time. The dependence on ϵ has been improved slightly by Chekuri and Quanrud [13], who gave a randomized algorithm with running time $\tilde{O}\left(\frac{\bar{N}}{\epsilon}+\frac{\bar{m}}{\epsilon^2}+\frac{\bar{n}}{\epsilon^3}\right)$, where $\tilde{O}(\cdot)$ hides a poly-logarithmic factor.

There has been a recent surge of interest in designing fast or nearly-linear time approximation algorithms for combinatorial optimization problems [11, 12, 9, 15, 34, 6].

Organization. The rest of the paper is organized as follows. In Section 2, we define some elementary notations used across the paper, and describe the result of Young [51] on solving mixed packing and covering LPs, and a template solver for packing LPs over an "easy" polytope. In Sections 3 and 4, we present our results for $R||C_{\max}$ and $R||\sum_j w_jC_j$. Due to the page limit, we leave our algorithms for $P|\text{prec}|\sum_j w_jC_j$ and the two special cases $1|\text{prec}|\sum_j w_jC_j$ and $P|\text{prec}, p_j=1|\sum_j w_jC_j$ to the full version of the paper. The full version also contains other technicalities, such as how to handle the case where input integers are not polynomially bounded, how to reduce problems to the promise versions and how to use the self-balancing binary search tree data structure to run a list scheduling algorithm.

2 Preliminaries

We use bold lowercase letters to denote vectors, and their correspondent italic letters to denote their coordinates. We use bold uppercase letters to denote matrices. $\mathbf{0}$ and $\mathbf{1}$ are used to denote the all-0 and all-1 vectors whose domain can be inferred from the context. Given a template vector $\mathbf{v}$ over some finite domain, and a subset S of the domain, let $v(S):=\sum_{e\in S}v_e$ be the sum of v-values over elements in S.

Given an (undirected) graph $H=(V_H,E_H)$, we use $\delta_H(v), N_H(v), \delta_H(U), N_H(U)$ to respectively denote the sets of incident edges of $v\in V_H$, neighbors of v, edges between the set $U\subseteq V_H$ and $V_H\setminus U$, and vertices in $V_H\setminus U$ with at least one neighbor in U, in the graph H. Given a directed graph $H=(V_H,E_H)$, for every $v\in V_H$, we use $\delta^+_H(v)$ and $\delta^-_H(v)$ to denote the sets of outgoing and incoming edges of v respectively. For every $U\subseteq V_H$, let $\delta^+_H(U):=\{uv\in E_H: u\in U, v\notin U\}$ and $\delta^-_H(U):=\{uv\in E_H: u\notin U, v\in U\}$ be the sets of edges from U to $V_H\setminus U$ and from $V_H\setminus U$ to U respectively. When $H=G$ for the graph G in the context (which can be undirected or directed), we omit the subscript H in the notations.

For cleanness of exposition, we use $\tilde{O}_\epsilon(\cdot)$ to hide factors that are polynomial in $\frac{1}{\epsilon}$ and poly-logarithmic in the size of the input. As we gave the first nearly-linear time algorithms for the studied problems, the hidden factors are small compared to the improvements we make. The final approximation ratios we get have an additive factor of $O(\epsilon)$ (instead of ϵ); but it can be reduced to ϵ if we start from a smaller ϵ. By default, for an (undirected or directed) graph $H=(V_H,E_H)$ we deal with, we assume every vertex is incident to at least one edge so $|E_H|=\Omega(V_H)$. For any $a\in\mathbb{R}$, we define $(a)_+$ as $\max\{a,0\}$.

2.1 Nearly-Linear Time Mixed Packing and Covering LP Solver

A mixed packing and covering LP is an LP of the following form:

$$\text{find } \mathbf{x} \quad \text{such that} \quad \mathbf{x} \geq 0, \quad \mathbf{Px} \leq \mathbf{1} \quad \text{and} \quad \mathbf{Cx} \geq \mathbf{1}, \tag{MPC}$$

where $\mathbf{P} \in \mathbb{R}_{\geq 0}^{\bar{m}_{\mathbf{P}} \times \bar{n}}$ and $\mathbf{C} \in \mathbb{R}_{\geq 0}^{\bar{m}_{\mathbf{C}} \times \bar{n}}$ for some positive integers $\bar{n}, \bar{m}_{\mathbf{P}}, \bar{m}_{\mathbf{C}}$. Let $\bar{m} = \bar{m}_{\mathbf{P}} + \bar{m}_{\mathbf{C}}$ and $\bar{N}$ be the total number of non-zeros in $\mathbf{P}$ and $\mathbf{C}$. Young [51] developed a nearly-linear time algorithm that solves (MPC) approximately:

▶ **Theorem 2.1** ([51]). *Given an instance of* (MPC) *and $\epsilon > 0$, there is an $O\left(\frac{\bar{N} \log \bar{m}}{\epsilon^2}\right)$-time algorithm that either claims* (MPC) *is infeasible, or outputs an $\mathbf{x} \in \mathbb{R}_{\geq 0}^{\bar{n}}$ such that $\mathbf{Px} \leq (1+\epsilon)\mathbf{1}$ and $\mathbf{Cx} \geq \frac{\mathbf{1}}{1+\epsilon}$.*

2.2 Template Packing LP Solver over a Simple Polytope

In this section, we describe a template MWU-based LP solver for a packing linear program with an additional requirement that the solution is inside an "easy" polytope $\mathcal{Q}$. The framework we describe here is introduced in [10] and later reformulated in [11].

Let $\mathbf{P} \in \mathbb{R}_{\geq 0}^{\bar{m} \times \bar{n}}$ be a non-negative matrix, with $\bar{N}$ non-zero entries. Let $\mathbf{a} \in \mathbb{R}_{\geq 0}^{\bar{n}}$ be a row vector, and $\mathcal{Q} \subseteq \mathbb{R}_{\geq 0}^{\bar{n}}$ be a polytope which is defined by "easy" constraints. We focus on the following linear program:

$$\max \ \mathbf{ax} \quad \text{subject to} \quad \mathbf{x} \in \mathcal{Q} \quad \text{and} \quad \mathbf{Px} \leq \mathbf{1}. \tag{$\mathrm{P}_{\mathcal{Q}}$}$$

Throughout the paper, we make sure all instances of ($\mathrm{P}_{\mathcal{Q}}$) we deal with are feasible.

▶ **Definition 2.2.** *Let $\epsilon \in (0,1), \phi > 0$ be two parameters. An (ϵ, ϕ)-approximate solution to* ($\mathrm{P}_{\mathcal{Q}}$) *is a vector $\mathbf{x} \in \mathcal{Q}$ satisfying $\mathbf{Px} \leq (1+\epsilon)\mathbf{1}$ and $\mathbf{ax} \geq \mathbf{ax}^* - \phi$, where $\mathbf{x}^* \in \mathcal{Q}$ is the optimum solution to* ($\mathrm{P}_{\mathcal{Q}}$).

As a hindsight, we only allow a loss of an additive factor ϕ in the objective function of the LP for $P|\text{prec}|\sum_j w_j C_j$, which will be set to be a polynomially small term. As is typical in a MWU framework, we need to solve the following LP where the constraints $\mathbf{Px} \leq \mathbf{1}$ are aggregated into one constraint $\mathbf{by} \leq 1$, where $\mathbf{b} \in \mathbb{R}_{\geq 0}^{\bar{n}}$ is a row vector:

$$\max \ \mathbf{ay} \quad \text{subject to} \quad \mathbf{y} \in \mathcal{Q} \quad \text{and} \quad \mathbf{by} \leq 1. \tag{1}$$

Again we guarantee all instances of (1) we encounter are feasible.

▶ **Definition 2.3.** *Let $\epsilon \in (0,1), \phi > 0$ be two parameters. An (ϵ, ϕ)-approximate solution to* (1) *is a vector $\mathbf{y} \in \mathcal{Q}$ satisfying $\mathbf{by} \leq 1 + \epsilon$ and $\mathbf{ay} \geq \mathbf{ay}^* - \phi$, where $\mathbf{y}^*$ is the optimum solution to the LP. An (ϵ, ϕ)-oracle for* (1) *is an algorithm that, given an instance of* (1)*, and $\epsilon \in (0,1), \phi > 0$, outputs an (ϵ, ϕ)-approximate solution $\mathbf{y}$ to* (1).

The template LP solver is described in Algorithm 1, where we use $\mathbf{P}_i$ to denote the i-th row vector of $\mathbf{P}$. By our assumption that ($\mathrm{P}_{\mathcal{Q}}$) is feasible, the instance of (1) defined in every execution of Step 3 is also feasible. The performance of the algorithm is summarized in the following theorem.

▶ **Theorem 2.4.** *Algorithm 1 will return an $(O(\epsilon), \phi)$-approximate solution $\mathbf{x}$ to* ($\mathrm{P}_{\mathcal{Q}}$)*, within $O(\frac{\bar{m} \log \bar{m}}{\epsilon^2})$ iterations of Loop 2.*

Algorithm 1 LP Solver for $(\mathrm{P}_{\mathcal{Q}})$.

Input: an instance of $(\mathrm{P}_{\mathcal{Q}})$, $\epsilon \in (0,1), \phi > 0$, and (ϵ,ϕ)-oracle $\mathcal{O}$ for (1)
Output: an $(O(\epsilon),\phi)$-approximate solution $\mathbf{x}$ for $(\mathrm{P}_{\mathcal{Q}})$

1: $t \leftarrow 0, \rho \leftarrow \frac{\ln \bar{m}}{\epsilon^2}, \mathbf{x}^{(0)} \leftarrow \mathbf{0} \in \mathbb{R}^{\bar{n}}_{\geq 0}, \mathbf{u}^{(0)} \leftarrow \mathbf{1} \in \mathbb{R}^{\bar{m}}_{\geq 0}$
▷ $\mathbf{x}^{(t)}$'s are column vectors and $\mathbf{u}^{(t)}$'s are row vectors
2: **while** $t < 1$ **do**
3: define $\mathbf{b} := \frac{\mathbf{u}^{(t)}}{|\mathbf{u}^{(t)}|}\mathbf{P}$, and run the oracle $\mathcal{O}$ for (1) to obtain an (ϵ,ϕ)-approximate solution $\mathbf{y}$ for (1)
4: $\delta \leftarrow \min\left\{\min_{i\in[\bar{m}]} \frac{1}{\rho \cdot \mathbf{P}_i\mathbf{y}}, 1-t\right\}$
5: **for** every $i \in [\bar{m}]$ **do** $u_i^{(t+\delta)} \leftarrow u_i^{(t)} \cdot \exp\left(\delta\epsilon\rho \cdot \mathbf{P}_i\mathbf{y}\right)$
6: $\mathbf{x}^{(t+\delta)} \leftarrow \mathbf{x}^{(t)} + \delta\mathbf{y}, t \leftarrow t+\delta$
7: **return** $\mathbf{x} := \mathbf{x}^{(1)}$

Proof. Focus on one iteration of Loop 2. Let t be the value of t at the beginning of the iteration, $\mathbf{y}$ and δ be the $\mathbf{y}$ and δ obtained in Step 3 and 4 in the iteration respectively. Then we have

$$|\mathbf{u}^{(t+\delta)}| = \sum_{i\in[\bar{m}]} u_i^{(t+\delta)} = \sum_{i\in[\bar{m}]} u_i^{(t)} \exp(\delta\epsilon\rho \cdot \mathbf{P}_i\mathbf{y}) \leq \sum_{i\in[\bar{m}]} u_i^{(t)}(1+(1+\epsilon)\epsilon \cdot \delta\rho \cdot \mathbf{P}_i\mathbf{y})$$
$$= |\mathbf{u}^{(t)}| + (1+\epsilon)\epsilon\delta\rho \cdot \mathbf{u}^{(t)}\mathbf{P}\mathbf{y} \leq |\mathbf{u}^{(t)}| + (1+\epsilon)^2\epsilon\delta\rho \cdot |\mathbf{u}^{(t)}| \leq |\mathbf{u}^{(t)}| \exp((1+\epsilon)^2\epsilon\delta\rho).$$

The inequality in the first line is by that $\delta\rho \cdot \mathbf{P}_i\mathbf{y} \in [0,1]$ for every $i \in [\bar{m}]$ and $e^{\epsilon\theta} \leq 1+\epsilon\theta+(\epsilon\theta)^2 \leq 1+\epsilon\theta+\epsilon^2\theta$ for every $\epsilon \in [0,1]$ and $\theta \in [0,1]$. The first inequality in the second line is by that $\frac{\mathbf{u}^{(t)}}{|\mathbf{u}^{(t)}|}\mathbf{P}\mathbf{y} = \mathbf{b}\mathbf{y} \leq 1+\epsilon$.

Combining the inequality over all iterations, we have

$$|\mathbf{u}^{(1)}| \leq |\mathbf{u}^{(0)}| \exp\left((1+\epsilon)^2\epsilon\rho\right) = \bar{m} \cdot \exp\left((1+\epsilon)^2\epsilon\rho\right). \tag{2}$$

For every $i \in [\bar{m}]$, we have $u_i^{(1)} = \exp\left(\epsilon\rho \cdot \mathbf{P}_i\mathbf{x}\right)$, where $\mathbf{x} := \mathbf{x}^{(1)}$ is the returned solution. So, by (2), we have $\exp(\epsilon\rho \cdot \mathbf{P}_i\mathbf{x}) \leq \bar{m} \cdot \exp((1+\epsilon)^2\epsilon\rho)$, which implies $\mathbf{P}_i\mathbf{x} \leq \frac{\ln \bar{m}}{\epsilon\rho} + (1+\epsilon)^2 \leq (1+\epsilon)^2 + \epsilon = 1+O(\epsilon)$.

In the end $\mathbf{x} = \mathbf{x}^{(1)}$ is a convex combination of vectors $\mathbf{y}$ obtained in all iterations. As each $\mathbf{y}$ is in $\mathcal{Q}$, we have $\mathbf{x} \in \mathcal{Q}$. Moreover, for the instance of (1) in any iteration, $\mathbf{x}^*$ is a valid solution. So, the optimum solution $\mathbf{y}^*$ to the instance of (1) has $\mathbf{a}\mathbf{y}^* \geq \mathbf{a}\mathbf{x}^*$, and the $\mathbf{y}$ returned by the oracle has $\mathbf{a}\mathbf{y} \geq \mathbf{a}\mathbf{y}^* - \phi \geq \mathbf{a}\mathbf{x}^* - \phi$. This implies our final $\mathbf{x}$ has $\mathbf{a}\mathbf{x} \geq \mathbf{a}\mathbf{x}^* - \phi$. Therefore, $\mathbf{x}$ is a $(O(\epsilon),\phi)$-approximate solution to $(\mathrm{P}_{\mathcal{Q}})$.

It remains to bound the number of iterations that Loop 2 can take. In every iteration of loop 2 except for the last one, some i has $\frac{1}{\rho\cdot\mathbf{P}_i\mathbf{y}} = \delta$, i.e., $\delta\epsilon\rho \cdot \mathbf{P}_i\mathbf{y} = \epsilon$. We say u_i is increased fully in the iteration. Notice by (2), each u_i can be increased fully in at most $\frac{\ln\left(\bar{m}\exp((1+\epsilon)^2\epsilon\rho)\right)}{\epsilon} = \frac{\ln\bar{m}+(1+\epsilon)^2\epsilon\rho}{\epsilon} = O\left(\frac{\ln\bar{m}}{\epsilon^2}\right)$ iterations. This bounds the number of iterations by $O\left(\frac{\bar{m}\log\bar{m}}{\epsilon^2}\right)$ as there are $\bar{m}$ different values of i. ◀

For each iteration of loop 2, the steps other than Step 3 takes $O(\bar{N})$ time. Therefore, the running time of Algorithm 1 is $O\left(\frac{\bar{m}\log\bar{m}\cdot\bar{N}}{\epsilon^2}\right)$, plus the time for running the oracle $O\left(\frac{\bar{m}\log\bar{m}}{\epsilon^2}\right)$ times.

3 Unrelated Machine Makespan Minimization

In this section, we give the nearly-linear time $(2+\epsilon)$-approximation algorithm for the unrelated machine makespan minimization problem, i.e, the problem $R||C_{\max}$. Recall that we are given a bipartite graph $G=(M,J,E)$ and a $p_{ij}\in\mathbb{Z}_{>0}$ for every $ij\in E$. Recall that $N(j), N(i), \delta(j)$ and $\delta(i)$ denote the set of neighbors or incident edges of a job $j\in J$ or a machine $i\in M$, in the graph G.

Via a standard technique described in the full version of the paper, we can focus on the following promise version:

- We are given a number $P\geq \mathsf{opt}$, where opt is the optimal makespan of the instance, and our goal is to construct an assignment of makespan at most $(2+O(\epsilon))P$.

For some $ij\in E$ with $p_{ij}>P$, we remove ij from E, as the optimum solution does not use the edge. The following is the natural LP relaxation for the problem:

$$\sum_{j\in N(i)} p_{ij}x_{ij}\leq P, \forall i\in M \quad (3) \qquad \sum_{i\in N(j)} x_{ij}\geq 1, \forall j\in J \quad (4) \qquad x_{ij}\geq 0, \forall ij\in E \quad (5)$$

In the correspondent integer program, $x_{ij}\in\{0,1\}$ for every $ij\in E$ indicates whether the job j is assigned to machine i. (3) requires that the makespan of the schedule to be at most P, (4) requires every job to be scheduled. In the linear program, we replace the requirement that $x_{ij}\in\{0,1\}$ with the non-negativity constraint (5).

By the promise that $P\geq\mathsf{opt}$, the LP is feasible. Therefore, applying Theorem 2.1, we can solve the LP in $\tilde{O}_\epsilon(|E|)$ time to obtain an approximate solution $\mathbf{x}\in[0,1]^E$. By scaling, we can assume (4) holds with equalities, and (3) holds with right side replaced by $(1+O(\epsilon))P$.

To round the solution to an integral assignment in $\tilde{O}_\epsilon(|E|)$-time, we use the grouping idea from [46]: For each machine $i\in M$, we break the fractional jobs assigned to i into groups, each containing $\frac{1}{1+\epsilon}$ fractional jobs. This gives us a bipartite graph H between jobs and groups. Any perfect matching (i.e., a matching covering all jobs J) will give a $(2+O(\epsilon))$-approximation for the makespan problem. In H, every subset $J'\subseteq J$ of jobs has at least $(1+\epsilon)|J'|$ neighbors. The $(1+\epsilon)$-factor allows us to design a $\tilde{O}_\epsilon(|E|)$-time algorithm to find a matching covering all jobs J, as stated in the following lemma:

▶ **Lemma 3.1.** *Assume we are given a bipartite graph $H=(S,T,E_H)$ and $\epsilon>0$ such that $|N_H(S')|\geq(1+\epsilon)|S'|$ for every $S'\subseteq S$. In $O\left(\frac{|E_H|}{\epsilon}\log|S|\right)$-time, we can find a matching in H covering all vertices in S.*

Proof. Let $L=\lfloor\log_{1+\epsilon}|S|\rfloor+1>\log_{1+\epsilon}|S|$. Then we use the shortest-augmenting path algorithm of Hopcroft and Karp [21] to find a matching for which there is no augmenting path of length at most $2L+1$. The running time of the algorithm can be made to $O(|E_H|L)=O(\frac{|E_H|}{\epsilon}\log|S|)$. It remains to show the following lemma:

▶ **Lemma 3.2.** *Let F be a matching in H for which there is no augmenting path of length at most $2L+1$. Then all vertices in S are matched in the matching F.*

Proof. Let $\vec{H}$ be the residual graph of H w.r.t the F: $\vec{H}$ is a directed graph over $S\cup T$, for every edge $st\in E_H$, we have $st\in\vec{H}$, and for every $st\in F$, we have $ts\in\vec{H}$. We say a vertex in S is free if it is unmatched in F. For every integer $\ell\in[0,L]$, define S^ℓ (T^ℓ resp.) to be the set of vertices in S (T, resp.) to which there exists a path in $\vec{H}$ of length *at most* 2ℓ ($2\ell+1$, resp.) from a free vertex. So, we have $S^0\subseteq S^1\subseteq S^2\subseteq\cdots\subseteq S^L$ and $T^0\subseteq T^1\subseteq T^2\subseteq\cdots\subseteq T^L$.

Notice that $T^\ell = N_H(S^\ell)$ for every $\ell \in [0, L]$. So for every $\ell \in [0, L]$, we have $(1+\epsilon)|S^\ell| \le |T^\ell|$ by the condition of the lemma. All vertices in T^L are matched by our assumption that there are no augmenting paths of length at most $2L+1$. So for every $\ell \in [0, L-1]$, we have $|T^\ell| \le |S^{\ell+1}|$ as all vertices in T^ℓ are matched to $S^{\ell+1}$.

Combining the two statements gives us $(1+\epsilon)|S^\ell| \le |S^{\ell+1}|$ for every $\ell \in [0, L-1]$. Thus $|S^L| \ge (1+\epsilon)^L |S^0|$, which contradicts the definition of L and that $|S^0| \ge 1, |S^L| \le |S|$. ◀

This finishes the proof of Lemma 3.1. ◀

With the lemma, we prove the following theorem using the grouping technique from [39]:

▶ **Theorem 3.3.** *Given $\mathbf{x} \in [0,1]^E$ satisfying $x(\delta(j)) = 1$ for every $j \in J$, and $\epsilon \in (0,1)$, there is an $O\left(\frac{|E|}{\epsilon} \log n\right)$-time algorithm that outputs an assignment $\sigma \in M^J$ of jobs to machines such that $\sigma_j j \in E$ and $x_{\sigma_j j} > 0$ for every $j \in J$, and for every $i \in M$, we have*

$$\sum_{j \in \sigma^{-1}(i)} p_{ij} \le (1+\epsilon) \sum_{j \in N(i)} p_{ij} x_{ij} + \max_{j \in \sigma^{-1}(i)} p_{ij}. \quad \textit{(Assume the maximum over } \emptyset \textit{ is 0.)}$$

Proof. We construct a bipartite graph $H = (V, J, E_H)$, starting with $V = \emptyset$ and $E_H = \emptyset$. For every machine $i \in M$, we run the following procedure. See Figure 1 for an illustration. (The notations defined in the paragraph depend on i; if a notation does not contain i in the subscript, it will only be used locally, in this paragraph.) Let D_i be the number of jobs j with positive x_{ij} values. Let $j_1, j_2, \cdots, j_{D_i}$ be these jobs j, sorted in non-increasing order of p_{ij}; that is, we have $p_{ij_1} \ge p_{ij_2} \ge \cdots \ge p_{ij_{D_i}}$. For every integer $d \in [0, D_i]$, we define $Z_d = \sum_{d'=1}^{d} x_{ij_{d'}}$. Let $R_i = \lceil (1+\epsilon) Z_{D_i} \rceil = \lceil (1+\epsilon) x(\delta(i)) \rceil$. For every $r = 1, 2, 3, \cdots, R_i$, we create a vertex ir and add it to V. We add to E_H an edge between $ir, r \in [R_i]$ and j_d, $d \in [D_i]$ if $(\frac{r-1}{1+\epsilon}, \frac{r}{1+\epsilon}) \cap (Z_{d-1}, Z_d) \ne \emptyset$, and we define $y_{(ir)j_d}$ to be the length of the interval. This finishes the construction of $H = (V, J, E_H)$, along with a vector $\mathbf{y} \in \left(0, \frac{1}{1+\epsilon}\right]^{E_H}$.

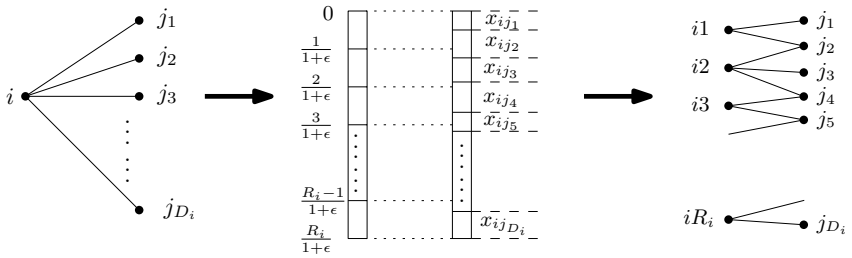

Figure 1 Construction of the H for the machine $i \in M$. In the bipartite graph between $\{i1, i2, \cdots, iD_i\}$ and $\{j_1, j_2, \cdots, j_{D_i}\}$ and there is an edge between j_d and (ir) iff the interval correspondent to j_d intersects the interval $(\frac{r-1}{1+\epsilon}, \frac{r}{1+\epsilon})$.

The number of edges in H for each i is at most $D_i + R_i - 1 \le |\delta(i)| + (1+\epsilon)x(\delta(i))$. Therefore the total number of edges we created in H is at most $|E| + (1+\epsilon)|J| = O(|E|)$. For every $ij \in E$, we have $\sum_{r:(ir)j \in E_H} y_{(ir)j} = x_{ij}$. This implies that for every $j \in J$, we have $y(\delta_H(j)) = 1$. For every $ir \in V$, we have $y\big(\delta_H(ir)\big) \le \frac{1}{1+\epsilon}$, and the inequality holds with equality except when $r = R_i$.

For every set $J' \subseteq J$, we have $|N_H(J')| \ge (1+\epsilon)|J'|$, as we can view $\mathbf{y}$ as a fractional matching in H where every $j \in J$ is matched to an extent of 1 and every $ir \in V$ is matched to an extent of at most $\frac{1}{1+\epsilon}$. Then we can use Lemma 3.1 [7] to find a matching in H that

[7] We need to switch the left and right sides when going from the bipartite graph H in Theorem 3.3 to that in Lemma 3.1. That is, we set $S = J$ and $T = V$.

covers all jobs J. The running time of the algorithm is $O\left(\frac{|E_H|}{\epsilon}\log n\right) = O\left(\frac{|E|}{\epsilon}\log n\right)$. The matching gives an assignment $\sigma \in M^J$: If j is matched to ir, then define $\sigma_j = i$. Fix some $i \in M$ with $\sigma^{-1}(i) \neq \emptyset$; we upper bound $\sum_{j\in\sigma^{-1}(i)} p_{ij}$:

$$\begin{aligned}\sum_{j\in\sigma^{-1}(i)} p_{ij} \leq & \max_{j\in\sigma^{-1}(i)} p_{ij} + \sum_{r=2}^{R_i} \max_{j\in N_H(ir)} p_{ij} \\ \leq & \max_{j\in\sigma^{-1}(i)} p_{ij} + (1+\epsilon)\sum_{r=2}^{R_i} \sum_{j\in N_H(i(r-1))} p_{ij} y_{(i(r-1))j} \\ \leq & \max_{j\in\sigma^{-1}(i)} p_{ij} + (1+\epsilon)\sum_{r=1}^{R_i} \sum_{j\in N_H(ir)} p_{ij} y_{(ir)j} \;=\; \max_{j\in\sigma^{-1}(i)} p_{ij} + (1+\epsilon)\sum_{j\in N(i)} p_{ij} x_{ij}.\end{aligned}$$

To see the first inequality, notice that the job j' matched to $i1$ (if it exists) has $p_{ij'} \leq \max_{j\in\sigma^{-1}(i)} p_{ij}$, and the job j' matched to each ir, $r \in [2, R_i]$, has $p_{ij'} \leq \max_{j\in\delta_H((ir))} p_{ij}$. Consider the second inequality. For every $r \in [2, R_i]$, any $j \in \delta_H(ir)$ and any $j' \in \delta_H(i(r-1))$, we have $p_{ij} \leq p_{ij'}$. Moreover, for every $r \in [2, R_i]$, we have $y\big(\delta_H(i(r-1))\big) = \frac{1}{1+\epsilon}$. The inequality in the third line follows from replacing r with $r+1$. The equality holds since for every $ij \in E$ we have $\sum_{r:(ir)j\in E_H} y_{(ir)j} = x_{ij}$. ◀

We can then apply Theorem 3.3 with the solution $\mathbf{x}$ we obtained from solving LP(3-5). Clearly we have $\max_{j\in\sigma^{-1}(i)} p_{ij} \leq P$ for every $i \in M$. So, the total load on any machine i is at most $P + (1+\epsilon)\cdot\sum_{j\in N(i)} p_{ij}x_{ij} \leq P + (1+\epsilon)\cdot(1+O(\epsilon))P = (2+O(\epsilon))P$, as (3) is satisfied with right side replaced by $(1+O(\epsilon))P$. This finishes the analysis of the algorithm for $R||C_{\max}$ and proves Theorem 1.1.

4 Unrelated Machine Weighted Completion Time Minimization

In this section, we give our nearly-linear time algorithm for $R||\sum_j w_j C_j$, with an approximation ratio of $1.45+\epsilon$, matching the current best ratio of Im and Li [22] achieved in polynomial time. Our result is based on formulating an LP relaxation that is equivalent to the rectangle LP introduced by Li [35]. The new LP relaxation has a nearly-linear size and the mixed packing and covering form; thus it can be solved in nearly-linear time using Theorem 2.1. We describe the rectangle LP (LP(6)), our new LP relaxation (LP(11)) and show their equivalence in Sections 4.1, 4.2 and 4.3 respectively.

In the full version of the paper we show how to construct a solution to LP(6) from one to LP(11) in nearly-linear time, finishing the proof of Theorem 1.2. We also show in the full version that the rounding algorithm of Im and Li can run in nearly-linear time; this finishes the proof of Theorem 1.3. Throughout the section, we assume all processing times are integers bounded by a polynomial of n. The general case is handled in the full version.

4.1 Rectangle LP Relaxation

We describe the rectangle LP relaxation for $R||\sum_j w_j C_j$ introduced by Li [35]. Let $T = \sum_{j\in J}\max_{i\in N(j)} p_{ij}$ so that any schedule will complete by time T. The following is the rectangle LP:

$$\min \quad \sum_{j\in J} w_j \sum_{i\in N(j), s\in[0,T)} z_{ijs}(s+p_{ij}) \tag{6}$$

$$\sum_{i\in N(j),s\in[0,T)} z_{ijs} \geq 1 \quad \forall j \in J \qquad (7)$$

$$\sum_{j\in N(i),s\in[t-p_{ij},t)} z_{ijs} \leq 1 \quad \forall i \in M, t \in [T] \qquad (8)$$

$$z_{ijs} = 0 \quad \forall ij \in E, s > T - p_{ij} \qquad (9)$$

$$z_{ijs} \geq 0 \quad \forall ij \in E, s \in [0,T) \qquad (10)$$

In the correspondent integer program, z_{ijs} for every $ij \in E$ and integer $s \in [0,T)$ indicates if job j is scheduled on machine i, with starting time s. The objective gives the weighted completion time of the schedule. (7) requires that every job j is scheduled. (8) requires that at any time on machine i, at most one job is being processed. (9) ensures that no jobs complete after time T. (10) is the non-negativity constraint. Im and Li [22] showed that given a solution $\mathbf{z}$ to LP(6), one can round it to an integral schedule, whose weighted completion time in expectation is at most 1.45 times the value of $\mathbf{z}$.

4.2 A Nearly-Linear Size LP Relaxation

In this section we formulate the relaxation that can be solved in nearly-linear time, and prove its equivalence to LP(6) in Section 4.3. We create a list of time points as follows: $T_0 = 0$, $T_d = \lfloor (1+\epsilon)T_{d-1} \rfloor + 1$ for every integer $d \geq 1$. Define $D = O(\frac{\log n}{\epsilon})$ to be the smallest integer so that $T_D \geq T$. We call $(T_{d-1}, T_d]$ the d-th *window*, and the time points $T_0, T_1, \cdots, T_D$ *window boundaries* (or simply boundaries). Define $\Delta_d = T_d - T_{d-1}$ to be the length of the d-th window.

Let $\eta_d := \lceil \epsilon \Delta_d \rceil$. We partition $(T_{d-1}, T_d]$ into *sub-windows* of length η_d, except that the last sub-window may be shorter. Then $q_d := \left\lceil \frac{\Delta_d}{\eta_d} \right\rceil \leq \frac{1}{\epsilon}$ is the number of sub-windows of $(T_{d-1}, T_d]$. Let $\tau_0^{(d)} = T_{d-1}, \tau_1^{(d)}, \tau_2^{(d)}, \cdots, \tau_{q_d}^{(d)} = T_d$ be the boundaries of the q_d sub-windows.

We describe the variables in the LP. For every $ij \in E$ and $d \in [D]$ with $p_{ij} \leq \Delta_d$, we introduce a variable x_{ijd}, indicating if j is scheduled on i inside the d-th window. Let S_j and C_j be the starting and completion time of j in the target optimum schedule (which the algorithm does not know). For every $ij \in E, 1 \leq d \leq e < D$, integers $u \in [0, q_d), v \in [0, q_{e+1})$, we *may* introduce a variable y_{ijdeuv} indicating if j is scheduled on i, $S_j \in [\tau_u^{(d)}, \tau_{u+1}^{(d)})$ and $C_j \in (\tau_v^{(e+1)}, \tau_{v+1}^{(e+1)}]$. That means, the scheduling interval $(S_j, C_j]$ of j contains the d'-th window for every $d' \in [d+1, e]$, and a non-empty part of the d-th and $(e+1)$-th windows. u and v approximately give the volumes of j processed in the two windows. It is disjoint from all other windows. As a hindsight, a sub-window is short enough and we can afford to incur an error equaling its length for every window. We only introduce a y-variable if the correspondent event can happen. That is, the following conditions need to be satisfied for the existence of y_{ijdeuv}: $\tau_v^{(e+1)} - \tau_{u+1}^{(d)} + 2 \leq p_{ij} \leq \tau_{v+1}^{(e+1)} - \tau_u^{(d)}$. Notice when $y_{ijdeuv} = 1$, then the scheduling interval $(S_j, C_j]$ of j intersects at least two windows.

For a variable y_{ijdeuv} and an integer $d' \in [D]$, we define

$$Q_{ijdeuvd'} := \begin{cases} 0 & \text{if } d' \leq d-1 \text{ or } d' \geq e+2 \\ \Delta_{d'} & \text{if } d+1 \leq d' \leq e \\ T_d - \tau_{u+1}^{(d)} + 1 & \text{if } d' = d \\ \tau_v^{(e+1)} - T_e + 1 & \text{if } d' = e+1 \end{cases}.$$

Assuming j starts at time $\tau_{u+1}^{(d)} - 1$ and ends at time $\tau_v^{(e+1)} + 1$ on machine i, we have that $Q_{ijdeuvd'}$ is the volume of job j processed in the d'-th window. So, if $y_{ijdeuv} = 1$ in a schedule, then $Q_{ijdeuvd'}$ gives a lower bound on the volume.

We say the quadruple $deuv$ left-covers the pair $d'u'$ if the sub-window $(\tau^{(d')}_{u'-1}, \tau^{(d')}_{u'}]$ is between the sub-windows $(\tau^{(d)}_{u}, \tau^{(d)}_{u+1}]$ (exclusive) and $(\tau^{(e+1)}_{v}, \tau^{(e+1)}_{v+1}]$ (inclusive) in the time horizon, or if $(\tau^{(d')}_{u'-1}, \tau^{(d')}_{u'}] = (\tau^{(d)}_{u}, \tau^{(d)}_{u+1}]$ and $\tau^{(d')}_{u'} - \tau^{(d')}_{u'-1} = 1$. So if $deuv$ left-covers $d'u'$ and $y_{ijdeuv} = 1$, then the scheduling interval of j will surely cover the left-most time unit of the sub-window $(\tau^{(d')}_{u'-1}, \tau^{(d')}_{u'}]$.

With the necessary definitions, we can formulate the LP relaxation as LP(11). For the sake of convenience, we assume if a variable does not exist, then it is not included in a summation.

$$\min \quad \sum_{ijd} w_j \cdot (T_{d-1} + 1) \cdot x_{ijd} + \sum_{ijdeuv} w_j \cdot (T_e + 1) \cdot y_{ijdeuv} \tag{11}$$

$$\sum_{id} x_{ijd} + \sum_{ideuv} y_{ijdeuv} \geq 1 \qquad \forall j \in J \tag{12}$$

$$\sum_{\substack{jdeuv \,:\, deuv \\ \text{left-covers } d'u'}} y_{ijdeuv} \leq 1 \qquad \forall i \in M, d' \in [D], u' \in [q_{d'}] \tag{13}$$

$$\sum_{j} p_{ij} \cdot x_{ijd'} + \sum_{jdeuv} Q_{ijdeuvd'} \cdot y_{ijdeuv} \leq \Delta_{d'} \qquad \forall i \in M, d' \in [D] \tag{14}$$

$$\text{all variables are non-negative} \tag{15}$$

Consider the correspondent integer program and an integral schedule. If $x_{ijd} = 1$, then the completion time of j is in $(T_{d-1}, T_d]$. If $y_{ijdeuv} = 1$, then it is in $(T_e, T_{e+1}]$. So, the objective (11) approximates and underestimates the total weighted completion time of the schedule.[8] (12) requires that every job is scheduled: either the scheduling interval of a job j is inside some window, or it overlaps with at least two windows. (13) follows from the definition of $deuv$ left-covering $d'u'$. If $x_{ijd'} = 1$, then the p_{ij} units of job j is processed in the d'-th window on machine i. If $y_{ijdeuv} = 1$, then at least $Q_{ijdeuvd'}$ units is processed. So (14) is valid as the volume of the jobs processed in the d'-th window is at most $\Delta_{d'}$. Therefore, LP(11) is valid, and its value is at most the weighted completion time of the optimum schedule for the instance.

There are at most $D|E|$ x-variables. We then count the number of tuples $ijdeuv$ such that y_{ijdeuv} is a variable in the LP. For fixed $ij \in E, d \in D$ and $u \in [0, q_d)$, there are at most $O(1)$ possibilities for (e, v), as the lengths of sub-windows do not decrease from left to right in the time horizon, except for the last sub-window of each window. Hence the number of y-variables is at most $O\big(\frac{D|E|}{\epsilon}\big) = O\big(\frac{|E| \log n}{\epsilon^2}\big)$.[9] The number of constraints is $O(n + \frac{m|D|}{\epsilon}) = O\big(n + \frac{m \log n}{\epsilon^2}\big)$. The number of non-zeros is at most $O\big(\frac{|E| \log^2 n}{\epsilon^4}\big)$ as each variable appears in at most $O(\frac{D}{\epsilon})$ constraints.

Therefore, by Theorem 2.1, in $O\left(\frac{|E| \log^3 n}{\epsilon^6}\right) = \tilde{O}_\epsilon(|E|)$ time, we can find a solution $(\mathbf{x}, \mathbf{y})$ satisfying the following conditions: Its cost is at most $1 + \epsilon$ times that of the optimum solution to the LP, all variables are non-negative, (12) holds with equalities, and (13) and

[8] A more precise estimation for the case $y_{ijdeuv} = 1$ is $\tau^{(e+1)}_{v} + 1$. But the estimation $T_e + 1$ is good enough.

[9] By cutting job lengths p_{ij} by a factor of ϵ, one can reduce the number of y variables to $O\Big(|E|\big(\frac{1}{\epsilon^2} + \frac{\log n}{\epsilon}\big)\Big)$. But we prioritize on giving a clean algorithm, rather than optimizing the poly$(\log n, \frac{1}{\epsilon})$-factor in the running time.

(14) hold with right sides replaced by $1+\epsilon$ and $(1+\epsilon)\Delta_{d'}$ respectively. For convenience, we call such a solution a $(1+\epsilon)$-approximate solution to LP(11); but keep in mind that it may violate (13) and (14) by a factor of $1+\epsilon$.

4.3 Equivalence of LP(11) and LP(6)

We use $\mathsf{lp}_{(6)}$ and $\mathsf{lp}_{(11)}$ to denote the values of LP(6) and LP(11) respectively. It is easy to show that $\mathsf{lp}_{(11)} \leq \mathsf{lp}_{(6)}$, as one can convert a solution to LP(6) into one to LP(11) with smaller or equal value. The following theorem gives the other direction, proving the equivalence of the two LPs up to a $1+O(\epsilon)$ factor:

▶ **Theorem 4.1** (Equivalence of LP(11) and LP(6))**.** *Let $(\mathbf{x},\mathbf{y})$ be a $(1+\epsilon)$-approximate solution to LP(11). Then in $\tilde{O}_\epsilon(|E|)$-time we can find a solution $\mathbf{z}$ to LP(6) except that (8) is only satisfied with the right-side replaced by $1+\epsilon$, such that the following is true for an absolute constant $c \geq 1$, every $ij \in E$ and integer $t \geq 0$:*

$$\sum_{s+p_{ij}>(1+c\epsilon)t} z_{ijs} \leq \sum_{d:T_{d-1}+1>t} x_{ijd} + \sum_{deuv:T_e+1>t} y_{ijdeuv}.$$

In words, for every $ij \in E$, and every time $t \geq 0$, the fraction of job j scheduled on i with completion time after $(1+c\epsilon)t$ in $\mathbf{z}$ is at most the fraction with completion time after t in $(\mathbf{x},\mathbf{y})$. Then, the following corollary is immediate:

▶ **Corollary 4.2.** *Let $(\mathbf{x},\mathbf{y})$ and $\mathbf{z}$ be defined as in Theorem 4.1. Then the value of $\mathbf{z}$ to LP(6) is at most $1+c\epsilon$ times that of $(\mathbf{x},\mathbf{y})$ to LP(11). This implies that the value of $\mathbf{z}$ to LP(6) is at most $(1+c\epsilon)(1+\epsilon)\cdot\mathsf{lp}_{(11)} \leq (1+O(\epsilon))\cdot\mathsf{lp}_{(6)}$.*

To better present the ideas behind the proof, we only show the existence of such a vector $\mathbf{z}$ in this section. That is, we are not concerned with the running time of the algorithm that constructs $\mathbf{z}$. In the full version of the paper we show how $\mathbf{z}$ can be constructed in nearly-linear time.

So the rest of this section is dedicated to proving the existence of $\mathbf{z}$ satisfying the conditions in Theorem 4.1. Till the end, we fix the solution $(\mathbf{x},\mathbf{y})$. We assume all variables in $(\mathbf{x},\mathbf{y})$ have values being integer multiplies of $1/\Phi$, and $(1+\epsilon)\Phi$ is an integer, for a large enough integer $\Phi > 0$. We fix a machine $i \in M$ and show how to construct the $\mathbf{z}$ values for this i. We create $(1+\epsilon)\Phi$ *mini-machines*, each serving as $1/\Phi$ fraction of the machine i. We create two types of *mini-jobs*:

- For every variable x_{ijd} with positive value, we create Φx_{ijd} mini-jobs of length p_{ij}; we call them *inside-mini-jobs*. Each such inside-mini-job has an *intended completion time* of $T_{d-1}+1$; this is the estimation used in the objective (11).
- For every variable y_{ijdeuv} with positive value, we create Φy_{ijdeuv} mini-jobs of length $\tau_v^{(e+1)} - \tau_{u+1}^{(d)} + 2$; we call them *cross-mini-jobs*. Notice the length may be smaller than p_{ij}. Similarly, the cross-mini-jobs have an *intended completion time* of T_e+1. We define the *blocking interval* of these mini-jobs to be the union of the sub-windows $(\tau_{u'-1}^{(d')}, \tau_{u'}^{(d')}]$ such that *deuv* left-covers $d'u'$. This is indeed an interval. As (13) holds with right side replaced by $1+\epsilon$, every time point is covered by blocking intervals of at most $(1+\epsilon)\Phi$ cross-mini-jobs.

Our goal becomes to schedule all the mini-jobs on the $(1+\epsilon)\Phi$ mini-machines integrally, guaranteeing that the completion time of each mini-job is at most $1+5\epsilon$ times its intended completion time (after we extend the lengths of cross-mini-jobs). The construction of the

schedule is given in Algorithm 2; recall that we are not concerned with the running time in this proof. The solution $\mathbf{z}$ to LP(6) will be the integral schedule scaled by a factor of $\frac{1}{\Phi}$: z_{ijs} is $\frac{1}{\Phi}$ times the number of mini-jobs for j that start at time s in the schedule.

Algorithm 2 Scheduling of mini-jobs on mini-machines for a machine $i \in M$.

1: define a vector σ : cross-mini-jobs $\to$ mini-machines, so that for every mini-machine h, the blocking intervals of $\sigma^{-1}(h)$ are disjoint.
2: **for** $d' \leftarrow 1$ to D **do**
3: **for** every cross-mini-job k for some variable y_{ijdeuv} with $d \le d' \le e+1$ **do**
4: $\mathsf{load}_{\sigma_k} \leftarrow \mathsf{load}_{\sigma_k} + Q_{ijdeuvd'}$
5: **if** $d' = e+1$ **then** append k to the mini-machine σ_k
6: **for** every inside-mini-job k for some variable $x_{ijd'}$ **do**
7: let h be the mini-machine with the smallest load_h
8: $\mathsf{load}_h \leftarrow \mathsf{load}_h + p_{ij}$, append k to the mini-machine h
9: extend the length of each cross-mini-job for a variable y_{ijdeuv} to p_{ij} in the constructed schedule

Step 1 of Algorithm 2 is possible since each point is covered by at most $(1+\epsilon)\Phi$ blocking intervals. When we schedule an inside-mini-job k on a mini-machine h, we increase load_h by the length of k (Step 8). The scheduling of a cross-mini-job k for some variable y_{ijdeuv} is done differently. First the mini-machine σ_k for k is pre-defined. Second, we append k to σ_k only in iteration $d' = e+1$ (Step 5), but we add the length of k to load_{σ_k} piece by piece: In iterations $d' = d, d+1, \cdots, e+1$, we increase the load by $Q_{ijdeuvd'}$ (Step 4). Still we ensure that the load to σ_k contributed by k is equal to the length of k. A mini-job for a variable y_{ijdeuv} may have length smaller than the desired length p_{ij}, so in Step 9 we extend these mini-jobs.

▶ **Lemma 4.3.** *At the end of iteration d' of Loop 2, every mini-machine has a load of at most $T_{d'} - 1 + \Delta_{d'}$.*

Proof. There are two types of loads added to mini-machines during iteration d' of Loop 2: those from cross-mini-jobs, and those from inside-mini-jobs. The total load (from both cross- and inside-mini-jobs) added to all mini-machines is at most $(1+\epsilon)\Phi\Delta_{d'}$: it is precisely Φ times the left-side of (14) for the machine i and d', which is at most $(1+\epsilon)\Phi\Delta_{d'}$ as the constraint is violated only by a factor of $1+\epsilon$.

The total load from cross-mini-jobs added to a mini-machine h in iteration d' is at most $\Delta_{d'}$ as the blocking intervals of all mini-jobs in $\sigma^{-1}(h)$ are disjoint. We need to check the case when one mini-job $k \in \sigma^{-1}(h)$ has blocking interval ending at $\tau_{u'}^{(d')}$ and another mini-job $k' \in \sigma^{-1}(h)$ has blocking interval starting at the time. If the length of the sub-window $(\tau_{u'-1}^{(d')}, \tau_{u'}^{(d')}]$ is at least 2, then the statement holds as we only gave 1 unit length to k and k' in this sub-window. If the length is 1, then because we handled the case in a special way in the definition of left-covering, we did not give any length to k' for the sub-window.

With the observations, we can prove the lemma. Before we add an inside-mini-job k for $x_{ijd'}$ to a mini-machine h in iteration d', the total load of all mini-machines is strictly less than $(1+\epsilon)\Phi\sum_{d''=1}^{d'}\Delta_{d''} = (1+\epsilon)\Phi T_{d'}$ (as the length of k has not been added to the loads yet). Therefore $\mathsf{load}_h < T_{d'}$ before we append k to h. After that, we have $\mathsf{load}_h \le T_{d'} - 1 + p_{ij} \le T_{d'} - 1 + \Delta_{d'}$.

Assume towards the contradiction that the lemma does not hold and consider the first time when the condition is violated. Assume this is at iteration d', and some mini-machine has a load of at least $T_{d'} + \Delta_{d'}$. This must be due to that we add the loads from cross-mini-jobs to

the machine. By our assumption, every mini-machine has a load of at most $T_{d'-1} - 1 + \Delta_{d'-1}$ at the end of iteration $d' - 1$. (A special case is when $d' = 1$; but this can be handled trivially.) As we argued, we add a load of at most $\Delta_{d'}$ from cross-mini-jobs to each mini-machine i in iteration d'. Therefore after we add the loads, every mini-machine has a load of at most $T_{d'-1} - 1 + \Delta_{d'-1} + \Delta_{d'} = T_{d'} - 1 + \Delta_{d'-1} \leq T_{d'} - 1 + \Delta_{d'}$, a contradiction. ◀

Now we consider how Step 9 changes the completion times. The length of a cross-mini-job for a variable y_{ijdeuv} is increased by at most $\eta_d - 1 + \eta_{e+1} - 1 \leq \epsilon\Delta_d + \epsilon\Delta_{e+1} \leq 2\epsilon(\Delta_d + \Delta_e)$. For all cross-mini-jobs assigned to the same mini-machine h, the correspondent intervals $\{d, d+1, \cdots, e\}$ are disjoint. Therefore, a mini-job scheduled in iteration d' of Loop 2 is delayed by at most $2\epsilon(\Delta_1 + \Delta_2 + \cdots + \Delta_{d'}) = 2\epsilon T_{d'}$ units time. In the final schedule constructed by Algorithm 2 the completion time of a mini-job scheduled in iteration d is at most

$$\begin{aligned} &T_d - 1 + \Delta_d + 2\epsilon T_d \leq T_d - 1 + ((1+\epsilon)T_{d-1} + 1) - T_{d-1} + 2\epsilon T_d \\ &= T_d + \epsilon T_{d-1} + 2\epsilon T_d \leq (1 + 5\epsilon)(T_{d-1} + 1). \end{aligned}$$

Setting $c = 5$, Theorem 4.1 follows from that $T_{d-1} + 1$ is the intended completion time of the mini-job.

Simulating Markovian Open Quantum Systems Using Higher-Order Series Expansion

Department of Computer Science and Engineering, Pennsylvania State University, University Park, PA, USA

Abstract

We present an efficient quantum algorithm for simulating the dynamics of Markovian open quantum systems. The performance of our algorithm is similar to the previous state-of-the-art quantum algorithm, i.e., it scales linearly in evolution time and poly-logarithmically in inverse precision. However, our algorithm is conceptually cleaner, and it only uses simple quantum primitives without compressed encoding. Our approach is based on a novel mathematical treatment of the evolution map, which involves a higher-order series expansion based on Duhamel's principle and approximating multiple integrals using scaled Gaussian quadrature. Our method easily generalizes to simulating quantum dynamics with time-dependent Lindbladians. Furthermore, our method of approximating multiple integrals using scaled Gaussian quadrature could potentially be used to produce a more efficient approximation of time-ordered integrals, and therefore can simplify existing quantum algorithms for simulating time-dependent Hamiltonians based on a truncated Dyson series.

1 Introduction

The last few decades have witnessed the exciting progress in quantum information science to understand and utilize systems that exhibit quantum properties. In the meantime, quantum algorithms for simulating quantum dynamics have received extensive attention. This is because such simulation algorithms are critical tools in many physics applications, and they have the potential to become the first application (if it is not factoring integers!) once large-scale fault-tolerant quantum computers are available. In fact, simulating quantum dynamics was one of the original motivations Feynman proposed quantum computers [13], who realized the unfavorable scaling for classical algorithms for this task and foresaw the power of quantum computation back in 1982.

Up to now, the majority of the research for simulating quantum dynamics is focused on the "Hamiltonian regime", where the system is governed by Schrödinger evolution and it has no interaction with the environment. Such idealized systems are often referred to as *closed systems*. However, if one believes that the universe is a closed system, then it is reasonable to assume that every quantum system, as a subsystem of the whole universe, is an *open system* because every realistic system is coupled to an uncontrollable environment in a non-negligible way. For example, we always model quantum gates as unitary matrices, while their implementations are always subject to noise induced by the environment no matter how hard one pushes the technology forward.

A key challenge in simulating the dynamics of open quantum systems is the lack of a microscopic description of the dynamics influenced by the physical law of the environment. Even if such a description exists, the degrees of freedom will involve numerous information, which would exceed the capacity of quantum computers. Fortunately, for a special class of open quantum systems, their dynamics can be *fully* described by operators acting on the system. This special class captures the scenario when the system is weakly coupled to the environment and the dynamics of the environment occur at a much faster rate than the system. Intuitively, the environment is fast enough so that the information only flows from the system to the environment and there is no information flowing back. Precisely due to such Markovianity, these open systems are called *Markovian open quantum systems*. Specifically, such dynamics are described in terms of the density matrix ρ by the differential equation

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho = \mathcal{L}(\rho) \coloneqq -i[H,\rho] + \sum_{j=1}^{m}\left(L_j\rho L_j^\dagger - \frac{1}{2}\left\{L_j^\dagger L_j, \rho\right\}\right) \tag{1}$$

which is referred to as the *Lindblad equation* [27, 15]. The superoperator $\mathcal{L}$ is called the *Lindbladian*, and the L_j's are often called the *jump operators*. The solution to the Lindblad equation is given by

$$\rho_t = e^{\mathcal{L}t}(\rho_0). \tag{2}$$

Here, the superoperator $e^{\mathcal{L}t}$ is a quantum channel for all $t \geq 0$.

It turns out that Markovian open quantum systems are general enough to model many realistic quantum systems in quantum physics [24, 42], quantum chemistry [30, 32], and quantum biology [12, 16, 31]. Computationally, such systems also arise in the context of entanglement preparation [23, 18, 36], thermal state preparation [17], quantum state engineering [41], and modeling the noise of quantum circuits [29, 33, 38].

The first quantum algorithm for simulating Markovian open quantum systems was presented by Kliesch et al. in [20] in 2011 and the complexity has scaling $O(t^2/\epsilon)$ for evolution time t and precision ϵ. In 2017, Childs and Li [7] constructed an improved algorithm with cost $O(t^{1.5}/\sqrt{\epsilon})$. Cleve and Wang [9] pushed the study further by reducing the complexity to nearly optimal: $O(t\,\mathrm{polylog}(t/\epsilon))$, which was the first to achieve the complexity that scales linearly in t and poly-logarithmically in $1/\epsilon$ – that is exponentially better than previous approaches. Recently, researchers have explored these simulation algorithms in various scenarios such as simulating heavy-ion collisions [11], simulating the non-equilibrium dynamics in the Hubbard model [40], simulating the non-equilibrium dynamics in the Schwinger model [10], and preparing thermal states [35].

The quantum algorithm by Cleve and Wang [9] is based on the first-order approximation of $e^{\mathcal{L}t}$, which can be further approximated by a completely positive map whose Kraus operators involve H and L_j's. Due to the inefficiency of the first-order approximation, the building blocks (the implementation of linear combination unitaries) of [9] need to be repeated many

times to simulate a constant-time evolution, which tends to break the poly-logarithmic dependence on $1/\epsilon$. However, it was shown in [9] that the state of the control qubits of the building blocks concentrates to low-Hamming weight states. Thus a compression scheme had to be employed in [9] to exponentially reduce the uses of the building blocks.

In the literature of Hamiltonian simulation, there is an elegant quantum algorithm that uses a truncated Taylor series [3]. This algorithm is conceptually much simpler than its first-order approximation predecessor [4] while keeping the same efficiency. Thus a natural question arises: Can we generalize the truncated Taylor series approach to simulating Lindblad evolution to obtain a much simpler algorithm? It was not known how to achieve this due to the obstacle that higher powers of the Lindbladian are too intricate to keep track of its completely positiveness, which is the key to implementing a superoperator. To demonstrate this challenge, consider the expression of $\mathcal{L}^2$. For simplicity, let us assume $H = 0$ and $m = 1$. We have

$$\begin{aligned}\mathcal{L}^2(\rho) = L^2\rho L^{\dagger 2} - \frac{1}{2}LL^\dagger L\rho L^\dagger - \frac{1}{2}L\rho L^\dagger LL^\dagger - \frac{1}{2}L^\dagger L^2\rho L^\dagger + \frac{1}{4}L^\dagger LL^\dagger L\rho \\ - \frac{1}{2}L\rho L^{\dagger 2}L + \frac{1}{2}L^\dagger L\rho L^\dagger L + \frac{1}{4}\rho L^\dagger LL^\dagger L.\end{aligned} \tag{3}$$

As the above shows, it is highly nontrivial to maintain the completely positive structure in the Taylor series $e^{\mathcal{L}} \approx \sum_{\ell=0}^{K} \frac{\mathcal{L}^\ell}{\ell!}$ even for this overly simplified case where $H = 0$ and $m = 1$.

In this paper, we present a quantum algorithm that takes advantage of a higher-order series expansion based on Duhamel's principle (this principle is briefly discussed in Section 2.1 for readers not familiar with this subject). Our quantum algorithm is conceptually simple and it only contains straightforward applications of simple quantum primitives such as oblivious amplitude amplification for isometries and linear combinations of unitaries (LCU) for channels (presented in the language of block-encodings) [7]. Our approach is inspired by a classical algorithm by Cao and Lu [6] based on the Duhamel's principle. The basic idea is to separate the Lindblad generator into two groups, the first group of which can be expressed as a matrix exponential that immediately induces a completely positive map. By applying the Duhamel's principle repeatedly, a series expansion with arbitrary order of accuracy can be obtained. We prove a rigorous error bound for this truncation. This procedure exhibits some level of resemblance to the time-dependent Hamiltonian simulation method using Dyson series [19]. However, an important focus in the simulation of Lindblad dynamics, due to the presence of jump operators, is to maintain the completely positive property. In addition, we apply Gaussian quadrature, which for any fixed number of quadrature points, has the optimal order of accuracy, to treat the multiple integrals in the series expansion. This approach, compared with the rectangle rule used in [19] and the mid-point rule used in [6], compressed drastically the number of terms in the Kraus form of the completely positive maps. The other added advantage is that it completely eliminates the need for time clocking, which requires either a compression scheme or a quantum sorting network to implement.

We consider a very general model of input, namely, the operators are given by their block-encodings. Informally, a unitary U_A is the block-encoding of A with normalizing factor α if the top-left block of U_A is A/α. This input model abstract but general enough to assume for most realistic physical models. In fact, traditional input models such as local Hamiltonians, sparse Hamiltonians, and a linear combination of tensor product of Paulis can all be efficiently converted to block-encodings. Suppose the operators H, and L_j's are given as block-encodings with corresponding normalizing factors α_0, α_j's, respectively. We define the following norm for the purpose of normalizing the magnitude of the Lindbladian in Equation (1).

$$\|\mathcal{L}\|_{\mathrm{be}} \coloneqq \alpha_0 + \sum_{j=1}^{m} \alpha_j^2. \tag{4}$$

Note that a similar norm $\|\mathcal{L}\|_{\mathrm{pauli}}$ was defined in [7], which is a special case of $\|\mathcal{L}\|_{\mathrm{be}}$ in the context of linear combination of unitaries input model. Our main result is stated as follows.

▶ **Theorem 1** (Informal version of Theorem 11). *For a Lindbladian $\mathcal{L}$ with m jump operators. Suppose we are given a block-encoding U_H of H, and a block-encoding U_{L_j} for each L_j. For all $t, \epsilon > 0$, there exists a quantum algorithm that approximates $e^{\mathcal{L}t}$ in terms of the diamond norm using $O(\tau \operatorname{polylog}(t/\epsilon))$ queries to U_H and U_{L_j} and $O(m\tau \operatorname{polylog}(t/\epsilon))$ additional 1- and 2-qubit gates, where $\tau \coloneqq t\|\mathcal{L}\|_{\mathrm{be}}$.*

Our approach trades off mathematical simplicity for technical conciseness. In fact, the majority of the analysis is devoted to proving the bound of the truncated series, and the accuracy for using a scaled Gaussian quadrature to approximate each layer of a multiple integral. Once the mathematical treatment is established, we obtain an approximate map for $e^{\mathcal{L}t}$ that is completely positive, represented in terms of Kraus operators. Then, it is straightforward to use simple quantum primitives including LCU for channels and oblivious amplitude amplification for isometries to implement this completely positive map. Moreover, it is more direct to obtain the gate complexity that scales linearly in m, for which the dependence was $O(m^2)$ as presented in [9] [1].

In this paper, we focus on time-independent Lindbladians. It is worth noting that our approach easily generalizes to time-dependent Lindbladians. We sketch this generalization in Appendix A.

The rest of the paper is structured as follows. We introduce the preliminaries, including an introduction to Duhamel's principle and the algorithmic tools in Section 2. In Section 3, we present the series expansion based on Duhamel's principle and prove the error bound. In Section 4, we show how to use scaled Gaussian quadrature to approximate multiple integrals. The main theorem is proved in Section 5 and our simulation algorithm is presented in the proof. Finally, we sketch how to generalize our method to simulating time-dependent Lindbladians in Appendix A.

2 Preliminaries

In this paper, we use $\|A\|$ to denote the *spectral norm* of a square matrix A, and we use $\|A\|_1$ to denote its *trace norm*. We use I to denote the identity matrix and we leave its dimension implicitly when it is clear from the context. We use calligraphic font, such as $\mathcal{L}$, $\mathcal{J}$ to denote *superoperators*. In particular, we use $\mathcal{I}$ to denote the *identity map*. We use $\mathcal{K}[A]$ to denote the completely positive map induced by the *Kraus operator* A, i.e.,

$$\mathcal{K}[A](\rho) \coloneqq A\rho A^\dagger \tag{5}$$

for all ρ. The *induced trace norm* of a superoperator $\mathcal{M}$, denoted by $\|\mathcal{M}\|_1$, is defined as $\|\mathcal{M}\|_1 \coloneqq \max\{\|\mathcal{M}(A)\|_1 : \|A\| \le 1\}$. The *diamond norm* of a superoperator $\mathcal{M}$, denoted by $\|\mathcal{M}\|_\diamond$, is defined as $\|\mathcal{M}\|_\diamond \coloneqq \|\mathcal{M} \otimes \mathcal{I}\|_1$, where the identity map $\mathcal{I}$ acts on a Hilbert space with the same dimension as the space $\mathcal{M}$ is acting on.

[1] We realized that it is possible to improve the dependence to $O(m)$ in [9] by a more careful construction of the encoding gate in their compression scheme.

We use *block-encodings* as the efficient description of the operators. Intuitively, we say a unitary U_A block-encodes a matrix A if A appears in the upper-left block of A, i.e.,

$$U_A = \begin{pmatrix} A/\alpha & \cdot \\ \cdot & \cdot \end{pmatrix}, \tag{6}$$

where α is the *normalizing factor*. More formally, an $(n+b)$-qubit unitary U_A is an (α, b, ϵ)-block-encoding of an n-qubit operator A if

$$\left\| A - \alpha(\langle 0^{\otimes b}| \otimes I) U_A (|0^{\otimes b}\rangle \otimes I) \right\| \leq \epsilon, \tag{7}$$

where the identity operator is acting on n qubits.

2.1 Duhamel's principle

For a differential equation written in the form of,

$$u'(t) = Lu + f\big(t, u(t)\big), \quad u(0) = u_0, \tag{8}$$

where L is a linear operator, but f can in principle be a nonlinear function of u.

The Duhamel's principle allows to separate the contribution to the solution from the initial condition and the contribution from the non-homogeneous term. Specifically, we can write the solution as

$$u = v + w, \tag{9}$$

where v satisfies the equation without f,

$$v'(t) = Lv, \quad v(0) = u_0, \tag{10}$$

while w follows the equation

$$w'(t) = Lw + f\big(t, u(t)\big), \quad w(0) = 0, \tag{11}$$

The solution v, due to the fact that Equation (10) is linear and homogeneous, can be simply written as $v(t) = e^{tL}u_0$. On the other hand, the equation for w can be rewritten as $(w(t)e^{-tL})' = e^{-tL} f\big(t, u(t)\big)$, from which a direct integration yields,

$$w(t) = \int_0^t g(t,s)\mathrm{d}s, \quad g(t,s) \coloneqq e^{(t-s)L} f\big(s, u(s)\big). \tag{12}$$

Notice that when s is held fixed, the function $g(t,s)$ also follows a homogeneous equation similar to Equation (10),

$$\frac{d}{dt} g(t,s) = Lg(t,s), \quad \lim_{t \to s} g(t,s) = f\big(s, u(s)\big), \tag{13}$$

which is typically how the Duhamel's principle is expressed.

The derivation of our algorithm will heavily involve the Duhamel's principle, which can be summarized into the following formula,

$$u(t) = e^{tL}u_0 + \int_0^t e^{(t-s)L} f\big(s, u(s)\big)\mathrm{d}s. \tag{14}$$

2.2 Algorithmic tools

Given a completely positive map whose Kraus operators are given as block-encodings, we use the following lemma to probabilistically implement this complete positive map. Note that this lemma is a reformulation of the LCU for channels [7] in the language of block-encodings.

▶ **Lemma 2** (Implementing completely positive maps via block-encodings of Kraus operators [26]). *Let $A_1, \ldots, A_m \in \mathbb{C}^{2^n}$ be the Kraus operators of a completely positive map. Let $U_1, \ldots, U_m \in \mathbb{C}^{2^{n+n'}}$ be their corresponding (s_j, n', ϵ)-block-encodings, i.e.,*

$$\|A_j - s_j(\langle 0| \otimes I)U_j |0\rangle \otimes I)\| \leq \epsilon, \quad \text{for all } 1 \leq j \leq m. \tag{15}$$

Let $|\mu\rangle \coloneqq \frac{1}{\sqrt{\sum_{j=1}^m s_j^2}} \sum_{j=1}^m s_j |j\rangle$. Then $(\sum_{j=1}^m |j\rangle\langle j| \otimes U_j) |\mu\rangle |0\rangle \otimes I$ implements this completely positive map in the sense that

$$\left\| I \otimes \langle 0| \otimes I \left(\sum_{j=1}^m |j\rangle\langle j| \otimes U_j \right) |\mu\rangle |0\rangle |\psi\rangle - \frac{1}{\sqrt{\sum_{j=1}^m s_j^2}} \sum_{j=1}^m |j\rangle A_j |\psi\rangle \right\| \leq \frac{m\epsilon}{\sqrt{\sum_{j=1}^m s_j^2}} \tag{16}$$

for all $|\psi\rangle$.

The following lemma shows how to construct the block-encoding as a linear combination of block-encodings.

▶ **Lemma 3** (Block-encoding of a sum of block-encodings [26]). *Suppose $A \coloneqq \sum_{j=1}^m y_j A_j \in \mathbb{C}^{2^n \times 2^n}$, where $A_j \in \mathbb{C}^{2^n \times 2^n}$ and $y_j > 0$ for all $j \in \{1, \ldots m\}$. Let U_j be an (α_j, a, ϵ)-block-encoding of A_j, and B be a unitary acting on b qubits (with $m \leq 2^b - 1$) such that $B |0\rangle = \sum_{j=0}^{2^b-1} \sqrt{\alpha_j y_j / s} |j\rangle$, where $s = \sum_{j=1}^m y_j \alpha_j$. Then a $(\sum_j y_j \alpha_j, a+b, \sum_j y_j \alpha_j \epsilon)$-block-encoding of $\sum_{j=1}^m y_j A_j$ can be implemented with a single use of $\sum_{j=0}^{m-1} |j\rangle\langle j| \otimes U_j + ((I - \sum_{j=0}^{m-1} |j\rangle\langle j|) \otimes I_{\mathbb{C}^{2^a}} \otimes I_{\mathbb{C}^{2^n}})$ plus twice the cost for implementing B.*

Finally, we need the oblivious amplitude amplification for isometries.

▶ **Lemma 4** (Oblivious amplitude amplification for isometries [9]). *For all $a, b \in \mathbb{N}_+$, let $|\hat{0}\rangle \coloneqq |0\rangle^{\otimes a}$ and $|\mu\rangle$ be arbitrary b-qubit state. For any n-qubit state $|\psi\rangle$, let $|\hat{\psi}\rangle \coloneqq |\hat{0}\rangle |\mu\rangle |\psi\rangle$. Also define $|\hat{\phi}\rangle \coloneqq |\hat{0}\rangle |\phi\rangle$, where $|\phi\rangle$ is a $(b+n)$-qubit state. Let $P_0 \coloneqq |\hat{0}\rangle\langle\hat{0}| \otimes I_{2^b} \otimes I_{2^n}$ and $P_1 \coloneqq |\hat{0}\rangle\langle\hat{0}| \otimes |\hat{\mu}\rangle\langle\hat{\mu}| \otimes I_{2^n}$ be two projectors. Suppose there exists an operator W satisfying*

$$W |\hat{\phi}\rangle = \frac{1}{2} |\hat{\phi}\rangle + \sqrt{\frac{3}{4}} |\hat{\phi}^\perp\rangle, \tag{17}$$

where $|\hat{\phi}\rangle$ satisfies $P_0 |\hat{\phi}^\perp\rangle = 0$. Then it holds that

$$-W(I - 2P_1)W^\dagger(I - 2P_0)W |\hat{\psi}\rangle = |\hat{\phi}\rangle. \tag{18}$$

3 Higher order series expansion based on Duhamel's principle

The goal of our quantum algorithm is to simulate the Lindblad equation defined in Equation (1). In the context of quantum trajectory theory [34], we view the commutator and the anti-commutator terms as the *drifting part*, and the $L_j \rho L_j^\dagger$ terms are regarded as *jump part*. Accordingly, motivated by the numerical method in [6]. We decompose $\mathcal{L}$ into two superoperators, the *drifting part* $\mathcal{L}_{\mathrm{D}}$ and the *jump part* $\mathcal{L}_{\mathrm{J}}$. Namely,

$$\mathcal{L} = \mathcal{L}_{\mathrm{D}} + \mathcal{L}_{\mathrm{J}}, \quad \text{and} \tag{19}$$

$$\mathcal{L}_{\mathrm{D}}(\rho) \coloneqq J\rho + \rho J^{\dagger}, \quad \mathcal{L}_{\mathrm{J}}(\rho) \coloneqq \sum_{j=1}^{m} L_j \rho L_j^{\dagger}. \tag{20}$$

Here we define J as

$$J \coloneqq -iH_{\mathrm{eff}}. \tag{21}$$

where an *effective Hamiltonian* H_{eff} is given by,

$$H_{\mathrm{eff}} \coloneqq H + \frac{1}{2i}\sum_{j=1}^{m} L_j^{\dagger} L_j. \tag{22}$$

Thus $\mathcal{L}_{\mathrm{D}}$ can be viewed as a generalized anti-commutator.

By treating the term with $\mathcal{L}_{\mathrm{D}}$ as a non-homogeneous term, the Duhamel's principle in Equation (14) can be applied, and we get,

$$\rho_t = e^{\mathcal{L}t}(\rho_0) = e^{\mathcal{L}_{\mathrm{D}}t}(\rho_0) + \int_0^t e^{\mathcal{L}_{\mathrm{D}}(t-s)}(\mathcal{L}_{\mathrm{J}}\rho_s)\mathrm{d}s. \tag{23}$$

Note that the solution ρ_s is still involved in the integral on the right hand side. Therefore, this equation does not provide an explicit formula for the solution; Rather, it offers an integral representation of the Lindblad equation. Nevertheless, one can apply Equation (14) again to ρ_s in the integral. After K such iterations, we arrive at

$$\begin{aligned}\rho_t = {} & e^{\mathcal{L}_{\mathrm{D}}t}(\rho_0) \\ & + \sum_{k=1}^{K} \int_{0\le s_1\le\cdots\le s_k\le t} e^{\mathcal{L}_{\mathrm{D}}(t-s_k)}\mathcal{L}_{\mathrm{J}} e^{\mathcal{L}_{\mathrm{D}}(s_k-s_{k-1})}\mathcal{L}_{\mathrm{J}}\cdots e^{\mathcal{L}_{\mathrm{D}}(s_2-s_1)}\mathcal{L}_{\mathrm{J}} e^{\mathcal{L}_{\mathrm{D}}(s_1)}(\rho_0)\mathrm{d}s_1\cdots\mathrm{d}s_k \\ & + \int_{0\le s_1\le\cdots\le s_{K+1}\le t} e^{\mathcal{L}_{\mathrm{D}}(t-s_{K+1})}\mathcal{L}_{\mathrm{J}} e^{\mathcal{L}_{\mathrm{D}}(s_{K+1}-s_K)}\mathcal{L}_{\mathrm{J}}\cdots e^{\mathcal{L}_{\mathrm{D}}(s_2-s_1)}\mathcal{L}_{\mathrm{J}}(\rho_{s_1})\mathrm{d}s_1\cdots\mathrm{d}s_{K+1}.\end{aligned} \tag{24}$$

Now notice that the first two terms on the right hand side only depend on the initial density matrix, and thus they are amenable to numerical approximations. Meanwhile, the last term will be regarded as a truncation error, which will be bounded later.

We first derive the Kraus representation of $e^{\mathcal{L}_{\mathrm{D}}t}$, which is the first term in the expansion, but also appears in each integral. The Kraus form can be obtained from a Taylor series. To see this, let us consider the case where $\mathcal{L}_{\mathrm{D}}$ is acting on a pure state $|\psi\rangle$:

$$\frac{\mathrm{d}}{\mathrm{d}t}|\psi\rangle = J|\psi\rangle. \tag{25}$$

Using the chain rule, we have

$$\frac{\mathrm{d}}{\mathrm{d}t}|\psi\rangle\langle\psi| = J|\psi\rangle\langle\psi| + |\psi\rangle\langle\psi|J^{\dagger} = \mathcal{L}_{\mathrm{D}}(|\psi\rangle\langle\psi|). \tag{26}$$

The above two equations also hold for general states ρ by linearity. Hence, solving Equation (25) and Equation (26) yields

$$e^{\mathcal{L}_{\mathrm{D}}t} = \mathcal{K}\left[e^{tJ}\right]. \tag{27}$$

Now, we adopt the notation from [6],

$$\mathcal{F}_k(s_k,\dots,s_1) \coloneqq \mathcal{K}[e^{J(t-s_k)}]\mathcal{L}_{\mathrm{J}}\mathcal{K}[e^{J(s_k-s_{k-1})}]\mathcal{L}_{\mathrm{J}}\cdots\mathcal{K}[e^{J(s_2-s_1)}]\mathcal{L}_{\mathrm{J}}\mathcal{K}[e^{J(s_1-0)}]. \tag{28}$$

We further define

$$\mathcal{G}_K(t) \coloneqq \mathcal{K}[e^{Jt}] + \sum_{k=1}^{K}\int_{0\le s_1\le\cdots\le s_k\le t}\mathcal{F}_k(s_k,\dots,s_1)\,\mathrm{d}s_1\cdots\mathrm{d}s_k. \tag{29}$$

At this point, the problem is reduced to approximating $e^{\mathcal{L}t}$ by $\mathcal{G}_M(t)$. We first prove an error bound.

▶ **Lemma 5.** *It holds that*

$$\left\|e^{\mathcal{L}t} - \mathcal{G}_K(t)\right\|_\diamond \le \frac{(2\|\mathcal{L}\|_{\mathrm{be}}t)^{K+1}}{(K+1)!}. \tag{30}$$

The proof of Lemma 5 is shown in the full version of this paper [43].

Eventually, we need to approximate the Kraus operator e^{Jt} in our quantum algorithm. This can be done by a truncated Taylor series. For notational simplicity, we define

$$\mathcal{J}_{K'} = \mathcal{K}\left[\sum_{\ell=0}^{K'}\frac{J^\ell t^\ell}{\ell!}\right]. \tag{31}$$

We quantify the error of this approximation in the following lemma.

▶ **Lemma 6.** *Suppose that $k\in\mathbb{N}$ such that $(k+1)!\ge 2\|J\|^{k+1}t^{k+1}$. Let $\mathcal{J}_k$ be defined in Equation* (31)*. It holds that*

$$\left\|\mathcal{K}[e^{Jt}] - \mathcal{J}_k(t)\right\|_\diamond \le \frac{8e^{\|\mathcal{L}\|_{\mathrm{be}}t}\|\mathcal{L}\|_{\mathrm{be}}^{k+1}t^{k+1}}{(k+1)!}. \tag{32}$$

The proof of Lemma 6 is shown in the full version of this paper [43].

We also provide the following useful lemma, which will be used in the final analysis of our algorithm

▶ **Lemma 7.** *Suppose that $k,K'\in\mathbb{N}$ such that $(K'+1)!\ge 8e^{\|\mathcal{L}\|_{\mathrm{be}}t}\|\mathcal{L}\|_{\mathrm{be}}^{K'+1}t^{K'+1}$. Let $\mathcal{J}_{K'}$ be defined in Equation* (31)*, and $\mathcal{F}_k$ be defined in Equation* (28)*. It holds that*

$$\begin{aligned}&\|\mathcal{J}_{K'}(t-s_m)\mathcal{L}_{\mathrm{J}}\mathcal{J}_{K'}(s_m-s_{m-1})\mathcal{L}_{\mathrm{J}}\cdots\mathcal{J}_{K'}(s_2-s_1)\mathcal{L}_{\mathrm{J}}\mathcal{J}_{K'}(s_1) - \mathcal{F}_k(s_k,\dots,s_1)\|_\diamond\\ &\qquad\le \frac{8e^{\|\mathcal{L}\|_{\mathrm{be}}t}\|\mathcal{L}\|_{\mathrm{be}}^{K'+1}}{(K'+1)!}(2\|\mathcal{L}\|_{\mathrm{be}})^k 2^k t^{K'+1}.\end{aligned} \tag{33}$$

The proof of Lemma 7 is shown in the full version of this paper [43].

4 Approximating multiple integrals using scaled Gaussian quadrature

To obtain an algorithm that can be directly implemented, we apply Gaussian quadrature formulas to approximate the multiple integrals in Equation (29). Due to their optimal accuracy, the number of terms in the approximation is significantly compressed. Typically, quadrature error depends on the smoothness of the function. For this purpose, we first bound the derivatives of $\mathcal{F}_k$.

▶ **Lemma 8.** *For all $k' \in [k]$, it holds that*

$$\left\| \frac{\mathrm{d}^{k'}}{\mathrm{d}s_j^{k'}} \mathcal{F}_k \right\|_\diamond \leq 2^{2k'+k} \|\mathcal{L}\|_{\mathrm{be}}^k \|J\|^{k'}. \tag{34}$$

The proof of Lemma 8 is shown in the full version of this paper [43].

We now discuss the quadrature approximation for the integral in Equation (29):

$$\int_{0 \leq s_1 \leq \cdots \leq s_k \leq t} \mathcal{L}_{\mathrm{J}} \mathcal{K}[e^{J(s_m - s_{m-1})}] \mathcal{L}_{\mathrm{J}} \cdots \mathcal{K}[e^{J(s_2 - s_1)}] \mathcal{L}_{\mathrm{J}} \mathcal{K}[e^{J(s_1 - 0)}] \, \mathrm{d}s_1 \cdots \mathrm{d}s_k. \tag{35}$$

For optimal accuracy, we use Gaussian quadrature. In the Gaussian quadrature rule, the interpolation nodes $0 \leq \hat{s}_1 \leq \cdots \leq \hat{s}_q \leq t$ and the weights $w_1, \ldots, w_q$ are independent of the function and can be pre-computed. More specifically, let $\{\mathscr{P}_i(x)\}_i$ be the standard Legendre polynomials. They are an orthonormal family of polynomials in the sense that

$$\int_{-1}^{1} \mathscr{P}_r(x) \mathscr{P}_s(x) \, \mathrm{d}x = \begin{cases} 0 & r \neq s, \\ 1 & r = s. \end{cases} \tag{36}$$

By a simple scaling,

$$\hat{\mathscr{P}}(x) \coloneqq \mathscr{P}\left(\frac{2x}{t} - 1\right). \tag{37}$$

we obtain the functions $\hat{\mathscr{P}}$ that are orthogonal for the interval $[0, t]$. Let $\{\hat{s}_i\}_{i=1}^n$ be the roots of the n-th degree polynomial $\hat{\mathscr{P}}_q$. We also define

$$\pi_q(x) \coloneqq (x - \hat{s}_1)(x - \hat{s}_2) \cdots (x - \hat{s}_q). \tag{38}$$

Then the i-th Lagrange polynomial for points $\hat{s}_1, \ldots, \hat{s}_q$ is

$$\mathscr{L}_{q-1,i}(x) = \frac{\pi_q(x)}{(x - \hat{s}_i)\pi_q'(\hat{s}_i)}. \tag{39}$$

Once the quadrature points are selected, the weight of the Gaussian quadrature can be expressed as

$$w_i = \int_0^t \mathscr{L}_{q-1,i}(x) \, \mathrm{d}x, \tag{40}$$

which can be direct deduced from a polynomial interpolation.

We refer to $\hat{s}_1, \ldots, \hat{s}_q$ as the *canonical quadrature points* and $w_1, \ldots, w_q$ as the *canonical weights*. In approximating $\int_0^t f(x) \, \mathrm{d}x$ using $\sum_{j=1}^q f(\hat{s}_j) w_j$, the error follows the standard bound,

$$E_q[f] = \int_0^t f(x) \, \mathrm{d}x - \sum_{j=1}^q f(\hat{s}_j) w_j = \frac{f^{(2q)}(\xi)}{(2q)!} \int_0^t \pi_q(x)^2 \mathrm{d}x, \tag{41}$$

for some $\xi \in [0, t]$.

To estimate the integral term in the error, we notice that,

$$\pi_q(x) = \frac{t^q q!}{2^q (2q-1)!!} \mathscr{P}_q\left(\frac{2x}{t} - 1\right), \tag{42}$$

The coefficient on the right hand side is determined by observing that $\pi_q(x)$ is a monic polynomial, and the leading coefficient of the standard Legendre polynomial is $(2q-1)!!/q!$. The notation !! indicates a double factorial, i.e., $(2q-1)!! = (2q-1)(2q-3)\cdots 1$ and we use the convention that $(-1)!! = 1$.

Combining these formulas, we arrive at an explicit bound

$$|E_q[f]| = \frac{\left|f^{(2q)}\right|(\xi)t^{2q+1}(q!)^2}{(2q)!2^{2q}(2q-1)!!(2q+1)!!} \leq \frac{\left|f^{(2q)}\right|(\xi)t^{2q+1}q}{(2q)!2^{4q-1}} \tag{43}$$

for some $\xi \in [0,t]$, where the inequality follows from the fact that $q!! = 2^{q/2}(q/2)!$ for even q. Here we also used the identity,

$$\int_{-1}^{1} \mathscr{P}_q^2(x)\,\mathrm{d}x = \frac{2}{2q+1}.$$

We hold t fixed. For an interval $[0, s_k]$ with $s_k \leq t$, we use a scaled canonical quadrature points and weights: $s_k\hat{s_1}/t, \ldots, s_k\hat{s}_q/t$, and $s_k w_1/t, \ldots, s_k w_q/t$. Then, $\int_0^{s_k} f(x)\,\mathrm{d}x$ can be approximated by the scaled quadrature points and weights with the same error bound:

$$\int_0^{s_k} f(x)\,\mathrm{d}x = \sum_j^n f\left(\frac{s_k\hat{s}_j}{t}\right)\frac{s_k w_j}{t} + \mathcal{O}\left(\frac{\left\|f^{(2n)}\right\|_\infty s_k^{2n+1} n}{(2n)!2^{4n-1}}\right). \tag{44}$$

For each $j \in [n]$, define the functions u_k and v_k as

$$u_j(x) \coloneqq x\hat{s}_j/t \tag{45}$$
$$v_j(x) \coloneqq x w_j/t. \tag{46}$$

Note that for any s_ℓ, $\{u_j(s_\ell)\}_{j=1}^q$ are the scaled canonical quadrature point and $\{v_j(s_\ell)\}_{j=1}^q$ are the scaled weights.

To simplify the notation, we extend Equation (45) and define

$$\hat{x}_{(j_k)} \coloneqq \hat{s}_{j_k}, \quad \text{and} \quad \hat{x}_{(j_k,\ldots,j_{k-\ell})} \coloneqq u_{j_{k-\ell}} \circ \cdots \circ u_{j_{k-1}}(\hat{s}_{j_k}) \text{ for all } 1 \leq \ell \leq k-1, \tag{47}$$
$$\hat{w}_{(j_k)} \coloneqq w_{j_k}, \quad \text{and} \quad \hat{w}_{(j_k,\ldots,j_{k-\ell})} \coloneqq v_{j_{k-\ell}}(\hat{x}_{(j_k,\ldots,j_{k-\ell+1})}) \text{ for all } 1 \leq \ell \leq k-1. \tag{48}$$

With these notations, the approximation of the integral in Equation (35) becomes,

$$\sum_{j_1=1}^{q} \cdots \sum_{j_k=1}^{q} \mathcal{F}_k\left(\hat{x}_{(j_k)}, , \ldots, \hat{x}_{(j_k,\ldots,j_1)}\right)\hat{w}_{(j_k)} \cdots \hat{w}_{(j_k,\ldots,j_1)}. \tag{49}$$

We first show some useful properties of the quadrature weights.

▶ **Lemma 9.** *for all $\ell \in \{0,\ldots,q\}$, it holds that*

$$\sum_{j=1}^{q} w_j \hat{s_j}^\ell = \frac{t^{\ell+1}}{\ell+1}. \tag{50}$$

In particular, when $\ell = 0$

$$\sum_{j=1}^{q} w_j = t. \tag{51}$$

For all positive integers k, ℓ with $\ell < k$, it also holds that

$$\sum_{j_k=1}^{q} \cdots \sum_{j_{k-\ell}=1}^{q} \hat{w}_{(j_k)} \cdots \hat{w}_{(j_k,\ldots,j_{k-\ell})} = \frac{t^{\ell+1}}{(\ell+1)!}. \tag{52}$$

In particular, when $\ell = k-1$, it holds that

$$\sum_{j_k=1}^{q} \cdots \sum_{j_1=1}^{q} \hat{w}_{(j_k)} \cdots \hat{w}_{(j_k,\ldots,j_1)} = \frac{t^{k}}{(k+1)!}. \tag{53}$$

The proof of Lemma 9 is shown in the full version of this paper [43].

With the bound on the derivatives of the integrand in Lemma 8 and the Gaussian quadrature error Equation (43), we can estimate the overall quadrature error, as stated in the following lemma,

▶ **Lemma 10.** *It holds that*

$$\begin{aligned} &\left\| \int_{0\le s_1\le\cdots\le s_k\le t} \mathcal{F}_k(s_k,\ldots,s_1)\,\mathrm{d}s_1\cdots\mathrm{d}s_k \right. \\ &\quad \left. - \sum_{j_1=1}^{q}\cdots\sum_{j_k=1}^{q} \mathcal{F}_k\left(\hat{x}_{(j_k)},,\ldots,\hat{x}_{(j_k,\ldots,j_1)}\right)\hat{w}_{(j_k)}\cdots\hat{w}_{(j_k,\ldots,j_1)} \right\|_\diamond \\ &= O\left(\frac{(2t)^{k-1}2^{k+1}\|\mathcal{L}\|_{\mathrm{be}}^{k}\|J\|^{(2q)}t^{2q+1}q}{(k-1)!(2q)!}\right). \end{aligned} \tag{54}$$

The proof of Lemma 10 is shown in the full version of this paper [43].

5 Quantum algorithm and the proof of the main theorem

In this section, we prove the main theorem and describe the algorithm in the proof. Our algorithm constructs a segment for constant evolution time, i.e., $t\|\mathcal{L}\|_{\mathrm{be}} = \Theta(1)$. For arbitrary evolution time, we just repeat the simulation segment $O(t\|\mathcal{L}\|_{\mathrm{be}})$ times with a scaled precision parameter.

We first present the higher order approximation of $e^{\mathcal{L}}$ as a completely positive map with explicit Kraus operators. Then we use Lemma 2 to implement this completely positive map with success probability 1/4, which can be calculated by analyzing the normalizing constants of the block-encodings of the Kraus operators. Then we show that the special state $|\mu\rangle$ required by Lemma 2 can be efficiently prepared. Finally, we analyze the error introduced by using a truncated Taylor series to approximate e^{Jt}, which is part of the Kraus operators.

▶ **Theorem 11.** *Suppose we are given an (α_0, a, ϵ')-block-encoding U_H of H, and an (α_j, a, ϵ')-block-encoding U_{L_j} for each L_j. For all $t, \epsilon \ge 0$ with $\epsilon' \le \epsilon/(t(\|\mathcal{L}\|_{\mathrm{be}})$, there exists a quantum algorithm for simulating $e^{\mathcal{L}t}$ using*

$$O\left(t\|\mathcal{L}\|_{\mathrm{be}}\frac{\log(t\|\mathcal{L}\|_{\mathrm{be}}/\epsilon)}{\log\log(t\|\mathcal{L}\|_{\mathrm{be}}/\epsilon)}\right) \tag{55}$$

queries to U_H and U_{L_j} and

$$O\left(mt\|\mathcal{L}\|_{\mathrm{be}}\left(\frac{\log(t\|\mathcal{L}\|_{\mathrm{be}}/\epsilon)}{\log\log(t\|\mathcal{L}\|_{\mathrm{be}}/\epsilon)}\right)^2\right) \tag{56}$$

additional 1- and 2-qubit gates.

Proof. We describe our simulation algorithm and prove the theorem as follows.

Completely-positive approximation. The final approximation to $e^{\mathcal{L}t}$ is

$$\mathcal{K}[e^{Jt}] + \sum_{k=1}^{K} \sum_{j_1=1}^{q} \cdots \sum_{j_k=1}^{q} \mathcal{F}_K\left(\hat{x}_{(j_k)}, , \ldots, \hat{x}_{(j_k,\ldots,j_1)}\right) \hat{w}_{(j_k)} \cdots \hat{w}_{(j_k,\ldots,j_1)}, \tag{57}$$

which is a completely positive map and the block-encodings of its Kraus operators can be easily obtained by a product of the block-encoding U_H of H, and the block-encodings U_{L_j} of L_j as well as positive factors determined by Taylor's expansion and the Gaussian quadrature weights. More specifically, define the index sets $\mathscr{I}$ as

$$\mathscr{I} \coloneqq \{k, \ell_1, \ldots, \ell_k, j_1, \ldots, j_k : k \in [K], \ell_1, \ldots, \ell_k \in [m], j_1 \ldots, j_k \in [q]\}. \tag{58}$$

The completely positive map in Equation (57) can be written as

$$A_0 \rho A_0^\dagger + \sum_{j \in \mathscr{I}} A_j \rho A_j^\dagger, \tag{59}$$

with $A_0 \coloneqq e^{Jt}$, and

$$A_j = \sqrt{\hat{w}_{(j_k)} \cdots \hat{w}_{(j_k,\ldots,j_1)}} e^{J(t-\hat{x}_{(j_k)})} L_{\ell_k} \cdots e^{J(\hat{x}_{(j_k,\ldots,j_2)} - \hat{x}_{(j_k,\ldots,j_1)})} L_{\ell_1} e^{J(\hat{x}_{(j_k,\ldots,j_1)})}, \tag{60}$$

for $j = (k, \ell_1, \ldots, \ell_{k-1}, j_1, \ldots, j_k) \in \mathscr{I}$.

Setting parameters for 1/4 success probability. We use Lemma 2 to implement the above map, and the success probability is determined by the sum-of-squares of the normalizing constants of the Kraus operators.

We first consider the Kraus operators of

$$\mathcal{F}_k(s_k, \ldots, s_1) = \mathcal{K}[e^{J(t-s_k)}] \mathcal{L}_{\mathrm{J}} \mathcal{K}[e^{J(s_k - s_{k-1})}] \mathcal{L}_{\mathrm{J}} \cdots \mathcal{K}[e^{J(s_2-s_1)}] \mathcal{L}_{\mathrm{J}} \mathcal{K}[e^{J(s_1-0)}], \tag{61}$$

for any $s_1 \leq \cdots \leq s_k$. For each $\mathcal{K}[e^{Js}]$, we use Lemma 3 to approximate its block-encoding as a truncated Taylor series. For the convenience of analysis, let us for now assume an infinite Taylor series is implemented. The normalizing constant of the block-encoding for e^{Js} is then

$$\sum_{\ell=0}^{\infty} \frac{s^\ell (\alpha_0 + \frac{1}{2}\sum_{j=1}^{m} \alpha_j^2)}{\ell!} = e^{s\|\mathcal{L}\|_{\mathrm{be}}}. \tag{62}$$

As a result, the sum-of-squares of the normalizing constants of the Kraus operators of $\mathcal{F}_k(s_k, \ldots, s_1)$ is

$$\sum_{j_1,\ldots,j_k=0}^{m} e^{2\|L\|_{\mathrm{be}}(t-s_k)} e^{2\|L\|_{\mathrm{be}}(s_k-s_{k-1})} \cdots e^{2\|L\|_{\mathrm{be}}(s_1-0)} \alpha_{j_1}^2 \cdots \alpha_{j_k}^2 = e^{2\|L\|_{\mathrm{be}} t} \left(\sum_{j=1}^{m} \alpha_j^2\right)^k \tag{63}$$

For the approximation of the integral,

$$\sum_{j_1=1}^{q} \cdots \sum_{j_k=1}^{q} \mathcal{F}_k\left(\hat{x}_{(j_k)}, , \ldots, \hat{x}_{(j_k,\ldots,j_1)}\right) \hat{w}_{(j_k)} \cdots \hat{w}_{(j_k,\ldots,j_1)}, \tag{64}$$

the sum-of-squares of the normalizing constants of its Kraus operators is

$$e^{2\|\mathcal{L}\|_{\text{be}}t}\left(\sum_{j=1}^{m}\alpha_j^2\right)^k\sum_{j_1=1}^{q}\cdots\sum_{j_k=1}^{q}\hat{w}_{(j_k)}\cdots\hat{w}_{(j_k,\ldots,j_1)}=\frac{t^k}{(k-1)!}e^{2\|\mathcal{L}\|_{\text{be}}t}\left(\sum_{j=1}^{m}\alpha_j^2\right)^k. \tag{65}$$

Finally, for the approximation

$$\mathcal{K}[e^t]+\sum_{k=1}^{K}\sum_{j_1=1}^{q}\cdots\sum_{j_k=1}^{q}\mathcal{F}_k\left(\hat{x}_{(j_k)},,\ldots,\hat{x}_{(j_k,\ldots,j_1)}\right)\hat{w}_{(j_k)}\cdots\hat{w}_{(j_k,\ldots,j_1)}, \tag{66}$$

the sum-of-squares of the normalizing constants of its Kraus operators is

$$e^{2\|\mathcal{L}\|_{\text{be}}t}+\sum_{k=1}^{K}\frac{t^k}{(k-1)!}e^{2\|\mathcal{L}\|_{\text{be}}t}\left(\sum_{j=1}^{m}\alpha_j^2\right)^k \tag{67}$$

$$=e^{2\|\mathcal{L}\|_{\text{be}}t}+te^{2\|\mathcal{L}\|_{\text{be}}t}\sum_j\alpha_j^2\sum_{k=1}^{K}\frac{t^{k-1}(\sum_j\alpha_j^2)^{k-1}}{(k-1)!} \tag{68}$$

$$\leq e^{2\|\mathcal{L}\|_{\text{be}}t}+t\sum_j\alpha_j^2e^{2\|\mathcal{L}\|_{\text{be}}t}e^{t\sum_j\alpha_j^2}. \tag{69}$$

Note that the inequality above provides an upper bound for the sum-of-squares of the normalizing constants. There is a closed-form expression for this quantity. By setting the right hand side to 2, and solve the equation, the above upper bound implies that t must satisfy

$$t\|\mathcal{L}\|_{\text{be}}=\Theta(1). \tag{70}$$

Then we use Lemma 4 to boost the success probability to 1 with only three application of the circuit.

Determining truncation orders. Now, we analyze the error by setting $t\|\mathcal{L}\|_{\text{be}}=\Theta(1)$. By Lemma 5 and Lemma 10, the total approximation error can be bounded by the following.

$$\left\|e^{\mathcal{L}t}-\mathcal{K}[e^{Jt}]-\sum_{k=1}^{K}\sum_{j_1=1}^{q}\cdots\sum_{j_k=1}^{q}\mathcal{F}_k\left(\hat{x}_{(j_k)},,\ldots,\hat{x}_{(j_k,\ldots,j_1)}\right)\hat{w}_{(j_k)}\cdots\hat{w}_{(j_k,\ldots,j_1)}\right\|_\diamond \tag{71}$$

$$\leq\frac{(2\|\mathcal{L}\|_{\text{be}})^{K+1}}{(K+1)!}+O\left(\sum_{k=1}^{K}\frac{(2t)^{k-1}2^{k+1}\|\mathcal{L}\|_{\text{be}}^k\|J\|^{(2q)}t^{2q+1}q}{(k-1)!(2q)!}\right) \tag{72}$$

$$=\frac{(2\|\mathcal{L}\|_{\text{be}})^{K+1}}{(K+1)!}+\frac{\|J\|^{2q}t^{2q+1}q}{(2q)!}O\left(\sum_{k=1}^{K}\frac{(2t)^{k-1}2^{k+1}\|\mathcal{L}\|_{\text{be}}^k}{(k-1)!}\right) \tag{73}$$

$$=\frac{(2\|\mathcal{L}\|_{\text{be}})^{K+1}}{(K+1)!}+\frac{\|J\|^{2q}t^{2q+1}q}{(2q)!}O\left(e^{4t\|\mathcal{L}\|_{\text{be}}}\right) \tag{74}$$

$$\leq\frac{(2\|\mathcal{L}\|_{\text{be}})^{K+1}}{(K+1)!}+\frac{\|\mathcal{L}\|_{\text{be}}^{2q}t^{2q+1}q}{(2q)!}O\left(e^{4t\|\mathcal{L}\|_{\text{be}}}\right), \tag{75}$$

where the last inequality follows from

$$\|J\|\leq\|H\|+\frac{1}{2}\sum_j\|L_j\|^2\leq\alpha_0+\frac{1}{2}\sum_j\alpha_j^2=\|\mathcal{L}\|_{\text{be}}. \tag{76}$$

With $t\|\mathcal{L}\|_{\text{be}} = \Theta(1)$, it suffices to set

$$K, q = O\left(\frac{\log(1/\epsilon)}{\log\log(1/\epsilon)}\right) \tag{77}$$

to make the approximation error at most $\epsilon/2$.

Applying the main algorithmic tool (Lemma 2). In Lemma 2, we need to prepare the special state $|\mu\rangle$ which encodes a superposition of normalizing constants of all Kraus operators. Now we show how to efficiently prepare this state. First observe that the normalizing constant for A_j in Equation (60) is

$$\sqrt{\hat{w}_{(j_k)}\cdots\hat{w}_{(j_k,\ldots,j_1)}}e^{\|\mathcal{L}\|_{\text{be}}(t-\hat{x}_{(j_k)})}\alpha_{\ell_k}\cdots e^{\|\mathcal{L}\|_{\text{be}}(\hat{x}_{(j_k,\ldots,j_2)}-\hat{x}_{(j_k,\ldots,j_1)})}\alpha_{\ell_1}e^{\|\mathcal{L}\|_{\text{be}}(\hat{x}_{(j_k,\ldots,j_1)})} \tag{78}$$

$$= \sqrt{\hat{w}_{(j_k)}\cdots\hat{w}_{(j_k,\ldots,j_1)}}e^{\|\mathcal{L}\|_{\text{be}}t}\alpha_{\ell_k}\cdots\alpha_{\ell_1} \tag{79}$$

$$= \frac{1}{\sqrt{t^{k(k-1)/2}}}\sqrt{w_{j_k}\hat{s}_{j_k}^{k-1}w_{j_{k-1}}\hat{s}_{j_{k-1}}^{k-2}\cdots w_{j_2}\hat{s}_{j_2}w_{j_1}}e^{\|\mathcal{L}\|_{\text{be}}t}\alpha_{\ell_k}\cdots\alpha_{\ell_1}, \tag{80}$$

and the normalizing constant for A_0 is $e^{\|\mathcal{L}\|_{\text{be}}t}$. Note that $e^{\|\mathcal{L}\|_{\text{be}}t}$ appears in every amplitude of $|\mu\rangle$ and therefore can be ignored. We use three registers in $|\mu\rangle$. The first register contains K qubits and it encodes k in unary representation, i.e., we use $\left|1^k0^{K-1}\right\rangle$ to represent k. The second register contains k subregisters of $\log m$ qubits to represent $\ell_1,\ldots,\ell_k$. The third register contains k subregisters of $\log q$ qubits to represent $j_1,\ldots,j_k$. We first prepare the normalized version of the state $\sum_{k=0}^{K}\frac{1}{\sqrt{t^{k(k-1)/2}}}\left|1^k0^{K-1}\right\rangle$, which can be done using $O(K)$ gates: we apply a rotation on the first qubit, and then apply a rotation on each subsequent qubit controlled by the previous qubit. For the second register, in each subregister we prepare the normalized version of $\sum_{j=1}^{m}\alpha_j|j\rangle$. The total gate cost for the second register is $O(Km)$. For the ℓ-th subregister of the third register, we prepare the normalized version of $\sum_{j=1}^{q}\sqrt{w_j s_j^{\ell-1}}|j\rangle$. The total gate cost for the third register is $O(Kq)$. Note that each gate acting on the ℓ-th subregister of the second and the third register is further controlled on the ℓ-th qubit of the first register, which effects the truncation. Therefore, the total gate cost for preparing $|\mu\rangle$ is $O(K(m+q))$.

Now, we show how to use Lemma 3 to approximate the block-encoding U_s of e^{Js} for any $0 < s \le t$, where s is provided in a time register containing $|s\rangle$. Here we use K' to denote the Taylor series truncation error. So we need to use Lemma 3 to implement a block-encoding of $\sum_{k=0}^{K'}s^kJ^k/k!$. Recall that $J = -iH - \frac{1}{2}\sum_{j=1}^{m}L_j^\dagger L_j$. In Lemma 3, we need to implement the B gate for preparing a superposition of coefficients. We use $K'+1$ control registers: the first register contains K qubits which encode k in unary; each subsequent register contains $O(\log(m))$ qubits. The B gate is implemented as follows. Controlled by the time register $|s\rangle$, we implement the normalized version of the state $\sum_{k=0}^{K'}\sqrt{s^k/k!}\left|1^k0^{K'-k}\right\rangle$ on the first control register, which can be done with $O(K)$ controlled-rotations. For each subsequent control resister, we implement the normalized version of the state $|0\rangle + \sum_{j=1}^{m}\sqrt{\alpha_j^2/2}|j\rangle$, which costs $O(m)$ gates. The controlled operation $\sum_j|j\rangle\langle j|\otimes A_j$ can be implemented by the controlled-U_H and controlled-U_{L_j} controlled by the $K+1$ control registers. Therefore, the total gate cost for implementing B is $O(K'm)$. The controlled rotations on the first control register controlled by the time register costs $O(\text{poly}(b))$ gates where b is the bits used to represent s. It suffices to set $b = O(\log(1/\epsilon))$ for a precise representation of s within ϵ. As a result, the cost $O(\text{poly}(b))$ is not dominating. As a result, the total gate cost for implementing $\sum_s|s\rangle\langle s|\otimes U_s$ is $O(Km)$.

Additional approximation. It is important to note that by a direct application of Lemma 3, the error of the block-encoding we implement is $O(\epsilon' e^{s\|\mathcal{L}\|_{\text{be}}})$. However, a more careful analysis shows a much better error bound: first assume we had implemented the infinity Taylor series. Then the error ϵ' of each block-encoding will cause error for the implementation that is bounded by[2] $\|e^{Js} - e^{\tilde{J}s}\| \leq \left\|J - \tilde{J}\right\| s \leq \epsilon' s \|\mathcal{L}\|_{\text{be}}$. Further, Lemma 6 implies that the error caused by the truncation is $\frac{(2e^{s\|\mathcal{L}\|_{\text{be}}})^{K'+1}}{(K'+1)'}$. By assuming $\epsilon' \leq \epsilon/(t(\|\mathcal{L}\|_{\text{be}})$, the truncation error will dominate by our choice of K'.

In Lemma 2, we need $|j\rangle\langle j| \otimes A_j$, where A_j is defined in Equation (60). This can be implemented by a sequence of at most K controlled-U_s and at most K controlled-U_{L_j}. Note that the time register required for implementing U_s can be extracted from the index j, and then uncomputed. Therefore, the gate cost for this is $O(KK'm)$. Therefore, the additional 1- and 2-qubits for this implementation is dominated by $O(KK'm)$.

Next, we analyze how the truncation of e^{Js} at order K' affects the total error. By Lemma 7, we have

$$\begin{aligned}&\|\mathcal{J}_{K'}(t-s_m)\mathcal{L}_{\text{J}}\mathcal{J}_{K'}(s_m-s_{m-1})\mathcal{L}_{\text{J}}\cdots\mathcal{J}_{K'}(s_2-s_1)\mathcal{L}_{\text{J}}\mathcal{J}_{K'}(s_1)-\mathcal{F}_k(s_k,\ldots,s_1)\|_\diamond \\ &\qquad\leq \frac{8e^{\|\mathcal{L}\|_{\text{be}}t}\|\mathcal{L}\|_{\text{be}}^{K'+1}}{(K'+1)!}(2\|\mathcal{L}\|_{\text{be}})^k 2^k t^{K'+1}.\end{aligned} \tag{81}$$

Taking the weighted sum for quadrature points, the error is at most

$$\begin{aligned}&\frac{8e^{\|\mathcal{L}\|_{\text{be}}t}\|\mathcal{L}\|_{\text{be}}^{K'+1}}{(K'+1)!}(2\|\mathcal{L}\|_{\text{be}})^k 2^k t^{K'+1}\sum_{j_1=1}^{q}\cdots\sum_{j_k=1}^{q}\hat{w}_{(j_k)}\cdots\hat{w}_{(j_k,\ldots,j_1)} \\ &\qquad= \frac{8t^k e^{\|\mathcal{L}\|_{\text{be}}t}\|\mathcal{L}\|_{\text{be}}^{K'+1}}{(k-1)!(K'+1)!}(2\|\mathcal{L}\|_{\text{be}})^k 2^k t^{K'+1}.\end{aligned} \tag{82}$$

Therefore, the total error is

$$\sum_{k=1}^{K}\frac{8t^k e^{\|\mathcal{L}\|_{\text{be}}t}\|\mathcal{L}\|_{\text{be}}^{K'+1}}{(k-1)!(K'+1)!}(2\|\mathcal{L}\|_{\text{be}})^k 2^k t^{K'+1} \leq \frac{32e^{5\|\mathcal{L}\|_{\text{be}}t}\|\mathcal{L}\|_{\text{be}}^{K'+2}t^{K'+2}}{(K'+1)!}. \tag{83}$$

With $t\|\mathcal{L}\|_{\text{be}} = \Theta(1)$, it suffices to set

$$K' = O\left(\frac{\log(1/\epsilon)}{\log\log(1/\epsilon)}\right) \tag{84}$$

to make this error $\leq \epsilon/2$. Therefore, the total error is bounded by ϵ.

Multiple simulation blocks. For arbitrary evolution time t, we divide it into $O(t\|\mathcal{L}\|_{\text{be}})$ segments and set

$$K, K', q = O\left(\frac{\log(t\|\mathcal{L}\|_{\text{be}}/\epsilon)}{\log\log(t\|\mathcal{L}\|_{\text{be}}/\epsilon)}\right) \tag{85}$$

so that the total error of the $O(t\|\mathcal{L}\|_{\text{be}})$ segments is within ϵ. For the remaining smaller segment of this division, the normalizing constant is smaller which yields a larger success probability. However, the amplitude amplification will overshoot. We use standard technique by adding an ancillary qubit and use a rotation to dilute the success probability to 1/4. ◀

[2] The inequality $\|e^{Js} - e^{\tilde{J}s}\| \leq \left\|J - \tilde{J}\right\| s$ does not hold for general matrices J. However, in our case it holds because J is dissipative and hence $\|e^{Js}\| \leq 1$ for all $s \geq 0$.

6 Conclusion and open questions

In this paper, we presented a quantum algorithm for simulating Lindblad evolution, which captures the dynamics of Markovian open quantum systems. The algorithm can be used to forecast the dynamics of a quantum system interacting with an environment. Informally, the complexity of our algorithm scales as $\mathcal{O}(t\,\mathrm{polylog}(t/\epsilon))$, which matches the previous state-of-the-art algorithm. Our algorithm is based on a conceptually novel mathematical treatment of evolution channel to preserve its complete positivity: we use a higher-order series expansion based on Duhamel's principle, and we approximate the integrals by scaled Gaussian quadrature, which exponentially reduces the number of terms in the summation. Our mathematical treatment trades off mathematical simplicity for technical conciseness, and it yields a much simpler algorithm based on linear combination of unitaries. We also outlined how our algorithm can be generalized to simulate time-dependent Lindbladians. Moreover, our approximation of multiple integrals using scaled Gaussian quadrature can be potentially used to produce a more efficient approximation of time-ordered integrals, which will simplify existing quantum algorithms for simulating time-dependent Hamiltonians based on a truncated Dyson series, e.g., [18].

The open questions of this work are summarized as follows.

- Can we achieve the additive complexity, i.e., $\mathcal{O}(t+\mathrm{polylog}(1/\epsilon))$? This additive complexity has been achieved for simulating Hamiltonian evolution by quantum signal processing [28] and quantum singular transformation [14], and it is proved to be optimal [5]. As Hamiltonian evolution is a special case of Lindblad evolution, the complexity for simulating the latter is at least $\Omega(t + \mathrm{polylog}(1/\epsilon))$. It is yet unknown how to generalize the techniques of quantum signal processing and quantum singular value transformation to superoperators.
- What are the practical performances of our algorithm? For Hamiltonian simulation, although LCU-based algorithms have a better asymptotic scaling, it was reported in [8] that Trotter-based algorithms surprisingly perform just as well in practice. Regarding simulating Lindblad evolution, do LCU-based algorithms, i.e., the algorithms presented in this paper and [9], have a practical advantage compared with Trotter-based simulation algorithms, e.g., [20, 7]? An empirical study on the performances of quantum algorithms for simulating open quantum systems would be beneficial.

A Simulating time-dependent Lindbladians

There exist natural generalizations to Lindblad equations. One such generalization is time-dependent Markovian open quantum systems, which arises in the context of quantum heat engine [1, 22, 2, 37] and controlling open quantum systems [21, 25, 39]. In this section, we sketch how our simulation techniques can be generalized to the case of time-dependent Lindbladians. More specifically, consider a time-dependent version of Equation (1):

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho = \mathcal{L}(t)(\rho) \coloneqq -i[H(t),\rho] + \sum_{j=1}^{m}\left(L_j(t)\rho L_j^{\dagger(t)} - \frac{1}{2}\left\{L_j(t)^\dagger L_j(t),\rho\right\}\right). \tag{86}$$

Now, $H(t)$ and $L_j(t)$ are time-dependent. We decompose this time-dependent Lindbladian into drift terms and jump terms as:

$$\mathcal{L}(t) = \mathcal{L}_{\mathrm{D}}(t) + \mathcal{L}_{\mathrm{J}}(t), \quad \text{and} \tag{87}$$

$$\mathcal{L}_{\mathrm{D}}(t)(\rho) \coloneqq J(t)\rho + \rho J(t)^\dagger, \quad \mathcal{L}_{\mathrm{J}}(t)(\rho) = \sum_{j=1}^{m} L_j(t)\rho L_j(t)^\dagger. \tag{88}$$

We express the evolution driven by $\mathcal{L}_{\mathrm{D}}$ as,

$$\rho_t = \mathcal{V}(0,t) \coloneqq V(0,t)\rho_0 V(0,t)^\dagger, \tag{89}$$

where $V(s,t)$ satisfies the equation,

$$\frac{d}{dt}V(s,t) = J(t)V(s,t), \quad \text{and} \quad V(s,s) = I. \tag{90}$$

One can express the unitary $V(0,t)$ using time-ordered evolution operators,

$$V(s,t) = \mathcal{T}e^{\int_s^t J(\tau)d\tau}. \tag{91}$$

Further, for Equation (1), the Duhamel's principle implies a generalization of Equation (23),

$$\rho_t = \mathcal{V}(0,t)(\rho_0) + \int_0^t \mathcal{V}(s,t)(\mathcal{L}_{\mathrm{J}}(s)(\rho_s))\mathrm{d}s. \tag{92}$$

In the Hamiltonian simulation [19], Such an operator is approximated by Dyson series,

$$V(0,t) = \sum_{k=0}^{K}\frac{t^k}{M^k k!}\sum_{j_1,j_2,\ldots,j_k=0}^{M-1}\mathcal{T}J(t_k)\cdots J(t_1) + \mathcal{O}\left(\frac{(\|J\|_{\max}t)^{K+1}}{(K+1)!} + \frac{t^2\|\dot{J}\|_{\max}}{M}\right), \tag{93}$$

where $\mathcal{T}$ indicates a strict time-ordering $t_1 \le t_2 \le \cdots \le t_k$ in the product. The formula here approximates the evolution from 0 to t. This can be easily extended to another interval, due to the observation that,

$$V(s,t) = \mathcal{T}e^{\int_s^t J(\tau)d\tau} = \mathcal{T}e^{\int_0^{t-s} J(s+\tau)d\tau}, \tag{94}$$

which leads to

$$V(s,t) = \sum_{k=0}^{K}\frac{t^k}{M^k k!}\sum_{j_1,j_2,\ldots,j_k=s}^{M-1}\mathcal{T}J(t_k)\cdots J(t_1) + \mathcal{O}\left(\frac{(\|J\|_{\max}t)^{K+1}}{(K+1)!} + \frac{t^2\|\dot{J}\|_{\max}}{M}\right). \tag{95}$$

This suggests that, by repeatedly applying Equation (23), we can adapt our series expansion in Equation (29) to

$$\mathcal{G}_K(t) \coloneqq \mathcal{K}[V(0,t)] + \sum_{k=1}^{K}\int_{0\le s_1\le\cdots\le s_k\le t}\mathcal{F}_k(s_k,\ldots,s_1)\,\mathrm{d}s_1\cdots\mathrm{d}s_k, \tag{96}$$

where

$$\begin{aligned}&\mathcal{F}_k(s_k,\ldots,s_1)\\&\coloneqq \mathcal{K}[V(s_k,t)]\mathcal{L}_{\mathrm{J}}(s_k)\mathcal{K}[V(s_{k-1},s_k)]\mathcal{L}_{\mathrm{J}}(s_{k-1})\cdots\mathcal{K}[V(s_1,s_2)]\mathcal{L}_{\mathrm{J}}(s_1)\mathcal{K}[V(0,s_1)].\end{aligned} \tag{97}$$

Then, we can approximate the integral using scaled Gaussian quadrature as in Section 4, and implement the completely positive map using the techniques presented in Section 5. Further note that we use a truncated Dyson series

$$\mathcal{J}_K = \mathcal{K}\left[\sum_{k=0}^{K}\frac{t^k}{M^k k!}\sum_{j_1,j_2,\cdots,j_k=s}^{M-1} J(t_k)\cdots J(t_1)\right]. \tag{98}$$

to approximate $V(s,t)$.

Space-Efficient Interior Point Method, with Applications to Linear Programming and Maximum Weight Bipartite Matching

Abstract

We study the problem of solving linear program in the streaming model. Given a constraint matrix $A \in \mathbb{R}^{m \times n}$ and vectors $b \in \mathbb{R}^m, c \in \mathbb{R}^n$, we develop a space-efficient interior point method that optimizes solely on the dual program. To this end, we obtain efficient algorithms for various different problems:

- For general linear programs, we can solve them in $\widetilde{O}(\sqrt{n}\log(1/\epsilon))$ passes and $\widetilde{O}(n^2)$ space for an ϵ-approximate solution. To the best of our knowledge, this is the most efficient LP solver in streaming with no polynomial dependence on m for both space and passes.
- For bipartite graphs, we can solve the minimum vertex cover and maximum weight matching problem in $\widetilde{O}(\sqrt{m})$ passes and $\widetilde{O}(n)$ space.

In addition to our space-efficient IPM, we also give algorithms for solving SDD systems and isolation lemma in $\widetilde{O}(n)$ spaces, which are the cornerstones for our graph results.

1 Introduction

Given a constraint matrix $A \in \mathbb{R}^{m \times n}$, vectors $b \in \mathbb{R}^m$ and $c \in \mathbb{R}^n$, the linear program problem asks us to solve the primal program (P) or its dual (D):

$$(P) = \max_{A^\top y \leq c, y \geq 0} b^\top y \text{ and } (D) = \min_{Ax \geq b} c^\top x \tag{1}$$

is one of the most fundamental problems in computer science and operational research. Many efforts have been dedicated to develop time-efficient linear program solvers in the past half a century, such as the simplex method [23], ellipsoid method [44] and interior point method [41]. In the last few years, speeding up linear program solve via interior point method (IPM) has been heavily studied [20, 55, 13, 35, 65, 25, 71]. The state-of-the-art IPM has the runtime of $O(m^{2+1/18} + m^{\omega})$ when $m \approx n$ and $O(mn + n^3)$ when $m \gg n$. To achieve these impressive improvements, most of these algorithms utilize randomized and dynamic data structures to maintain the primal and dual solutions simultaneously. While these algorithms are time-efficient, it is highly unlikely that they can be implemented in a *space-efficient* manner: maintaining the primal-dual formulation requires $\Omega(m + n^2)$ space, which is particularly unsatisfactory when $m \gg n$.

In this paper, we study the problem of solving a linear program in the streaming model: At each pass, we can query the i-th row of A and the corresponding of the b. The goal is to design an LP solver that is both space and pass-efficient. By efficient, our objective is to obtain an algorithm with no polynomial dependence on m, or more concretely, we present a robust IPM framework that uses only $\widetilde{O}(n^2)$ space and $\widetilde{O}(\sqrt{n}\log(1/\epsilon))$ passes.[1] To the best of our knowledge, this is the most efficient streaming LP algorithm that achieves a space and pass independent of m. Current best streaming algorithms for LP either require $\Omega(n)$ passes or $\Omega(n^2 + m^2)$ space for $O(\sqrt{n})$ passes. For the regime of tall dense LP ($m \gg n$), our algorithm achieves the best space and passes.

The key ingredient for obtaining these LP algorithms is a paradigm shift from the time-efficient primal-dual IPM to a less time-efficient dual-only IPM [64]. From a time perspective, dual-only IPM requires $\widetilde{O}(\sqrt{n}\log(1/\epsilon))$ iterations, with each iteration can be computed in $\widetilde{O}(mn + \mathrm{poly}(n))$ time. However, it is much more space-efficient than that of primal-dual approach. Specifically, we show that per iteration, it suffices to maintain an $n \times n$ Hessian matrix in place. To obtain $\widetilde{O}(\sqrt{n}\log(1/\epsilon))$ passes, we show that non-trivial quantities such as the Lewis weights [56, 21] can be computed recursively, in an in-place fashion with only $\widetilde{O}(n^2)$ space.

Now that we have a space and pass-efficient IPM for general LP in the streaming model, we instantiate it with applications for graph problems in the semi-streaming model. In the semi-streaming model, each edge is revealed along with its weight in an online fashion and might subject to an adversarial order, and the algorithm is allowed to make multiples passes over the stream in $\widetilde{O}(n)$ space.[2] We particularly focus on the *maximum weight bipartite matching* problem, in which the edges with weights are streamed to us, and the goal is to find a matching that maximizes the total weights in it. While there is a long line of research ([2, 36, 24, 3, 9] to name a few) on this problem, most algorithms can only compute an approximate matching, meaning that the weight is at least $(1 - \epsilon)$ of the maximum weight. For the case of exact matching, a recent work [6] provides an algorithm that takes $n^{4/3+o(1)}$ passes in $\widetilde{O}(n)$ space for computing a maximum *cardinality* matching. It remains an open question to compute an exact maximum *weight* bipartite matching in semi-streaming model, with $o(n)$ passes.

We answer this question by presenting a semi-streaming algorithm that uses $\widetilde{O}(n)$ space and $\widetilde{O}(\sqrt{m})$ passes, this means that as long as the graph is relatively sparse, i.e., $m = o(n^2)$, we achieve $o(n)$ passes. To obtain an $\widetilde{O}(n)$ space algorithm for *any graph*, we require

[1] We use $\widetilde{O}(\cdot)$ notation to hide polylogarithmic dependence on n and m.

[2] Some authors define the space in the streaming model to be the number of cells, where each cell can hold $O(\log n)$ bits or even a number with infinite precision. Our bounds remain unchanged even if each cell only holds $O(1)$ bits, i.e., when arithmetic only applies to $O(1)$-bits operands.

additional machinery; more specifically, for each iteration of our dual-only IPM, we need to compute the Newton step via a symmetric diagonal dominant (SDD) solve in $\widetilde{O}(n)$ space. Since the seminal work of Spielman and Teng [67], many efforts have been dedicated in designing a time-efficient SDD system solver [45, 46, 43, 19]. This solvers run in $\widetilde{O}(m)$ time with improved dependence on the logarithmic terms. However, all of them require $\widetilde{\Theta}(m)$ space. To achieve $\widetilde{O}(n)$ space, we make use of small-space spectral sparsifiers [38] as preconditioners to solve the system in a space and pass-efficient manner.

Finally, we note that with $\widetilde{O}(n)$ space, we essentially solve the dual problem, which is the *generalized minimum vertex cover* on bipartite graph. To turn a solution on vertices to a solution on edges, we utilize the isolation lemma [60] and implement it in $\widetilde{O}(n)$ bits via a construction due to [17].

1.1 Our contribution

In this section, we showcase three main results of this paper and discuss their consequences.

The first result regards solving a general linear program in the streaming model with $\widetilde{O}(n^2)$ space and $\widetilde{O}(\sqrt{n}\log(1/\epsilon))$ passes.

▶ **Theorem 1** (General LP, informal version of Theorem 7.4 in Full version [57]). *Given a linear program with m constraints and n variables and $m \geq n$ in the streaming model, there exists an algorithm that outputs an ϵ-approximate solution to the dual program (Eq. (1)) in $\widetilde{O}(n^2)$ space and $\widetilde{O}(\sqrt{n}\log(1/\epsilon))$ passes.*

By ϵ-approximate solution, we mean that the algorithm finds $x \in \mathbb{R}^n$ such that $c^\top x - c^\top x^* \leq \epsilon$, where x^* is the optimal solution. The key to obtain our result is a small space implementation of leverage score and Lewis weights, so that we can utilize the Lee-Sidford barrier [51], with the number of passes depending on the smaller dimension.

In conjunction with an SDD solver in $\widetilde{O}(n)$ space, our next result shows that in the semi-streaming model, we can solve the minimum vertex cover problem on a bipartite graph with $\widetilde{O}(\sqrt{m})$ passes.

▶ **Theorem 2** (Minimum vertex cover, informal version of Theorem 9.7 in Full version [57]). *Given a bipartite graph G with n vertices and m edges, there exists a streaming algorithm that computes a minimum vertex cover of G in $\widetilde{O}(\sqrt{m})$ passes and $\widetilde{O}(n)$ space with probability $1 - 1/\operatorname{poly}(n)$.*[3]

The reason we end up with $\widetilde{O}(\sqrt{m})$ passes instead of $\widetilde{O}(\sqrt{n})$ passes is that to compute some fundamental quantities such as leverage scores or Lewis weights, we need to solve $\Theta(m)$ SDD systems and result in a total of $\widetilde{O}(m\sqrt{n})$ passes. By using the logarithmic barrier, we only need to solve $O(1)$ SDD systems per iteration, which gives the $\widetilde{O}(\sqrt{m})$ passes.

We are now ready to present our result for bipartite matching in $\widetilde{O}(\sqrt{m})$ passes, which solves the longstanding problem of whether maximum weight matching can be solved in $o(n)$ passes for any $m = n^{2-c}$ with $c > 0$.

▶ **Theorem 3** (Maximum weight bipartite matching, informal version of Theorem 10.1 in Full version [57]). *Given a bipartite graph G with n vertices and m edges, there exists a streaming algorithm that computes an (exact) maximum weight matching of G in $\widetilde{O}(\sqrt{m})$ passes and $\widetilde{O}(n)$ space with probability $1 - 1/\operatorname{poly}(n)$.*

[3] We can actually solve a *generalized* version of the minimum vertex cover problem in bipartite graph: each edge e needs to be *covered* for at least $b_e \in \mathbb{Z}^+$ times, where the case of $b = \mathbf{1}_m$ is the classic minimum vertex cover.

Our matching result relies on turning the solution to the dual minimum vertex cover problem, to a primal solution for the maximum weight matching. We achieve so by an $\widetilde{O}(n)$ space implementation of the isolation lemma [60, 17].

1.2 Related work

Interior point method for solving LP. The interior point method was originally proposed by Karmarkar [41] for solving linear program. Since then, there is a long line of work on speeding up interior point method for solving classical optimization problems, e.g., linear program [68, 64, 69, 61, 22, 50, 51, 52, 20, 55, 53, 12, 13, 71, 35, 25, 65, 33]. In 1987, the running time of LP solver becomes $O(n^3)$ [68, 64]. In 1989, Vaidya proposed an $O(n^{2.5})$ LP solver based on a specific implementation of IPMs, known as the *central path algorithm* [68, 69]. Lee and Sidford show how to solve LP in $\sqrt{n}(\text{nnz}(A) + n^\omega)$ time [49, 50, 51], where ω is the exponent of matrix multiplication [70, 48, 4][4] (the first $\sqrt{n}$-iteration IPM). In 2019, [20] show how to solve LP in $n^\omega + n^{2.5-\alpha} + n^{2+1/6}$, where α is the dual exponent of matrix multiplication [31][5]. This is the first breakthrough result improving $O(n^{2.5})$ from 30 years ago. Later, [35] improved that running time to $n^\omega + n^{2.5-\alpha} + n^{2+1/18}$ by maintaining two layers of data-structure instead of one layer of data-structure as [20]'s algorithm. In 2020, [13] improved the running time of LP solver on tall matrices to mn when $m \geq \text{poly}(n)$. Another line of work focuses on solving linear program with small treewidth [25, 71] in time $\widetilde{O}(m\tau^2)$.

Small space algorithms for solving LP. Simplex algorithm is another popular approach to solve linear programs. It has an even better compatibility with streaming algorithms. For instance, [15] shows that the non-recursive implementation of Clarkson's algorithm [18] gives a streaming LP solver that uses $O(n)$ passes and $\widetilde{O}(n\sqrt{m})$ space. They also show that the recursive implementation gives a streaming LP solver that uses $n^{O(1/\delta)}$ passes and $(n^2 + m^\delta)\,\text{poly}(1/\delta)$ space. [7] proposes a streaming algorithm for solving n-dimensional LP that uses $O(nr)$ pass and $O(m^{1/r})\,\text{poly}(n, \log m)$ space, where $r \geq 1$ is a parameter. All above algorithms needs space depending on m.

Streaming algorithms for approximate matching. Maximum matching has been extensively studied in the streaming model for decades, where almost all of them fall into the category of approximation algorithms. For algorithms that only make one pass over the edges stream, researchers make continuous progress on pushing the constant approximation ratio above $1/2$, which is under the assumption that the edges are arrived in a uniform random order [37, 5, 27, 11]. The random-order assumption makes the problem easier (at least algorithmically). A more general setting is multi-pass streaming with adversarial edge arriving. Under this setting, the first streaming algorithm that beats the $1/2$-approximation of bipartite cardinality matching is [29], giving a $2/3 \cdot (1-\epsilon)$-approximation in $1/\epsilon \cdot \log(1/\epsilon)$ passes. The first to achieve a $(1-\epsilon)$-approximation is [59], which takes $(1/\epsilon)^{1/\epsilon}$ passes.[6] Since then, there is a long line of research in proving upper bounds and lower bounds on the number of passes to compute a maximum matching in the streaming model [2, 26, 32, 26, 36, 24, 3, 8, 10, 9] (see next subsection for more details). Notably, [2, 3] use linear programming and duality theory (see the next subsection for more details).

[4] Currently, $\omega \approx 2.37$.
[5] Currently, $\alpha \approx 0.31$.
[6] For the weighted case, there is a $(1/2-\epsilon)$-approximation algorithm that only takes one pass [62].

However, all the algorithms above can only compute an approximate maximum matching: to compute a matching whose size is at least $(1-\epsilon)$ times the optimal, one needs to spend $\text{poly}(1/\epsilon)$ passes (see [24, 3] and the references therein). For readers who are interested in the previous techniques for solving matching, we refer to Section A in full version [57] which contains a brief summary.

Recent developments for exact matching. Recently, [6] proposes an algorithm that computes a $(1-\epsilon)$-approximate maximum *cardinality* matching in $O(\epsilon^{-1}\log n\log\epsilon^{-1})$ passes and $\widetilde{O}(n)$ space. Their method leverages recent advances in ℓ_1-regression with several ideas for implementing it in small space, leading to a streaming algorithm with no dependence on ϵ in the space usage, and thus improving over [3]. The resulted semi-streaming algorithm computes an exact maximum *cardinality* matching (not for weighted) in $n^{3/4+o(1)}$ passes.

Streaming spectral sparsifer. Initialized by the study of cut sparsifier in the streaming model [1], a simple one-pass semi-streaming algorithm for computing a spectral sparsifier of any weighted graph is given in [42], which suffices for our applications in this paper. The problem becomes more challenging in a dynamic setting, i.e., both insertion and deletion of edges from the graph are allowed. Using the idea of linear sketching, [38] gives a single-pass semi-streaming algorithm for computing the spectral sparsifier in the dynamic setting. However, their brute-force approach to recover the sparsifier from the sketching uses $\Omega(n^2)$ time. An improved recover time is given in [39] but requires more spaces, e.g., $\epsilon^{-2}n^{1.5}\log^{O(1)}n$. Finally, [40] proposes a single-pass semi-streaming algorithm that uses $\epsilon^{-2}n\log^{O(1)}n$ space and $\epsilon^{-2}n\log^{O(1)}n$ recover time to compute an ϵ-spectral sparsifier which has $O(\epsilon^{-2}n\log n)$ edges. Note that $\Omega(\epsilon^{-2}n\log n)$ space is necessary for this problem [14].

SDD solver. There is a long line of work focusing on fast SDD solvers [66, 45, 46, 43, 19, 63, 47]. Spielman and Teng give the first nearly-linear time SDD solver, which is simplified with a better running time in later works. The current fastest SDD solver runs in $O(m\log^{1/2}n\,\text{poly}(\log\log n)\log(1/\epsilon))$ time [19]. All of them require $\widetilde{\Theta}(m)$ space.

2 Technical overview

We start with an overview of our IPM framework. We first note that many recent fast IPM algorithms do not fit into $\widetilde{O}(n^2)$ space. Algorithms such as [51, 35, 13] need to maintain *both* primal and dual solutions, thus require $\Omega(m)$ space. In fact, any algorithms that rely on the primal formulation will need $\Omega(m)$ space to maintain the solution. To bypass this issue, we draw inspiration from the state-of-the-art SDP solver [34]: in their setting, $m=\Omega(n^2)$, which means any operation on the dimension m will be too expensive to perform. They instead resort to the *dual-only* formulation. The dual formulation provides a more straightforward optimization framework on small dimension and makes it harder to maintain key quantities. This is exactly what we want: an algorithm that operates on the smaller dimension, removing the polynomial dependence on m. While efficient maintenance is the key to design time-efficient IPM, it is less a concern for us since our constraining resource is space, not time. To this end, we show that Renegar's IPM algorithm [64] can be implemented in a streaming fashion with only $\widetilde{O}(n^2)$ space. As the number of passes of an IPM crucially depends on the barrier function being used, the [64] algorithm only gives a pass bound of $\widetilde{O}(\sqrt{m}\log(1/\epsilon))$. To further improve the number of passes required, we show that the nearly-universal barrier of Lee and Sidford [51, 53] can also be implemented in $\widetilde{O}(n^2)$ space.

This involves computing Lewis weights in an extremely space-efficient manner. We present a recursive algorithm with $\widetilde{O}(1)$ depth, based on [28], that uses only $\widetilde{O}(n^2)$ space. This gives the desired $\widetilde{O}(\sqrt{n}\log(1/\epsilon))$ passes.

We now turn to our graph results, which is a novel combination of the space-efficient IPM, SDD solvers, duality and the isolation lemma. Note that for both graph problems only allow $\widetilde{O}(n)$ space, so it won't suffice to directly apply our IPM algorithms .

To give a better illustration of the $\widetilde{O}(n)$ space constraint, note that storing a matching already takes $\widetilde{\Theta}(n)$ space, meaning that we have only a polylogarithmic space overhead per vertex to store auxiliary information. The conventional way of solving maximum bipartite matching using an IPM solver would get stuck at the very beginning - maintaining the solution of the relaxed linear program, which is a fractional matching, already requires $\Omega(m)$ space for storing all LP constraints, which seems inevitable.

Our key insight is to show that solving the *dual* form of the above LP, which corresponds to the generalized (fractional) minimum vertex cover problem, is sufficient, and therefore only $\widetilde{O}(n)$ space is needed for maintaining a fractional solution. We use several techniques to establish this argument. The first idea is to use complementary slackness for the dual solution to learn which n edges will be in the final maximum matching and therefore reduce the size of the graph from m to n. However, this is not always the case: For instance, in a bipartite graph that admits a perfect matching, all left vertices form a minimum vertex cover, but the complementary slackness theorem gives no information on which edges are in the perfect matching. To circumvent this problem, we need to slightly perturb the weight on every edge, so that the minimum vertex cover (which is now unique) indeed provides enough information. We use the isolation lemma [60] to realize this objective.

It is then instructive to implement the isolation lemma in limited space. Perturbing the weight on every edge requires storing $\widetilde{O}(m)$ bits of randomness, since the perturbation should remain identical across two different passes. We bypass this issue by using the generalized isolation lemma proposed by [17], in which only $O(\log(Z))$ bits of randomness is needed, where Z is the number of candidates. In our case, $Z \leq n^n$ is the number of all possible matchings. So $\widetilde{O}(n)$ space usage perfectly fits into the semi-streaming model. We design an oracle that stores $\widetilde{O}(n)$ random bits and outputs the same perturbations for all edges in all passes.

Now that we can focus on solving the minimum vertex cover problem in $\widetilde{O}(n)$ space. When the constraint matrix is an incidence matrix, each iteration of our IPM can be implemented as an SDD (or Laplacian) solver, so it suffices to show how to solve SDD system in the semi-streaming model, which, to the best of our knowledge, has not been done prior to our work.

In the following subsections we elaborate on each of the above components:

- In Section 2.1, we provide a high-level picture of how our dual-only interior point method works.
- In Section 2.2, we show evidences that our interior point method can run in space independent of m for all of the three different barriers.
- In Section 2.3, we describe our contribution on our implementations of SDD solver, IPM, and the isolation lemma in the streaming model. We show a novel application of the isolation lemma to turn dual into primal.

2.1 Dual-only robust IPM

The cornerstone of our results is to design a robust IPM framework that works only on the dual formulation of the linear program. The framework fits in barriers including the logarithmic barrier, hybrid barrier and Lee-Sidford barrier. It is also robust enough as it can tolerate approximation errors in many quantities, while preserving the convergence behavior.

Algorithm 1 is a simplified version of our dual-only IPM. The earlier works of Renegar's algorithm [64] require the Newton's direction be computed exactly as $\Delta x = -H(x)^{-1}\nabla f_t(x)$, in order to get double exponential convergence rate of Newton's method. To strengthen its guarantee, we develop a more robust framework for this IPM. Specifically, we show that the Hessian of the barrier functions, the gradient and the Newton's direction can all be approximated. This requires a much more refined error analysis. Below, we carefully bound the compound errors caused by three layers of approximations.

First, from Δx to δ_x (Line 9), we allow our Hessian to be spectrally approximated within any small constant factor. This provides us enough leeway to implement the Hessian of barrier functions in a space-efficient manner. For example, the Hessian of the volumetric barrier is $H(x) = A_x^\top(3\Sigma_x - 2P_x^{(2)})A_x$, where Σ_x is a diagonal matrix and $P_x^{(2)}$ is taking entry-wise square of a dense projection matrix. But $\widetilde{H}(x) = A_x^\top \Sigma_x A_x$ is a 5-approximation of $H(x)$ and we can compute it in the same space as computing leverage scores.

Second, from δ_x (Line 9) to δ'_x (Line 11), we allow approximation on the gradient in the sense that it has small local norm with respect to the true gradient, i.e., $\|\nabla f_t(x) - \widetilde{\nabla} f_t(x)\|_{H(x)^{-1}} \leq 0.1$.[7] To give a concrete example, let $\sigma \in \mathbb{R}^m$ denote the leverage score vector, and suppose the Hessian matrix is in the form of $H(x) = A^\top \Sigma A$ and the gradient is $\nabla f(x) = A^\top \sigma$. The leverage score σ can then be approximated in an entry-wise fashion: each entry can tolerate a multiplicative $(1 \pm O(1/\sqrt{n}))$ error. This is because

$$\begin{aligned}
\|\nabla f_t(x) - \widetilde{\nabla} f_t(x)\|^2_{H(x)^{-1}} &= \mathbf{1}_m^\top(\Delta\Sigma)A(A^\top\Sigma A)^{-1}A^\top(\Delta\Sigma)\mathbf{1}_m \\
&= \mathbf{1}_m^\top(\Delta\Sigma)\Sigma^{-1/2}\Sigma^{1/2}A(A^\top\Sigma A)^{-1}A^\top\Sigma^{1/2}\Sigma^{-1/2}(\Delta\Sigma)\mathbf{1}_m \\
&\leq \mathbf{1}_m^\top(\Delta\Sigma)\Sigma^{-1}(\Delta\Sigma)\mathbf{1}_m \\
&= \sum_{i=1}^m \frac{(\sigma_i - \widetilde{\sigma}_i)^2}{\sigma_i} \\
&\leq \frac{0.01}{n} \cdot n = 0.01,
\end{aligned}$$

where the first inequality follows from property of projection matrix (for any projection matrix P, we have $P \preceq I$. Then we know $x^\top P x \leq x^\top x$ for all vector x), the last inequality follows from $\sum_{i=1}^m \sigma_i = n$.

Third, from δ'_x (Line 11) to $\widetilde{\delta}$ (Line 12), we can tolerate the approximation error on the Newton's direction $\|\widetilde{\delta} - \delta'_x\|_{H(x)} \leq 0.1$. This is crucial for our graph applications, since we need to use small space SDD solver to approximate the Newton's direction.

2.2 Solve LP in small space

In this section, we show how to implement our IPM in space not polynomially dependent on m for different barrier functions.

[7] For a vector y and a positive semidefinite matrix A, we define $\|y\|_A := \sqrt{y^\top A y}$.

Algorithm 1 A simplified version of our algorithm.

procedure OurAlgorithm($A \in \mathbb{R}^{m\times n}, b \in \mathbb{R}^m, c \in \mathbb{R}^n$)
  Choose $F(x) \in \mathbb{R}^n \to \mathbb{R}$ to be any θ^2-self concordant barrier function
  Let $f_t(x) := t \cdot c + \nabla F(x) \in \mathbb{R}^n$
  Let $H(x) := \nabla^2 F(x) \in \mathbb{R}^{n\times n}$
  Let T be the number of iterations
  Initialize x, t
  for $k \leftarrow 1$ to T **do**
    Let $\widetilde{H}(x)$ be any PSD matrix that $\frac{1}{\log m}\widetilde{H}(x) \preceq H(x) \preceq \widetilde{H}(x)$
    Let $\delta_x := -\widetilde{H}(x)^{-1} \cdot \nabla f_t(x)$
    Let $\widetilde{\nabla} f_t(x)$ be that $\|\widetilde{\nabla} f_t(x) - \nabla f_t(x)\|_{H(x)^{-1}} \leq 0.1$
    Let $\delta'_x := -\widetilde{H}(x)^{-1} \cdot \widetilde{\nabla} f_t(x)$
    Let $\widetilde{\delta}_x$ be any vector that $\|\widetilde{\delta}_x - \delta'_x\|_{H(x)} \leq 0.1$
    $x \leftarrow x + \widetilde{\delta}_x$
    $t \leftarrow t \cdot (1 + \theta^{-1})$
  end for
  Output x
end procedure

For three barriers (logarithmic, hybrid and Lee-Sidford), all of their Hessians take the form of $A^\top HA \in \mathbb{R}^{n\times n}$ for an $m \times m$ non-negative diagonal matrix H. For logarithmic barrier, $H_{i,i} = s_i(x)^{-2}$, as $s_i(x)$ can be computed in $O(1)$ space, it is not hard to see that the Gram matrix can be computed as $\sum_{i\in[m]} H_{i,i} \cdot a_i a_i^\top$ in $O(n^2)$ space.

The more interesting case is to consider the hybrid barrier and Lee-Sidford barrier. The gradient and Hessian of the hybrid barrier requires us to compute m leverage scores defined as $\mathrm{diag}(\sqrt{H}A(A^\top HA)^{-1}A^\top\sqrt{H})$. Forming this projection matrix will require a prohibitive m^2 space. To implement it in n^2 space, we rely on an observation that $\sigma_i = H_{i,i} \cdot a_i^\top (A^\top HA)^{-1} a_i$, thus, if we can manage to maintain $(A^\top HA)^{-1}$ in $O(n^2)$ space, then we can compute the leverage score. Similar to the logarithmic barrier scenario, $A^\top HA$ can be computed in 1 pass and $O(n^2)$ space, then the inverse can be computed in $O(n^2)$ space. Thus, we can supply the i-th leverage score in $O(n^2)$ space, and compute the gradient and Hessian in designated space constraint.

Given an oracle that can compute the i-th leverage score in $O(n^2)$ space, we can even implement the $\ell_{\log m}$ Lewis weights in $\widetilde{O}(n^2)$ space. To do so, we rely on an iterative scheme introduced in [28]. Unfortunately, as we are only allowed a space budget of $O(n^2)$, we cannot store the intermediate Lewis weights. To circumvent this issue, we develop a recursive algorithm to query Lewis weights from prior iterations. Each recursion takes $O(n^2)$ space, and the algorithm uses at most $O(\mathrm{poly}(\log m))$ iterations, therefore, we can compute the Lewis weights in $\widetilde{O}(\sqrt{n})$ space.

2.3 Semi-streaming maximum weight bipartite matching in $\widetilde{O}(\sqrt{m})$ passes

Recall that in the semi-streaming model, we are only allowed with $\widetilde{O}(n)$ space. For the IPMs we've developed before, we can not meet such space constraint. For general graphs, we have to invent more machinery to realize the $\widetilde{O}(n)$ space.

For matching, we start by noting that the constraint matrix $A \in \mathbb{R}^{m \times n}$ is a graph incidence matrix. This means that for logarithmic barrier, the Hessian matrix $A^\top S^{-2} A$ can be treated as a Laplacian matrix with edge weight s_i^{-2}. Therefore, computing the Newton direction reduces to perform an SDD solve in $\widetilde{O}(n)$ space.

SDD solver in the semi-streaming model. Though solving SDD system can be done in an extremely time-efficient manner, it is unclear how to compute them when only $\widetilde{O}(n)$ space is allowed. To circumvent this problem, we rely on two crucial observations. Let L_G denote the SDD matrix corresponding to the Hessian.

- Solving a system $L_G \cdot x = b$ will require $\widetilde{\Omega}(m)$ space, but multiplying L_G with a vector $v \in \mathbb{R}^n$ can be done in $O(n)$ space: as $L_G = \sum_{i \in [m]} \frac{a_i a_i^\top}{s_i^2}$, $L_G \cdot v$ can be computed as $a_i (a_i^\top v)/s_i^2$ in $O(n)$ space, and accumulate the sum over a pass of the graph.
- Suppose we have a sparse graph H with only $\widetilde{O}(n)$ edges, then the system $L_H \cdot x = b$ can be solved in $\widetilde{O}(n)$ space.

It turns out that these two observations are enough for us to solve a general SDD system in $\widetilde{O}(n)$ space. Given the graph G, we first compute a $(1 \pm \delta)$-spectral sparsifier with only $\widetilde{O}(\delta^{-2} n \log^{O(1)} n)$ edges in a single pass [40]. Let H denote this sparsifier, we then use L_H^{-1} as a preconditioner for solving our designated SDD system. More concretely, let $r_t := b - L_G \cdot x_t$ denote the residual at t-th iteration, we solve the system $L_H \cdot y_t = r_t$. As $y_t = L_H^{-1} \cdot b - L_H^{-1} L_G \cdot x_t$, we can then update the solution via the preconditioned-solution $x_{t+1} = x_t + y_t$. The residual is then $r_{t+1} = b - L_G \cdot x_{t+1} = b - L_G \cdot x_t - L_G \cdot y_t = r_t - L_G \cdot y_t$, i.e., we only need to implement one matrix-vector product with L_G. After $\widetilde{O}(1)$ iterations, we have refined an accurate enough solution for the SDD system.

From dual to primal. Though we can solve the dual in $\widetilde{O}(n)$ space, it only produces a solution to the minimum vertex cover and we need to transform it to a solution to maximum weight matching.

Turning an optimal dual solution to an optimal primal solution for general LP requires at least solving a linear system, which takes $O(n^\omega)$ time and $O(mn)$ space (Lee, Sidford and Wong [54]), which is unknown to be implemented in the semi-streaming model even for bipartite matching LP.[8] We bypass this issue by using the complementary slackness theorem to highlight n tight dual constraints and therefore sparsify the original graph from m edges to n edges without losing the optimal matching. However, this is only true if the solution to the primal LP is **unique**.

To give a better illustration, let us consider a simple example. Suppose the graph has a (maximum weight) perfect matching (see Figure 1 for example). Then the following trivial solution is optimal to the dual LP: choosing all vertices in V_L. Let us show what happens when applying the complementary slackness theorem. The complementary slackness theorem says that when y is a feasible primal solution and x is a feasible dual solution, then y is optimal to the primal and x is optimal to the dual **if and only if**

$$\langle y, Ax - \mathbf{1}_m \rangle = 0 \quad \text{and} \quad \langle x, \mathbf{1}_n - A^\top y \rangle = 0. \tag{2}$$

From the above case, we have $Ax - \mathbf{1}_m = 0$, so the first equality $\langle y, Ax - \mathbf{1}_m \rangle = 0$ puts no constraint on y. Therefore, any solution $y \geq \mathbf{0}_m$ to the linear system $a_i^\top y_i = 1,\ \forall i \in V_L$ is an optimal solution, where a_i is the i-th column of A. Note that this linear system has m variables and $|V_L|$ equations, which is still hard to find a solution in $\widetilde{O}(n)$ space.

[8] In general, the inverse of a sparse matrix can be dense, which means the standard Gaussian elimination method for linear system solving does not apply in the semi-streaming model.

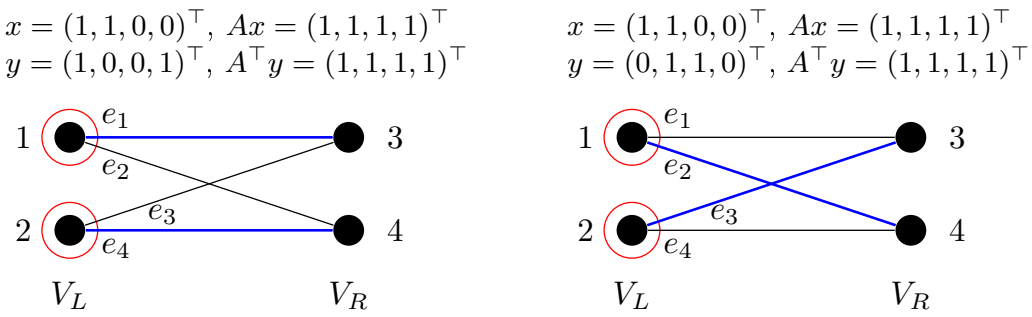

Figure 1 The red circle is a minimum vertex cover, which is an optimal dual solution. The blue edge is a maximum matching, which is an optimal primal solution. In both examples, the primal and dual satisfy complementary slackness Eq. (2).

Now consider perturbing the primal objective function by some vector $b \in \mathbb{R}^m$ such that the optimal solution to the following primal LP is **unique**:

$$\textbf{Primal} \quad \max_{y \in \mathbb{R}^m} b^\top y, \qquad \text{s.t. } A^\top y \leq \mathbf{1}_n \text{ and } y \geq \mathbf{0}_m.$$

Suppose we find the optimal solution x in the dual LP and we want to recover the optimal solution y in the primal LP. Again by plugging in the complementary slackness theorem, we get at most n equations from the second part $\langle x, \mathbf{1}_n - A^\top y \rangle = 0$. Since the optimal y is unique and y has dimension m, the first part $\langle y, Ax - \mathbf{1}_m \rangle$ must contribute to at least $m - n$ equations. Note that these equations have the form

$$y_i = 0, \ \forall i \in [m] \text{ s.t. } (Ax)_i - 1 > 0.$$

This means that the corresponding edges are *unnecessary* in order to get one maximum matching. As a result, we can reduce the number of edges from m to n, then compute a maximum matching in $\widetilde{O}(n)$ space without reading the stream.

Isolation lemma in the semi-streaming model. It remains to show how to perturb the objective so that the primal solution is unique. As the perturbation is over all edges, one natural idea is to randomly perturb them using $\widetilde{O}(m)$ bits of randomness. This becomes troublesome when the random bits need to be stored since the perturbation should remain consistent across different passes. We resolve this problem via the isolation lemma.

Let us recall the definition of the isolation lemma (see Section C in full version [57] for details).

▶ **Definition 4** (Isolation lemma). *Given a set system $(S, \mathcal{F})$ where $\mathcal{F} \subseteq \{0,1\}^S$. Given weight w_i to each element i in S, the weight of a set F in $\mathcal{F}$ is defined as $\sum_{i \in F} w_i$. The isolation lemma says there exists a scheme that can assign weight oblivious to $\mathcal{F}$, such that there is a unique set in $\mathcal{F}$ that has the minimum (maximum) weight under this assignment.*

The isolation lemma says that if we randomly choose weights, then with a good probability the uniqueness is ensured. However, this does not apply to the streaming setting since the weight vector is over all edges, which require $\Omega(m)$ space.

To apply isolation lemma for bipartite matching, we note that the set S is all the edges and the family $\mathcal{F}$ contains all possible matchings. The total number of possible matchings is at most $(n+1)^n$, as each vertex can choose none or one of the vertices to match. We

leverage this parameterization and make use of [17], which requires $\log(|F|)$ random bits. For matching, we only need $O(n \log n)$ bits, which suits in our space budget. To the best of our knowledge, this is the first use of isolation lemma in the streaming model.

2.4 Discussions

For matching, improving $\sqrt{m}$ passes to $\sqrt{n}$ passes will require us to compute fundamental quantities such as leverage scores and Lewis weights by solving $\widetilde{O}(1)$ SDD systems. As reachability [58] and single source shortest path [30, 16] can be solved in $n^{1/2+o(1)}$ passes in the semi-streaming model, we believe it is an important open problem to close the gap between bipartite matching and these problems.

Abstract

Despite numerous results about the list decoding of Hamming-metric codes, development of list decoding on rank-metric codes is not as rapid as its counterpart. The bound of list decoding obeys the Gilbert-Varshamov bound in both the metrics. In the case of the Hamming-metric, the Gilbert-Varshamov bound is a trade-off among rate, decoding radius and alphabet size, while in the case of the rank-metric, the Gilbert-Varshamov bound is a trade-off among rate, decoding radius and column-to-row ratio (i.e., the ratio between the numbers of columns and rows). Hence, alphabet size and column-to-row ratio play a similar role for list decodability in each metric. In the case of the Hamming-metric, it is more challenging to list decode codes over smaller alphabets. In contrast, in the case of the rank-metric, it is more difficult to list decode codes with large column-to-row ratio. In particular, it is extremely difficult to list decode square matrix rank-metric codes (i.e., the column-to-row ratio is equal to 1).

The main purpose of this paper is to explicitly construct a class of rank-metric codes $\mathcal{C}$ of rate R with the column-to-row ratio up to $2/3$ and efficiently list decode these codes with decoding radius beyond the decoding radius $(1-R)/2$ (note that $(1-R)/2$ is at least half of relative minimum distance δ). In literature, the largest column-to-row ratio of rank-metric codes that can be efficiently list decoded beyond half of minimum distance is $1/2$. Thus, it is greatly desired to efficiently design list decoding algorithms for rank-metric codes with the column-to-row ratio bigger than $1/2$ or even close to 1. Our key idea is to compress an element of the field $\mathbb{F}_{q^n}$ into a smaller $\mathbb{F}_q$-subspace via a linearized polynomial. Thus, the column-to-row ratio gets increased at the price of reducing the code rate. Our result shows that the compression technique is powerful and it has not been employed in the topic of list decoding of both the Hamming and rank metrics. Apart from the above algebraic technique, we follow some standard techniques to prune down the list. The algebraic idea enables us to pin down the message into a structured subspace of dimension linear in the number n of columns. This "periodic" structure allows us to pre-encode the message to prune down the list.

1 Introduction

Rank-metric codes were first introduced by Delsarte in [1] and have found various applications [14, 16]. A rank-metric code $\mathcal{C}$ of rate R and relative minimum distance δ must obey the Singleton bound $1 - R \geqslant \delta$ (see Subsection 2.1). The equality $1 - R = \delta$ holds if the code $\mathcal{C}$ is maximum rank distance (MRD for short). As for every alphabet size q and ratio ρ, one can always construct an MRD code. Therefore, we view decoding radius $(1 - R)/2$ as the half of minimum distance decoding radius or unique decoding radius.

The unique decoding algorithms for rank-metric codes have been extensively studied [3, 14]. However, the list decoding algorithm of the rank-metric codes are not understood very well. Despite of many results about the list decoding of Hamming-metric codes in literature, very few were known about the list decoding of rank-metric codes. In particular, for the column-to-row ratio bigger than $\frac{1}{2}$, there are no known explicit constructions of rank-metric codes that can be list decoded beyond half the minimum distance decoding radius. On the other hand, with high probability, a square random rank-metric code of rate R can be list decoded up to its decoding radius $1 - \sqrt{R}$ (see [2]). Note that $1 - \sqrt{R}$ is always bigger than $(1 - R)/2$. This means that with high probability, a random square rank-metric code can be list decoded beyond the half of minimum distance decoding radius.

In the the Hamming-metric case, it is more challenging to list decode codes over small alphabets. As we will see in the next subsection, in contrast, it becomes more difficult to list decode codes with large column-to-row ratio (i.e., the ratio between the numbers of rows and columns). In particular, it is extremely difficult to list decoding of square matrix rank-metric codes (i.e., the column-to-row ratio is equal to 1). Therefore, it is a great challenge to design efficient algorithms to list decode rank-metric codes with the column-to-row ratio close to 1 and decoding radius beyond $(1 - R)/2$.

1.1 Known results

Let us fix some notations before stating known results. Denote by $\mathbb{F}_q^{t\times n}$ the collection of $t \times n$ matrices over $\mathbb{F}_q$. We may assume that $n \leqslant t$. Otherwise, we can consider transpose of matrices. One can define the rank-metric within $\mathbb{F}_q^{t\times n}$ (see the detailed definition in Subsection 2.1). A subset $\mathcal{C}$ of $\mathbb{F}_q^{t\times n}$ equipped with rank-metric is called a rank-metric code. Unlike Hamming-metric codes, apart from rate and minimum distance there is an important parameter $\rho(\mathcal{C}) := \frac{n}{t}$ which is called the column-to-row ratio.

▶ **Definition 1.** Let $\tau \in (0, 1)$ and $L \geqslant 1$ be an integer. A rank-metric code $\mathcal{C}$ is (τ, L)-list decodable if for every $X \in \mathbb{F}_q^{t\times n}$

$$|\mathcal{B}_R(X, \tau n) \cap \mathcal{C}| \leq L,$$

where $\mathcal{B}_R(X, \tau n)$ is a rank-metric ball defined in Subsection 2.1.

Limit to list decodability of rank-metric codes and list decodability of random rank-metric codes are known [2, 15]. More precisely, we have the following result (see [2]):

- **(i)** If the ratio n/t tends to a fixed real ρ, a rank-metric code $\mathcal{C} \subseteq \mathbb{F}_q^{t\times n}$ of rate R that is (τ, L)-list decodable with $L = \text{poly}(n)$ must obey the Gilbert-Varshamov bound, i.e., $R \leqslant (1 - \tau)(1 - \rho\tau)$.
- **(ii)** With high probability a random rank-metric code can be list decoded up to the Gilbert-Varshamov bound, i.e., a random rank-metric code of rate R in $\mathbb{F}_q^{t\times n}$ is $(\tau, O(1/\varepsilon))$-list decodable with $R = (1 - \tau)(1 - \rho\tau) - \varepsilon$ for any small real $\varepsilon > 0$. In particular, if the

ratio n/t is a small constant ε, then with high probability a random rank-metric code of rate R in $\mathbb{F}_q^{t\times n}$ is $(1-R-\varepsilon, O(1/\varepsilon))$-list decodable.

Let us introduce the state-of-art results by comparing list decoding of Hamming-metric and rank-metric codes. First of all, we note that both Hamming-metric and rank-metric codes obey the Gilbert-Varshamov bounds in each metric for list decoddability. In the case of the Hamming-metric, the Gilbert-Varshamov bound is a trade-off among rate, decoding radius and alphabet size, while in the case of the rank-metric, the Gilbert-Varshamov bound is a trade-off among rate, decoding radius and column-to-row ratio. Hence, alphabet size and column-to-row ratio play the similar role for list decodability in each metric. We will see from the following paragraph that the small column-to-row ratio for list decoding of rank-metric codes is compatible with large alphabet size for list decoding of Hamming-metric codes and vice versa.

Recall that in the case of the Hamming-metric, the limit on list decodability is the Hamming-metric Gilbert-Varshamov bound $1-H_q(\tau)$, where $H_q(x)$ is the entropy function, and a random code can be list decoded up to the Hamming-metric Gilbert-Varshamov bound [5]. When alphabet size $q=\exp(\Omega(\frac{1}{\varepsilon}))$, the Hamming-metric Gilbert-Varshamov bound $1-H_q(\tau)$ tends to the Singleton bound $1-R-\varepsilon$. Currently, for list decoding of Hamming-metric codes over large alphabet q, the best result is that, for $q=O(\frac{1}{\varepsilon^2})$, by making use of folded algebraic geometry codes or algebraic geometry codes with evaluation points in subfields (for convenience let us call them subfield algebraic geometry codes) one can list decode Hamming-metric codes up to the Singleton bound $1-R-\varepsilon$ (see [10, 11, 12]). Thus, for list-decoding of Hamming-metric codes over large alphabet q, it remains an open problem to design efficient algorithm to list decode up to $1-R-\varepsilon$ for q-ary codes with $q=\Omega(\frac{1}{\varepsilon})$. On the other hand, for sufficiently small column-to-row ratio, say $\rho=O(\varepsilon)$, the rank-metric Gilbert-Varshamov also tends the Singleton bound $1-R-\varepsilon$. Furthermore, when the column-to-row ratio $\rho=O(\varepsilon^2)$, an efficient list decoding of rank-metric codes up to the Singleton bound $1-R-\varepsilon$ was introduced in [11, 12] by making use of subfield Gabidulin codes. Hence again, it remains an open problem to design efficient algorithm to list decode rank-metric codes up to $1-R-\varepsilon$ for with column-to-row ratio $\rho=\Omega(\varepsilon)$.

For the regime of small alphabets q such as $q=2$, there is not much work on efficient list decoding algorithms for Hamming-metric codes except for the concatenation techniques. Precisely speaking, by making use of concatenation technique, one can list decode binary Hamming-metric codes up to the Blokh-Zyablov bound [7]. Similarly, in the case of rank-metric codes, not much work has been done for large column-to-row ratio, in particular, for ratio $\rho=1$, i.e., the square matrix case. The largest column-to-row ratio ρ is $\frac{1}{2}$ for which the list decoding bound lies beyond the unique decoding radius. In [17], by making use of folded Gabidulin codes, one can list decode beyond the unique decoding radius $(1-R)/2$ with the column-to-row ratio ρ arbitrarily close to $1/2$.

1.2 Our result

We propose a compression technique which is the key to construct list decodable rank-metric codes with the ratio ρ up to $\frac{2}{3}$. This moves one step further towards the ratio $\rho=1$. Our list decodable rank-metric codes are obtained by compressing folded Gabidulin codes. The following theorem summarizes our main result.

▶ **Main Theorem 1.** *For every constant finite field $\mathbb{F}_q$, any small real $\varepsilon>0$ and integer $s>1$, there exists an explicit constriction of $\mathbb{F}_q$-linear rank metric codes with the ratio ρ and rate R that are $\left(\frac{1-sR}{\rho(s+1)}-\varepsilon, q^{O((s-1)^2/\varepsilon)}\right)$-list-decodable. The algorithm runs in time*

poly(n, q). *Furthermore, if* $\rho < \frac{2(1-R)}{(s+1)(1-sR)}$, *then the decoding radius* $\tau = \frac{1-sR}{\rho(s+1)} - \varepsilon$ *exceeds the unique decoding radius* $\frac{1-R}{2}$.

▶ Remark 2. If we take $s = 2$, then we get rank-metric codes of the ratio ρ and rate R that are $\left(\frac{1-2R}{3\rho} - \varepsilon, q^{O(1/\varepsilon)}\right)$-list decodable. In particular, if $\rho < \frac{2(1-R)}{3(1-2R)}$, then the list decoding radius is bigger than $(1-R)/2$. Furthermore, when the rate R tends to 0, there exists an explicit construction of rank-metric codes with any ratio $\rho < \frac{2}{3}$. Note that our decoding radius depends on the ratio ρ, while the unique decoding radius is independent of the ratio ρ. Let us draw a diagram to illustrate our main result.

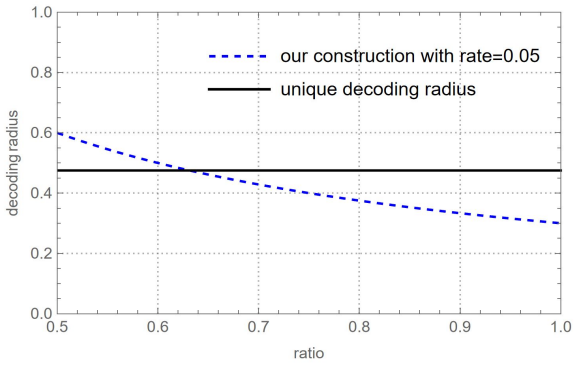

Figure 1 Comparison of our decoding radius with the unique decoding radius for different ratios.

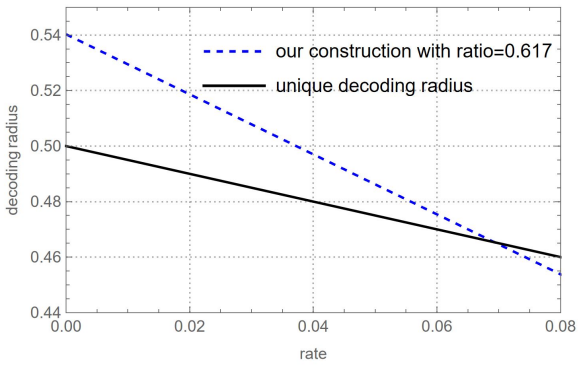

Figure 2 Comparison of our decoding radius with the unique decoding radius for different rates.

1.3 Our Techniques

In the topics of list decoding, folded codes and subfield codes are used to increase decoding radius. In the case of Hamming-metric, folding codes or taking evaluation points from a subfield increases code alphabet size, while in the case of rank-metric, folding codes or taking evaluation points from a subfield would reduce the column-to-row ratio. In the Subsection 1.1, we reviewed some techniques employed in the explicit constructions of list decodable rank-metric codes. We start from a family of list decodable rank-metric codes, i.e., folded Gabidulin codes. The list decoding algorithm for this family was already known

[11, 12, 17]. In this paper, we introduce a new technique, namely the compression technique. By combing our compression technique with the existing techniques of folded codes, we are able to increase the column-to-row ratio.

Let us illustrate our idea by combining the compression technique with the techniques of folded codes. The folded technique for list decoding of rank-metric codes was introduced in [17]. Similar to list decoding of folded Reed-Solomon codes, one can list decode folded Gabidulin codes. However, when Gabidulin codes are folded, the number of columns increases. This means that the column-to-row ratio decreases. In order to make the column-to-row ratio larger for folded Gabidulin codes, one can take a linear map that sends every element of $\mathbb{F}_{q^n}$ to a smaller $\mathbb{F}_q$-subspace of $\mathbb{F}_{q^n}$. Thus, the number of columns shrinks. At the meantime, we still want a large list decoding radius or at least a list decoding radius exceeding $(1-R)/2$. We can choose the compression map to be a linearized polynomial and use the existing linear algebra list decoding technique [8, 10, 11, 12] to achieve our goal.

1.4 Organization of the paper

In Section 2, we introduce some preliminaries including definitions of rank-metric codes and rank-metric balls, Gabidulin codes, subspace design and periodic subspaces. In Section 3, we compress folded rank-metric code and design an efficient list decoding algorithm.

2 Preliminaries

2.1 Rank-metric codes

We first introduce some basic notations and properties about rank-metric codes. Denote by $\mathbb{F}_q^{t\times n}$ the collection of all $t\times n$ matrices over $\mathbb{F}_q$. Without loss of generality, we assume that $n\leq t$ in this paper or otherwise we can consider transpose of matrices. A rank-metric code is a subset of $\mathbb{F}_q^{t\times n}$. Denote by ρ the column-to-row ratio, i.e, $\rho=\frac{n}{t}$, then we always have $\rho\leq 1$. For any $X,Y\in\mathbb{F}_q^{t\times n}$, the rank distance between X and Y is defined by

$$d_R(X,Y):=\mathrm{rank}(X-Y),$$

where rank denotes the rank of matrices. It is straightforward to verify that d_R is indeed a distance. Similar to classical block codes, we can define minimum rank distance and rate for a rank-metric code $\mathcal{C}$ by

$$d_R(\mathcal{C})=\min_{X\neq Y\in\mathcal{C}}\{\mathrm{rank}(X-Y)\}\quad \textit{and}\quad R(\mathcal{C})=\frac{\log_q|\mathcal{C}|}{nt}.$$

A rank-metric code in $\mathbb{F}_q^{t\times n}$ with $n\leqslant t$ must obey the following Singleton bound

$$d_R(\mathcal{C})\leqslant n-R(\mathcal{C})n+1. \tag{1}$$

The rank-metric ball, an analog to the Hamming ball in classical block codes, is used to count the number of matrices within a given rank distance. The formal definition is given as follows.

▶ **Definition 3.** For a real $\tau\in[0,1]$, the rank-metric ball with center $X\in\mathbb{F}_q^{t\times n}$ and distance τn is defined by

$$\mathcal{B}_R(X,\tau n):=\{Y\in\mathbb{F}_q^{t\times n}:\ d_R(X,Y)\leq\tau n\}.$$

The size of a rank-metric ball is independent of the center.

For convenience, a vector of length t over $\mathbb{F}_q$ is identified with a column vector of $\mathbb{F}_{q^t}$ under a fixed basis. Thus, a row vector in $\mathbb{F}_{q^t}^n$ can be viewed as an $t\times n$ matrix over $\mathbb{F}_q$. We denote by $d_R(\mathbf{x},\mathbf{y})$ the rank distance $d_R(X,Y)$, where $\mathbf{x},\mathbf{y}$ are vectors in $\mathbb{F}_{q^n}^t$ corresponding to X,Y, respectively.

2.2 Gabidulin codes

A code achieving the Singleton bound (1) is called Maximal Rank Distance (or MRD for short) code. The most famous MRD codes are Gabidulin codes which are defined by using polynomial evaluations.

To better understand our codes, we briefly review the construction of Gabidulin codes [4]. A polynomial of the form $f(x) = \sum_{i=0}^{\ell} a_i x^{q^i}$ is called q-linearized, where coefficients a_i belong to the algebraic closure of $\mathbb{F}_q$. The q-degree of $f(x)$, denoted by $\deg_q(f)$, is defined to be ℓ if $a_\ell \neq 0$. Denote by $\mathcal{L}_q(n,k)$ the subset

$$\mathcal{L}_q(n,k) := \left\{ \sum_{i=0}^{k-1} a_i x^{q^i} \,:\, a_i \in \mathbb{F}_{q^n} \right\}. \tag{2}$$

Then $\mathcal{L}_q(n,k)$ is an $\mathbb{F}_{q^n}$-vector space of dimension k and it is also an $\mathbb{F}_q$-vector space of dimension kn. Denote by $\mathcal{L}_q(n)$ the union $\cup_{k=1}^{\infty}\mathcal{L}_q(n,k)$, i.e., $\mathcal{L}_q(n)$ is the collection of q-linearized polynomials over $\mathbb{F}_{q^n}$.

Fix an $\mathbb{F}_q$-linearly independent set $\{\alpha_1, \ldots, \alpha_n\}$ of $\mathbb{F}_{q^t}$. For every q-linearized polynomial $f \in \mathbb{F}_{q^t}[X]$ of q-degree at most $k-1$ with $1 \leqslant k \leqslant n$, we can encode f by the row vector $\big(f(\alpha_1), \ldots, f(\alpha_n)\big)$ over $\mathbb{F}_{q^t}$. By fixing a basis of $\mathbb{F}_{q^t}$ over $\mathbb{F}_q$, we can also think of this row vector as an $t \times n$ matrix over $\mathbb{F}_q$. This yields the Gabidulin code

$$\mathcal{G}_q(n,k) := \{\big(f(\alpha_1), \ldots, f(\alpha_n)\big) \in \mathbb{F}_q^{t\times n} \,:\, f \in \mathcal{L}_q(n,k)\}. \tag{3}$$

The Gabidulin code $\mathcal{G}_q(n,k)$ is an MRD code with rate $\frac{k}{n}$ and minimum rank distance $n-k+1$.

2.3 Subspace design

Subspace design was introduced in [11] to reduce list size from a structured list. Let us recall the definition.

▶ **Definition 4.** A collection $\mathcal{S}$ of $\mathbb{F}_q$-subspaces $H_1, \ldots, H_M \subseteq \mathbb{F}_q^n$ is called an $(s, \ell, n)_q$-subspace design if for every $\mathbb{F}_q$-linear space $W \subset \mathbb{F}_q^n$ of dimension s, one has $\sum_{i=1}^{M} \dim_{\mathbb{F}_q}(H_i \cap W) \leq \ell$.

Random subspace designs are studied in [11]. Guruswami and Kopparty [6] gives an explicit subspace design based on Wronskian determinant.

▶ **Lemma 5.** *For $\varepsilon \in (0,1)$, any prime power q and positive integers s, n with $s < \varepsilon n/4$, there is an explicit collection of $M = q^{\Omega(\varepsilon n/s)}$ subspaces in $\mathbb{F}_q^n$, each of codimension at most εn and form an $(s, 2s^2/\varepsilon, n)_q$-subspace design. Moreover, bases for $N \leqslant M$ elements of this collection can be computed in time* $\mathrm{poly}(N, n, q)$.

▶ Remark 6.

(i) If $q > n$, one can improve the intersection size from $2s^2/\varepsilon$ to $2s/\varepsilon$ by applying the subspace design based on the folded Reed-Solomon directly. For $q < n$, the approach in [6] first constructed a weak subspace design and then turn this weak subspace design to a subspace design given in Definition 4. Such transformation yields a $(s, 2s^2/\varepsilon, n)$-subspace design instead of $(s, 2s/\varepsilon, n)$-subspace design.

(ii) If $s = \Omega(\log_q n)$, then a construction of subspace designs with better parameters was given in [13]. For our applications, we are interested in the case where s is a constant.

2.4 Periodic Subspaces

The periodic subspace was introduced in [10] to characterize the list of candidates outputted by the list decodable codes. By exploiting the structure of periodic subspace, they manage to cut down the list size to polynomial size at cost of losing arbitrary small rate.

For a vector $\mathbf{a} = (a_1, a_2, \ldots, a_N) \in \mathbb{F}_q^N$ and positive integers $t_1 \leqslant t_2 \leqslant m$, we denote by $\mathrm{proj}_{[t_1,t_2]}(\mathbf{a}) \in \mathbb{F}_q^{t_2-t_1+1}$ its projection onto coordinates t_1 through t_2, i.e., $\mathrm{proj}_{[t_1,t_2]}(\mathbf{a}) = (a_{t_1}, a_{t_1+1}, \ldots, a_{t_2})$. When $t_1 = 1$, we use $\mathrm{proj}_t(\mathbf{a})$ to denote $\mathrm{proj}_{[1,t]}(\mathbf{a})$. These notions are extended to subsets of strings in the obvious way: $\mathrm{proj}_{[t_1,t_2]}(S) = \{\mathrm{proj}_{[t_1,t_2]}(\mathbf{x}) : \mathbf{x} \in S\}$.

▶ **Definition 7.** For positive integers s, b, n, an affine subspace $H \subset \mathbb{F}_q^{nb}$ is $(s, n, b)_q$-periodic if there exists a subspace $W \subseteq \mathbb{F}_q^n$ of dimension at most s such that for every $j = 1, 2, \ldots, b$, and every "prefix" $\mathbf{a} \in \mathbb{F}_q^{(j-1)n}$, the projected affine subspace of $\mathbb{F}_q^n$ defined as

$$\{\mathrm{proj}_{[(j-1)n+1,jn]}(\mathbf{x}) : \mathbf{x} \in H \text{ and } \mathrm{proj}_{(j-1)n}(\mathbf{x}) = \mathbf{a}\}$$

is contained in an affine subspace of $\mathbb{F}_q^n$ given by $W + \mathbf{v_a}$ for some vector $\mathbf{v_a} \in \mathbb{F}^n$ dependent on $\mathbf{a}$.

By combining subspace design and periodic affine spaces, we can pin down list of massages in Sections 3 and 4. The detailed result is shown below and was given in [11].

▶ **Lemma 8.** *Suppose $H_1, H_2, \ldots, H_b$ is an (s, ℓ, n)-subspace design in $\mathbb{F}_q^n$, and T is a (s, n, b)-periodic affine subspace of $\mathbb{F}_q^{nb}$. Then the set $\mathcal{T} = \{(\mathbf{f_1}, \mathbf{f_2}, \ldots, \mathbf{f_b}) \in T : \mathbf{f_j} \in H_j \text{ for } j = 1, 2, \ldots, b\}$ is an affine subspace of $\mathbb{F}_q^{nb}$ of dimension at most ℓ.*

3 Compressing the folded Gabidulin codes

In this section, we introduce the compression technique and combine this technique with folded Gabidulin codes in order to increase the ratio of folded Gabidulin codes.

3.1 Encoding Algorithm

The encoding algorithm consists of two steps. The first step is to encode a linearized polynomial $f(x)$ to a codeword. In this step, we use $\alpha_1, \ldots, \alpha_n$ as the $\mathbb{F}_q$-basis of $\mathbb{F}_{q^n}$ and evaluate $f(x)$ as $(f(\alpha_1), \ldots, f(\alpha_n))$. The second step is to choose a linearized polynomial $g(x)$ whose kernel is a σn-dimensional subspace of $\mathbb{F}_{q^n}$ for some $\sigma \in (0, 1)$ when $g(x)$ is viewed as an $\mathbb{F}_q$-linear map from $\mathbb{F}_{q^n}$ to itself, then the vector

$$\Big(g(f)(\alpha_1), g(f)(\alpha_2), \ldots, g(f)(\alpha_n)\Big)$$

belongs to a smaller subspace $\mathrm{Im}(g)$, where $\mathrm{Im}(g)$ stands for the image of $g(x)$, i.e., $g(\mathbb{F}_{q^n})$. As $\mathbb{F}_{q^{(1-\sigma)n}} \cong \mathrm{Im}(g)$, the vector $(g(f)(\alpha_1), g(f)(\alpha_2), \ldots, g(f)(\alpha_n))$ can be viewed as a matrix in $\mathbb{F}_q^{(1-\sigma)n \times n}$.

The choice of $g(x)$ can be done as follows. Choose an $\mathbb{F}_q$-subspace $V \subseteq \mathbb{F}_{q^n}$ of dimension σn and define the linearized polynomial $g(x) = \prod_{v \in V}(x - v)$ over $\mathbb{F}_{q^n}$. It follows that $\dim_{\mathbb{F}_q}(\ker(g)) = \sigma n$ and $\dim_{\mathbb{F}_q}(\mathrm{Im}(g)) = (1 - \sigma)n$. For a q-linearized polynomial $a(x) = \sum_{i=0}^{\ell} a_i x^{q^i} \in \mathbb{F}_{q^n}[x]$ and $j \geqslant 0$, we denote by $a^{(j)}(x)$ the polynomial $\sum_{i=0}^{\ell} a_i^{q^j} x^{q^i}$, i.e., $a^{(j)}(x)$ is obtained from $a(x)$ by raising each coefficient to its q^j-th power.

Denote by W_j the image space of $g^{(j)}(x)$. It is clear that W_j is of dimension $(1 - \sigma)n$ as well. Therefore, one can define the $\mathbb{F}_q$-linear isomorphism $\phi_j : W_j \to \mathbb{F}_q^{(1-\sigma)n}$. Let $\mathcal{F}_k(g) := \{g(f(x)) \in \mathcal{L}_q(n) : \deg_q(f) < k\}$. The following lemma shows that if k is not too large, the elements in $\mathcal{F}_k(g)$ are distinct.

▶ **Lemma 9.** *Let $f_1(x), f_2(x)$ be linearized polynomial of q-degree at most $k-1$. If $k+\sigma n \leqslant n$, then $g(f_1(x)) = g(f_2(x))$ if and only if $f_1(x) = f_2(x)$.*

Proof. Assume that $g(f_1(x)) = g(f_2(x))$. Suppose that $f_1(x) \neq f_2(x)$. Then as a linear of map from $\mathbb{F}_{q^n}$ to $\mathbb{F}_{q^n}$, the kernel of $f_1 - f_2$ has dimension at most $k-1$. Thus, the image of $f_1 - f_2$ has dimension at least $n-k+1$. Since $g(x)$ is a q-linearized polynomial, we have

$$g(f_1(x) - f_2(x)) = g(f_1(x)) - g(f_2(x)) = 0.$$

This means that $g(f_1(x) - f_2(x))$ send every element of $\mathbb{F}_{q^n}$ to 0. Hence, $g(x)$ maps every element in the the image of $f_1 - f_2$ to 0. This implies that the image of $f_1 - f_2$ is contained in the kernel of $g(x)$. On the other hand, the dimension of the kernel of $g(x)$ is at most the q-degree of $g(x)$ which is σn. This gives that $\sigma n \geqslant n - k + 1$, i.e., $k + \sigma n \geqslant n + 1$. This contradiction shows that $f_1(x) = f_2(x)$.

The other direction is clear. The proof is completed. ◀

Given linearized polynomials $g(x)$ and $f(x)$, we denote by g_f the linearized polynomial $g(f(x))$. It is easy to see that $g_f^{(i)}(x) = g^{(i)}\big(f^{(i)}(x)\big)$. We encode $g(f(x)) \in \mathcal{F}_k(g)$ to the codeword as follows:

$$M_s(g,f) := \begin{pmatrix} \phi_0\big(g_f(\alpha_1)\big) & \phi_0\big(g_f(\alpha_2)\big) & \cdots & \phi_0\big(g_f(\alpha_n)\big) \\ \phi_1\big(g_f^{(1)}(\alpha_1)\big) & \phi_1\big(g_f^{(1)}(\alpha_2)\big) & \cdots & \phi_1\big(g_f^{(1)}(\alpha_n)\big) \\ \vdots & \vdots & \ddots & \vdots \\ \phi_{s-1}\big(g_f^{(s-1)}(\alpha_1)\big) & \phi_{s-1}\big(g_f^{(s-1)}(\alpha_2)\big) & \cdots & \phi_{s-1}\big(g_f^{(s-1)}(\alpha_n)\big) \end{pmatrix} \in \mathbb{F}_q^{(1-\sigma)sn \times n},$$

where ϕ_j is a fixed $\mathbb{F}_q$-linear isomorphism from W_j to $\mathbb{F}_q^{(1-\sigma)n}$. Therefore, $M_s(g,f)$ has $(1-\sigma)sn$ rows and n columns. Each entry in the above matrix is viewed as a row vector of $\mathbb{F}_q^{(1-\sigma)n}$.

Fix a q-linearized polynomial $g(x) \in \mathcal{L}_q(n, \sigma n)$ with the kernel of dimension σn, let $\mathcal{C}_q(n,k;s,\sigma)$ be the collection of $M_s(g,f)$ for all $f(x) \in \mathcal{L}_q(n,k)$ defined in (2).

▶ **Lemma 10.** *If $k + \sigma n \leqslant n$, then the ratio, distance and rate of $\mathcal{C}_q(n,k;s,\sigma)$ satisfy*

$$\rho = \frac{1}{(1-\sigma)s}, \quad d_R(\mathcal{C}_q(n,k;s,\sigma)) \geq n - k - \sigma n + 1, \quad \text{and} \quad R(\mathcal{C}_q(n,k;s,\sigma)) = \frac{k}{s(1-\sigma)n},$$

respectively.

Proof. The ratio is clear. Given a nonzero linearized polynomial $f(x)$, suppose that $M_s(g,f)$ has rank less than $n - k - \sigma n + 1$. The solution space U of $M_s(g,f)x^T = 0$ has dimension at least $k + \sigma n$. Then, $g_f(x)$ has at least $q^{k+\sigma n}$ roots. This implies that g_f is a linearized polynomial of q-degree at least $k + \sigma n$. However, the q-degree of g_f is upper bounded by $k + \sigma n - 1$ as the q-degree of g is σn and the q-degree of f is at most $k-1$. This is a contradiction. It is easy to see that the map $f \mapsto M_s(g,f)$ is $\mathbb{F}_q$-linear and injective, our rank-metric codes are $\mathbb{F}_q$-linear space and its size is q^{kn}. Hence, the rate of this code is $\frac{\log_q(\mathcal{C}_q(n,k,\sigma))}{s(1-\sigma)n^2} = \frac{k}{s(1-\sigma)n}$. ◀

3.2 List Decoding Algorithm

The list decoding algorithm consists of two subroutine algorithms. The first algorithm is an interpolation algorithm which outputs the interpolation polynomial that passes through all points in the vector space of the transmitted matrix. The second algorithm is a root-finding

algorithm which finds out all roots to the interpolation algorithm that belong to the message space $\mathcal{L}_q(n,k)$. However, if our message space is the whole space of $\mathcal{L}_q(n,k)$, the output of this list decoding algorithm may be exponentially large. To reduce the list size, we make use of the subspace design [6] to "re-encode" our rank-metric codes. As far as we know, this technique was the only known method to construct the explicit list-decodable rank-metric codes [17, 9]. The resulting rank-metric code is a subcode of the original rank-metric code with ε rate loss. The list size of our resulting rank-metric code is reduced to a constant $q^{O(\frac{1}{\varepsilon})}$.

Fix a positive integer $e \leq n-s$. Suppose that a codeword $M_s(g,f)$ is transmitted and $M_y = (y_{i,j})_{0\leq i\leq s-1, 1\leq j\leq n}$ is received with at most e errors, i.e., $\mathrm{rank}(M_s(g,f) - M_y) \leq e$. Our goal is to recover the linearized polynomial $f(x)$ from M_y. Note that ϕ_j is an $\mathbb{F}_q$-isomorphism for $j = 0, \ldots, s-1$. We define the matrix $M_z = (z_{i,j})_{0\leq i\leq s-1, 1\leq j\leq n}$, where $z_{i,j} = \phi_i^{-1}(y_{i,j})$. That is, we apply the inverse maps $\phi_0^{-1}, \ldots, \phi_{s-1}^{-1}$ to M_y to retrieve $sn \times n$ matrix M_z over $\mathbb{F}_q$. Define the matrix

$$M'_s(g,f) := \begin{pmatrix} g_f(\alpha_1) & g_f(\alpha_2) & \cdots & g_f(\alpha_n) \\ g_f^{(1)}(\alpha_1) & g_f^{(1)}(\alpha_2) & \cdots & g_f^{(2)}(\alpha_n) \\ \vdots & \vdots & \ddots & \vdots \\ g_f^{(s-1)}(\alpha_1) & g_f^{(s-1)}(\alpha_2) & \cdots & g_f^{(s-1)}(\alpha_n) \end{pmatrix}$$

The following lemma shows that the error $\mathrm{rank}(M_s(g,f) - M_y)$ does not amplify under the inverse maps $\phi_0^{-1}, \ldots, \phi_{s-1}^{-1}$.

▶ **Lemma 11.** *If* $\mathrm{rank}(M_s(g,f) - M_y) \leq e$, *then* $\mathrm{rank}(M'_s(g,f) - M_z) \leq e$.

Proof. Since $\mathrm{rank}(M_s(g,f) - M_y) \leq e$, the solution space $U \subseteq \mathbb{F}_q^n$ of $(M_s(g,f) - M_y)\mathbf{x}^T = \mathbf{0}$ has dimension at least $n-e$, i.e, for every $(c_1, c_2, \ldots, c_n) \in U$ and $i = 0, 1, \ldots, s-1$,

$$\phi_i\left(g_f^{(i)}\left(\sum_{j=1}^n c_j\alpha_j\right)\right) = \sum_{j=1}^n c_j\phi_i\left(g_f^{(i)}(\alpha_j)\right) = \sum_{j=1}^n c_j y_{i,j}.$$

By taking ϕ_i^{-1} on the both sides of the above identity, we get

$$g_f^{(i)}\left(\sum_{j=1}^n c_j\alpha_j\right) = \sum_{j=1}^n \phi_i^{-1}(c_j y_{i,j}) = \sum_{j=1}^n c_j\phi_i^{-1}(y_{i,j}) = \sum_{j=1}^n c_j z_{i,j}.$$

Since it holds for every $(c_1, c_2, \ldots, c_n) \in U$, we come to the conclusion that $\mathrm{rank}(M'_s(g,f) - M_z) \leq e$. ◀

Assuming $\mathrm{rank}(M_s(g,f) - M_z) \leq e$, we will show how to list decode M_z. To begin with, we introduce the interpolation polynomials.

▶ **Definition 12.** *Let* $\mathcal{L}$ *be the space of polynomials* $Q \in \mathbb{F}_{q^n}[X, Z_1, Z_2, \ldots, Z_s]$ *of the form* $Q(X, Z_1, \ldots, Z_s) = A_0(X) + A_1(Z_1) + \cdots + A_s(Z_s)$ *with each* $A_0 \in \mathcal{L}_q(n, D + k + \sigma n)$ *and* $A_i \in \mathcal{L}_q(n, D)$ *for* $i = 1, \ldots, s$.

The interpolation polynomial $Q(X, Z_1, \ldots, Z_s)$ was used to interpolate the points $(\alpha_j, z_{0,j}, \ldots, z_{s-1,j})$ for $j = 1, \ldots, n$. Since our interpolation polynomial is q-linearized, it means Q pass all points in the subspace spanned by $(\alpha_j, z_{0,j}, \ldots, z_{s-1,j})$.

▶ **Lemma 13.** *Assume that* $D > \frac{1}{s+1}(n-k-\sigma n)$. *There exists a nonzero polynomial* $Q \in \mathcal{L}$ *such that* $Q(\alpha_i, z_{0,i}, \ldots, z_{s-1,i}) = 0$ *for* $i = 1, \ldots, n$. *Furthermore,* Q *can be found in time* $poly(n, \log q)$.

Proof. We view coefficients of $A_i(X)$ as variables. Since there are n equations and $(s+1)D + k + \sigma n - 1$ unknowns in $Q(X, Z_1, \ldots, Z_s)$, we require that $(s+1)D + k + \sigma n - 1 > n$ or equivalently $D > \frac{1}{s+1}(n-k+1-\sigma n)$. Note that the n constraints amount to n linear equations. This implies that we can interpolate polynomial Q in running time $O(n^3)$ by Gauss elimination. Moreover, as long as the number of unknowns is bigger than the number of equations, there exists a nonzero polynomial Q satisfying all these n constraints. ◀

We next prove that those codewords with small distance from M_z are the roots of Q. Then, it remains to design a root-finding algorithm to find all the roots of Q.

▶ **Lemma 14.** *Let* $g_f \in \mathcal{F}_k(g)$ *be a* q*-linearized polynomial. If* $\mathrm{rank}(M'_s(g,f) - M_z) \le e$ *and* $D + k + \sigma n - 1 < n - e$, *then* $Q(x, g_f(x), g_f^{(1)}(x), \ldots, g_f^{(s-1)}(x)) = 0$.

Proof. The condition that $\mathrm{rank}(M'_s(g,f) - M_z) \le e$ implies that there exists an $\mathbb{F}_q$-linear subspace U of dimension at least $n-e$ such that for every $(c_1, c_2, \ldots, c_n) \in U$, we have $\sum_{j=1}^n c_j z_{i,j} = \sum_{j=1}^n c_j g_f^{(i)}(\alpha_j)$ for all $i = 0, 1, \ldots, s-1$. This gives

$$\begin{aligned} 0 &= \sum_{j=1}^n c_j Q(\alpha_j, z_{0,j}, \ldots, z_{s-1,j}) = Q\left(\sum_{j=1}^n c_j\alpha_j, \sum_{j=1}^n c_j z_{0,j}, \ldots, \sum_{j=1}^n c_j z_{s-1,j}\right) \\ &= Q\left(\sum_{j=1}^n c_j\alpha_j, \sum_{j=1}^n c_j g_f(\alpha_j), \ldots, \sum_{j=1}^n c_j g_f^{(s-1)}(\alpha_j)\right) \\ &= Q\left(\sum_{j=1}^n c_j\alpha_j, g_f\left(\sum_{j=1}^n c_j\alpha_j\right), \ldots, g_f^{(s-1)}\left(\sum_{j=1}^n c_j\alpha_j\right)\right) \end{aligned}$$

Note that g_f is a linearized polynomial of q-degree at most $k + \sigma n - 1$. Then, $Q(x, g_f(x), \ldots, g_f^{(s-1)}x)$ is a q-linearized polynomial of q-degree at most $D + k + \sigma n - 1$ which is less than the dimension $n - e$ of the kernel. It must be the case that $Q(x, g_f(x), \ldots, g_f^{(s-1)}(x)) = 0$. ◀

▶ **Theorem 15.** *If* $e \le \frac{s}{s+1}((1-\sigma)n - k)$, *then* $Q(x, g_f(x), \ldots, g_f^{(s-1)}x) = 0$ *holds for all linearized polynomials* $g_f(x)$ *with* $rank(M'_{g_f} - M_z) \le e$.

Proof. Set $D = \left\lfloor \frac{1}{s+1}(n-k-\sigma n) + 1 \right\rfloor$. Then Lemma 14 ensures existence of a polynomial $Q(X, Z_1, \ldots, Z_s)$ passing through points $(\alpha_i, z_{0,i}, \ldots, z_{s-1,i})$ for $i = 1, \ldots, n$. Furthermore, Lemma 13 ensures that all linearized polynomials $g_f(x)$ with $\mathrm{rank}(M'_s(g,f) - M_z) \le e$ is a solution to $Q(x, g_f(x), \ldots, g_f^{(s-1)}x) = 0$. This completes the proof. ◀

Recall that the rate of $\mathcal{C}_q(n, k; s, \sigma)$ is $R := \frac{k}{s(1-\sigma)n}$. Plugging $k = sR(1-\sigma)n$ into the expression of $e \le \frac{s}{s+1}((1-\sigma)n - k)$, we obtain the list decoding radius $\tau = \frac{s}{s+1}(1-\sigma)(1-sR)$. As the ratio $\rho = \frac{1}{(1-\sigma)s}$, τ can be expressed as $\frac{1-sR}{\rho(s+1)}$ in terms of the ratio ρ. If we want that the list decoding radius τ exceeds the unique decoding, i.e., $\tau > \frac{1-R}{2}$, then the rate R must satisfy $R < \frac{2-(s+1)\rho}{2s-(s+1)\rho}$. This implies that $\rho < \frac{2}{s+1}$.

If we set $s = 2$, then for any ratio $\rho \in (0, \frac{2}{3})$, we obtain a list decodable rank-metric code of the ratio ρ that exceeds the unique decoding radius $\frac{1-R}{2}$. However, we still need to make sure that the list size of this code is at most polynomial in q, n and there exists explicit list

decoding algorithm to find all candidates. The following lemma tells us the structure of the solutions to $Q(x, g_f(x), g_f^{(1)}(x), \ldots, g_f^{(s-1)}(x)) = 0$. We follow the idea given in [9] to show how to obtain the structure of $g(f(x))$ from Q via the root-finding algorithm.

▶ **Lemma 16.** *Let* $a(x) = \sum_{i=0}^{\sigma n+k-1} a_i x^{q^i} \in \mathcal{L}_q(n)$. *Then the set of solutions* $(a_0, a_1, \ldots, a_{\sigma n+k-1})$ *to the equation*

$$Q(x, a(x), a^{(1)}(x), \ldots, a^{(s-1)}(x)) = 0 \tag{4}$$

forms an $(s-1, n, \sigma n + k - 1)$*-periodic subspace.*

Proof. Let $D = \left\lfloor \frac{1}{s+1}(n-k-\sigma n) + 1 \right\rfloor$. Note that we have already recovered $A_0(x), \ldots, A_s(x)$ by interpolation that satisfy the indentity

$$Q(x, a(x), a^{(1)}(x), \ldots, a^{(s-1)}(x)) = A_0(x) + A_1(a(x)) + \cdots + A_s(a^{(s-1)}(x)) = 0. \tag{5}$$

Assume that $A_0(X) = \sum_{i=0}^{D+k+\sigma n-1} b_{0,i} x^{q^i}$ and $A_j(x) = \sum_{i=0}^{D-1} b_{j,i} x^{q^i}$. If $b_{0,0}, \ldots, b_{s,0}$ are all zero, then (5) gives a new identity $(A_0'(x) + A_1'(a(x)) + \cdots + A_s'(a^{(s-1)}(x)))^q = 0$, i.e.,

$$A_0'(x) + A_1'(a(x)) + \cdots + A_s'(a^{(s-1)}(x)) = 0 \tag{6}$$

with $\deg_q(A_i) \geqslant \deg_q(A_i')$ for all $i = 0, 1, \ldots, s$. Moreover, not all A_i' are zero polynomials. Thus, without loss of generality, we may assume that at least one of $b_{0,0}, \ldots, b_{s,0}$ is nonzero.

Let $a(x) = \sum_{i=0}^{k+\sigma n-1} a_i x^{q^i}$, where $a_i \in \mathbb{F}_{q^n}$ are variables. Plugging the expression of $a(x)$ into (5) and compareing the coefficient of x on both sides give

$$b_{0,0} + \sum_{i=0}^{s-1} b_{i+1,0} a_0^{q^i} = 0. \tag{7}$$

The solution a_0 to $b_{0,j} + \sum_{i=0}^{s} b_{i,j} a_0^{q^{i-1}} = 0$ is an affine subspace of dimension at most $s-1$. For $i = 0, \ldots, k + \sigma n - 1$, define the linearized polynomial

$$B_i(x) = \sum_{j=1}^{s-1} b_{j,i} x^{q^j}.$$

Our assumption shows $B_0(x) \neq 0$. The solutions $\beta \in \mathbb{F}_{q^n}$ to $B_0(x)$ forms a subspace W of dimension at most $s-1$. Fix $i \in \{0, \ldots, k + \sigma - 1\}$. By comparing the coefficient of x^{q^i} in Equation (5), we get

$$b_{0,i} + B_i(a_0^{q^i}) + B_{i-1}(a_1^{q^{i-1}}) + \cdots + B_1(a_{i-1}^q) + B_0(a_i) = 0.$$

This implies $a_i \in W + \theta_i$ for some $\theta_i \in \mathbb{F}_{q^n}$ that is determined by $a_0, \ldots, a_i$. Thus, each choice of a_{i-1} is contained in the coset of W. The proof is completed. ◀

▶ Remark 17. For each a_i, we may have q^{s-1} solutions. Thus, the list of candidate $g_f(x)$ could be exponentially large. To cut down the list size, we pick a subspace of $\mathcal{L}_q(n,k)$ by subspace design. By imposing some constraints on our codeword, we can prune the list to a constant size. We leave it to the next subsection.

Assume that we are given a solution $a(x)$ to $Q(x, a(x), a^{(1)}(x), \ldots, a^{(s-1)}(x))$. Next lemma shows how to obtain $f(x)$ from $a(x)$. Note that not all solutions to

$$Q(x, a(x), a^{(1)}(X), \ldots, a^{(s-1)}(x)) = 0$$

are of the form $g(f(x))$.

▶ **Lemma 18.** *Given a linearized polynomial $a(x)$ of q-degree at most $k+\sigma n-1$, we can find in time $O(n^2)$ whether there exists an unique linearized polynomial $f(x)$ of q-degree at most $k-1$ such that $a(x)=g(f(x))$. Furthermore, $f(x)$ can be uniquely determined if it exists.*

Proof. Let $a(x)=\sum_{i=0}^{k+\sigma n-1} a_i x^{q^i}$, $f(x)=\sum_{i=0}^{k-1} f_i x^{q^i}$ and $g(x)=\sum_{i=0}^{\sigma n} g_i x^{q^i}$. Suppose that $a(x)=g(f(x))$. It follows that

$$a(x)=\sum_{i=0}^{\sigma n} g_i f(x)^{q^i}.$$

Comparing the coefficient of x on both sides, we get $f_0 g_0 = a_0$. Recall that the roots of $g(x)$ form a σn-dimensional subspace which implies $g(x)$ has $q^{\sigma n}$ different roots including 0. This implies g_0 is nonzero and thus f_0 is uniquely determined. Assume that $f_0,\dots,f_{i-1}$ are determined. We compare the coefficient of x^{q^i} on both sides

$$a_i = g_0 f_i + g_1 f_{i-1} + g_2 f_{i-2} + \cdots + g_i f_0.$$

Thus, f_i is uniquely determined. After all coefficients of $f(x)$ are determined, we check whether $a(x)=g(f(x))$. If the equation holds, $f(x)$ is the unique solution. Otherwise, there do not exist any solutions. It is easy to see that all operations run in time $O(n^2)$. ◀

3.3 Prune the list

We follow the standard list decoding procedure introduced in [10, 11, 12] to pre-encode and prune the list size.

▶ **Theorem 19.** *For every finite field $\mathbb{F}_q$, small real $\gamma>0$ and integer $s>1$, there exists an explicit constriction of $\mathbb{F}_q$-linear rank metric codes with the column-to-row ratio ρ and rate R that are $\left(\frac{(1-sR)}{\rho(s+1)}-\gamma, q^{O((s-1)^2/\gamma)}\right)$-list-decodable. The algorithm runs in time poly(n,q). Furthermore, if $\rho<\frac{2}{s+1}$, then the decoding radius $\tau=\frac{(1-sR)}{\rho(s+1)}-\gamma$ exceeds the unique decoding radius $\frac{1-R}{2}$.*

Proof. Note that the message space of our rank metric code is $\mathcal{F}_k(g)=\{g(f):\ f\in\mathcal{L}_q(n,k)\}$. Lemma 5 says that there exists an explicit construction of $((s-1),2(s-1)^2/\varepsilon,n)_q$-subspace design $H_0,\dots,H_{\sigma n+k-1}\subseteq\mathbb{F}_{q^n}$, each has the $\mathbb{F}_q$-dimension $n(1-\varepsilon)$. Define the polynomial set $\mathcal{S}=\{h(x)=\sum_{i=0}^{\sigma n+k-1} h_i x^{q^i} : h_i\in H_i\}$. Our new message space is $\mathcal{F}'_k(g)=\mathcal{F}_k(g)\cap\mathcal{S}$. Note that

$$\begin{aligned}
&\dim_{\mathbb{F}_q}(\mathcal{F}'_k(g)) = \dim_{\mathbb{F}_q}(\mathcal{F}_k(g)) + \dim_{\mathbb{F}_q}(\mathcal{S}) - \dim_{\mathbb{F}_q}(\mathcal{F}_k(g)+\mathcal{S})\\
&\geqslant \dim_{\mathbb{F}_q}(\mathcal{F}_k(g)) + \dim_{\mathbb{F}_q}(\mathcal{S}) - \dim_{\mathbb{F}_q}(\mathbb{F}_{q^n}^{\sigma n+k})\\
&= kn + (\sigma n+k)(1-\varepsilon)n - (\sigma n+k)n = n(k-\varepsilon(\sigma n+k))
\end{aligned}$$

Given a linearized polynomial $g(f(x))\in\mathcal{F}'_k(g)$, we encode it into the codeword $M_s(g,f)$. The new rank-metric code becomes $\mathcal{C}'(n,k;s,\sigma)$. The rate of this code is $R=\frac{n(k-\varepsilon(\sigma n+k))}{n^2 s(1-\sigma)}=\frac{1}{1-\sigma}\left(\frac{k}{n}-\frac{\varepsilon}{s}\left(\sigma+\frac{k}{n}\right)\right)\geqslant\frac{1}{1-\sigma}\left(\frac{k}{n}-\varepsilon\right)=R'-\frac{\varepsilon}{1-\sigma}$ where R' is the rate of $\mathcal{C}(n,k;s,\sigma)$ in Lemma 10.

Since our new code is a subcode of the rank metric code proposed in the Subsection 3.1. The same encoding and list decoding algorithm can be applied to this code. Assume that there are at most $\tau n=\frac{(1-sR')n}{\rho(s+1)}$ rank errors, Lemma 16 says that all candidates $(a_0,\dots,a_{\sigma n+k-1})\in\mathcal{F}_k(g)$ are contained in an $(s-1,n,\sigma n+k)$-periodic subspace. This implies that the collection of such candidates $(a_0,\dots,a_{\sigma n+k-1})\in\mathcal{F}'_k(g)$ is contained in an

affine space of dimension at most $(s-1)^2/\varepsilon$ followed by the property of subspace design Lemma 8. This implies there are at most $q^{(s-1)^2/\varepsilon}$ codewords in the list. Put $\gamma = \frac{2\varepsilon s}{\rho(1-\sigma)(s+1)}$, then $\tau = \frac{(1-sR')}{\rho(s+1)} = \frac{(1-sR)}{\rho(s+1)} - \gamma$.

It takes at most $O(n^3 q^{(s-1)^2/\gamma})$ time to find all candidates. Thus, this list decoding algorithm runs in polynomial time. Our proof is completed. ◀

Abstract

In the Min k-Cut problem, the input is a graph G and an integer k. The task is to find a partition of the vertex set of G into k parts, while minimizing the number of edges that go between different parts of the partition. The problem is NP-complete, and admits a simple $3^n \cdot n^{\mathcal{O}(1)}$ time dynamic programming algorithm, which can be improved to a $2^n \cdot n^{\mathcal{O}(1)}$ time algorithm using the fast subset convolution framework by Björklund et al. [STOC'07]. In this paper we give an algorithm for Min k-Cut with running time $\mathcal{O}((2-\varepsilon)^n)$, for $\varepsilon > 10^{-50}$. This is the first algorithm for Min k-Cut with running time $\mathcal{O}(c^n)$ for $c < 2$.

1 Introduction

A *k-cut* of a graph G is a partition of the vertex set $V(G)$ into k non-empty parts. The *weight* of a k-cut is the total number of edges with endpoints in different parts of the partition. In the Min k-Cut problem the input is a graph G on n vertices and m edges, and an integer k. The task is to find a k-cut of G of minimum weight.

The problem is known to be NP-complete [23] and is extremely well studied from the perspective of approximation algorithms [42, 47, 48], parameterized algorithms [35, 13, 15], extremal combinatorics [33, 27, 28], and more recently parameterized approximation [26, 25, 34, 40]. For all of the above perspectives the best known algorithmic results come quite close to asymtotically matching existing combinatorial or complexity theoretic lower bounds: On one hand, there are several $2(1-\frac{1}{k})$-approximation algorithms that run in time polynomial in n and k [42, 47, 48]. On the other hand, this approximation ratio cannot be improved assuming the Small Set Expansion Hypothesis (SSE) [41]. A $(1+\epsilon)$-approximation algorithm with running time $(k/\epsilon)^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$ was recently obtained by Lokshtanov et al. [40], the running time of this algorithm cannot be substantially improved without violating the Exponential Time Hypothesis (ETH).

The fastest known algorithm with parameter k by Gupta et al. [25] runs in time $\mathcal{O}(f(k)n^{k+o(1)})$. At the same time, an algorithm with running time $\mathcal{O}(f(k)n^{(1-\epsilon)\frac{\omega}{3}+o(1)})$ for $\epsilon > 0$, where $\omega < 2.373$ [2] is the matrix multiplication exponent, would imply an improved algorithm for k-Clique. An $\mathcal{O}(f(k)n^{(1-\epsilon)k+o(1)})$ time algorithm for $\epsilon > 0$ for the edge weighted version of Min k-Cut would imply an improved algorithm for Max-Weight k-Clique. This has been conjectured not to exist [1, 3]. The algorithm of Gupta et al. [27, 28] also proves that the number of minimum weight k-cuts in a graph is upper bounded by $\mathcal{O}(f(k)n^{k+o(1)})$, coming very close to matching the $(n/k)^k$ lower bound obtained from the complete k-partite graph.

While exact algorithms for Min k-Cut for small values of k have received considerable attention since the early 1990's [23], exact exponential time algorithms whose running time is measured in terms of the number n of vertices only remain largely unexplored.

Naive Algorithm. A simple $3^n n^{\mathcal{O}(1)}$ time algorithm can be obtained by reduction to finding a minimum weight path on exactly k edges in the following directed acyclic graph S_G: The graph S_G has a vertex for every subset X of $V(G)$. For every pair X, Y of vertex subsets, S_G has an edge from X to Y if X is a subset of Y. The weight of this edge is the number of edges in G with one endpoint in X and the other in $Y \setminus X$. It is easy to see that S_G is a directed acyclic graph, and that there is a one to one correspondence between k-cuts in G and paths from $\emptyset$ to $V(G)$ in S_G using exactly k edges. The graph S_G has 2^n vertices and 3^n edges because every edge XY in S_G corresponds to a partition of $V(G)$ into 3 parts, namely $(X, Y \setminus X, V(G) \setminus Y)$. Finding a minimum weight path using exactly k edges in a DAG can be done in time $\mathcal{O}(k(|V(S_G)| + |E(S_G)|)) = 3^n n^{\mathcal{O}(1)}$. Note that this beats $\mathcal{O}(n^k)$ time algorithms for instances where $k \geq \frac{2n}{\log n}$.

In 2009 Björklund et al. [9] gave a general purpose approach, based on the inclusion-exclusion principle, to solve partitioning problems in $2^n n^{\mathcal{O}(1)}$ time. Their applications (see [9, Proposition 6]) include a $2^n n^{O(1)}$ time algorithm for Min k-Cut. Prior to this work the algorithm of Björklund et al. [9] has remained the state of the art.

When the best algorithm for a well-studied problem is stuck at 2^n for a long time it is prudent to ask whether it is possible to do better at all, or whether 2^n really is the best possible. On one hand, better than 2^n time algorithms have been found for a number of problems, including, among many others k-SAT [49, 46] and the satisfiability problem for a number of circuit classes [10, 39, 38], Hamiltonian Cycle [4], k-Coloring for $k \in \{3, 4, 5, 6\}$ [19, 57], Bin Packing [45], Max-Cut [51], Chordal Vertex Deletion [11], Treewidth [21] and Scheduling Partially Ordered Jobs [17]. On the other hand the failure to find better than 2^n time algorithms for the satisfiability of CNF formulas and Set Cover has led to conjectures [14, 31] that no substantially better algorithms for these problems are possible, driving the field of fine-grained complexity [53, 54, 52]. For problems such as Directed Hamiltonicity, Travelling Salesman and Chromatic Number, obtaining better than 2^n time algorithms are outstanding open problems [20, 44, 55, 56]. In this paper we give the first algorithm for Min k-Cut with running time $\mathcal{O}((2-\varepsilon)^n)$ for $\varepsilon > 0$.

▶ **Theorem 1.** *There exists an algorithm that takes as input an unweighted simple graph G on n vertices, an integer $k > 0$ and returns the min k-cut of G in time $\mathcal{O}(2-\varepsilon)^n$ for some $\varepsilon > 0$.*

Observe that Theorem 1 only considers *unweighted simple graphs*. For Min k-Cut on *weighted* graphs, previous to our work, the best algorithm was the $\mathcal{O}(2^n W^{O(1)})$ time algorithm of Björklund et al. [9]. Our naive $\mathcal{O}(3^n)$ time algorithm described above can

easily be made to work for weighted graphs with running time $3^n(\log W)^{\mathcal{O}(1)}$. As part of the proof of Theorem 1 we make an alternative algorithm for weighted graphs that runs in time $2^{n+o(n)}(\log W)^{\mathcal{O}(1)}$.

▶ **Theorem 2.** *There exists an algorithm that takes as input an edge-weighted graph G on n vertices having weights on edges from $[0, W]$, an integer $k > 0$ and returns the min k-cut of G in time $2^{n+o(n)}(\log W)^{\mathcal{O}(1)}$.*

Theorem 2 is the current best algorithm for Min k-Cut for the weighted case. A natural question that arises here is whether one can improve the running time to $(2-\epsilon)^n(\log W)^{\mathcal{O}(1)}$. The answer seems to be leaning towards a no, or at the very least towards a "that's a pretty difficult question". From the perspective of $(2-\epsilon)^n$ time algorithms it is folklore that (Edge Weighted) Densest Subgraph is at least as hard as Edge Weighted Clique. In the latter problem the goal is to find a maximum weight clique in an edge weighted graph having edge weights that may be positive, negative, or even exponential in n. The best known algorithms for Edge Weighted Clique are $2^n \cdot (\log W)^{\mathcal{O}(1)}$ and $2^{\frac{\omega}{3}n}W^{\mathcal{O}(1)}$, where W is the maximum edge weight and ω is the matrix multiplication exponent. Edge Weighted Clique is a basic problem - n^k hardness of the problem is a conjecture that is sometimes used as a basis for hardness in fine grained complexity [1, 3]. From here it is not too big of a leap to conjecture that it is hard to get $(2-\epsilon)^n \cdot (\log W)^{O(1)}$ time algorithms as well. So it makes a lot more sense to focus on a $(2-\epsilon)^n \cdot (\log W)^{O(1)}$ time algorithm for Edge Weighted Clique before attempting such an algorithm for (Edge Weighted) Min k-Cut.

At a very high level our algorithm for Min k-Cut is based on a dynamic programming algorithm operating on a pruned state space having less than 2^n states. Based on how the input instance and optimal solution look, we use different methods to prune the state space. We show that the cases for which such pruning strategies don't work are "Densest t-Subgraph instances in disguise" with the optimal solution having only one non-singleton part. Here we apply the $\mathcal{O}(2^{\frac{\omega n}{3}}n^{\mathcal{O}(1)})$ time matrix multiplication based algorithm for Densest t-Subgraph by Chang et.al. [12]. The final running time is just the maximum over the running time of the algorithms we design for the various cases we consider. Our algorithm carefully balances various tools and techniques from past work on Min k-Cut, graph theory and the exact algorithms world. This includes DP table sparsification, Thorup tree packing, split and list, graph sparsification, as well as the $\binom{p+q}{p}$ combinatorial bound for the number of connected vertex sets of size p with q neighbors.

Admittedly our algorithm chops the input space into various pieces based on the properties of the input instance and the optimal solution and thus uses quite a handful of cases. One might ask to which degree this amount of case work is necessary. At the very least, the same reduction[1] that showed that *weighted* Min k-Cut is at least as hard as *weighted* Densest t-Subgraph shows that *unweighted* Min k-Cut is at least as hard as *unweighted* Densest t-Subgraph. The only known $(2-\epsilon)^n$ time algorithm [12] for Densest t-Subgraph is based on the Split and List method of Williams [51]. Therefore, the set of inputs to Min k-Cut contains both "Densest t-Subgraph instances in disguise", as well as instances that behave very differently. For an example instances with a few large cliques with few edges between each other behave much more like instances of classic "cut and separation" or clustering problems, and do not appear to be solvable by Split and List based approaches. Hence, a $(2-\epsilon)^n$ algorithm for unweighted Min k-Cut either has to invent a new method for Densest t-Subgraph (which is a very interesting research goal in and of itself) or somehow

[1] To reduce from Densest t-Subgraph to Min k-Cut, add a universal vertex and set $k = n + 2 - t$.

separate the instances of Min k-Cut into ones that are "Densest t-Subgraph instances in disguise" and the ones that can be handled by other means. Of course this only justifies the split into two cases, as opposed to our rather large case tree. It is a nice open problem whether it is possible to handle all of the non-Densest t-Subgraph instances in a more uniform way. This would likely also result in a better running time bound.

We remark that the improvement over 2^n obtained in Theorem 1 is small and holds only for unweighted simple graphs. But importantly it shows that 2^n is not the boundary for Min k-Cut. We hope that this work will initiate a line of research on exact algorithms for Min k-Cut just as the $(2-\epsilon)$-approximation by Gupta et.al [26] kick started a series of work [25, 34, 40] on FPT approximation for Min k-Cut, or the $\mathcal{O}(k^{\mathcal{O}(k)}n^{(\frac{2\omega}{3}+o(1))k})$ time algorithm of Gupta et al. [25] led to a chain of improvements [37, 27, 29, 30] for $n^{\mathcal{O}(k)}$ time algorithms for the problem.

1.1 Algorithm Overview

The first substantial hurdle in designing an algorithm for Min k-Cut that beats the bound of 2^n, is that even getting an algorithm with running time 2^n is non-trivial. The Min k-Cut problem is a graph partitioning problem, and thus the first approach to design an algorithm for Min k-Cut is to explore methods developed for such problems. All known general methods for set partitioning problems, such as those developed by Björklund et al. [9, 5], rely on enumerating all vertex subsets. Known approaches to speed up such methods rely on the input graph being sufficiently sparse, such as having bounded degree or bounded average degree [6, 7, 8, 16, 24]. As we cannot make any such assumptions here we first design an alternative stand-alone $2^{n+o(n)}$ time algorithm that does not make use of the methods for set partitioning problems of Björklund et al. [9].

Our new $2^{n+o(n)}$ time algorithm is based on the fact that Min k-Cut is solvable in time $n^{\mathcal{O}(k)}$. Note that the running time of the naive algorithm, based on a reduction to finding a minimum weight path on exactly k edges in the state graph S_G, is 3^n because S_G has many edges. If we restrict ourselves to only using edges of S_G that correspond to parts of size at most $\mathcal{O}(\frac{n}{\log n})$, then the out-degree of every vertex in the state graph drops to $2^{o(n)}$, leading to an algorithm of running time $2^{n+o(n)}$, that computes for every subset $S \subseteq V(G)$ and integer $k \leq n$ the best way of partitioning S into k parts, each of size at most $\frac{n}{\log n}$. After doing this, in order to find the best partition of $V(G)$ that may or may not use large parts (i.e parts bigger than $\frac{n}{\log n}$), we go over all choices of S and find the best partition of $V(G) \setminus S$ using the $n^{\mathcal{O}(k)}$ time algorithm of Thorup [50]. Since, all the parts in $V(G) \setminus S$ are large we only need to invoke the $n^{\mathcal{O}(k)}$ time algorithm with $k = \mathcal{O}(\log n)$. In the remainder of this outline, when we talk about the state graph S_G we will refer to the *sparsified* state graph with only $2^{n+o(n)}$ edges whose paths correspond to cuts with parts of size at most $\frac{n}{\log n}$

To design an algorithm for Min k-Cut with running time $\mathcal{O}((2-\varepsilon)^n)$, for some fixed $\varepsilon > 0$, we consider many special cases and design faster algorithms for each individual case. Some of the cases are handled by standard methods, while some require interesting new insights. In Figure 1 we provide a case tree depicting the various cases our algorithm branches into - we suggest the reader to refer to the case tree while reading the overview to get a complete picture. The first case we consider is when $k < 0.24n$. Here, k is so small that one would expect ideas from the $n^{\mathcal{O}(k)}$ time algorithm to apply, but too large to use them as black boxes because this leads to a running time of $n^{\mathcal{O}(n)}$. We use the main object behind the deterministic $n^{\mathcal{O}(k)}$ time algorithm, namely Thorup trees [50].

Thorup's algorithm is based on a tree-packing theorem which allows to efficiently find a tree T that crosses the optimal k-cut at most $2k-2$ times. Using T one can design a $\binom{n}{2k}3^{2k}$ time algorithm [50]. If $k < 0.24n$ then we can pick a random edge e from the tree and

declare that it is not part of the cut. We know that we fail (i.e. that we picked an edge from the optimal solution) with probability at most $\frac{2k}{n} \leq 0.48$. However, if we succeed we can contract the edge e, leading to an instance with $n-1$ vertices. Standard running-time/success probability trade-offs now yield that the running time of our algorithm is upper bounded by the recurrence $T(n) \leq \frac{T(n-1)}{0.52}$, which solves to $\mathcal{O}(1.93^n)$. Since we aim for a deterministic algorithm, instead of picking edges at random we directly use a pseudo-random construction from [18] instead.

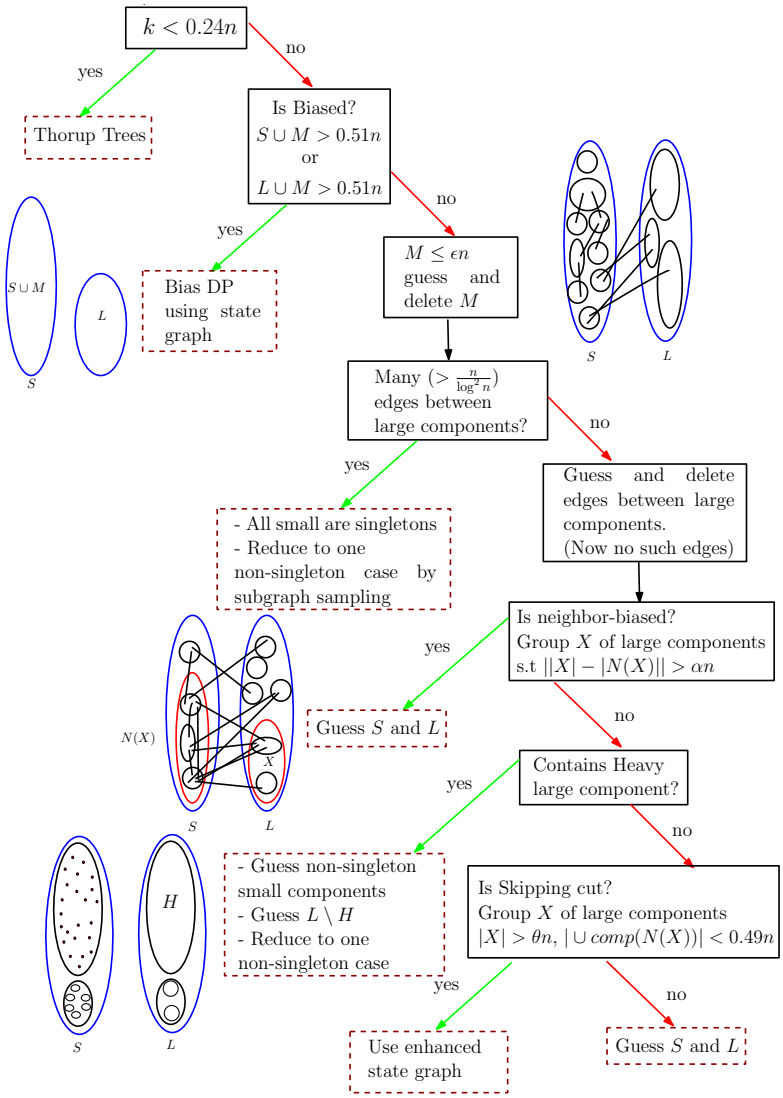

Figure 1 Case Tree depicting the various cases our algorithm branches into. Leaf cases are denoted by dotted brown boxes. Supporting figures are inserted to visualize the cases. The notation $\cup comp(N(X))$ denotes the set of all vertices in components having vertices from $N(X)$.

From now onwards we assume that $k \geq 0.24n$. Let C be a hypothetical solution, that is, an optimum k-cut. We split the parts of the solution into small, medium, and large, as follows. A component is said to be *small* if its size is at most $\log n$, *medium* if its size is greater than $\log n$ and less than $\frac{n}{\log n}$, and *large* if its size is at least $\frac{n}{\log n}$. Given a cut C

of G, we denote the set of all vertices in small, medium, and large components in C by S, M and L, respectively. The next case we deal with is that $|S|$ is at most $n(\frac{1}{2}-\epsilon)$. Here, our main observation is that we can make the $2^{n+o(n)}$ time algorithm already run in time $\mathcal{O}((2-\varepsilon)^n)$; only build the state graph, S_G, for vertex sets of size at most $n(\frac{1}{2}-\epsilon)$. For each choice of S use the $\binom{n}{2k}3^{2k}$ time algorithm to find the best partition of $V(G)\setminus S$ into medium and large size parts. Since, $k \leq \frac{n}{\log n}$, the $\binom{n}{2k}3^{2k}$ time algorithm runs in time $(\frac{en}{n/\log n})^{n/\log n}3^{\mathcal{O}(n/\log n)} = 2^{o(n)}$.

The next case we handle is when $|S \cup M| \geq n(\frac{1}{2}+\epsilon)$. This is the first interesting case. We use the fact that $k > 0.24n$ to infer that there are many small parts. Indeed, observe that at most $0.2n$ parts of C can have size at least 5. Thus, at least $0.04n$ parts of C have size at most 4. To handle this case we extend the idea of Koivisto [36] for speeding up the algorithm for Set Cover when all sets are small (also see the recent generalization by Nederlof [43]). This case is similar to the Set Cover case handled by Nederlof in [43] and our algorithm is based on ideas similar to those used in [36, 43, 45]. Nevertheless we are not able to directly apply these results (it would not be surprising to us if the *methods* used in [43] do apply in this setting).

Specifically, our algorithm proceeds as follows, we pick uniformly at random a set Q, which has the following properties with probability close to 1.

- $|Q| = \frac{n}{2} \pm o(n)$,
- $|Q \cap (S \cup M)| = \frac{|S\cup M|}{2} \pm o(n)$
- At least $\frac{n}{100} - o(n)$ parts P of C of size at most 10 satisfy that $|P \setminus Q| > |P \cap Q|$.
- At least $\frac{n}{100} - o(n)$ parts P of C of size at most 10 satisfy that $|P \setminus Q| < |P \cap Q|$.

Consider now the *ordered* partition **of parts in** C in which: all parts with $|P \cap Q| > |P \setminus Q|$ come first, ordered by size (smaller parts first). Then come all parts P with $|P \cap Q| = |P \setminus Q|$ in any order, followed by all parts with $|P \cap Q| < |P \setminus Q|$ ordered by size (this time smaller parts last). A simple counting argument shows that the path C' in the state graph that corresponds to this ordered partition only visits sets X with the following property:

- $|X| \leq n(\frac{1}{2} - \frac{\epsilon}{10})$ or,
- $|X| \geq n(\frac{1}{2} + \frac{\epsilon}{10})$ or,
- $|X \cap L| \geq \frac{n}{2}(\frac{1}{2} + \frac{\epsilon}{100})$

Thus, to find the path C' we only need to build the subgraph of the state graph with vertices of the three types above. The total number of vertices of this types is upper bounded by $\mathcal{O}((2-\varepsilon)^n)$, leading to an improved algorithm.

The instances not handled by any of the previously discussed cases must satisfy: $k > 0.24n$, $|S|$ and $|L|$ are both between $n(\frac{1}{2}-\epsilon)$ and $n(\frac{1}{2}+\epsilon)$, and $|M|$ is at most $2\epsilon n$. Note that we (the algorithm designers) have control over ϵ and we can choose it as small as we like. The price we pay is that as ϵ becomes smaller the running time of our algorithm comes closer and closer to 2^n. This prevents us from choosing $\epsilon = o(1)$. We design an algorithm with running time $\mathcal{O}((2-\delta)^n)$ for instances where $|S|$ and $|L|$ are both between $n(\frac{1}{2}-\tau)$ and $n(\frac{1}{2}+\tau)$ and $M = \emptyset$. This implies a $\mathcal{O}((2-\epsilon)^n)$ time algorithm for the case where $|M| \leq 2\epsilon n$, whenever ϵ is small enough compared to δ. We can just guess M, run the $n^{\mathcal{O}(k)}$ algorithm on $G[M]$ and run the $\mathcal{O}((2-\delta)^n)$ time algorithm on $G - M$. The total running time is at most $\mathcal{O}(\binom{n}{2\epsilon n}(2^{o(n)} + (2-\delta)^n))$, which beats 2^n whenever ϵ is small enough.

We now turn our attention to the case when $k > 0.24n$, $|S|$ and $|L|$ are both between $n(\frac{1}{2}-\epsilon)$ and $n(\frac{1}{2}+\epsilon)$, and $M = \emptyset$. Our initial intuition was that it should not be too hard to extend the biasing argument from the case that $|S \cup M| \geq n(\frac{1}{2}+\epsilon)$ to also handle these cases, however we were unable to do this. In fact, for a long time we were only able to handle a very special subcase: when all small parts of the optimal solution have size precisely 1, and there

is one large part that covers all of L. We call this special case the *at most one non-singleton case*. Observe that solving this case is equivalent to solving the Densest $(n-k+1)$-subgraph problem. Thus we can solve this case in $\mathcal{O}(2^{\frac{\omega n}{3}} n^{\mathcal{O}(1)})$ time using a known algorithm for Densest ℓ-subgraph by Chang et al. [12]. Their algorithm is an adaptation of the celebrated split and list algorithm of Williams [51] for the Max-Cut problem. At a glance it would appear that this very restricted special case is not useful at all for handling the general case. However, this special case turns out to be pivotal! Indeed, the (rather long and technical) remainder of our argument is to reduce most of the remaining instances of the problem to precisely this special case.

Hard Case. We now provide a high level overview of the tools and techniques used to handle the hard case where $k > 0.24n$, $|S|$ and $|L|$ are both between $n(\frac{1}{2}-\epsilon)$ and $n(\frac{1}{2}+\epsilon)$, and $M = \emptyset$.

First we divide further into two cases based on whether the number of cut edges between the large components in C is greater than $\frac{n}{\log^2 n}$ or not. The idea behind such a split is that there are only $\binom{n^2}{n/\log^2 n} \leq n^{2n/\log^2 n} = 2^{\log n \cdot \frac{2n}{\log^2 n}} = 2^{o(n)}$ subsets of edges of size at most $\frac{n}{\log^2 n}$. So if there are only a few($\leq \frac{n}{\log^2 n}$) cut edges between the large components, we guess and remove them with a $2^{o(n)}$ overhead. This reduces the few cut edges between large components case to one that has no such cut edges. But the no cut edges between large components case turns out to be harder than the many($> \frac{n}{\log^2 n}$) cut edges between large components case. We next show how to handle the latter case followed by the harder one.

1.) Many cut edges between large components. To handle this case, we first observe that all small components are singletons. Indeed, there are at most $\log n$ large parts but there are at least $\frac{n}{\log^2 n}$ cut edges between them. So there exists two large parts P_1 and P_2 having more than $\log n$ cut edges between them. If there exists a non-singleton small part, then combining P_1 and P_2 into a single part and removing a vertex from a non-singleton small part, which by definition has size at most $\log n$, as a singleton gives a strictly better cut.

We use this property to reduce to disjoint instances of the at most one non-singleton case. Here, (a) except for at most $\log n$ many vertices in L, all vertices in L have at least $\frac{n}{\log^4 n}$ neighbors within their large component in C – Suppose a set X of $\log n$ vertices in L have at most $\frac{n}{log^4 n}$ neighbors within their large component. Then, making $L - X$ one big component and all other vertices in X a singleton yields a better cut than C. Also, (b) the number of cut edges between large parts can be upper bounded by $n \log n$ – If not, we can remove $\log n$ vertices in L as singletons and merge all other vertices in L into one big component to obtain a strictly better cut. This is because there are at most $\log n$ large parts.

Next we sample a subgraph G' of G having $V(G') = V(G)$. We keep every edge in G in G' with probability $\frac{1}{\log^3 n}$. We use (a) and (b) to show that G' with high probability satisfies: (A) contains only few ($\leq \frac{n}{\log^2 n}$) cut edges between large components in C and (B) except for $(\log n)^{\mathcal{O}(1)}$ many vertices in L, all vertices in L still have at least $\frac{n}{\log^8 n}$ neighbors in G' within their large component in C.

In G', because of (A), with just $2^{o(n)}$ overhead we guess and remove all remaining cut edges between large components in C. Next, using (B) we show that for each large component X in C we have a set of $(\log n)^{\mathcal{O}(1)}$ vertices $V_X \subset X$ such that $X \subseteq N_{G'}(V_X)$. For every large component X, we guess V_X – There are at most $\log n$ large components and for each, this guessing incurs a $n^{(\log n)^{\mathcal{O}(1)}}$ overhead. Recall that all small components in C are singletons. Next because we removed all cut edges between large components in C in G', V_X has no neighbors in any large component apart from X in G'. Thus for every distinct pair X_1, X_2

of large components in C, every vertex in $N_{G'}(V_{X_1}) \cap N_{G'}(V_{X_2})$ is a singleton in C and can be removed. Finally, in the resulting graph each $V_X \cup N(V_X)$ is a disjoint instance of the at most one non-singleton case.

2.) No cut edges between large components. We handle this case by either reducing to the at most one non-singleton case or by identifying S and L. In the latter case, we use S and L to obtain a cut as good as C. We now show how to efficiently compute a cut as good as C given S and L. To find the part of the cut induced by L, we just use the n^k exact algorithm on $G[L]$ as there are at most $\log n$ large parts. So we shift our focus to finding the part of the cut induced by S. For this, we use the state graph with some guessing. Recall that the vertices of the state graph S_G correspond to subsets of vertices and the edges correspond to components. A path from $\emptyset$ to any subset S in S_G can be mapped to the cut containing all parts corresponding to the edges in P and vice versa. Thus using less than 2^n time, we precompute and store for each state X having $|X| \leq n(\frac{1}{2} - \delta)$ the best ℓ-cut of X containing only small components - $small(X, \ell)$. For this we only build S_G for vertex sets of size at most $n(\frac{1}{2} - \epsilon)$ and edges corresponding to small parts. For bounding our run times, we use that for $\tau \in [0, 1]$, $\binom{n}{\tau n} \leq 2^{h(\tau)n}$, where h is the binary entropy function [32]. So precomputing $small$ takes time at most $\mathcal{O}(2^{h(\frac{1}{2}-\delta)n+o(n)})$. Given S, we guess a union X of small parts in C such that $|S \setminus S'| \leq n(\frac{1}{2} - \delta)$. Then we do a lookup of $small(S', \ell) \cup small(S \setminus S', k - \ell)$ to obtain the part of the cut induced by S. Thus given S and L, we can compute C in time $\binom{\frac{n}{2}+\epsilon n}{(\epsilon+\delta)n} \leq 2^{h(\epsilon+\delta)n}$ since $|S - \frac{n}{2}| \leq \epsilon n$.

Next, to explain the subcases we divide into, we introduce some properties of the cut. Why we need these properties will become clear when we use them to solve the subcases. We say that C is α-*neighbor-biased* if there is a union X of large components whose neighborhood size substantially differs from its size. More precisely if $||X| - |N(X)|| > \alpha n$. If there is no such union of large components, we say C is *neighbor-balanced*. We call a large component θ-*heavy* if it contains all vertices of L except at most θn of them. Look at the order: $\epsilon, \delta, \alpha, \theta$, in which we defined our parameters. We set these parameters such that for each parameter, the ones before it in the order are small enough for our ideas to work. So we start by setting θ which is the highest, followed by α, then δ and finally ϵ. Another nice tool that we use to recover some sets and their neighborhoods is: all p-sized subsets of vertices having a q-sized neighborhood in a graph can be enumerated in time $\mathcal{O}(n\binom{p+q}{q})$ [22, Lemma 3.2].

With that, we divide into three subcases - (i) neighbor-biased (ii) neighbor-balanced with a heavy large component and (iii) neighbor-balanced with no heavy large component.

2.1) α-Neighbor-biased. The core idea in this case is to use the bias in size between X and $N(X)$ to efficiently guess L. We guess X in time $\binom{|X|+|N(X)|}{|X|}$ and recover $N(X)$. Next we guess $L \setminus X$ in time $2^{n-|X|-|N(X)|}$. This lets us recover L and S in time $\binom{|X|+|N(X)|}{|X|} \cdot 2^{n-|X|-|N(X)|}$. Given S and L we do some guessing and lookup of $small$ to compute C in time $2^{h(\epsilon+\delta)n}$ as discussed above. Our final runtime ends up being $\binom{|X|+|N(X)|}{|X|} \cdot 2^{n-|X|-|N(X)|} \cdot 2^{h(\epsilon+\delta)n}$. A simple calculation simplifying $\binom{|X|+|N(X)|}{|X|}$ in terms of h shows that the final runtime is substantially less than 2^n as long as α is sufficiently large as compared to ϵ and δ.

2.2) α-Neighbor-balanced with a θ-heavy large component. Set $\theta = 10^{-5}$. Here we reduce to the at most one non-singleton case. Recall that the case we reduce to can be solved in $\mathcal{O}(2^{\frac{\omega}{3}n})$ time. Thus we can afford an overhead of $2^{(0.999-\frac{\omega}{3})n}$ to get to that case.

First we guess the set $L \setminus H$ of vertices in L not in the heavy component H. This incurs a cost of $\binom{n}{\theta n} \leq 2^{h(\theta)n}$. Then we guess the set X of vertices in non-singleton small components. We show that $|X|$ is actually very small and that the $\binom{n}{|X|}$ overhead to guess X is acceptable.

Observe that we can compute the cut induced by $L \setminus H$ in $2^{o(n)}$ time using the n^k algorithm and the cut induced by X in $\mathcal{O}(1)$ time by a lookup of *small*. Thus after guessing $L \setminus H$ and X we reduce to the one non-singleton case. All that remains to do now is to prove $|X|$ is small enough to be able to guess X. We bound $|X|$ by $0.01n$. Then $\binom{n}{|X|} \leq \binom{n}{0.01n} \leq 2^{h(0.01)n}$, which is an easily affordable overhead.

Suppose $|X| > 0.01n$, we show that C can be improved. We call a non-singleton component *good* if the heavy component is adjacent to 99% of the vertices in it. Since C is neighbor-balanced and $0.01 >> (\theta = 10^{-5})$, we can show that the heavy component is adjacent to almost all vertices in many non-singleton components; that there are at least $n/(\log n)^{\mathcal{O}(1)}$ good components. Because there are $n/(\log n)^{\mathcal{O}(1)}$ good components and good components are all small, we can find an $i(\leq \log n)$ such that there are i good components of size i. Merging $i-1$ good components of size i with the heavy component and breaking one good component of size i into singletons improves C; the extra cost to break is only $0.05\binom{i}{2}$ while the savings from merging is $0.99(i-1)i$.

2.3) Neighbor-balanced with no heavy large component. As a first step, we make our state graph more robust to handle special cases. Recall that the edges of the state graph correspond to components. We build the state graph for vertex sets of size either at most $n(\frac{1}{2} - \epsilon)$ or at least $n(\frac{1}{2} + \epsilon)$ and edges corresponding to small parts. We then add a few additional edges that correspond to groups of components. For each pair X, $X \cup Y$ of vertex sets in the new state graph, we draw an edge from X to $X \cup Y$ if Y is a union of a set of at most $\log n$ connected components in $G[V \setminus X]$. We call the constructed state graph the *enhanced* state graph. Observe that the enhanced state graph has size $\mathcal{O}((2-\varepsilon)^n)$. Now we demonstrate how the new edges help.

Skipping Cut. Suppose C has a union of small components S' and union of large components L' such that (i) $|S'| \leq n(\frac{1}{2} - \theta)$ (ii) $|S' \cup L'| \geq n(\frac{1}{2} + \theta)$ and (iii) $N(L') \subseteq S'$. Also recall that C does not contain edges between large components. In this case, there is a path P in the new state graph from $\emptyset$ to V corresponding to C. We decompose P into 4 portions: (1) a path from $\emptyset$ to S' using the edges corresponding to parts in S', (2) a edge from S' to $S' \cup L'$ corresponding to parts in L', (3) a path from $S' \cup L'$ to $S \cup L'$ using the edges corresponding to parts in $S \setminus S'$ and (4) an edge from $S \cup L'$ to V corresponding to parts in $L \setminus L'$. We say C is a *skipping* cut if it satisfies (i), (ii) and (iii) as we can find C in the modified state graph by skipping between states of size at most $n(\frac{1}{2} - \theta)$ and states of size at least $n(\frac{1}{2} + \theta)$ but by avoiding states of size $\frac{n}{2}$. In conclusion, if C is neighbor balanced with no heavy large component but C is a skipping cut then we can find C using the enhanced state graph in time $\mathcal{O}(2-\epsilon)^n$.

We now turn our attention to the final case: neighbor-balanced with no heavy large component and not skipping. To solve this case we reduce to a special case in which S and L can be identified efficiently using $2^{\frac{n}{2}}$ time. Thus we can afford an overhead of $2^{0.499n}$ to get to that case; but we incur a much smaller overhead. First we highlight the properties of C required for the special case and show how to use them to obtain S and L. Then we show how to guess a few vertices in S to reduce to the case we want.

Let C satisfy the following properties: (i) All large components in C can be grouped into two parts L_1 and L_2 each having size nearly $\frac{n}{4}$ (ii) $N(L_1) \cap N(L_2) = \emptyset$ (iii) All small components in C are of size two and contain one vertex from $N(L_1)$ and the other from $N(L_2)$. To find L and S, we first guess L_1 in time $2^{|L_1|+|N(L_1)|}$ and recover $N(L_1)$. We then recover $N(L_2)$ as $N(N(L_1)) \setminus L_1$. Then the set of remaining vertices is L_2, yielding $L = L_1 \cup L_2$. This in total only takes about $2^{|L_1|+|N(L_1)|} \leq 2^{\frac{n}{2}}$ time since $|L_1| \sim \frac{n}{4}$.

Suppose property (i) is not satisfied, let L' be a group of large components having size at least θn but less than $\frac{n}{4}$; such a group exists because there is no heavy large component. Then C is a skipping cut with witness L' and S' for some $S' \supseteq N(L')$ which exists because C is neighbor balanced. All that remains to be done is to show that we can guess some vertices in S to satisfy properties (ii) and (iii). Let S' be the set of vertices in small components of size two that contain one vertex from $N(L_1) \setminus N(L_2)$ and the other from $N(L_2) \setminus N(L_1)$. Also let $\mathcal{F}'$ be the family containing all such components. We guess $S \setminus S'$. One can easily verify that removing $S \setminus S'$ guarantees properties (ii) and (iii). To conclude that such a guess is feasible, we need to bound the size of $S \setminus S'$. We prove $|S \setminus S'| \leq 30(\epsilon + \theta + \alpha)n$.

Let $\mathcal{F}$ to be the family of all small components X in C that satisfy: (a) X has no vertex from $S \setminus N(L)$, (b) X has a vertex from $N(L_1)$ and a vertex from $N(L_2)$, and (c) X has no vertex from $N(L_1) \cap N(L_2)$.
Observe that the subfamily of all components of size two in $\mathcal{F}$ is $\mathcal{F}'$. We use this to obtain a bound on $|S \setminus S'|$. By definition, every component in $\mathcal{F}$ has at least two vertices, one in $N(L_1) \setminus N(L_2)$ and one in $N(L_2) \setminus N(L_2)$. Thus $|S| - 2|\mathcal{F}|$ will account for all but two vertices in components of size three or more in $\mathcal{F}$ and for all vertices in S not in any component in $\mathcal{F}$. This in turn implies $3 \cdot (|S| - 2|\mathcal{F}|)$ is an upper bound for the number of vertices in S not contained in any component of size two in $\mathcal{F}$, i.e bound for $|S \setminus S'|$. We will show $|S| - 2|\mathcal{F}| \leq 10(\epsilon + \alpha + \theta)n$ from which we can infer $|S \setminus S'| \leq 3(|S| - 2|\mathcal{F}|) \leq 30(\epsilon + \alpha + \theta)n$.

Next, for each of the properties $(a) - (c)$, we bound the number of small components that do not satisfy that property. Since $|S|$ and $|L|$ are both between $n(\frac{1}{2} - \epsilon)$ and $n(\frac{1}{2} + \epsilon)$ and C is α-neighbor-balanced, there are at most $(2\epsilon + \alpha)n$ vertices in S that are not in $N(L)$. Thus $|S \setminus N(L)| \leq (2\epsilon + \alpha)n$. So at most $(2\epsilon + \alpha)n$ small components do not satisfy (a). At most $(\epsilon + \theta/2)n$ small components do not have a neighbor in L_1. If not, since $|S| \leq n(\frac{1}{2} + \epsilon)$, we can show that C is a skipping cut with witness $L' = L_1$ and some $S' \supset N(L_1)$. The same argument holds with respect to L_2. Thus, at most $(2\epsilon + \theta)n$ small components do not satisfy (b). Next, since C is α-neighbor-balanced, $|N(L)| = |N(L_1)| + |N(L_2)| - |N(L_1) \cap N(L_2)| \leq |L_1| + \alpha n + |L_2| + \alpha n - |N(L_1) \cap N(L_2)|$. So $|N(L_1) \cap N(L_2)| \leq |L| - |N(L)| + 2\alpha n \leq 3\alpha n$. This bounds the number of small components not satisfying (c) by $3\alpha n$.

For an easy read, until this point we mentioned $k > 0.24n$. But in our algorithm, we set $k > \frac{n}{4} - \epsilon n$ and need it for this case to work. Since $k > \frac{n}{4} - \epsilon n$, using all the three bounds obtained, $|\mathcal{F}| \geq 0.25n - \epsilon n - (2\epsilon + \alpha)n - (2\epsilon + \theta)n - 3\alpha n \geq 0.25n - (5\epsilon + 4\alpha + \theta)n$. Thus, $|S| - 2|\mathcal{F}| \leq (0.5 + \epsilon)n - 2(0.25n - (5\epsilon + 4\alpha + \theta)n) \leq (10\epsilon + 8\alpha + 2\theta)n \leq 10(\epsilon + \alpha + \theta)n$. Note that the main proof is structured differently for tighter bounds with these being the core ideas.

2 Preliminaries

Given a graph G, we use $V(G)$ and $E(G)$ to denote the vertex sets and edge sets, respectively. For any subset $X \subseteq V(G)$, let $G[X]$ denote the induced subgraph of G on X. A subset $X \subseteq V(G)$ is said to be connected if $G[X]$ is a connected graph. We denote the number of connected components in G by $cc(G)$. Given a path P in G, let $E(P)$ denote the edges in the path. Given a subset $E' \subseteq E(G)$, we denote the subgraph G' having $V(G') = V(G)$ and $E(G') = E(G) \setminus E'$ by $G \setminus E'$. For any subset $X \subseteq V(G)$, let $N_G(X)$ denote the set of vertices in G adjacent to some vertex in X and let $N_G[X] = N_G(X) \cup X$. We will omit the subscript when the graph is clear from context.

A k-*cut* of a graph G is a partition of the vertex set $V(G)$ into k non-empty parts. We will refer to the parts of a cut as *components* of the cut. The *weight* of a k-cut is the total number of edges with endpoints in different parts of the partition. We refer to the edges of G having end points in different components in C as *cut edges* of C. We use $\mathsf{best}(X, l)$ to denote a least weight l-cut of $G[X]$. For any two disjoint subsets A, B of $V(G)$, we denote the number of edges having one end point in A and the other in B by $w(A, B)$. For every $E' \subseteq E(G)$, we let $w(E') = |E'|$. For every $X \subseteq V(G)$, we let $\delta(X)$ denote the set of edges having exactly one end point in X in G.

If G is an edge-weighted graph, then the *weight* of a k-cut is the sum of weights of edges with endpoints in different parts of the partition. For any two disjoint subsets A, B of $V(G)$, we denote the sum of weights of edges having one end point in A and the other in B by $w(A, B)$. For every $E' \subseteq E(G)$, we denote the sum of weights of all edges in E' by $w(E')$. We consider G to be a simple unweighted graph throughout the paper except in Section where we provide the $2^{n+o(n)}(\log W)^{\mathcal{O}(1)}$ time algorithm for edge-weighted graphs.

We also need the following lemma to enumerate connected sets of size $b+1$ with at most f neighbors in our algorithms.

▶ **Lemma 3** ([22, Lemma 3.2]). *All vertex sets of size $b+1$ with f neighbors in a graph G can be enumerated in time $\mathcal{O}(n\binom{b+f}{b})$ by making use of polynomial space.*

There exists an algorithm for Min k-Cut using Thorup trees that runs in time $\mathcal{O}(\binom{n}{2k}3^{2k})$. We express this runtime in this way because it enables us to obtain a $2^{o(n)}$ algorithm for k-cut whenever $k \leq \frac{n}{\log n}$. Given a polynomial in n, m, and $\log n$ sized family of spanning trees that contains a Thorup tree, the algorithm for each tree guesses all possible sets of edges of size at most $2k-2$, removes them and contracts the remaining forests into vertices and solves k-cut on this contracted graph in time 3^{2k}.

▶ **Lemma 4** (Exact Algorithm [50]). *Given a graph G, positive integer k, the min k-cut of G can be found in time $\mathcal{O}(\binom{n}{2k}3^{2k})$.*

The cut induced by a cut C of X on a subset Y of X is the cut obtained by taking the intersection of each component in C with Y. We define the union of two disjoint cuts C_1 of vertex set X_1 and C_2 of vertex set X_2 as the cut C of $X_1 \cup X_2$ that induces cut C_1 on X_1 and cut C_2 on X_2. We define the union of a subfamily $\{Y_0, \cdots, Y_z\}$ of components of a cut to be $\cup_{i \leq z} Y_i$, the set of all vertices in any component in the subfamily. Given a family $\mathcal{F}$ of subsets of $V(G)$, let $U(\mathcal{F}) = \cup_{X \in \mathcal{F}} X$ denote the set of all vertices in some set in $\mathcal{F}$. We will refer to a cut having a single component as just a set of vertices for convenience.

We also need the following classical single source shortest path algorithm to traverse the state graph, S_G (formally defined in later)[2].

▶ **Lemma 5** (Dijkstra's Algorithm). *Given an edge weighted directed graph D on n vertices and m edges, with two special vertices s and t, we can find a minimum weight shortest path from s to t in time $\mathcal{O}((n+m)\log n)$.*

We also need the following upper bounds on binomial coefficients for our purposes.

▶ **Lemma 6** ([32]). *Let n be a positive integer and $\alpha \in [0, 1]$, then $\binom{n}{\alpha n} \leq 2^{h(\alpha)n}$, where $h(\alpha)$ represents the entropy of a Bernoulli random variable with probability of success α, satisfying $h(\alpha) = -\alpha \log \alpha - (1-\alpha)\log(1-\alpha)$. Further, for a positive integer $k \leq n$, $\binom{n}{k} \leq \left(\frac{en}{k}\right)^k$, where e is the base of natural logarithms.*

[2] S_G will be a DAG, so one can also resort to other means to find single source shortest paths.

By truncating the Taylor series for h, given by

$$h(p) = 1 - \frac{1}{2\ln 2}\sum_{n=1}^{\infty}\frac{(1-2p)^{2n}}{n(2n-1)},$$

we get the following useful upper bound for h, when η is close to $\frac{1}{2}$.

▶ **Lemma 7.** *For $\eta \leq 1/10$, we have that $h(\frac{1}{2}-\eta) \leq 1 - \frac{\eta^2}{\ln 2}$.*

We also need the following definition of "contraction and uncontraction of edges".

▶ **Definition 8** ((Un)Contraction of Cuts and Graphs). *Given a graph G and an edge $e = uv$, the graph G/uv obtained by* contracting *the edge uv, is the one where we delete the vertices $\{u, v\}$, and introduce a new vertex v_e and add edges from v_e to every vertex in $N(u)$ and $N(v)$. If $w \in N(u) \cap N(v)$, then the process will make multi-edges.*

Given a cut C and an edge uv such that, u, v belongs to the same part in C, then by contraction of cut*, denoted by C/uv, we mean the cut constructed from C, where we replace the part P in C, that contains u and v with $(P \setminus \{u, v\}) \cup \{v_e\}$. Similarly, given a vertex set X, we define* uncontraction of a cut *C, denoted by $C/^{-1}X$, as a cut where we replace each vertex $x \in X$, with the set of vertices that has been contracted into x.*

3 Proof of Main Theorem and Case Breakdown

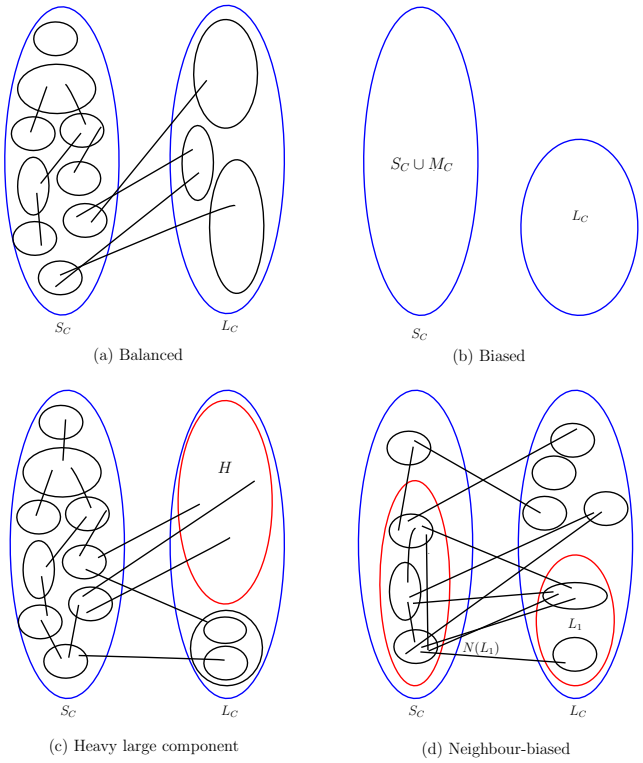
In this section we provide an overview of our algorithm with a case breakdown showing how we organize our cases throughout the paper. We first introduce some basic terminology used in the algorithm. Then we provide a guide to the different cases with pointers to various subroutines called in the algorithm. Finally we define a data structure that is used by most of our subroutines and state a known result for the at most one non-singleton case.

3.1 Properties of Cuts and Special Cases

In this section we define multiple properties of cuts that will be helpful for designing our algorithm. Let G be a graph on n vertices. We will design algorithms to find a cut with different combinations of these properties in G and then combine them to obtain our final algorithm. We divide the components of any cut of G into three types depending on their size.

▶ **Definition 9** (Component Types). *A component is said to be* small *if its size is at most $\log n$. A component is said to be* medium *if its size is greater than $\log n$ and less than $\frac{n}{\log n}$. A component is said to be* large *if its size is at least $\frac{n}{\log n}$. Given a cut C of G, we denote the set of all vertices in small, medium and large components in C by S_C, M_C and L_C respectively.*

This notion is useful because the number of subsets of $V(G)$ that can be small or medium components is at most $n\binom{n}{\frac{n}{\log n}} \leq n(\frac{en}{n/\log n})^{n/\log n} = 2^{o(n)}$. Also, for any subset L of $V(G)$ and $\ell \leq \log n$, we can find a ℓ-cut of $G[L]$ having weight no more than a minimum weight an ℓ-cut of $G[L]$ containing only large components in time $2^{o(n)}$ using Lemma 4. This is because there can be at most $\log n$ large components in any cut. We will use both these facts crucially while designing our algorithms. The above discussion leads us to define the following definitions.



(a) Balanced (b) Biased

(c) Heavy large component (d) Neighbour-biased

Figure 2 Visualizing cut properties (a) Balanced cut has $|S_C|$ nearly equal to $|L_C|$ and no medium components. (b) Biased cut has one of $|S_C \cup M_C|$ or $|L_C \cup M_C|$ substantially higher. (c) Heavy large component H contains nearly all vertices in L_C. (d) Neighbor-biased cut has a union of heavy components L_1 such that $||L_1| - |N(L_1)||$ is high.

▶ **Definition 10.** *For a subset $X \subseteq V(G)$ and $\ell \leq n$, $\mathsf{small}(X, \ell)$ represents an ℓ-cut of $G[X]$ having weight no more than the weight of a least weight ℓ-cut of $G[X]$ containing only small and medium components.*

▶ **Definition 11** (Biased and Balanced Cuts)**.** *For any $0 < \delta < \frac{1}{2}$, a cut C is said to be* δ-biased *if either $|M_C \cup S_C| \geq n(\frac{1}{2} + \delta)$ or $|M_C \cup L_C| \geq n(\frac{1}{2} + \delta)$ and it is said to be* δ-balanced *if it contains no medium components, $|S_C| \leq n(\frac{1}{2} + \delta)$ and $|L_C| \leq n(\frac{1}{2} + \delta)$.*

▶ **Definition 12** (Properties of Large Components)**.** *We say that a cut C of G has* many edges between large components *if the number of cut edges of C having both end points in L_C is greater than $\frac{n}{\log^2 n}$. We say that the cut has* few edges between large components *if the number of such edges is at most $\frac{n}{\log^2 n}$.*

Observe that we can reduce the case of few edges between large components to no edges by guessing the set of edges between the large components with just $2^{o(n)}$ guesses. This again will prove helpful for us to get more structure.

▶ **Definition 13.** *For any $0 \leq \alpha < 1$, we say that a large component X in a cut C of G is* α-heavy *if it has all vertices in L_C except for at most αn vertices, i.e $|L_C \setminus X| \leq \alpha n$.*

▶ **Definition 14.** *For any $0 \leq \alpha < \frac{1}{2}$ and $0 < \rho < \frac{1}{2}$, we say that a α-balanced cut C is ρ-neighbor-biased if there is a union X of large components in C having p vertices such that $N(X) \subseteq S_C$, $|N(X)| = q$ and $|p - q| > \rho n$. Otherwise the cut is said to be ρ-neighbor-balanced.*

We note that we will use the last two properties only on balanced cuts having no edges between large components. Figure 2 captures all the properties defined above.

3.2 Steps of Our Algorithm

Armed with all the technical definitions, we now provide a guide to the different cases our algorithm for Min k-Cut handles. First, we summarize the different parameters that we use in our algorithm and the final value we set them to obtain our main result.

- $\alpha_1 = 10^{-20}$: $k < \frac{n}{4} - \alpha_1 n$ and $k \geq \frac{n}{4} - \alpha_1 n$
- $\alpha_2 = 10^{-20}$: α_2-balanced or $\frac{\alpha_2}{2}$-biased cut
- $\alpha_3 = 10^{-5}$: α_3-heavy large component
- $\alpha_4 = 10^{-2}$: number of non singletons
- $\alpha_5 = 10^{-5}$: α_5-neighbor biased or balanced
- $\delta = 10^{-20}$: δ-small cut data structure

Note that our results will work for a range of these parameters but for convenience we fix these parameters to a particular value and obtain our final result. Given an input graph G on n vertices and integer k, let C be a *hypothetical* min k-cut of G. Our goal is to compute C. We divide into cases based on the value of k and the properties of C. We use Lemmas 6 and 7 to upper bound the running time for each case by $(2-\varepsilon)^n$ for some $\varepsilon > 10^{-50}$. In the summary, for each case we mention which one of the two Lemmas is used to bound the running time in parenthesis.

(Case 1: $k < \frac{n}{4} - \alpha_1 n$.) In this case we apply Lemma 15 and directly solve the problem in time $\frac{2^{n+o(n)}}{(1+4\alpha_1)^{\alpha_1 n}}$ (Lemma 6).

▶ **Lemma 15 (*).** *There exists an algorithm that takes as input a graph G on n vertices, an integer $k < \frac{n}{4} - \alpha_1 n$ and returns the min k-cut of G in time $\frac{2^{n+o(n)}}{(1+4\alpha_1)^{\alpha_1 n}}$.*

(Case 2: $k \geq \frac{n}{4} - \alpha_1 n$) Since k is large, we have the property that the number of components of size at most 4 is at least $0.04n$. We then break this case based on how efficiently we can use this property. We use it in the case when C is $\frac{\alpha_2}{2}$-biased and handle the balanced case separately, leading to the subsequent subcases. This case is handled in Lemma 16 in time $2^{n\frac{1}{2}(1+h(\frac{1}{2}+\frac{\alpha_2}{20}))+o(n)} + 2^{(h(\alpha_2)+h(\frac{1}{2}-\alpha_2))n+o(n)}$ (Lemma 6).

▶ **Lemma 16 (*).** *There exists an algorithm that takes as input a graph G on n vertices, an integer $k \geq \frac{n}{4} - \alpha_1 n$ and returns the min k-cut of G in time $2^{n\frac{1}{2}(1+h(\frac{1}{2}+\frac{\alpha_2}{20}))+o(n)} + 2^{h(\alpha_2)+h(\frac{1}{2}-\alpha_2)n+o(n)}$, when $\alpha_1 = \alpha_2 = 10^{-20}$.*

Case 2a: ($\frac{\alpha_2}{2}$-biased case) We completely handle this case in Lemma*[3] 5.3 in time $2^{\frac{n}{2}(1+h(\frac{1}{2}+\frac{\alpha_2}{20}))+o(n)}$ (Lemma 7).

Case 2b: (α_2-balanced case) We further divide this case based on whether the number of edges between large components in C is large ($> \frac{n}{\log^2 n}$) or not. We handle this in Lemma* 5.4 in time $2^{h(\frac{1}{2}-\alpha_2)n+o(n)}$ (Lemma 7).

Case 2b (i): (Many edges between large components) We solve this case by reducing to the case of finding a cut having at most one non-singleton component. We handle this case in Lemma* 7.1 using Lemma* 3.2 as a subroutine in time $2^{\frac{\omega n}{3}+o(n)}$ (Lemma 6).

[3] We use Lemma* to refer to the Lemmas stated and proved in the full version; Lemma* 5.3 is Lemma 5.3 in the full version.

Case 2b (ii): (Few edges between large components) This is our final case and we deal with this by designing algorithms for the following cases. This case can be found in Lemma* 7.2 and the algorithm runs in time $2^{h(\frac{1}{2}-\alpha_2)n+o(n)}$ (Lemma 7).

- **(a) (α_5-neighbor biased)** This case is handled in Lemma* 7.3. Here we use the fact that C is neighbor-biased to find a family of partitions of $V(G)$ containing the partition $S_C \dot\cup L_C$ of $V(G)$ and use Lemma* 3.1 to find a cut having weight no more than a α_2-balanced cut C' with $S_C = S'_C$ and $L_C = L'_C$. We handle this case in time $2^{h(\frac{1}{2}-\alpha_2)n+o(n)}$ (Lemma 7).
- **(b) (α_5-neighbor balanced and α_3-heavy component)** In this case we argue that there are not too many non-singleton components and solve the case by reducing to the case of finding a cut having at most one non-singleton component. We handle this case in Lemma* 7.4 using Lemma* 3.2 as a subroutine in time $2^{(h(\alpha_3)+h(\alpha_4)+\frac{\omega}{3})n+o(n)}$ (Lemma 6).
- **(c) (α_5-neighbor balanced and no α_3-heavy component)** We handle this case completely in Lemma* 7.5. Here we first run Lemma* 4.2 that involves using the state graph. Then similar to Case A, here we find a family of partitions of $V(G)$ containing the partition $S_C \dot\cup L_C$ of $V(G)$ and use Lemma* 3.1 on it. This case runs in time $2^{h(\frac{1}{2}-\alpha_2)n+o(n)}$ (Lemma 7).

A case tree depicting the various cases can be found in Figure 1. We now provide the proof of our main Theorem assuming Lemma 15($k < \frac{n}{4} - \alpha_1 n$) and Lemma 16($k \geq \frac{n}{4} - \alpha_1 n$).

Proof of Theorem 1. If $k < \frac{n}{4} - \alpha_1 n$ we run Lemma 15 with G and k else we run Lemma 16 with G and k and return the obtained k-cut. The correctness follows from the corresponding Lemmas. To bound the running time of the algorithm, we show that the running time of each subroutine mentioned above in the summary is bounded by $\mathcal{O}(2-\varepsilon)^n$, for some $\varepsilon > 10^{-50}$. To do this, we set the values of the parameters as summarized in the beginning of this subsection and use Lemma 7 and 6 as mentioned in the summary. ◀

4 Conclusion

In this paper we designed the first algorithm for Min k-Cut running in time better than 2^n. In particular, we designed an algorithm with running time $\mathcal{O}((2-\varepsilon)^n)$, for $\varepsilon > 10^{-50}$. We hope that our methods will be useful to design $\mathcal{O}(c^n)$ time algorithms for $c < 2$ for other graph partitioning problems for which progress has stopped at 2^n, including Cutwidth, Edge Multiway Cut, and more generally Edge Multicut on undirected graphs. Finally, it remains an interesting open problem to obtain a $\mathcal{O}(c^n)$ time algorithm for Min k-Cut for a constant $c < 2$ which is bounded away from 2 by more than a rounding error.

A Tight $(1.5 + \epsilon)$-Approximation for Unsplittable Capacitated Vehicle Routing on Trees

Claire Mathieu
CNRS Paris, France

Hang Zhou
École Polytechnique, Institut Polytechnique de Paris, France

Abstract

In the unsplittable capacitated vehicle routing problem (UCVRP) on trees, we are given a rooted tree with edge weights and a subset of vertices of the tree called terminals. Each terminal is associated with a positive demand between 0 and 1. The goal is to find a minimum length collection of tours starting and ending at the root of the tree such that the demand of each terminal is covered by a single tour (i.e., the demand cannot be split), and the total demand of the terminals in each tour does not exceed the capacity of 1.

For the special case when all terminals have equal demands, a long line of research culminated in a quasi-polynomial time approximation scheme [Jayaprakash and Salavatipour, TALG 2023] and a polynomial time approximation scheme [Mathieu and Zhou, TALG 2023].

In this work, we study the general case when the terminals have arbitrary demands. Our main contribution is a polynomial time $(1.5 + \epsilon)$-approximation algorithm for the UCVRP on trees. This is the first improvement upon the 2-approximation algorithm more than 30 years ago. Our approximation ratio is essentially best possible, since it is NP-hard to approximate the UCVRP on trees to better than a 1.5 factor.

1 Introduction

In the *unsplittable capacitated vehicle routing problem (UCVRP)* on *trees*, we are given a rooted tree with edge weights and a subset of vertices of the tree called *terminals*. Each terminal is associated with a positive *demand* between 0 and 1. The root of the tree is called the *depot*. The goal is to find a minimum length collection of tours starting and ending at the depot such that the demand of each terminal is covered by a *single* tour (i.e., the demand cannot be split), and the total demand of the terminals in each tour does not exceed the *capacity* of 1.

The UCVRP on trees has been well studied in the special setting when all terminals have *equal* demands:[1] Hamaguchi and Katoh [17] gave a polynomial time 1.5-approximation; the approximation ratio was improved to 1.35078 by Asano, Katoh, and Kawashima [3] and

[1] Up to scaling, the equal demand setting is equivalent to the *unit demand* version of the capacitated vehicle routing problem in which each terminal has unit demand, and the capacity of each tour is a positive integer k.

was further reduced to 4/3 by Becker [4]; Becker and Paul [5] gave a bicriteria polynomial time approximation scheme; and very recently, Jayaprakash and Salavatipour [18] gave a quasi-polynomial time approximation scheme, based on which Mathieu and Zhou [21] designed a polynomial time approximation scheme.

In this work, we study the UCVRP on trees in the general setting when the terminals have *arbitrary* demands. Our main contribution is a polynomial time $(1.5+\epsilon)$-approximation algorithm (Theorem 1). This is the first improvement upon the 2-approximation algorithm of Labbé, Laporte, and Mercure [20] more than 30 years ago. Our approximation ratio is essentially best possible, since it is NP-hard to approximate the UCVRP on trees to better than a 1.5 factor [14].

▶ **Theorem 1.** *For any $\epsilon > 0$, there is a polynomial time $(1.5+\epsilon)$-approximation algorithm for the unsplittable capacitated vehicle routing problem on trees.*

The UCVRP on trees generalizes the UCVRP on *paths*. The latter problem has been studied extensively due to its applications in scheduling, see Section 1.1. As an immediate corollary of Theorem 1, we obtain the first polynomial time $(1.5+\epsilon)$-approximation algorithm for the UCVRP on paths. This ratio is essentially best possible, since it is NP-hard to approximate the UCVRP on paths to better than a 1.5 factor.

1.1 Related Work

Originally introduced by Dantzig and Ramser in 1959 [10], the UCVRP generalizes the *traveling salesman problem*, and is one of the most basic problems in Operations Research.

UCVRP on general metrics

The classical tour partitioning algorithm [16] introduced by Haimovich and Rinnooy Kan in 1985 was proved to be a constant-factor approximation on general metrics [2]. Very recently, Blauth, Traub, and Vygen [6] achieved the first improvement upon the tour partitioning algorithm. The best-to-date approximation ratio for general metrics stands at roughly 3.194 due to Friggstad, Mousavi, Rahgoshay, and Salavatipour [13].

UCVRP on paths

The UCVRP on paths is equivalent to the scheduling problem of minimizing the makespan on a single batch processing machine with non-identical job sizes [26]. Many heuristics have been proposed and evaluated empirically, e.g., [26, 12, 22, 9, 19, 24, 7, 1, 23]. Prior to our work, the best approximation ratio for the UCVRP on paths was 1.6 due to Wu and Lu [27].

The UCVRP on paths has also been studied in special cases. For example, when the optimal value is at least $\Omega(1/\epsilon^6)$ times the maximum distance between any terminal and the depot, asymptotic polynomial time approximation schemes are known [11, 25, 8].[2] In contrast, the algorithm in Theorem 1 applies to *any* path instance.

UCVRP in the Euclidean plane

In the two-dimensional Euclidean plane, the UCVRP admits a $(2+\epsilon)$-approximation [15].

[2] The UCVRP on paths is called the *train delivery problem* in [11, 25, 8].

2 Overview of Techniques

To prove Theorem 1, at a high level, our approach is to modify the problem and add enough structural constraints so that the structured problem contains a $(1.5 + O(\epsilon))$-approximate solution and can be solved in polynomial time by dynamic programming.

2.1 Preprocessing

We start by some preprocessing as in [21]. We assume without loss of generality that every vertex in the tree has two children, and the terminals are the leaf vertices of the tree [21]. Furthermore, we assume that the tree has bounded distances (Section 3.2). Next, we decompose the tree into *components* (Figure 1 and Section 3.3).

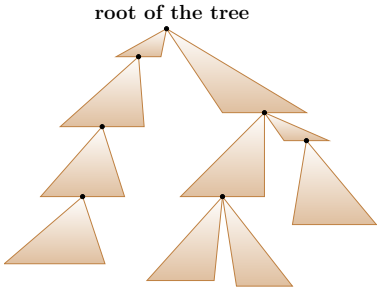

Figure 1 Decomposition of the tree into *components*. Figure extracted from [21]. Each brown triangle represents a *component*. Each component has a *root* vertex and at most one *exit* vertex.

2.2 Solutions Within Each Component

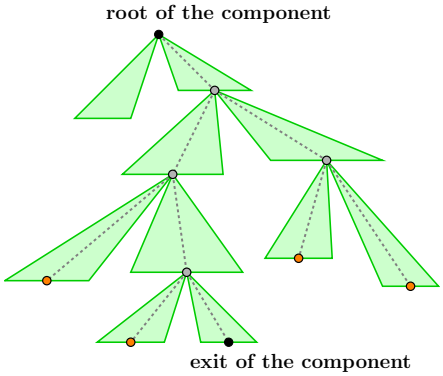
A significant difficulty is to compute solutions within each component. It would be natural to attempt to extend the approach in the setting when all terminals have equal demands [21]. In that setting, the *demands of the subtours*[3] in each component are among a polynomial number of values; since the component is visited by a constant number of tours in a near-optimal solution, that solution inside the component can be computed exactly in polynomial time using a simple dynamic program. However, when the terminals have arbitrary demands, the demands of the subtours in each component might be among an exponential number of values.[4] Indeed, unless $P = NP$, we cannot compute in polynomial time a better-than-1.5 approximate solution inside a component, since that problem generalizes the bin packing problem.

To compute in polynomial time good approximate solutions within each component, at a high level, we simplify the solution structure in each component, so that the demands of the subtours in that component are among a *constant* $O_\epsilon(1)$ number of values,[5] while increasing the cost of the solution by at most a multiplicative factor $1.5 + O(\epsilon)$.

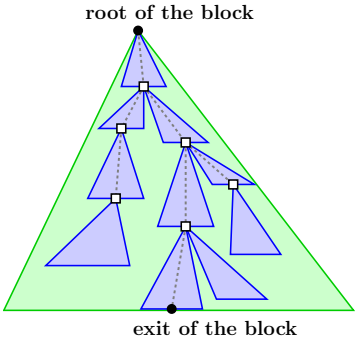
Where does the 1.5 factor come from? Intuitively, our construction creates an additional subtour to cover a selected subset of terminals, charging each edge on that subtour to *two* existing subtours using that edge, thus adding a 0.5 factor to the cost.

In the rest of this section, we explain our approach in more details.

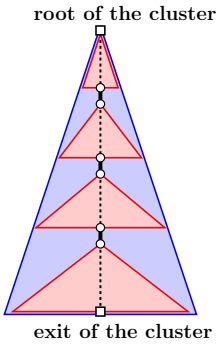
[3] The *demand of a subtour* is the total demand of the terminals visited by that subtour.
[4] For example, consider a component that is a star graph with $\Theta(n)$ leaves, where the i^{th} leaf has demand $1/2^i$.
[5] The notation $O_\epsilon(1)$ stands for $O(f(\epsilon))$ where $f(\epsilon)$ is any function on ϵ.



(a) Decomposition of a component into *blocks*. The orange nodes represent the *big* terminals in the component. The black nodes represent the *root* and the *exit* vertices of the component (defined in Lemma 6). The gray nodes are the branching vertices in the subtree spanning the orange and the black nodes. Splitting the component at the orange, the black, and the gray nodes results in a set of *blocks*, represented by green triangles. Each block has a *root* vertex and at most one *exit* vertex. See Section 4.1.



(b) Decomposition of a block into *clusters*. The green triangle represents a block. Each blue triangle represents a *cluster*. Each cluster has a *root* vertex and at most one *exit* vertex. A cluster is *passing* if it has an exit vertex, and is *ending* otherwise. Each passing cluster has a *spine* (dashed). See Section 4.2.



(c) Decomposition of a passing cluster into *cells*. The blue triangle represents a passing cluster. Removing the thick edges from the cluster results in a set of at most $1/\epsilon$ *cells*. Each red triangle represents a cell. Each of those cells has a *root* vertex, an *exit* vertex, and a *spine* (dashed). See Section 4.3.

Figure 2 Three-level decomposition of a component.

2.2.1 Multi-Level Decomposition (Section 4)

We partition each component into $O_\epsilon(1)$ parts using a *multi-level decomposition*.

In the first level, the component is decomposed into $O_\epsilon(1)$ *blocks* so that all terminals strictly inside a block are *small* (we distinguish *big* and *small* terminals depending on their demands). See Figure 2a and Section 4.1.

In the second level, each block is decomposed into $O_\epsilon(1)$ *clusters* so that the overall demand of each cluster is roughly an ϵ fraction of the demand of a component. See Figure 2b and Section 4.2.

In the third level, each cluster is decomposed into $O_\epsilon(1)$ *cells* so that the *spine* of each cell is roughly an ϵ fraction of the *spine* of the cluster, where the *spine* of a cell (resp. a cluster) is the path traversing that cell (resp. that cluster). See Figure 2c and Section 4.3.

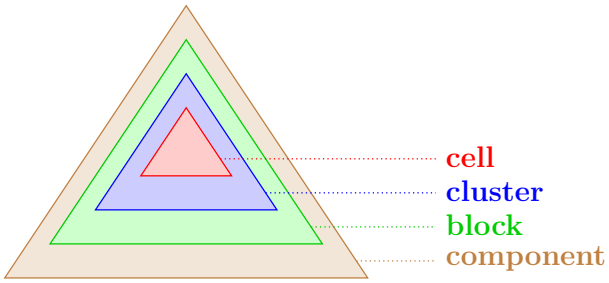


Figure 3 Relation of the multiple levels in the decomposition.

Comparison with the decomposition in [21]

The distinction between big and small terminals plays an important role in UCVRP. This distinction does not exist in the equal demand setting in [21]. In the current paper, the decomposition into blocks is new and enables us to deal with big and small terminals separately; the decomposition into clusters is similar to the decomposition in [21]; the decomposition into cells is a main novelty (see the usage of cells in Section 2.2.2).

2.2.2 Simplifying the Local Solution (Section 5)

The main technical contribution in this paper is the Local Theorem (Theorem 13), which simplifies a local solution inside a component so that, *in each cell, a single subtour visits all small terminals*, while increasing the cost of the local solution by at most a multiplicative factor $1.5 + O(\epsilon)$. The Local Theorem builds upon techniques from [5, 21] together with substantial new ideas.

A first attempt is to reassign all small terminals of each cluster to a single subtour. However, there are two obstacles. First, in order to maintain the connectivity of the resulting subtours, we need to pay for an extra copy of the spines of the clusters, which is expensive. Secondly, using a lemma of Becker and Paul [5], the resulting subtours exceed their capacities slightly. To reduce the demands of the subtours exceeding capacities, an extra cost of only an ϵ fraction of the solution cost is sufficient in the equal demand setting [21], but this is no longer achievable in the arbitrary demand setting.

To overcome those obstacles, we decompose each cluster into *cells* and we reassign all small terminals of each cell to a single subtour. In the analysis, we introduce the technical concept of *threshold cells* (Figure 4a), and we ensure that each cluster contains *at most*

one threshold cell. In order to maintain the connectivity of the resulting subtours, we only need to pay for an extra copy of *the spines of the threshold cells* (Figure 4b), whose cost is negligible.

To reduce the demand of each resulting subtour exceeding capacity, we select some cells from that subtour, and we remove all pieces in that subtour belonging to those cells. We show that each removed piece is connected to the root through at least *two* subtours in the solution (Lemma 20). That property is a main technical novelty in this paper. It enables us to reconnect all removed pieces with an extra cost of at most *half* of the solution cost (Lemma 21), hence an approximation ratio of $1.5 + O(\epsilon)$.

2.3 Postprocessing

We modify the tree of components using the techniques in [21] so that the new tree has only $O_\epsilon(1)$ levels of components. Consider a near-optimal solution in the new tree. We apply the Local Theorem (Theorem 13) to simplify the local solutions in all components. Then we combine the simplified local solutions into a global solution. The combination requires particular care to deal with the additional subtour in each component created in the Local Theorem.

Next, we apply the *adaptive rounding* technique to the resulting global solution. The adaptive rounding technique for capacitated vehicle routing was first used by Jayaprakash and Salavatipour [18] in their design of a QPTAS in the equal demand setting. This technique enables us reduce the number of subtour demands in each subtree to a constant $O_\epsilon(1)$.

Finally, we design a polynomial time dynamic program to compute the best solution that satisfies the structural constraints established previously. The computed solution is a $(1.5 + O(\epsilon))$-approximation.

This completes the proof of Theorem 1. See the full version of the paper for more details.

▶ Remark 2. When the overall cost of all edges in the tree is fixed, letting W denote this cost, it is possible to adapt our analysis to obtain an *asymptotic polynomial time approximation scheme*. To that end, we observe that in the proof of the Local Theorem (Theorem 13), the extra cost to connect all removed pieces in a component is at most twice the overall cost of all edges in that component, so the overall extra cost over all components is at most $2W$. Thus the cost of the computed solution is at most $1 + O(\epsilon)$ times the optimal cost plus $2W$.

3 Preliminaries

3.1 Formal Problem Description and Notations

Let T be a rooted tree (V, E) with edge weights $w(u, v) \geq 0$ for all $(u, v) \in E$. Let n denote the number of vertices in V. The *cost* of a tour (resp. a subtour) t, denoted by $\text{cost}(t)$, is the overall weight of the edges on t. For a set S of tours (resp. subtours), the *cost* of S, denoted by $\text{cost}(S)$, is $\sum_{t \in S} \text{cost}(t)$.

▶ **Definition 3** (UCVRP on trees). *An instance of the* unsplittable capacitated vehicle routing problem (UCVRP) *on* trees *consists of*

- *an edge weighted* tree $T = (V, E)$ *with* root $r \in V$ *representing the* depot,
- *a set* $V' \subseteq V$ *of* terminals,
- *for each terminal* $v \in V'$, *a* demand *of* v, *denoted by* $\text{demand}(v)$, *which belongs to* $(0, 1]$.

A feasible solution is a set of tours *such that*

- *each tour starts and ends at* r,

- *the demand of each terminal is covered by a* single *tour, i.e., the demand cannot be split,*
- *the total demand of the terminals covered by each tour does not exceed the* capacity *of 1.*

The goal is to find a feasible solution of minimum cost.

For any two vertices $u, v \in V$, let $\text{dist}(u, v)$ denote the distance between u and v in the tree T.

We say that a tour (resp. a subtour) *visits* a terminal if it covers the demand of that terminal. For technical reasons, we allow *dummy* terminals of appropriate demands to be included. The *demand* of a tour (resp. a subtour) t, denoted by $\text{demand}(t)$, is defined to be the total demand of all terminals (including dummy terminals) visited by t.

3.2 Reduction to Instances of Bounded Distances

▶ **Definition 4** (bounded distances, Definition 2.1 in [21]). *Let $D_{\min}$ (resp. $D_{\max}$) denote the minimum (resp. maximum) distance between the depot and any terminal in the tree T. We say that T has* bounded distances *if $D_{\max} < (1/\epsilon)^{(1/\epsilon)-1} \cdot D_{\min}$.*

The next theorem (Theorem 5) enables us to assume without loss of generality that the tree T has bounded distances.

▶ **Theorem 5** (Theorem 2.3 and Section 9 in [21]). *For any $\rho \geq 1$, if there is a polynomial time ρ-approximation algorithm for the UCVRP on trees with* bounded distances*, then there is a polynomial time $(1 + 5\epsilon)\rho$-approximation algorithm for the UCVRP on trees with* general distances*.*

3.3 Decomposition Into Components

The next lemma decomposes the tree T into *components*.

▶ **Lemma 6** (Lemma 4.2 in [21]). *Let $\Gamma = 12/\epsilon$. There is a polynomial time algorithm to compute a partition of the edges of the tree T into a set $\mathcal{C}$ of* components *(see Figure 1), such that all of the following properties are satisfied:*

1. *Every component $c \in \mathcal{C}$ is a connected subgraph of T; the* root *vertex of the component c, denoted by r_c, is the vertex in c that is closest to the depot.*
2. *A component c shares vertices with other components at vertex r_c and possibly at one other vertex, called the* exit *vertex of the component c and denoted by e_c. We say that c is an* internal *component if c has an exit vertex, and is a* leaf *component otherwise.*
3. *The total demand of the terminals in each component $c \in \mathcal{C}$ is at most 2Γ.*
4. *The number of components in $\mathcal{C}$ is at most $\max\{1, 3 \cdot \text{demand}(T)/\Gamma\}$, where $\text{demand}(T)$ denotes the total demand of the terminals in the tree T.*

▶ **Definition 7** (Definition 4.4 in [21]). *Let $c \in \mathcal{C}$ be any component. A* subtour in component c *is a path t that starts and ends at the root r_c of component c, and such that every vertex on t is in component c. We say that a subtour t is a* passing subtour *if c has an exit vertex and that vertex belongs to t, and is an* ending subtour *otherwise.*

4 Multi-Level Decomposition in a Component

Let $c \in \mathcal{C}$ be any component. We partition c using a *multi-level decomposition*: first, c is decomposed into *blocks* (Section 4.1); next, each block is decomposed into *clusters* (Section 4.2); and finally, each cluster is decomposed into *cells* (Section 4.3).

We introduce some notations. Let z denote any block (resp. any cluster or any cell). Then z has a *root* vertex and at most one *exit* vertex. We say that a terminal v is *strictly* inside z if v belongs to z and v is different from the root vertex and the exit vertex of z. The *demand* of z is defined as the total demand of all terminals *strictly* inside z. If z has no exit vertex, then z is called *ending*; otherwise z is called *passing*, and the path between the root vertex and the exit vertex of z is called the *spine* of z.

We distinguish *big* and *small* terminals depending on their demands.

▶ **Definition 8** (big and small terminals). *Let* $\alpha = \epsilon^{(1/\epsilon)+1}$. *Let* $\Gamma' = \epsilon \cdot \alpha/\Gamma$, *where* Γ *is defined in Lemma 6. We say that a terminal* v *is* big *if* $\text{demand}(v) > \Gamma'$ *and* small *otherwise.*

4.1 Decomposition of a Component Into Blocks (Figure 2a)

Let c be a component. Let $U \subseteq V$ denote the set of vertices consisting of the big terminals in c, the *root* vertex of c, and possibly the *exit* vertex of c if c is an *internal* component (see Lemma 6 for definitions). Let T_U denote the subtree of c spanning the vertices in U. We say that a vertex in T_U is a *key* vertex if either it belongs to U or it has two children in T_U. We define a *block* to be a maximally connected subgraph of component c in which any key vertex has degree 1; in other words, blocks are obtained by splitting the component at the key vertices. Note that any terminal strictly inside a block is small. The blocks form a partition of the edges of component c.

4.2 Decomposition of a Block Into Clusters (Figure 2b)

As an adaptation from Lemma 6, we decompose a block into clusters in Lemma 9.

▶ **Lemma 9.** *Let* b *be any block. There is a polynomial time algorithm to compute a partition of the edges of the block* b *into a set of* clusters, *such that all of the following properties are satisfied:*

1. *Every cluster* x *is a connected subgraph of* b*; the* root *vertex of the cluster* x*, denoted by* r_x*, is the vertex in* x *that is closest to the depot.*
2. *A cluster* x *shares vertices with other clusters at vertex* r_x *and possibly at one other vertex, called the* exit *vertex of the cluster* x *and denoted by* e_x*. If block* b *has an exit vertex* e_b*, then there is a cluster* x *in* b *such that* $e_x = e_b$*.*
3. *The demand of each cluster in* b *is at most* $2\Gamma'$*.*
4. *The number of clusters in* b *is at most* $3 \cdot (\text{demand}(b)/\Gamma' + 1)$*.*

4.3 Decomposition of a Cluster Into Cells (Figure 2c)

Let x be any cluster.

Case 1: x is an ending cluster. The decomposition of x consists of a single *cell*, which is the entire cluster x.

Case 2: x is a passing cluster. Let ℓ denote the cost of the spine of cluster x. If $\ell = 0$, the decomposition of x consists of a single *cell*, which is the entire cluster x. Next, we assume that $\ell > 0$. For each integer $i \in [1, (1/\epsilon) - 1]$, there exists a unique edge (u, v) on the spine of cluster x satisfying $\min(\text{dist}(r_x, u), \text{dist}(r_x, v)) \leq i \cdot \epsilon \cdot \ell < \max(\text{dist}(r_x, u), \text{dist}(r_x, v))$; let e_i denote that edge. Removing the edges $e_1, e_2, \ldots, e_{(1/\epsilon)-1}$ from cluster x results in at most $1/\epsilon$ connected subgraphs; each subgraph is called a *cell*. Observe that those cells form a partition of the vertices of cluster x.

The (unique) cell inside an ending cluster is an ending cell, and any cell inside a passing cluster is a passing cell. Fact 10 follows directly from the construction.

▶ **Fact 10.** *Let x be a passing cluster. The cost of the spine of any cell in x is at most an ϵ fraction of the cost of the spine of x.*

▶ **Fact 11.** *In any component c, the number of cells and the number of big terminals are both $O_\epsilon(1)$.*

Proof. By Lemma 6, the total demand of the terminals in component c is at most 2Γ. Since the demand of a big terminal is at least Γ', there are at most $2\Gamma/\Gamma' = O_\epsilon(1)$ big terminals in c.

From the construction in Section 4.1, the set U consists of at most $2 + 2\Gamma/\Gamma'$ vertices. Since each vertex in c has at most two children, the number of blocks in c is at most $2|U| \leq 4 + 4\Gamma/\Gamma'$. From the construction in Section 4.2, each block b is partitioned into at most $3 \cdot (\text{demand}(b)/\Gamma' + 1)$ clusters, where demand(b) is at most the total demand of the terminals in component c, which is at most 2Γ. From the construction in Section 4.3, each cluster is partitioned into at most $1/\epsilon$ cells. So the number of cells in c is at most $(4 + 4\Gamma/\Gamma') \cdot (3 \cdot (2\Gamma/\Gamma' + 1)) \cdot (1/\epsilon) = O_\epsilon(1)$. ◀

▶ **Definition 12** (Adaptation from Definition 7)**.** *A* subtour in a cluster (resp. cell) *is a path t that starts and ends at the root of that cluster (resp. cell), and such that every vertex on t is in that cluster (resp. cell). We say that a subtour t is a* passing subtour *if that cluster (resp. cell) has an exit vertex and that vertex belongs to t, and is an* ending subtour *otherwise. The* spine subtour *in a passing cluster (resp. passing cell) consists of the spine of that cluster (resp. cell) in both directions.*

5 Simplifying the Local Solution

In this section, we prove the Local Theorem (Theorem 13).

▶ **Theorem 13** (Local Theorem)**.** *Let c be any component. Let S_c denote a set of at most $(2\Gamma/\alpha) + 1$ subtours in component c visiting all terminals in c. Then there exists a set S_c^* of subtours in component c visiting all terminals in c, such that all of the following properties hold:*

1. *For each cell in c, a single subtour in S_c^* visits all small terminals in that cell;*
2. *S_c^* contains one particular subtour $\bar{t}$ of demand at most 1, and the subtours in $S_c^* \setminus \{\bar{t}\}$ are in one-to-one correspondence with the subtours in S_c, such that for every subtour t in S_c and its corresponding subtour t^* in $S_c^* \setminus \{\bar{t}\}$, the demand of t^* is at most the demand of t, and in addition, if t is a passing subtour in c, then t^* is also a passing subtour in c;*
3. *The cost of S_c^* is at most $1.5 + 2\epsilon$ times the cost of S_c.*

▶ Remark 14. Note that the cost to connect the newly generated subtour $\bar{t}$ to the depot is negligible thanks to the properties of the components.

5.1 Construction of S_c^*

The construction of S_c^* starts from S_c and proceeds in 5 steps. In particular, Step 2 uses a new concept of *threshold cells* and is the main novelty in the construction.

The following lemma due to Becker and Paul [5] will be used in Step 1 and Step 3.

▶ **Lemma 15** (Assignment Lemma, Lemma 1 in [5]). *Let $G = (V[G], E[G])$ be an edge-weighted bipartite graph with vertex set $V[G] = A \uplus B$ and edge set $E[G] \subseteq A \times B$, such that each edge $(a, b) \in E[G]$ has a weight $w(a, b) \geq 0$. For each vertex $b \in B$, let $N(b)$ denote the set of vertices $a \in A$ such that $(a, b) \in E[G]$. We assume that $N(b) \neq \emptyset$ and the weight $w(b)$ of the vertex b satisfies $0 \leq w(b) \leq \sum_{a \in N(b)} w(a, b)$. Then there exists a function $f : B \to A$ such that each vertex $b \in B$ is assigned to a vertex $a \in N(b)$ and, for each vertex $a \in A$, we have*

$$\sum_{b \in B | f(b) = a} w(b) - \sum_{b \in B | (a,b) \in E[G]} w(a, b) \leq \max_{b \in B} \{w(b)\}.$$

Step 1: Combining ending subtours within each cluster

Let A_0 denote S_c. We define a weighted bipartite graph G in which the vertices in one part represent the subtours in A_0 and the vertices in the other part represent the clusters in c.[6] There is an edge in G between a subtour $a \in A_0$ and a cluster x in c if and only if a contains an ending subtour t in x; the weight of the edge is defined to be demand(t). For each cluster x in c, we define the weight of x in G to be the sum of the weights of its incident edges in G. We apply the Assignment Lemma (Lemma 15) to the graph G (deprived of the vertices of degree 0) and obtain a function f that maps each cluster x in c to some subtour $a \in A_0$ such that (a, x) is an edge in G.

We construct a set of subtours A_1 as follows: for every cluster x in c and for every subtour $a \in A_0$ containing an ending subtour t in x, the subtour t is removed from a and added to the subtour $f(x)$. Observe that each resulting subtour in A_1 is connected. From the construction, *for each cluster x, at most one subtour in A_1 has an ending subtour in x*. In particular, for any *ending cell*, which is equivalent to an ending cluster, a single subtour in A_1 visits all small terminals in that cell.

Step 2: Extending ending subtours within threshold cells

Let x be any passing cluster in c such that there is a subtour in A_1 containing an ending subtour in x. From Step 1 of the construction, such a subtour in A_1 is unique; let t_e denote the corresponding ending subtour in x.

We define the **threshold cell** of cluster x to be the deepest cell in x containing vertices of t_e. See Figure 4a.

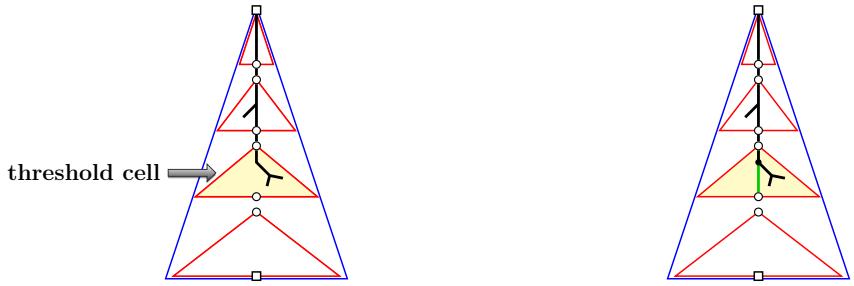
Then we add to t_e the part of the *spine subtour in the threshold cell of x* that does not belong to t_e, resulting in a subtour $\tilde{t}_e$; see Figure 4b.

Let A_2 denote the resulting set of subtours in c after the extension within all threshold cells. From the construction, *for each passing cell s, all subtours in s that are contained in A_2 are passing subtours in s.*

Step 3: Combining passing subtours within each passing cell

We define a weighted bipartite graph G' in which the vertices in one part represent the subtours in A_2 and the vertices in the other part represent the passing cells in c.[7] There is an edge in G' between a subtour $a \in A_2$ and a passing cell s in c if and only if a contains a non-spine passing subtour t in s; the weight of the edge is defined to be the total demand of the small terminals on t. For each passing cell s in c, we define the weight of s in G' to

[6] With a slight abuse, we identify a vertex in G with either a subtour in A_0 or a cluster in c.
[7] With a slight abuse, we identify a vertex in G' with either a subtour in A_2 or a passing cell in c.



(a) Subtour before extension. **(b)** Subtour after extension.

Figure 4 The threshold cell and the extension of an ending subtour. The outermost triangle in blue represents a cluster x. In Figure 4a, the black segments represent the ending subtour t_e in x. The *threshold cell* of cluster x is the *deepest* cell visited by t_e and is represented by the yellow triangle. In Figure 4b, subtour t_e is extended within the threshold cell: the green segment represents the part of the *spine subtour of the threshold cell* that is added to t_e, resulting in a subtour $\tilde{t}_e$.

be the sum of the weights of its incident edges in G'. We apply the Assignment Lemma (Lemma 15) to the graph G' (deprived of the vertices of degree 0) and obtain a function f' that maps each passing cell s in c to some subtour $a \in A_2$ such that (a, s) is an edge in G'.

We construct a set of subtours A_3 as follows: for every passing cell s in c and for every subtour $a \in A_2$ containing a non-spine passing subtour t in s, the subtour t is removed from a except for the spine subtour of s; the removed part is added to the subtour $f'(s)$. Observe that each resulting subtour in A_3 is connected. From the construction, *for each passing cell s, a single subtour in A_3 visits all small terminals in s.*

Step 4: Correcting subtour capacities

For each subtour t_3 in A_3, let t_0 denote the corresponding subtour in A_0. As soon as the demand of t_3 is greater than the demand of t_0, we repeatedly modify t_3 as follows: find a terminal v that is *visited by t_3 but not visited by t_0*; let s denote the cell containing v and let t_s denote the subtour of t_3 in cell s; if s is an ending cell, then remove t_s from t_3; and if s is a passing cell, then remove t_s from t_3 except for the spine subtour of s.

Let A_4 denote the resulting set of modified subtours. Observe that each subtour in A_4 is connected. From the construction, *the demand of each subtour in A_4 is at most the demand of the corresponding subtour in A_0.* Note that the big terminals in each subtour in A_4 are the same as the big terminals in the corresponding subtour in A_0.[8]

Let $\mathcal{R}$ denote the set of the removed pieces. We claim that the total demand of the pieces in $\mathcal{R}$ is at most 1 (Lemma 22).

Step 5: Creating an additional subtour

We connect all pieces in $\mathcal{R}$ by a single subtour $\bar{t}$, which is the minimal subtour in component c that connects all pieces in $\mathcal{R}$ to the root of component c.

Finally, let S_c^* denote $A_4 \cup \{\bar{t}\}$.

[8] Any big terminal cannot be removed, since it is the exit vertex of some cell, thus belongs to the spine of that cell.

5.2 Analysis on the Cost of S_c^*

From the construction of S_c^*, we observe that the cost of S_c^* equals the cost of S_c plus the extra costs in Step 2 and in Step 5 of the construction, denoted by W_2 and W_5, respectively.

To analyze the extra costs, first, in a preliminary lemma (Lemma 16), we bound the overall cost of the spines of the threshold cells. Lemma 16 will be used to analyze both W_2 (Corollary 17) and W_5 (Lemma 21).

▶ **Lemma 16.** *The overall cost of the spines of all threshold cells in the component c is at most $(\epsilon/2) \cdot \text{cost}(S_c)$.*

Proof. Consider any threshold cell s. Let x be the passing cluster that contains s. By Fact 10, the cost of the spine of cell s is at most an ϵ fraction of the cost of the spine of x. Since x is a passing cluster, at least one subtour in S_c contains a passing subtour in x; let t_x denote that passing subtour in x. Observe that t_x contains each edge of the spine of cluster x in both directions (Definition 12), so the cost of the spine of x is at most $\text{cost}(t_x)/2$. Thus the cost of the spine of s is at most $(\epsilon/2) \cdot \text{cost}(t_x)$. We *charge* the cost of the spine of s to t_x.

From the construction, each cluster contains at most one threshold cell. Thus the costs of the spines of all threshold cells are charged to disjoint parts of S_c. The claim follows. ◀

Observe that the extra cost in Step 2 of the construction is at most the overall cost of the spine subtours in all threshold cells in the component c, which equals twice the overall cost of the spines of those cells by Definition 12.

▶ **Corollary 17.** *The extra cost W_2 in Step 2 of the construction is at most $\epsilon \cdot \text{cost}(S_c)$.*

Next, we bound the extra cost in Step 5 of the construction.

▶ **Fact 18.** *Let t denote any subtour in S_c. Let x denote any cluster in c. Let r_c and r_x denote the root vertices of component c and of cluster x, respectively; let e_x denote the exit vertex of cluster x. If the r_c-to-r_x path (resp. the r_c-to-e_x path) belongs to t, then that path belongs to the corresponding subtour of t throughout the construction in Section 5.1.*

▶ **Definition 19** (nice edges)**.** *We say that an edge e in component c is* nice *if e belongs to* at least two *subtours in A_2.*

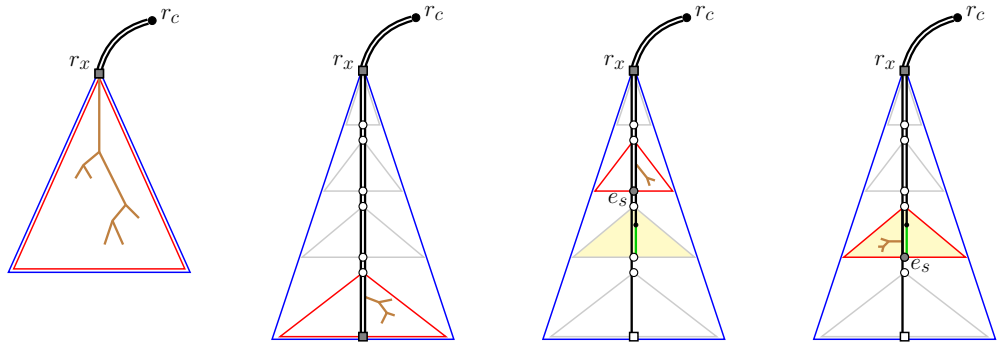
The next Lemma (Lemma 20) is the main novelty in the analysis.

▶ **Lemma 20.** *Any piece in $\mathcal{R}$ is connected to the root r_c of component c through nice edges in c.*

Proof. Consider any piece $q \in \mathcal{R}$. Let s be the cell containing q. Let x be the cluster containing q. See Figure 5. Let r_s and r_x denote the root vertices of cell s and of cluster x, respectively. Observe that the terminals in x are visited by at least two subtours in S_c. This is because, if all terminals in cluster x are visited by a single subtour in S_c, then those terminals belong to the corresponding subtour throughout the construction, thus none of those terminals belongs to a piece in $\mathcal{R}$, contradiction. Thus the r_c-to-r_x path belongs to at least two subtours in S_c. By Fact 18, the r_c-to-r_x path belongs to at least two subtours in A_2, thus every edge on the r_c-to-r_x path is nice. It suffices to show the following Claim:

Piece q is connected to vertex r_x through nice edges in c. (*)

There are two cases:



(a) Case 1. **(b)** Subcase 2(i). **(c)** Subsubcase 2(ii)(α). **(d)** Subsubcase 2(ii)(β).

Figure 5 Illustrations for the different cases in the proof of Lemma 20. A piece $q \in \mathcal{R}$ is in brown. The cell s containing that piece is represented by the triangle in red; the cluster x containing that piece is represented by the outermost triangle in blue. The black node r_c is the root of component c. In Figure 5a, x is an ending cluster. In Figure 5b, x is a passing cluster, and the solution S_c contains two passing subtours in x. In Figures 5c and 5d, x is a passing cluster, and the solution S_c contains a unique passing subtour in x; the yellow triangle represents the threshold cell of x. In the case when q belongs to the threshold cell (Figure 5d), q is connected to r_c through at least two subtours, thanks to the extension of the ending subtour within the threshold cell.

Case 1: x is an ending cluster. See Figure 5a. From the decomposition in Section 4.3, s is an ending cell and s equals x. Piece q is an ending subtour in x and in particular contains r_x. Claim (*) follows trivially.

Case 2: x is a passing cluster. Let e_s and e_x denote the exit vertices of cell s and of cluster x, respectively. Observe that at least one subtour in S_c contains a passing subtour in x. There are two subcases.

Subcase 2(i): At least two subtours in S_c contain passing subtours in x. See Figure 5b. Then the r_c-to-e_x path belongs to at least two subtours in S_c. By Fact 18, the r_c-to-e_x path belongs to at least two subtours in A_2, thus each edge on the spine of x is nice. Since piece q contains a vertex on the spine of x, Claim (*) follows.

Subcase 2(ii): Exactly one subtour in S_c contains a passing subtour in x. See Figures 5c and 5d. Let t_p denote that passing subtour in x. As observed previously, at least two subtours in S_c visit terminals in x, so there must be at least one subtour in S_c that contains an ending subtour in x. Let $t_e^1, \ldots, t_e^m$ (for some $m \geq 1$) denote the ending subtours in x contained in the subtours in S_c. In Step 1 of the construction, the m ending subtours are combined into a single ending subtour, denoted by t_e (recall that the threshold cell of x is defined with respect to t_e); and in Step 2 of the construction, subtour t_e is extended to a subtour $\tilde{t}_e$ (Figure 4). Note that the passing subtour t_p remains unchanged in Steps 1 and 2 of the construction. We observe that cell s is either above or equal to the threshold cell of x. This is because, if cell s is below the threshold cell of x, then all terminals in s are visited by a single subtour in S_c, i.e., the subtour t_p, so those terminals belong to the corresponding subtour of t_p throughout the construction, thus none of those terminals belongs to a piece in $\mathcal{R}$, contradiction. Hence the following two subsubcases.

Subsubcase 2(ii)(α): s is above the threshold cell of x. See Figure 5c. Each edge on the r_x-to-e_s path belongs to both subtours t_p and t_e, hence is nice. Since q contains some vertex on the spine of s, Claim (*) follows.

Subsubcase 2(ii)(β): s equals the threshold cell of x. See Figure 5d. Observe that each edge on the r_x-to-e_s path belongs to $\tilde{t}_e$ due to the extension of the ending subtour t_e within the threshold cell (Step 2 of the construction). Thus each edge on the r_x-to-e_s path belongs to both subtours t_p and $\tilde{t}_e$, hence is nice. Since q contains some vertex on the spine of s, Claim (*) follows. ◀

▶ **Lemma 21.** *The extra cost W_5 in Step 5 of the construction is at most $(0.5+\epsilon)\cdot \text{cost}(S_c)$.*

Proof. Let W_{nice} denote the overall cost of the nice edges in c. We show that $W_5 \leq 2 \cdot W_{\text{nice}}$. Let H be the multi-subgraph in c that consists of the pieces in $\mathcal{R}$ and two copies of each nice edge in c (one copy for each direction). Since any piece in $\mathcal{R}$ is connected to the root r_c of component c through nice edges (Lemma 20), H induces a connected subtour in c. So $W_5 \leq 2 \cdot W_{\text{nice}}$.

Next, we analyze W_{nice}. From the construction, any nice edge e in c is of at least one of the two cases:

Case 1: e belongs to at least two subtours in S_c. Then e has at least 4 copies in S_c, since each subtour to which e belongs contains 2 copies of e (one for each direction). Thus the overall cost of the edges e in this case is at most $0.25 \cdot \text{cost}(S_c)$.

Case 2: e belongs to the spine of a threshold cell in component c. By Lemma 16, the overall cost of the edges e in this case is at most $(\epsilon/2) \cdot \text{cost}(S_c)$.

Hence the overall cost W_{nice} of the nice edges is at most $(0.25+\epsilon/2)\cdot \text{cost}(S_c)$. Therefore, $W_5 \leq 2 \cdot W_{\text{nice}} \leq (0.5+\epsilon)\cdot \text{cost}(S_c)$. ◀

From Corollary 17 and Lemma 21, we conclude that

$$\text{cost}(S_c^*) = \text{cost}(S_c) + W_2 + W_5 \leq (1.5+2\epsilon)\cdot \text{cost}(S_c).$$

Hence the third property of the claim in the Local Theorem (Theorem 13).

5.3 Feasibility

From the construction, S_c^* is a set of subtours in c visiting all terminals in c. The first property of the claim in the Local Theorem (Theorem 13) follows from the construction. The second property of the claim follows from the construction, Fact 18, and the following Lemma 22.

▶ **Lemma 22.** *The total demand of the pieces in $\mathcal{R}$ is at most 1.*

Proof. Observe that the pieces in $\mathcal{R}$ are removed from subtours in A_3. Let t_3 denote any subtour in A_3. Let t_0, t_1, t_2, and t_4 denote the corresponding subtours of t_3 in A_0, A_1, A_2, and A_4, respectively. Let Δ denote the overall demand of the pieces that are removed from t_3 in Step 4 of the construction. Observe that $\Delta = \text{demand}(t_3) - \text{demand}(t_4)$. To bound Δ, first, by Step 1 of the construction and the Assignment Lemma (Lemma 15), the demand of each subtour in A_0 is increased by at most the maximum demand of a cluster. Thus $\text{demand}(t_1) - \text{demand}(t_0)$ is at most the maximum demand of a cluster, which is at most $2\Gamma'$ by the definition of clusters (Section 4.2). By Step 2 of the construction, $\text{demand}(t_2) = \text{demand}(t_1)$. By Step 3 of the construction and the Assignment Lemma (Lemma 15), the demand of each subtour in A_2 is increased by at most the maximum demand of a cell. Thus $\text{demand}(t_3) - \text{demand}(t_2)$ is at most the maximum demand of a cell, which is at most $2\Gamma'$ by the definition of cells (Section 4.3). By Step 4 of the construction, $\text{demand}(t_0) - \text{demand}(t_4)$ is at most the maximum demand of a cell, which is at most $2\Gamma'$. Combining, we have $\Delta = \text{demand}(t_3) - \text{demand}(t_4) \leq 6\Gamma'$.

The number of subtours in A_3 equals the number of subtours in S_c, which is at most $(2\Gamma/\alpha)+1$ by assumption. Thus total demand of the pieces in $\mathcal{R}$ is at most $6\Gamma' \cdot ((2\Gamma/\alpha)+1) < 13\epsilon < 1$, assuming $\epsilon < 1/13$. ◀

This completes the proof of the Local Theorem (Theorem 13).

Abstract

Motivated by cloud computing applications, we study the problem of how to optimally deploy new hardware subject to both power and robustness constraints. To model the situation observed in large-scale data centers, we introduce the *Online Demand Scheduling with Failover* problem. There are m identical devices with capacity constraints. Demands come one-by-one and, to be robust against a device failure, need to be assigned to a pair of devices. When a device fails (in a failover scenario), each demand assigned to it is rerouted to its paired device (which may now run at increased capacity). The goal is to assign demands to the devices to maximize the total utilization subject to both the normal capacity constraints as well as these novel failover constraints. These latter constraints introduce new decision tradeoffs not present in classic assignment problems such as the Multiple Knapsack problem and AdWords.

In the worst-case model, we design a deterministic $\approx \frac{1}{2}$-competitive algorithm, and show this is essentially tight. To circumvent this constant-factor loss, which represents substantial capital losses for big cloud providers, we consider the stochastic arrival model, where all demands come i.i.d. from an unknown distribution. In this model we design an algorithm that achieves sub-linear additive regret (i.e. as OPT or m increases, the multiplicative competitive ratio goes to 1). This requires a combination of different techniques, including a configuration LP with a non-trivial post-processing step and an online monotone matching procedure introduced by Rhee and Talagrand.

1 Introduction

A critical challenge faced by cloud providers is how to deploy new hardware to satisfy the increasing demand for cloud resources, and the main bottleneck in this process is power. Data centers consist of power devices with limited capacity and each demand for hardware (e.g.

[1] Work performed as intern at Microsoft Research, Redmond.

rack of servers) has a power requirement. The goal is to assign demands to power devices to fulfill their requirements while using the available power in the data centers efficiently. This allows cloud providers to maximize return on investment on existing data centers before incurring large capital expenses for new data centers to accommodate additional demand.

An important consideration that sets this demand assignment process apart from other applications is *reliability*. Cloud users are promised a high availability of service which mandates that cloud capacity can only be unavailable for very short durations (between a few minutes and a few hours per year). As a result, assigning each demand to a single power device leads to an unacceptable level of risk; if that device fails, the capacity for the demand becomes unavailable, leading to potentially millions of dollars in costs for the provider and jeopardizing the cloud business model that is highly dependent on users' trust. To this end, power *redundancy* is built into the assignment process.

We consider a specific model of redundancy used by large cloud providers [19]. In this model, each demand gets assigned to two power devices. In normal operations (no device failure), the demand obtains half of its required power from each device. If one of the devices fails, the remaining device must provide the full power amount to the demand (see Figure 1 for an example). In these failover scenarios, the remaining devices may run at an increased capacity temporarily to accommodate their increased load. The provider uses this time to take ad-hoc corrective actions, for instance, shut down certain workloads and reduce the power of others in order to bring the power utilization of each device back within its normal limits. As in [19] we consider a single device failure at a time.

This architecture is favored in practice because it provides strong reliability guarantees with a small increase in overhead and complexity. One could consider more complex architectures, where demands could be assigned with a power split other than half-half to each device or to more than two devices, but this comes at an increased cost in hardware and operational complexity. Further, a common goal of large cloud providers is to provide statistical guarantees for high service availability, e.g., 99.99% availability for certain cloud resources or services; cloud operators have determined that accounting for a single device failure with the described architecture provides such target guarantees.

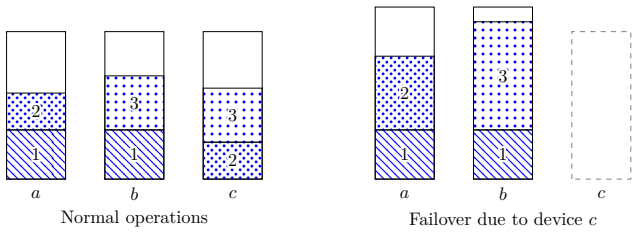

Figure 1 In normal operations (left), each demand (denoted with a different pattern) is assigned to two devices and gets half of its required power from each device. In the failover scenario where device c has failed (right), the demands that were assigned to c now get their full power from the remaining devices that may run at increased capacity.

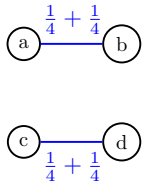
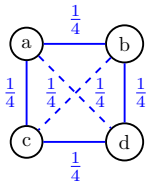
We introduce the *Online Demand Scheduling with Failover* problem (FAILOVER) to model this issue of assigning demands to power devices with redundancy. Formally, in this problem there are m identical devices (or machines) and n demands. Each device has two capacities: a nominal capacity that is normalized to 1 and a failover capacity $B \geq 1$. Each demand j has some size $s_j \geq 0$, which for convenience is defined as its per-device power requirement (so the total power requirement of the demand is $2s_j$). The demands arrive online one-by-one and there is no knowledge about future demands. The goal is to irrevocably assign the arriving

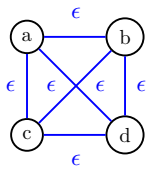


(a) Bad assignment.

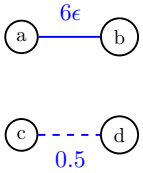


(b) Good assignment.

Figure 2 Illustration of Example 1.



(a) Bad assignment.



(b) Good assignment.

Figure 3 Illustration of Example 2.

demands to pairs of devices (or edges, where we consider each device as a node) satisfying:

1. (Nominal Constraints) For every device u, its total load has to be at most 1, namely $L_u := \sum_{v \neq u} L_{uv} \leq 1$, where we define $L_{uv} = \sum_{j \to uv} s_j$ to be the total load on edge uv (i.e., all demands assigned to the pair of devices uv).
2. (Failover Constraints) For every device u, we have $L_u + \max_{v \neq u} L_{uv} \leq B$ (i.e., if a device $v \neq u$ fails, all demands assigned to uv have to be supplied solely by u, which sees its load increased by the amount L_{uv} that was formerly supplied to them by device v; the increased load has to fit the failover capacity B).

We assume that each demand size s_j fits on a pair of devices by itself, so $s_j \in [0, \min(1, B/2)]$. We are not allowed to reject demands, so the algorithm assigns arriving demands to the available devices until a demand cannot be scheduled, in which case the algorithm terminates. Our objective is to maximize the total size of all assigned demands (i.e., the utilization). We compare the algorithm against the optimal offline strategy that knows the demand sequence in advance (but still subject to the same no-rejection requirement). We use OPT to denote the total utilization of this optimal offline strategy.

This problem has similarities with several classical packing problems. For example, in the Multiple Knapsack problem (and related problems such as Generalized Assignment [18], AdWords [14], etc.) we are given a set of items each with a weight and size, and the goal is to select a subset of the items to pack in capacitated bins in order to maximize the total weight. However, one fundamental difference in our setting, besides the need to assign each demand to a pair of devices instead of a single device, is the failover constraint. Unlike in previously studied resource allocation problems, here the capacity constraints are not just determined by the total demand incident to a node, but rather they depend also on how the demands are arranged across its edges. See the next example.

▶ **Example 1.** Consider an instance with 4 power devices a, b, c, d with failover capacity $B = 1$. There are 6 demands of size $\frac{1}{4}$ that arrive sequentially; suppose 4 demands have arrived so far. One possible assignment has placed 2 demands on each of the pairs ab and cd (see Figure 2a), while a different one may place each of the 4 demands on a different pair (see Figure 2b, in solid lines). While in the second option all remaining demands can be placed (dashed lines in Figure 2b), the first option cannot accommodate more demands due to the Failover capacity. To see this, suppose we assign another demand to device a, say. If device b fails, then the total load on a will become at least $\frac{5}{4}$ violating its Failover capacity.

The above example suggests that due to the Failover constraints we should "spread out" the demands by not putting too many demands on one edge, because if one of its endpoints fails then this edge can have a large contribution to the Failover constraint of the other endpoint. However, there is a danger in spreading out the demands too much and not leaving enough devices free.

▶ **Example 2.** Consider again the same 4 power devices a, b, c, d with failover capacity $B = 1$. Now, there are 7 demands; the first 6 have a small size $\varepsilon > 0$ and the last demand has size 0.5. Assume the first 6 demands have arrived. A first option is to assign one demand of size ϵ per device pair (see Figure 3a). In this case, the remaining demand of size 0.5 cannot be placed, as the Failover capacities would be exceeded. The second option groups the first 6 demands on a single edge (see Figure 3b); in this case, all demands can be fulfilled by assigning the last demand on a disjoint edge (dashed edge of Figure 3b).

Taking these two examples together, there is a delicate balance between spreading demands out across edges to minimize their impact in failover scenarios and leaving enough devices open for future demands, as to not prematurely end up with an unassignable demand.

1.1 Our results

We first consider the FAILOVER problem in the worst-case and design a deterministic algorithm with competitive ratio $\approx \frac{1}{2}$. Since no deterministic algorithm can be better than $\frac{1}{2}$-competitive (see the full version of the paper for upper bound), this result is almost best possible.

▶ **Theorem 3.** *There is a deterministic poly-time online algorithm for* FAILOVER *in the worst-case model with competitive ratio* $\frac{1}{2} - O(\frac{1}{m^{1/3}})$,[2] *where* m *is the number of devices.*

A $\frac{1}{2}$-competitive solution may, roughly speaking, underutilize by a factor of $\frac{1}{2}$ the available power; in the context of big cloud providers, this inefficiency translates to substantial capital expenses due to the extra data centers required to accommodate the demands. Since such losses are unavoidable in the worst-case model, we consider the FAILOVER problem in the *stochastic arrival model*. Here the demand sizes are drawn i.i.d. from an unknown distribution μ supported on $[0, \min(1, B/2)]$.

We show that in this stochastic model it is possible to obtain *sublinear additive regret*.

▶ **Theorem 4.** *For the* FAILOVER *problem in the stochastic arrival model, there is a poly-time algorithm that achieves utilization* $\mathsf{OPT} - O(\mathsf{OPT}^{5/6} \log \mathsf{OPT})$ *with probability* $1 - O(\frac{1}{m})$.

We remark that since OPT grows like $\Theta(\xi)$, where $\xi := \min\{n, m\}$ (see Lemma 9), this guarantee implies the multiplicative approximation $(1 - O(\log \xi \,/\, \xi^{1/6})) \cdot \mathsf{OPT}$. So as the number of demands and devices grow, the competitive ratio of this algorithm goes to 1.

As a subroutine of this algorithm, we need to solve the natural *offline minimization* variant of demand scheduling with failover: Given a collection of demands, minimize the number of devices needed to assign all demands satisfying the Nominal and Failover constraints. We also design an (offline) algorithm with sublinear additive regret for this problem (Section 4).

1.2 Technical Overview

We illustrate the main technical challenges in the FAILOVER problem in both the worst-case and stochastic models, as well as in the offline minimization subproblem needed for the latter.

Online Worst-Case (Section 2). The examples from Figure 2 and 3 show that the main difficulty is dealing with the trade-off between spreading out the demands, which allows for a better use of the failover budgets, and co-locating demands on fewer edges, keeping some edges free for future big demands.

[2] Throughout the paper we use $O(x)$ to mean "$\leq cst \cdot x$" for some constant cst independent of x.

To effectively strike this balance and get near optimal guarantees, the main idea is to group demands based on their sizes using intervals I_k and schedule each group separately on cliques of size k. That is, we will "open" a set of k unused devices and assign the demands in I_k only to the edges between these devices (opening new k-cliques as needed). Interestingly, we assign at most one demand per edge of the clique (other than for tiny demands, which are handled separately). This means the algorithm tries to co-locate demands in controlled *regions*, which allows for the right use of the failover budgets.

Online Stochastic Arrivals (Section 3). First, note that because demands are i.i.d. from a distribution with bounded support, the total utilization of the first ℓ demands grows as $\ell \cdot \mathbb{E}_{S\sim\mu}S$. Thus, it suffices to show that our algorithm "survives" for as many demand arrivals as possible without needing to reject one due to lack of space. Our approach is to try and assign prefixes of arrivals to the (approximately) minimum number of devices possible. This ensures that if our algorithm fails due to needing more than m devices to feasibly assign another demand, then OPT will fail shorty after.

Our algorithm is based on a learn-and-pack framework, where we use knowledge of the first ℓ arrivals to compute a good template assignment for the next ℓ arrivals. To compute this template, we need a subroutine that (approximately) solves the offline minimization subproblem mentioned above. Concretely, we run the subroutine on the realized sizes of the first ℓ arrivals, which gives a possible assignment of these demands into, say m' unused devices. We use the "slots" of this possible assignment as a template to assign the future ℓ demands by employing the *online monotone matching* process of Rhee-Talgrand [16]: For each future arrival, we assign it to a (carefully-chosen) open slot in the template that has a larger size – if we cannot find such an open slot, then we assign this demand to its own disjoint edge (using 2 more devices).

It is known that this matching process leaves $o(\ell)$ unmatched demands with high probability. Further, our offline minimization subroutine has sublinear additive regret, that is, it uses only $o(\ell)$ more devices than the optimal offline assignment. Since these losses are sublinear in the prefix size, it seems that by repeating this process together with doubling the prefix size we should obtain a final sublinear regret guarantee.

But there is still a major issue: This strategy uses *disjoint* sets of devices to fulfill the first ℓ demands and the next ℓ demands (for each doubling ℓ). But this is possibly very wasteful: even using the optimal assignment for each of these ℓ demands separately may require many more devices (up to double) compared to reusing the leftover space from the first batch of ℓ demands for the next batch (i.e. assigning the batches to a common set of devices). Wasting a constant fraction of devices would lead to the unwanted constant-competitive loss. To overcome this, we show that M_ℓ, the minimum number of devices to assign ℓ i.i.d. demands, is approximately linear in ℓ (Theorem 8), e.g. $M_\ell + M_\ell$ (assigning batches separately) is approximately $M_{2\ell}$ (assigning them together). This is a non-trivial task (another Rhee-Talagrand paper [15] is entirely devoted to doing this for the simpler Bin Packing problem). Perhaps surprisingly, our proof relies on our algorithm for the offline device minimization problem, which is LP-based. The crucial property is that the optimal LP value doubles if we duplicate the items on its input, which (with additional probabilistic arguments) translates into the additivity of M_ℓ.

Offline Minimization (Section 4). Our algorithm for offline minimization of the number of devices needed to fulfill a set of demands is based on a configuration LP inspired by the classic Gomory-Gilmore LP for the Bin Packing problem. Consider a fixed assignment of

demands to some number of devices. We want to interpret each device as a configuration, which captures the arrangement of demands on this device's edges. Our LP will minimize the number of configurations needed in order to assign all demands.

There is a tension between two issues in this approach. First, the Failover constraint depends not only on the subset of demands on this device's edges, but also how they are arranged within these edges (because the most-loaded edge contributes to the Failover constraint). This suggests that a configuration should not only specify a subset of demands, but also have enough information about the edge assignment to control the most-loaded edge. Second, each demand must be assigned to a pair of devices rather than a single device, so our configurations are not "independent" of each other. Thus, we need to "match" configurations to ensure that a collection of configurations can be realized in an edge assignment. In summary, our configurations should be expressive enough to capture the Failover constraints, but also simple enough so that we can actually realize them in an actual assignment.

Our solution to this is to define a configuration to be a subcollection, say C, of demands satisfying $\sum_{s\in C} s \leq 1$ (the Nominal constraint) and $\sum_{s\in C} s + \max_{s\in C} s \leq B$ (a relaxed Failover constraint). Note that this notion of configuration does not capture the arrangement of the demands C across a device's edges – we assume the best case that every demand is on its own edge to minimize their impact in failover scenarios. It is not clear that there even exists a near-optimal assignment that assigns at most one demand per edge, let alone that we can obtain one from the LP solution. However, our LP post-processing procedure will show that – by opening slightly more devices – we can match configurations of this form to realize them in a near-optimal assignment.

1.3 Related work

Despite a vast literature on assignment-type problems, none of the ones considered addresses the main issue of redundancy, modeled in the Failover problem. Arguably the Coupled Placement [11] problem is the closest to Failover. Given a bipartite graph with capacities at the nodes and a set of jobs, the goal is to assign a subset of the jobs to the edges of the graph to maximize the total value (each assigned job gives a value that also depends on its assigned edge), while respecting the capacity of the nodes (each assigned job consumes capacity from its edge's endpoints). [11] gives a $\frac{1}{15}$-approximation to the offline version of this problem (see also [1]). While this problem involves the allocation of jobs to a pair of nodes (albeit on a bipartite graph) and has the additional difficulty that the value and consumption of a job depends on which pair of nodes it is assigned, it does not have any Failover type constraints, a crucial component of our problem.

As already mentioned, several classic assignment problems are related to ours, such as the Multiple Knapsack [4], Generalized Assignment (GAP) [18], and AdWords problem [14, 7]. The latter is the closest to our problem: there are m bins (i.e. advertisers) of different capacities, and jobs (i.e. keyword searches) that come one-by-one and need to be assigned to the bins; each assignment consumes some of the bin's capacity and incurs an equal amount of value (i.e. bid). The goal is maximize total value subject to bin capacities. Despite the similarities, this problem does not consider critical aspects of our problem, namely the need to assign a job/demand to a pair of bins/devices and the Failover constraints.

There is also a large literature on survivable network design problems, where failures in the network are explicitly considered [6], but the nature of the problems is quite different from our assignment problem, as the focus there is typically on routing flows.

Finally, a problem related to our device minimization problem, and from which we borrow some tools and techniques, is Bin Packing. Here jobs of different sizes need to be assigned to a minimum number of bins of size 1. Results are known in both offline [9] and online settings [2, 16]. In the online stochastic setting, [16] obtains an additive $+O(\sqrt{\mathsf{OPT}}\cdot\log^{3/4}\mathsf{OPT})$ sublinear approximation (see [5, 8, 13] for improvements under different assumptions).

2 FAILOVER Problem in the Online Worst-Case Model

In this section we consider the FAILOVER in the online worst-case model. We design an algorithm that achieves competitive ratio $\approx \frac{1}{2}$ in this setting (restated from the introduction).

▶ **Theorem 3.** *There is a deterministic poly-time online algorithm for* FAILOVER *in the worst-case model with competitive ratio* $\frac{1}{2} - O(\frac{1}{m^{1/3}})$,[3] *where* m *is the number of devices.*

Recall that in the full version of the paper, we also show the almost matching upper bound of $\frac{1}{2}$ on such competitive ratio, and design another algorithm whose competitive ratio approaches 1 as the size of the largest demand goes to 0. To convey the main ideas more clearly, here we focus only on Theorem 3.

2.1 Algorithm

As suggested in the technical overview, our algorithm will group demands by size, and assign each group of demands to sub-cliques of an appropriate size. To make this precise, set in hindsight $L := m^{1/3}$ and for $k = 2, \ldots, L-1$ define the interval

$$I_k := \left(\min\left\{\frac{1}{k}, \frac{B}{k+1}\right\}, \ \min\left\{\frac{1}{k-1}, \frac{B}{k}\right\}\right].$$

(Notice there is no $k = 1$, because the upper limit of I_2 is the max size of a demand.) This definition ensures that it is feasible to assign one demand of such size to each edge of a k-clique, as we argue in the next subsection. Also define the interval of small sizes

$$I_{\geq L} := \left[0, \min\left\{\frac{1}{L-1}, \frac{B}{L}\right\}\right].$$

The algorithm is then the following:

Algorithm 1 **FailoverWostCase.**

1: When a demand arrives, determine the interval I_k (or $I_{\geq L}$) that it belongs to based on its size.

2: If it belongs to an interval I_k with $k \in \{2, \ldots, L-1\}$, assign the demand to any "empty" edge (i.e. that has not received any demands) of a k-clique opened for I_k. If no such edge exists, then open a new k-clique for I_k.

3: Otherwise it belongs to $I_{\geq L}$, so assign it to an edge of one of its L-cliques using *first-fit* (so here we **can assign multiple demands to the same edge**) making sure that the total load on each edge is at most $\min\{\frac{1}{L-1}, \frac{B}{L}\}$. By first-fit we mean that the edges of the $I_{\geq L}$ cliques are arbitrarily ordered and the demand is assigned to the first possible edge. Open a new L-clique for $I_{\geq L}$ if need be.

4: If the demand cannot fit in the appropriate clique and it is not possible to open a new clique (i.e. there are not enough unused machines to form a clique of the desired size), then stop.

[3] Throughout the paper we use $O(x)$ to mean "$\leq cst \cdot x$" for some constant cst independent of x.

2.2 Analysis

We first quickly verify that the assignment done by the algorithm is feasible, i.e. satisfies the Nominal and Failover constraints. Consider a node/machine u on an I_k clique opened by the algorithm (for machines in an $I_{\geq L}$ clique the argument is analogous). For the Nominal capacity constraint: Every demand assigned to u is actually assigned to one of the $k-1$ edges in this clique incident on u; each such edge receives at most 1 demand from I_k (and no other demands), so using the upper limit of this interval we see that u receives total size at most $(k-1)\cdot\min\{\frac{1}{k-1}, \frac{B}{k}\} \leq 1$, so within its Nominal capacity. For the Failover capacity: in a failover scenario one of these $(k-1)$ demands has "both ends" assigned to u, so the total size it receives is now $k\cdot\min\{\frac{1}{k-1}, \frac{B}{k}\} \leq B$, so within the Failover capacity. Hence the algorithm produces a feasible assignment.

Now we show that the value obtained by the algorithm is at least $\left(\frac{1}{2} - O(\frac{1}{m^{1/3}})\right)\mathsf{OPT}$. The idea is to show that for (essentially) each clique opened by the algorithm, we get on average value at least $\approx \frac{1}{4}$ per vertex. Since each node has Nominal capacity 1 and each demand must be scheduled on two nodes, OPT can only get at most $\frac{1}{2}$ value from each node on average, showing that our algorithm is a $\approx \frac{1}{2}$-approximation. However, there are two exceptions where we may get less than $\approx \frac{1}{4}$ per vertex on average. The first is the last clique for each I_k, which may not be "fully used" (but by setting L appropriately there are not too many nodes involved in this loss). More importantly, the second exception is the "big items" I_2, which may not allow us to get average value $\frac{1}{4}$ per node (e.g. when the failover is $B=1$, a demand of size $\frac{1}{3}+\varepsilon$ falls in the group I_2 and is put by itself on an edge, giving value $\frac{1}{6}+\frac{\varepsilon}{2} \ll \frac{1}{4}$ per node used). However, in this case we show that we can obtain a stronger upper bound for these demands for OPT.

We now make this precise. Assume throughout that the algorithm has stopped before the end of the input (else it scheduled everything, so it is OPT). We account for the value obtained on each type of clique separately.

Cliques for $I_{\geq L}$. We will use two observations: (i) when the algorithm opens a new $I_{\geq L}$ clique, every edge of the previous $I_{\geq L}$ cliques has some demand assigned to it, and (ii) across all $I_{\geq L}$ cliques, out of all edges with some demand assigned to them, at most one can have total size assigned to it less than $\alpha := \frac{1}{2}\min\left\{\frac{1}{L-1}, \frac{B}{L}\right\}$ (i.e. half of its "capacity").

Both observations stem from the first-fit strategy used to assign these demands. In particular, the algorithm will only open a new clique when a demand in $I_{\geq L}$ does not fit in the edges of the existing cliques, implying that all of these edges already have some demand assigned; this shows the first statement. For the second statement, by contradiction assume that at some point there are at least two edges on $I_{\geq L}$ cliques with total load less than α. Then the first demand that was assigned to the last such edge has size less than α. But this means that it could have been assigned to an earlier edge with load less than α, contradicting the first-fit procedure.

Let $c_{\geq L}$ be the total number of $I_{\geq L}$ cliques that the algorithm opened, and $m_{\geq L} := c_{\geq L}\cdot L$ the number of nodes associated with those cliques. Combining the above two observations, at the end of the execution either: (i) every edge of the first $c_{\geq L}-1$ of these cliques has load at least α or; (ii) all but one edge in the first $c_{\geq L}-1$ cliques has load at least α and some edge of the last $c_{\geq L}$-th (e.g., the one that "opened" it) has load at least α. In both cases, the total size of demands assigned by the algorithm to the edges of these cliques is at least

$$(c_{\geq L}-1)\cdot\binom{L}{2}\cdot\alpha = (c_{\geq L}-1)\cdot\frac{L}{4}\cdot\min\left\{1, \frac{(L-1)B}{L}\right\} \geq m_{\geq L}\cdot\frac{1}{4}\left(1-\frac{1}{L}\right) - O(L), \qquad (1)$$

yielding roughly average value $\frac{1}{4}$ from each node of these cliques, as claimed.

Cliques for I_k, for $k \geq 3$. Consider any clique for I_k except the last one to be opened. All edges of this clique have some demand from I_k assigned to it; given the lower limit for this interval, this means that the algorithm has assigned to each such clique total size at least

$$\binom{k}{2} \cdot \min\left\{\frac{1}{k}, \frac{B}{k+1}\right\} = \frac{k}{2} \cdot \min\left\{\frac{k-1}{k}, \frac{B(k-1)}{k+1}\right\}.$$

Since $k \geq 3$ and $B \geq 1$, the right-hand side is at least $\frac{k}{4}$. Letting again c_k denote the number of cliques for I_k that the algorithm opens and m_k the corresponding number of nodes/machines, we can count the total value of all but the last I_k clique and we see that the algorithm has assigned to them total size at least $(c_k - 1) \cdot \frac{k}{4} = m_k \cdot \frac{1}{4} - O(k)$.

Cliques for I_2. (Recall that there is no $k = 1$, so this is the last case to consider.) Given the lower limit of the interval I_2, each I_2 clique (which being a 2-clique is just an edge) has a demand of size at least $\min\{\frac{1}{2}, \frac{B}{3}\}$ assigned to it. So the algorithm assigns total size at least $m_2 \cdot \min\{\frac{1}{4}, \frac{B}{6}\}$ to these I_2 cliques, where m_2 is the number of nodes in these cliques.

Total value of Alg. Since we assumed that the algorithm stops at some point, it means that it could not open more cliques. This means that all but at most $L-1$ nodes belong to one such clique (the worst case is that it tried to open an L-clique but could not), so $m_{\geq L} + \sum_{k=3}^{L-1} m_k + m_2 \geq m - L$. Then adding the above estimates for the values obtained on each type of clique, we see that the algorithm gets total value at least

$$\begin{aligned}\mathsf{Alg} &\geq \frac{1}{4}\left(1 - \frac{1}{L}\right) \cdot \left(m - m_2 - L\right) - O(L^2) + m_2 \cdot \min\left\{\frac{1}{4}, \frac{B}{6}\right\} \\ &= \frac{1}{4} \cdot (m - m_2) + m_2 \cdot \min\left\{\frac{1}{4}, \frac{B}{6}\right\} - O(m^{2/3})\end{aligned}$$

where the last inequality uses the fact that $L = m^{1/3}$.

If the minimum in the last line is $\frac{1}{4}$, then we obtain $\mathsf{Alg} \geq \left(\frac{1}{2} - O(\frac{1}{m^{1/3}})\right)\mathsf{OPT}$ as desired (recall $\mathsf{OPT} \leq \frac{m}{2}$ since each machine has Nominal capacity 1 and each demand is assigned to two machines). **So assume this is not the case, namely $B < \frac{3}{2}$.** Under this assumption

$$\mathsf{Alg} \overset{with\ ass.}{\geq} \frac{1}{4} \cdot (m - m_2) + \frac{B}{6} \cdot m_2 - O(m^{2/3}) \tag{2}$$

Value of OPT. We analyze OPT again under the assumption $B < \frac{3}{2}$. The Failover constraints also ensure that in order to accommodate the demand from I_2 in case of failure, any node that receives a demand from I_2 can have total size assigned to it a most $B - \min\{\frac{1}{2}, \frac{B}{3}\} \overset{with\ ass.}{=} \frac{2B}{3}$, due to the assumption $B < \frac{3}{2}$. For all other nodes, OPT can assign at most size 1 per node due to the Nominal capacity constraint. Let m_2^{OPT} be the number of nodes where OPT schedules a demand from I_2. Again, since the size of each demand is counted towards the Nominal capacity of two nodes, the total size scheduled by OPT is

$$\mathsf{OPT} \leq \frac{1}{2}\left(m_2^{\mathsf{OPT}} \cdot \frac{2B}{3} + (m - m_2^{\mathsf{OPT}}) \cdot 1\right) = \frac{1}{2} \cdot (m - m_2^{\mathsf{OPT}}) + \frac{B}{3} \cdot m_2^{\mathsf{OPT}} \tag{3}$$

Notice that since every demand in I_2 has size $> \min\{\frac{1}{2}, \frac{B}{3}\} \geq \frac{1}{3}$, the Failover constraints ensure that in OPT (as well as in our algorithm) the demands from I_2 that are scheduled form a matching, i.e. no 2 such demands can share a node/machine. So m_2^{OPT} (resp. m_2) is

just twice the number of I_2 demands scheduled by OPT (resp. our algorithm). Moreover, both Alg and OPT schedule a prefix of the instance. Since OPT gets at least as much value as Alg, it means that it scheduled a prefix that is at least as long; in particular it schedules at least as many I_2 demands as our algorithm. Together these observations imply that that $m_2^{\mathsf{OPT}} \geq m_2$. Then given inequalities (2) and (3), under the assumption $B < \frac{3}{2}$ we obtain that $\mathsf{Alg} \geq \left(\frac{1}{2} - O(\frac{1}{m^{1/3}})\right)\mathsf{OPT}$ as desired. This concludes the proof of Theorem 3.

3 Sublinear Additive Regret in the Stochastic Model

We now consider FAILOVER in the online stochastic model, where, instead of being adversarial, the size S_t of each demand now comes independently from an unknown distribution μ over $[0, \min\{1, \frac{B}{2}\}]$. Again, at time t the algorithm observes the size S_t of the current demand and irrevocably assigns it to two of the m machines. We still use $\mathsf{OPT} = \mathsf{OPT}(S_1, \ldots, S_n)$ to denote the value of (sum of the sizes scheduled by) the optimal strategy, which is now a random quantity. Our main result is algorithm FailoverStochastic that achieves a sublinear additive loss compared to OPT in this model (restated from the introduction for convenience).

▶ **Theorem 4.** *For the* FAILOVER *problem in the stochastic arrival model, there is a poly-time algorithm that achieves utilization* $\mathsf{OPT} - O(\mathsf{OPT}^{5/6} \log \mathsf{OPT})$ *with probability* $1 - O(\frac{1}{m})$.

The algorithm relies on a learn-and-pack approach that uses previously seen items to compute a *template* for packing the next items. This process is performed in rounds. Each round starts by assigning the first demand of the round on a pair of (empty) machines. Then, we iteratively create a template based on the first $n_k := 2^k$ items of the round, which we use to schedule the next n_k items. When the number of machines needed for the template (along with some slack) exceeds the number of available machines, the current round terminates and the next round begins. The next round maintains no knowledge of the previous demands; it only takes as input the number of empty machines $\tilde{m}$ which it is allowed to use.

Before describing the algorithm in more detail, an important question that arises is how to use the templates to schedule the future demands. A crucial component in this process are *monotone matchings*, which only match two values if the second is at least as big as the first.

▶ **Definition 5** (Monotone matching). *Given two sequences* $x_1, \ldots, x_n \in \mathbb{R}$ *and* $y_1, \ldots, y_n \in \mathbb{R}$, *a* monotone matching π *from the* x_t*'s to the* y_t*'s is an injective function from a subset* $I \in \{1, \ldots, n\}$ *to* $\{1, \ldots, n\}$ *such that* $x_i \leq y_{\pi(i)}$ *for all* $i \in I$. *We say that* x_i *is* matched *to* $y_{\pi(i)}$ *if* $i \in I$, *and* x_i *is* unmatched *otherwise.*

Monotone matchings will allow us to match future demands (x_i's) to the demands that are part of a template ($y_{\pi(i)}$'s) and put the former in the place of the latter (since $x_t \leq y_{\pi(i)}$). A surprising result of Rhee and Talagrand [16] is that if the two sequences are sampled i.i.d. from the same distribution, then almost all items can be matched, and moreover such a matching can be found online (see the paper for a more general result where the sequences may come form different distributions).

▶ **Theorem 6** (Monotone Matching Theorem [16]). *Suppose the random variables* $A_1, \ldots, A_n$ *and* $B_1, \ldots, B_n$ *are all sampled independently from a distribution* μ. *Then there is a constant cst such that with probability at least* $1 - e^{-cst \cdot \log^{3/2} n}$ *there is a monotone matching* π *of the* A_i*'s to the* B_i*'s where at most* $cst \cdot \sqrt{n} \log^{3/4} n$ *of the* A_i*'s are unmatched. Moreover, this matching can be computed even if the sequence* $A_1, \ldots, A_n$ *is revealed online.*

3.1 Algorithm

We are now ready to present the details of the FailoverStochastic algorithm.

FailoverStochastic. The algorithm just repeatedly calls the procedure OneRound below, passing to it the number of machines that are still available/unopened (e.g. initially it calls OneRound(m)); it does this for $\frac{\log m}{\log 4/3}$ rounds.

OneRound($\tilde{m}$). This procedure receives as input the number $\tilde{m}$ of machines that it is allowed to open. It is convenient to rename the demands and use Y_t to denote the t-th demand seen by OneRound (which are still sampled i.i.d. from μ). Similar to the work of Rhee and Talagrand [16], this algorithm works in phases: As mentioned earlier, each phase k sees the previous $n_k = 2^k$ items and creates a template based on them, which will then be used to schedule the next n_k items. To create this template, we define the offline problem OffMinFailover of minimizing the number of machines that are required to schedule these n_k items. To solve this problem, we design an approximation algorithm OffMinFailoverAlg achieving a sublinear approximation guarantee (more on this soon). Specifically, let $\overline{\mathsf{OPT}}_{mach}(x_1, \ldots, x_n)$ be the number of machines that OffMinFailoverAlg (with $\varepsilon = 1/n_k^{1/6}$) uses to schedule the demands $x_1, \ldots, x_n$. OneRound is then as follows:

Algorithm 2 OneRound**:** Given a number of available machines $\tilde{m}$.

1: Assign the first demand Y_1 to an empty edge by itself, opening 2 machines.

2: For phases $k = 0, 1, 2, \ldots$

(a) See the first n_k items $Y_1, \ldots, Y_{n_k}$. Run the algorithm OffMinFailoverAlg from Section 4 (with $\varepsilon = 1/n_k^{1/6}$) to find a solution for them that uses $\overline{\mathsf{OPT}}_{mach}(Y_1, \ldots, Y_{n_k})$ machines; let $templ(t)$ denote the pair of machines that Y_t is assigned to. This solution is our template.

(b) STOP if

$$\#\{\text{already open machines}\} + \underbrace{\overline{\mathsf{OPT}}_{mach}(Y_1, \ldots, Y_{n_k})}_{\text{machines from template}} + \underbrace{cst_1 \cdot \sqrt{n_k} \log^{3/4} n_k}_{\text{predicted unmatched demand}} + 2m^{5/6} > \tilde{m}.$$

(c) Else, open a clique of $\overline{\mathsf{OPT}}_{mach}(Y_1, \ldots, Y_{n_k})$ machines. Upon the arrival of each of the next n_k demands $Y_{n_k+1}, \ldots, Y_{2n_k}$, assign them to machines based on the template. More precisely, find the Rhee-Talagrand monotone matching π guaranteed by Theorem 6 from the new to the old demands (as the new ones arrive online). Schedule each matched new demand Y_t to the pair of machines that $Y_{\pi(t)}$ occupied in the template, namely the machine pair $templ(\pi(t))$. For each unmatched new demand, schedule it on an edge by itself (opening two more machines for each). If at any point the execution tries to open more than $\tilde{m}$ machines, declare FAIL.

3.2 Analysis

We next discuss the main ideas for the analysis of the algorithm FailoverStochastic, leading to the proof of Theorem 4. We assume throughout that m is at least a sufficiently large constant, else the success probability $1 - O(\frac{1}{m})$ trivially holds. Due to space constraints, we mostly state and discuss at a high-level the main components of the proof and show how they imply Theorem 4, deferring details to the full version of the paper.

First, we need to develop two important and complex components. Let $\mathsf{OPT}_{mach}(J)$ denote the minimum number of devices needed to assign all demands from a set of demands J, satisfying the Nominal and Failover constraints.

First component. The first component is the aforementioned algorithm OffMinFailoverAlg that is called within OneRound. It relies on a novel configuration LP, (LP_{mach}), and a post-processing algorithm to realize a rounded LP solution as a feasible assignment. It has the following guarantee:

▶ **Theorem 7.** *There exists a poly-time algorithm,* OffMinFailoverAlg*, that given $\varepsilon \in (0,1)$, finds a solution for* OffMinFailover *with at most $\big(1+O(\varepsilon)\big)\mathsf{LP}_{mach} + O(\frac{1}{\varepsilon^5}) \le \big(1+O(\varepsilon)\big)\mathsf{OPT}_{mach} + O(\frac{1}{\varepsilon^5})$ machines.*

Choosing ε appropriately, we can create a template using at most $\mathbb{E}\,\mathsf{OPT}_{mach}(Y_1,\ldots,Y_{n_k}) + o(n_k)$ devices in expectation for the next n_k arrivals. This result is proved in Section 4.

Second component. Recall from the technical overview that a worrisome aspect of FailoverStochastic is that each call to OneRound does not re-use machines from previous rounds. To show that this is not too wasteful, we prove that $\mathbb{E}\,\mathsf{OPT}_{mach}(X_1,\ldots,X_T)$ is approximately linear in T. We do so by giving a quantitative convergence theorem of $\mathbb{E}\,\mathsf{OPT}_{mach}(X_1,\ldots,X_T)$ to $T\cdot c(\mu)$, where $c(\mu)$ is a constant that characterizes the "average number of devices needed per demand." Furthermore, we use the bounded-differences inequality [3] to show that the number of machines $\mathsf{OPT}_{mach}(X_1,\ldots,X_T)$ is concentrated around this mean. That is, in the full version of the paper we show the following:

▶ **Theorem 8.** *Let μ be a distribution supported on $[0,\min\{1,\frac{B}{2}\}]$. Then there exists a scalar $c(\mu)$ such that for every $T\in\mathbb{N}$ and $\lambda>0$, we have*

$$\mathsf{OPT}_{mach}(X_1,\ldots,X_T) \;\in\; T\cdot c(\mu) \pm O(T^{5/6}) \pm \lambda\sqrt{T}$$

with probability at least $1-2e^{-\frac{\lambda^2}{2}}$, where $X_1,\ldots,X_T$ are i.i.d. samples from μ.

Thus splitting the first $2n_k$ demands into two rounds of n_k demands each costs us only an extra $o(n_k)$ devices.

With those two results in hand, the core of the analysis is that OneRound gets good value density, i.e., the ratio of value over number of machines m. We use $\mathbb{E}S_0$ to denote the expected value of the size of a demand (which is the same as $\mathbb{E}S_t$ for any t).

Specifically, according to Theorem 8, there is a scalar $c(\mu)$ such that OPT is able to fit roughly $\frac{1}{c(\mu)}$ demands per machine. Each such demand gives value roughly $\mathbb{E}S_0$; so the intuition is that the best possible density value/machine should be around $\frac{\mathbb{E}S_0}{c(\mu)}$. We first make this formal in the next lemma.

▶ **Lemma 9.** *With probability at least $1-\frac{2}{m^2}$ we have*

$$\mathsf{OPT} \le m\cdot\frac{\mathbb{E}S_0}{c(\mu)} + O(m^{5/6}) \quad \textit{and} \quad \mathsf{OPT} \ge \min\left\{ n\cdot\mathbb{E}S_0 - \sqrt{n\log m}\;,\; m\cdot\frac{\mathbb{E}S_0}{c(\mu)} - O(m^{5/6}) \right\}.$$

Crucially, the next lemma says that OneRound almost achieves this density.

▶ **Lemma 10.** *Let Open be the number of machines opened by* OneRound$(\tilde{m})$ *(which is a random variable). Then with probability at least $1-\frac{1}{m^2}$, the total value of the demands scheduled by* OneRound$(\tilde{m})$ *is at least*

$$\textit{value of } \mathsf{OneRound}(\tilde{m}) \ge \frac{\mathbb{E}S_0}{c(\mu)}\cdot \mathit{Open} - O(m^{5/6}).$$

Given this lemma, we see that the total value of the FailoverStochastic algorithm (which repeatedly calls OneRound) is approximately $\frac{\mathbb{E}S_0}{c(\mu)}$ times the total machines opened during the execution. By showing that the number of machines FailoverStochastic opens is $\approx m$, we then almost match the upper bound on OPT from Lemma 9.

▶ **Lemma 11.** *There is a constant cst_5 such that with probability $1-O(\frac{1}{m})$, FailoverStochastic opens at least $m - 5cst_5 \cdot m^{5/6}$ machines.*

These lemmas quickly lead to the proof of Theorem 4.

Proof of Theorem 4. Let $L := \frac{\log m}{\log 4/3}$ denote the number of calls to OneRound that FailoverStochastic makes, and let val_i and $Open_i$ be the value obtained and number of machines opened by the i-th call. Employing Lemma 10 on these L calls, we have that with probability at least $1 - \frac{L}{m^2}$ the total value of FailoverStochastic is

$$\text{algo value} \;=\; val_1 + \ldots + val_L \;\geq\; \frac{\mathbb{E}S_0}{c(\mu)} \cdot \sum_{i \leq L} Open_i \;-\; O(m^{5/6} \log m).$$

Moreover, from Lemma 11, with probability at least $1 - O(\frac{1}{m})$ the total number of machines open $\sum_{i \leq L} Open_i$ is at least $m - 5cst_5 \cdot m^{5/6}$, in which case we get

$$\text{algo value} \;\geq\; m \cdot \frac{\mathbb{E}S_0}{c(\mu)} \;-\; O(m^{5/6} \log m). \tag{4}$$

Furthermore, from Lemma 9 we have that $\mathsf{OPT} \leq m \cdot \frac{\mathbb{E}S_0}{c(\mu)} + O(m^{5/6})$ with probability at least $1 - \frac{2}{m^2}$. So by taking a union bound and combining this with the above lower bound on the algorithm's value, we get that with probability $1 - O(\frac{1}{m})$

$$\text{algo value} \;\geq\; \mathsf{OPT} \;-\; O(m^{5/6} \log m).$$

Since (4) also implies that $\mathsf{OPT} \geq \Omega(m)$, the previous bound is at least $\mathsf{OPT} - O(\mathsf{OPT}^{5/6} \log \mathsf{OPT})$. This concludes the proof of Theorem 4. ◀

We conclude this section by proving the lower bound on the value density of OneRound from Lemma 10. We defer the proofs of Lemma 9 and 11 to the full version of the paper.

3.2.1 Proof of Lemma 10

First, we control in high-probability the number of phases that OneRound($\tilde{m}$) executes before stopping or failing; this is important to avoid dependencies on the total number of demands n in the instance, which can be arbitrarily bigger than the scale of the effective instance.

▷ Claim 12. With probability $1 - \frac{1}{m^3}$, the number of phases within OneRound is at most

$$\bar{k} := \log\left(\frac{\tilde{m}}{c(\mu)} + O(\tilde{m}^{5/6}) + 3\log^{\frac{3}{2}} m\right). \tag{5}$$

Proof. Recall that the demand sizes $Y_1, Y_2, \ldots$ that OneRound sees are still i.i.d. samples from the original distribution μ. Using Theorem 8, it is not hard to show that with probability at least $1 - \frac{1}{m^3}$ OneRound can schedule at most $\frac{\tilde{m}}{c(\mu)} + O(\tilde{m}^{5/6}) + 3\log^{\frac{3}{2}} m$ many of these demands (for intuition, Theorem 8 indicates that even OPT requires more than $\tilde{m}$ machines to schedule these many demands). Since this quantity is exactly $n_{\bar{k}}$, OneRound cannot complete phase $\bar{k}$ (there are $2n_{\bar{k}}$ demands by the end of it) and the claim holds. ◁

Next, we need to bound how many machines are opened by OneRound, which in particular affects the probability of it failing. For a phase k, let $M_k := \overline{\mathsf{OPT}}_{mach}(Y_1, \ldots, Y_{n_k})$ denote the number of machines in the template solution, and let U_k be the number of additional machines that had to be open to accommodate the unmatched demands among $Y_{n_k+1}, \ldots, Y_{2n_k}$, namely twice the number of unmatched items. Notice that these quantities are well defined even for phases that the algorithm did not execute. The quantity $M_k + U_k$ is then the number machines that the algorithm OneRound opens in phase k (if it executes it). We have the following bounds for the number of machines open, at least for a phase k where the number of items n_k is sufficiently large (but still sublinear in m).

▷ Claim 13. Let $k_0 := (\frac{2}{cst_2} \log m)^{2/3}$ for a sufficiently small constant cst_2. Then there is a constant cst_1 such that:

1. For $k \geq k_0$, we have $M_k \in n_k \cdot c(\mu) \pm cst_1 \cdot n_k^{5/6}$ with probability $\geq 1 - \frac{1}{m^3}$
2. For $k \geq k_0$, we have $U_k \leq cst_1 \cdot \sqrt{n_k} \log^{3/4} n_k$ with probability $\geq 1 - \frac{1}{m^3}$
3. $n_{k_0} \leq m^{5/6}$.

Proof. Consider a phase $k \geq k_0$. Since the demand sizes $Y_1, \ldots, Y_{2n_k}$ seen in this phase are i.i.d. samples from the original distribution μ, we can bound the minimum number of machines $\mathsf{OPT}_{mach}(Y_1, \ldots, Y_{n_k})$ (using Theorem 8 with $\lambda = n_k^{1/3}$) as

$$\mathsf{OPT}_{mach}(Y_1, \ldots, Y_{n_k}) \in n_k \cdot c(\mu) \pm O(n_k^{5/6})$$

with probability at least $1 - 2e^{-\frac{n_k^{2/3}}{2}}$. Moreover, employing the guarantee of the algorithm OffMinFailoverAlg used to build the template (Theorem 7 with $\varepsilon = 1/n_k^{1/6}$), we get that M_k is in the range $n_k \cdot c(\mu) \pm cst_1 \cdot n_k^{5/6}$ with probability at least $1 - 2\exp(-\frac{n_k^{2/3}}{2})$ for some constant cst_1. But since $n_k = 2^k \geq 2^{k_0}$, a quick calculation shows that this probability is at least $1 - \frac{1}{m^3}$, proving the first item of the claim.

To control U_k, we can use the Monotone Matching Theorem (Theorem 6) with the first sequence of sizes being the demands from the template, i.e., $(B_1, \ldots, B_{n_k}) = (Y_1, \ldots, Y_{n_k})$, and the second one being the demands that we attempted to match to them, namely $(A_1, \ldots, A_{n_k}) = (Y_{n_k+1}, \ldots, Y_{2n_k})$ to obtain that the number of unmatched demands is at most $cst \cdot \sqrt{n_k} \log^{3/4} n_k$ with probability at least $1 - e^{-cst \cdot \log^{3/2} n_k}$, and hence with this probability $U_k \leq 2cst \cdot \sqrt{n_k} \log^{3/4} n_k$. Again because $k \geq k_0$, we get that this probability is at least $1 - \frac{1}{m^3}$, proving Item 2 of the claim (by taking $cst_1 \geq 2cst$ we can just replace the latter by the former).

The last item $n_{k_0} \leq m^{5/6}$ of the claim can be directly verified using the fact that we assumed m is at least a sufficiently large constant. ◁

Recall that OneRound only fails when the number of machines $M_k + U_k$ actually opened in a phase is bigger than it "predicted" in Line 2.b, and this prediction is exactly M_k plus the upper bound U_k from Claim 13 plus a slack of $2m^{5/6}$. By considering all phases, it is now easy to upper bound the probability that OneRound fails ($\bar{k}$ is defined in (5)).

▷ Claim 14. The probability that OneRound fails is at most $\frac{\bar{k}+1}{m^3}$.

Proof. Fix any phase k, and we claim that the probability that OneRound fails on this phase is at most $\frac{1}{m^3}$. If OneRound fails on phase k, then it did not STOP in Line 2.b, so

$$\#\,[\text{machines open before phase } k] + \overline{\mathsf{OPT}}_{mach}(Y_1, \ldots, Y_{n_k}) + cst_1 \cdot \sqrt{n_k} \log^{3/4} n_k + 2m^{5/6} \leq \tilde{m},$$

but it ran out of machines during phase k, namely

$$\#\,[\text{machines open before phase } k] + (M_k + U_k) > \tilde{m}.$$

Since $M_k = \overline{\mathsf{OPT}}_{mach}(Y_1, \ldots, Y_{n_k})$, these observations imply that $U_k > cst_1 \cdot \sqrt{n_k}\, \log^{3/4} n_k + 2m^{5/6}$. This is impossible if $n_k \leq m^{5/6}$, because the number of machines U_k opened for the unmatched demands is at most twice the number n_k of demands considered for the matching. So we must have $n_k > m^{5/6}$ (and so from Claim 13 $k \geq k_0$) and at least $U_k > cst_1 \cdot \sqrt{n_k}\, \log^{3/4} n_k$; but again by Claim 13 the latter happens with probability at most $\frac{1}{m^3}$. Thus, the probability that OneRound fails on phase k is at most $\frac{1}{m^3}$.

Moreover, by Claim 12, with probability at least $1 - \frac{1}{m^3}$ OneRound has at most $\bar{k}$ phases. Then taking a union bound, we see that the event that OneRound has at most $\bar{k}$ phases and in all of them it does not fail holds with probability at least $1 - \frac{\bar{k}+1}{m^3}$; in particular, with at least this much probability the algorithm does not fail in its execution, proving the claim. ◁

We now finally lower bound the value that OneRound gets. Let τ be the (random) index of the last phase attempted by OneRound, namely where Line 2.c is executed. As long as it does not fail on the last phase τ (which by the previous claim happens with probability at least $1 - \frac{\bar{k}+1}{m^3}$) OneRound gets the value of all items up until this phase, that is

$$\text{value of OneRound} \geq Y_1 + \ldots + Y_{2n_\tau} \geq Y_1 + \ldots + Y_{2n_{\min\{\tau,\bar{k}\}}}. \tag{6}$$

Recall that the Y_i's are independent and each has mean $\mathbb{E}S_0$. Then employing the Chernoff bound (Theorem 2.8 of [3]), for any fixed $t \leq n_{\bar{k}}$ we have that

$$Y_1 + \ldots + Y_t \geq t \cdot \mathbb{E}S_0 - \sqrt{n_{\bar{k}} \log(m^3 \cdot n_{\bar{k}})} \qquad \text{with probability at least } 1 - \frac{1}{m^3 \cdot n_{\bar{k}}}.$$

Then taking a union bound over (6), the previous displayed inequality for all $t \leq n_{\bar{k}}$, and over the event that OneRound has at most $\bar{k}$ phases (which holds with probability at least $1 - \frac{1}{m^3}$) we get that

$$\begin{aligned} \text{value of OneRound} &\geq 2n_{\min\{\tau,\bar{k}\}} \cdot \mathbb{E}S_0 - \sqrt{n_{\bar{k}} \log(m^3 \cdot n_{\bar{k}})} \\ &= 2n_\tau \cdot \mathbb{E}S_0 - \sqrt{n_{\bar{k}} \log(m^3 \cdot n_{\bar{k}})} \\ &\geq 2n_\tau \cdot \mathbb{E}S_0 - O(m^{5/6}) \qquad \text{with probability} \geq 1 - \frac{\bar{k}+3}{m^3}. \end{aligned} \tag{7}$$

To conclude the proof of Lemma 10 we just need to relate this quantity to the number of machines opened by OneRound. Let $Open_\ell$ be the number of machines opened until (including) phase ℓ, and recall that $Open$ is the number of machines opened over all phases. Since the number of machines opened on phase k is $M_k + U_k$ (plus two machines for the first demand Y_1), we have

$$Open_\ell = 2 + (M_1 + U_1) + \ldots + (M_\ell + U_\ell) \tag{8}$$

To upper bound the right-hand side, for the phases $k < k_0$ we just use the fact that $M_k + U_k \leq 2n_k + 2n_k = 4n_k$, since both in the template and for the unmatched demands we never open more than 2 machines per demand considered (and n_k demands are considered in each part). For each phase $k = k_0, \ldots, \bar{k}$ we can use Claim 13 to upper bound $M_k + U_k$ with probability at least $1 - \frac{2}{m^3}$ by

$$M_k + U_k \leq n_k \cdot c(\mu) + cst_1 \cdot n_k^{5/6} + cst_1 \cdot \sqrt{n_k}\, \log^{3/4} n_k \leq n_k \cdot c(\mu) + cst_3 \cdot n_k^{5/6}$$

for some constant cst_3. Together these bounds give that with probability at least $1 - \frac{2\ell}{m^3}$

$$Open_\ell \leq 2 + \sum_{k<k_0} 4n_k + \sum_{k=k_0}^{\ell} \left(n_k \cdot c(\mu) + cst_3 \cdot n_k^{5/6} \right).$$

To further upper bound the first summation on the right-hand side, because of the exponential relationship $n_k = 2^k$, we have $\sum_{k<k_0} 4n_k \leq 8n_{k_0-1} \leq O(m^{5/6})$, the last inequality coming from Claim 13; for the second summation, we analogously have $\sum_{k=k_0}^{\ell} n_k \leq 2n_\ell$ and $\sum_{k=k_0}^{\ell} n_k^{5/6} \leq O(n_\ell^{5/6})$. Therefore,

$$Open_\ell \leq 2n_\ell \cdot c(\mu) + O(n_\ell^{5/6}) + O(m^{5/6}) \qquad \text{with probability at least } 1 - \frac{2\ell}{m^3}. \tag{9}$$

Finally, since by Claim 12 the number of phases τ performed by OneRound is at most $\bar{k}$ with probability at least $1 - \frac{1}{m^3}$, the total number of machines open can be upper bounded

$$Open \leq Open_{\min\{\tau,\bar{k}\}} \leq 2n_\tau \cdot c(\mu) + O(n_{\bar{k}}^{5/6}) + O(m^{5/6}) \leq 2n_\tau \cdot c(\mu) + O(m^{5/6})$$

with probability at least $1 - \frac{2\bar{k}+1}{m^3}$.

Finally, taking a union bound to combine this inequality with (7), we get that

$$\text{value of OneRound} \geq \frac{\mathbb{E}S_0}{c(\mu)} \cdot Open - O(m^{5/6})$$

with probability at least $1 - \frac{3\bar{k}+4}{m^3}$. Since m is at least a sufficiently large constant, we have $m \geq 3\bar{k} + 4$, and the bound from the displayed inequality holds with probability at least $1 - \frac{1}{m^2}$. This finally concludes the proof of Lemma 10.

4 Offline Machine Minimization

In this section we consider the aforementioned (offline) minimization version of FAILOVER, which we call OFFMINFAILOVER: Given a failover capacity $B \geq 1$ and a collection of demands such that demand j has size $s_j \in [0, \min\{1, \frac{B}{2}\}]$, we need to assign *all demands* to pairs of machines while satisfying the Nominal and Failover constraints, and the goal is to minimize the number of machines used. As before, we use $\mathsf{OPT}_{mach} = \mathsf{OPT}_{mach}(s_1, \ldots, s_n)$ to denote the cost of (i.e. number of machines in) the optimal solution.

The main result of this section (Theorem 7, restated) is an efficient algorithm with a sublinear additive regret for this problem (when ε is set appropriately). We remark that a sublinear regret (compared to, say, a constant approximation) is necessary due to its use in Section 3. In fact, the algorithm compares against the stronger optimum of an LP relaxation for the problem (denoted by (LP_{mach}), and defined below). We let LP_{mach} denote the optimal value of this LP.

▶ **Theorem 7.** *There exists a poly-time algorithm,* OffMinFailoverAlg*, that given $\varepsilon \in (0,1)$, finds a solution for* OFFMINFAILOVER *with at most $\big(1 + O(\varepsilon)\big)\mathsf{LP}_{mach} + O(\frac{1}{\varepsilon^5}) \leq \big(1 + O(\varepsilon)\big)\mathsf{OPT}_{mach} + O(\frac{1}{\varepsilon^5})$ machines.*

As hinted above, our algorithm is based on converting a solution of a configuration LP into a good assignment of demands to pairs of machines. But crucially, while the configuration of each machine controls the total size of demands serviced by it, it has no information how these demands are distributed over the "edges" incident to the machine, which is important for adequately handling the Failover constraints. The post-processing of the LP solution is the one in charge of creating a feasible (and low-cost) assignment from this limited control offered by the LP.

4.1 Configuration LP

Consider an assignment of the demands into some number of machines. We can view the collection of demands assigned to (the edges incident to) a given machine as a configuration. Precisely, we define a *configuration* C to be a subset of the demands such that $\sum_{s\in C} s \leq 1$ and $\sum_{s\in C} s + \max_{s\in C} s \leq B$. Note that the first constraint is exactly the Nominal constraint, while the second is a relaxation of the Failover constraint, because the most-loaded edge incident on some machine can be larger than the single largest demand assigned to that machine. Thus, our notion of configuration does not take in to account how the demands are assigned to the respective edges incident on each machine.

To define our configuration LP, we suppose the input collection of demands is partitioned into T *demand types* such that type t consists of n_t-many demands each with size s_t. Thus each configuration C can be represented by a number $n_t(C) \in \mathbb{N}$ of demands for each type t such that $\sum_t n_t(C)\cdot s_t \leq 1$ and $\sum_t n_t(C)\cdot s_t + \max_{t|\, n_t(C)>0} s_t \leq B$. We are ready to define our configuration LP:

$$\begin{array}{lrll} \min & \sum_C x_C & & \\ s.t. & \sum_C n_t(C)\cdot x_C & \geq 2n_t & \forall t \\ & x & \geq 0 & \end{array} \qquad (\mathsf{LP}_{mach})$$

Note that the definition of (LP_{mach}) depends on how the demands are partitioned into types. We show in the full version of the paper that the optimal value of (LP_{mach}) does not depend on the particular type partition. Thus, throughout the analysis, we will use whichever type partition is convenient (unless a particular one is specified).

It is immediate that (LP_{mach}) is a relaxation of OffMinFailover by taking the natural setting of the x-variables defined by a feasible assignment to machines: just let x_C be the number of machines whose collection of demand sizes assigned to its edges are exactly those in C. In particular, we have that $\mathsf{LP}_{mach} \leq \mathsf{OPT}_{mach}$.

Although (LP_{mach}) has exponentially many variables in general, we can approximately solve it via column generation similar to the standard bin packing configuration LP [10, 17] (proof in the full version of the paper).

▶ **Lemma 15.** *We can find in poly-time an extreme point solution of* (LP_{mach}) *with objective value at most* $\mathsf{LP}_{mach} + 1$.

Further, observe that (LP_{mach}) only has T non-trivial constraints, so by the standard rank argument (see for example Lemma 2.1.3 of [12]) any extreme point solution of (LP_{mach}) has at most T non-zero variables. Thus, the next lemma follows immediately by rounding up all the fractional variable of an extreme point solution.

▶ **Lemma 16.** *Given an extreme point of* (LP_{mach}) *with objective value Val, rounding up all fractional variables to the next largest integer gives an integral solution to* (LP_{mach}) *with objective value at most* $Val + T$.

To summarize this section, we can efficiently obtain a collection of configurations, each corresponding to a machine, that "covers" all the demands. However, these configurations do not specify how to actually assign the demands to the edges incident on the corresponding machine. This is the goal of the next section.

4.2 Matching configurations

We say that a collection $\mathcal{C}$ of configurations is feasible if it comes from an integer solution for (LP_{mach}), i.e. setting x_C to be the number of times C appears in $\mathcal{C}$ gives a feasible solution for (LP_{mach}). Our goal in this section is to realize such collection by actually assigning demands to edges. The main challenge is satisfying the actual Failover constraints.

For simplicity assume $\sum_{C \in \mathcal{C}} n_t(C) = 2n_t$ for all types t, i.e. each demand appears on exactly 2 configurations (drop from the configurations what is extra). We can think of $\mathcal{C}$ (with, say, N configurations) as a graph on N nodes/machines, where node/machine $C \in \mathcal{C}$ has $n_t(C)$ "slots" for demands of type t. While this gives the right number of slots $2n_t$ to accommodate the demands of each type t, we still need to specify to which *edge* (pair of machines) each of the n_t demands of type t is assigned in a way that satisfies the Nominal and Failover constraints. (We can alternatively see this as a graph realization problem: each node C as having a requirement $n_t(C)$ of "edges of type t" (which we call its t-*degree*) and we want to create edges of different types (i.e., assignment of demands to pairs of nodes) to satisfy these requirements while also satisfying the Nominal and Failover constraints.)

To see the challenge, consider a fixed node/configuration C. Regardless of how we assign demands to edges (as long as it is consistent with the slots of the configurations), the Nominal constraint of C is satisfied: it will receive total size $\sum_t n_t(C) \cdot s_t = \sum_{s \in C} s$, which is at most 1 by definition of a configuration. This is not the case for the Failover constraint. This is again because the definition of configuration only gives us the relaxed version of the Failover constraint $\sum_{s \in C} s + \max_{s \in C} s \leq B$, In particular, the blue term only considers the largest demand assigned to machine C instead of the most-loaded edge incident to C. However, these two quantities are the same *if we are able to assign at most one demand per edge*. (In the graph realization perspective, it means that it suffices to construct a *simple* graph with the desired t-degrees.) But it is not clear that such an assignment should even exist, let alone be found efficiently.

The main result of this section is that – by opening slightly more machines – we can find such an assignment that realizes any given collection of configurations satisfying both the Nominal and Failover constraints.

▶ **Theorem 17.** *Consider an instance of* OffMinFailover *with T demand types. Given a collection $\mathcal{C}$ of N configurations that is feasible for (LP_{mach}), we can find in poly-time a feasible solution for* OffMinFailover *that uses at most $N + O(DT)$ machines, where D is the maximum number of demands in any configuration in $\mathcal{C}$.*

For that, we will need the following subroutine to assign some demands outside of their respective configurations. This result easily follows by opening disjoint edges as needed, and assigning demands arbitrarily to an already-opened edge is possible.

▶ **Lemma 18.** *There is a poly-time algorithm for* OffMinFailover *that uses at most $8 \cdot S + 2$ machines, where S is the sum of the size of the demands in the instance.*

The algorithm guaranteed by Theorem 17 is the following. In order to simplify the notation, as before we assume without loss of generality that $\mathcal{C}$ has $\sum_{C \in \mathcal{C}} n_t(C) = 2n_t$ for all types t.

Proof of Theorem 17. It is clear that MatchConfigs runs in polynomial time, and assigns all demands to edges. Further, this assignment satisfies both the Nominal and Failover constraints, because we assign at most one demand per edge in Step 4 (see discussion in the beginning of this section), and Step 5 guarantees a feasible assignment for the remaining demands.

It remains to show that it opens $N + O(DT)$ machines. In particular, by Lemma 18 it suffices to show that the total size of all unassigned demands that reach Step 5 is $O(DT)$. When considering demand type t, there are two possibilities:

Algorithm 3 MatchConfigs: Given a collection $\mathcal{C}$ of N configurations.

1: Open N machines – one corresponding to each configuration in $\mathcal{C}$.

2: Consider demand types in arbitrary order $t = 1, \dots, T$.

3: When considering demand type t, partition the collection $\mathcal{C}$ into two collections $\mathcal{L}_t$ and $\mathcal{R}_t$ such that their total t-degrees $\sum_{C\in\mathcal{L}_t} n_t(C)$ and $\sum_{C\in\mathcal{R}_t} n_t(C)$ differ by at most D_t, where D_t is the maximum number of type t demands in any configuration. (This can be achieved, e.g., by initializing $\mathcal{L}_t, \mathcal{R}_t = \emptyset$, and adding configurations one-by-one to the set with minimum total t-degree.)

4: Given this partition, as long as there exists a configuration $C \in \mathcal{L}_t$ that is currently assigned less than $n_t(C)$ demands of type t, we pick such a configuration and assign a demand of type t to an arbitrary edge (C, C') (for $C' \in \mathcal{R}_t$) that has not yet been assigned a demand of any type and such that C' is currently assigned less than $n_t(C')$ demands of type t. If no such edge exists, then we stop and move on to the next demand type.

5: Once we are done considering all demand types, assign all the currently unassigned demands to new machines using Lemma 18.

Case 1: Step 4 assigns $n_t(C)$ type t demands to each $C \in \mathcal{L}_t$. In this case it assigns $\sum_{C\in\mathcal{L}_t} n_t(C)$ type t demands to edges between $\mathcal{L}_t$ and $\mathcal{R}_t$, while the total number of type t demands is

$$n_t = \frac{1}{2}\left(\sum_{C\in\mathcal{L}_t} n_t(C) + \sum_{C\in\mathcal{R}_t} n_t(C)\right) \leq \sum_{C\in\mathcal{L}_t} n_t(C) + \frac{D_t}{2}, \tag{10}$$

where the inequality uses the fact that the t-degree of $\mathcal{R}_t$ is at most that of $\mathcal{L}_t$ plus D_t. Thus, at most $\frac{D_t}{2}$ demands of type t remain unassigned and reach Step 5. The total size of these demands it at most $\frac{1}{2}$, since D_t demands of type t are in a valid configuration. Hence the total size of the unassigned demands of all types is at most $\frac{T}{2} \leq O(DT)$.

Case 2: Step 4 fails to assign $n_t(\bar{C})$ to a configuration $\bar{C} \in \mathcal{L}_t$. In this case, for each $C' \in \mathcal{R}_t$, either the edge $(\bar{C}, C')$ is already assigned some demand (call such C' *blocked*) or C' has already been assigned $n_t(C')$ demands of type t. But there are at most D blocked C''s, since the configuration $\bar{C}$ has at most D slots to receive demands. Thus the total number of type-t demands assigned is at least

$$\sum_{C'\in\mathcal{R}_t\setminus\text{blocked}} n_t(C') \geq \sum_{C'\in\mathcal{R}_t} n_t(C') - D\cdot\max_{C'\in\text{blocked}} n_t(C') \geq \sum_{C'\in\mathcal{R}_t} n_t(C') - D\cdot D_t.$$

Moreover, exchanging the roles of $\mathcal{L}_t$ and $\mathcal{R}_t$ in the argument from (10) we get that $\sum_{C'\in\mathcal{R}_t} n_t(C') \geq n_t - \frac{D_t}{2}$, and thus at least $n_t - D\cdot D_t - \frac{D_t}{2}$ demands of type t are assigned by Step 4. Thus at most $O(D\cdot D_t)$ demands (hence total size $O(D)$) of this type remain unassigned and reach Step 5. This a total size of $O(DT)$, over all demand types, that reach the latter step, as desired. ◀

We summarize the main results of this section and the previous with the next theorem: By approximately solving (LP_{mach}) (Lemma 15), rounding the solution (Lemma 16), and using the above algorithm to obtain an assignment of demands to edges (Theorem 17), we obtain the following.

▶ **Theorem 19.** *Consider an instance of* OffMinFailover *that has most T demands types and where each configuration has at most D demands. Then there is a poly-time algorithm that finds a feasible solution that uses at most $\mathsf{LP}_{mach} + O(DT)$ machines.*

To obtain our main result, Theorem 7, we need to modify the input instance to make D and T small enough. In the full version of this paper – by losing a multiplicative $(1 + O(\epsilon))$-factor – we show how to ensure that $D, T = poly(\frac{1}{\epsilon})$ by rounding demand sizes and handling the small demands separately. This concludes the proof of Theorem 7.

Abstract

Let $\mathcal{G}$ be a minor-closed graph class and let G be an n-vertex graph. We say that G is a *k-apex* of $\mathcal{G}$ if G contains a set S of at most k vertices such that $G \setminus S$ belongs to $\mathcal{G}$. Our first result is an algorithm that decides whether G is a k-apex of $\mathcal{G}$ in time $2^{\mathsf{poly}(k)} \cdot n^2$. This algorithm improves the previous one, given by Sau, Stamoulis, and Thilikos [ICALP 2020, TALG 2022], whose running time was $2^{\mathsf{poly}(k)} \cdot n^3$. The *elimination distance* of G to $\mathcal{G}$, denoted by $\mathsf{ed}_{\mathcal{G}}(G)$, is the minimum number of rounds required to reduce each connected component of G to a graph in $\mathcal{G}$ by removing one vertex from each connected component in each round. Bulian and Dawar [Algorithmica 2017] proved the existence of an FPT-algorithm, with parameter k, to decide whether $\mathsf{ed}_{\mathcal{G}}(G) \leq k$. This algorithm is based on the computability of the minor-obstructions and its dependence on k is not explicit. We extend the techniques used in the first algorithm to decide whether $\mathsf{ed}_{\mathcal{G}}(G) \leq k$ in time $2^{2^{2^{\mathsf{poly}(k)}}} \cdot n^2$. This is the first algorithm for this problem with an explicit parametric dependence in k. In the special case where $\mathcal{G}$ excludes some apex-graph as a minor, we give two alternative algorithms, one running in time $2^{2^{\mathcal{O}(k^2 \log k)}} \cdot n^2$ and one running in time $2^{\mathsf{poly}(k)} \cdot n^3$. As a stepping stone for these algorithms, we provide an algorithm that decides whether $\mathsf{ed}_{\mathcal{G}}(G) \leq k$ in time $2^{\mathcal{O}(\mathsf{tw} \cdot k + \mathsf{tw} \log \mathsf{tw})} \cdot n$, where tw is the treewidth of G. This algorithm combines the dynamic programming framework of Reidl, Rossmanith, Villaamil, and Sikdar [ICALP 2014] for the particular case where $\mathcal{G}$ contains only the empty graph (i.e., for treedepth) with the representative-based techniques introduced by Baste, Sau, and Thilikos [SODA 2020]. In all the algorithmic complexities above, poly is a polynomial function whose degree depends on $\mathcal{G}$, while the hidden constants also depend on $\mathcal{G}$. Finally, we provide explicit upper bounds on the size of the graphs in the minor-obstruction set of the class of graphs $\mathcal{E}_k(\mathcal{G}) = \{G \mid \mathsf{ed}_{\mathcal{G}}(G) \leq k\}$.

1 Introduction

The *distance from triviality* is a concept formalized by Guo, Hüffner, and Niedermeier [24] to express the closeness of a graph to a supposedly "simple" target graph class. One such a measure of closeness is, for instance, the number of vertices or edges that one must delete/add from/to a graph G to obtain a graph in the target graph class. This concept of distance to a graph class has recently gained the interest of the parameterized complexity community. The motivation is that, if a problem is tractable on a graph class $\mathcal{G}$, it is natural to study other classes of graphs according to their "distance to $\mathcal{G}$". In this paper, we focus on two such measures of distance from triviality: Given a target graph class $\mathcal{G}$, we consider the *vertex deletion distance* to $\mathcal{G}$ and the *elimination distance* to $\mathcal{G}$, which we formalize next.

Given a target graph class $\mathcal{G}$ and a non-negative integer k, we define $\mathcal{A}_k(\mathcal{G})$ as the set of all graphs containing a set S of at most k vertices whose removal results in a graph in $\mathcal{G}$. If $G \in \mathcal{A}_k(\mathcal{G})$, then we say that G is a *k-apex* of $\mathcal{G}$. We refer to S as a *k-apex set of G for the class $\mathcal{G}$*. In other words, we consider the following meta-problem for a fixed class $\mathcal{G}$.

Vertex Deletion to $\mathcal{G}$
Input: A graph G and a non-negative integer k.
Objective: Find, if it exists, a k-apex set of G for the class $\mathcal{G}$.

Throughout the paper, we denote by n (resp. m) the number of vertices (resp. edges) of the input graph of the problem under consideration. The importance of Vertex Deletion to $\mathcal{G}$ can be illustrated by the variety of graph modification problems that it encompasses. For instance, if $\mathcal{G}$ is the class of edgeless (resp. acyclic, planar, bipartite, (proper) interval, chordal) graphs, then we obtain the Vertex Cover (resp. Feedback Vertex Set, Vertex Planarization, Odd Cycle Transversal, (proper) Interval Vertex Deletion, Chordal Vertex Deletion) problem.

The second measure of distance from triviality that we study was recently introduced by Bulian and Dawar [10, 11]. Given a graph class $\mathcal{G}$, we define the *elimination distance* of a graph G to $\mathcal{G}$, denoted by $\mathsf{ed}_{\mathcal{G}}(G)$, as follows:

$$\mathsf{ed}_{\mathcal{G}}(G) = \begin{cases} 0 & \text{if } G \in \mathcal{G}, \\ 1 + \min\{\mathsf{ed}_{\mathcal{G}}(G \setminus \{v\}) \mid v \in V(G)\} & \text{if } G \text{ is connected}, \\ \max\{\mathsf{ed}_{\mathcal{G}}(H) \mid H \text{ is a connected component of } G\} & \text{otherwise.} \end{cases}$$

Given that $\mathsf{ed}_{\mathcal{G}}(G) \leq k$, a set $S \subseteq V(G)$ of vertices recursively deleted from G to achieve $\mathsf{ed}_{\mathcal{G}}(G)$ is called a *k-elimination set of G for $\mathcal{G}$*. We define the (parameterized) class of graphs $\mathcal{E}_k(\mathcal{G}) = \{G \mid \mathsf{ed}_{\mathcal{G}}(G) \leq k\}$. The above notion can be seen as a natural generalization of *treedepth* (denoted by td), which corresponds to the case where $\mathcal{G}$ contains only the empty graph. Treedepth, along with treewidth, are two of the most studied and widely used parameters to measure the structural complexity of a graph [12, 36, 43]. The second meta-problem that we consider is the following, again for a fixed graph class $\mathcal{G}$.

Elimination Distance to $\mathcal{G}$
Input: A graph G and a non-negative integer k.
Objective: Find, if it exists, a k-elimination set of G for the class $\mathcal{G}$.

Unsurprisingly, Vertex Deletion to $\mathcal{G}$ is NP-hard for every non-trivial graph class $\mathcal{G}$ [41], while Elimination Distance to $\mathcal{G}$ is NP-hard even when $\mathcal{G}$ contains only the empty graph [45]. To circumvent this intractability, we study both problems from the parameterized

complexity point of view and consider their parameterizations by k. In this setting, the most desirable behavior is the existence of an algorithm running in time $f(k) \cdot n^{\mathcal{O}(1)}$, where f is a computable function depending only on k. Such an algorithm is called *fixed-parameter tractable*, or FPT-*algorithm* for short, and a parameterized problem admitting an FPT-algorithm is said to belong to the parameterized complexity class FPT. Also, the function f is called *parametric dependence* of the corresponding FPT-algorithm, and the challenge is to design FPT-algorithms with small parametric dependencies and with a polynomial factor of small degree [12, 14, 17, 44]. We may also consider XP-*algorithms*, i.e., algorithms running in time $f(k) \cdot n^{g(k)}$ for some computable functions f and g depending only on k.

In general, for any of the two considered problems, we cannot expect FPT-algorithms for every graph class $\mathcal{G}$. For instance, the two problems are NP-hard, even for $k = 0$, for every graph class $\mathcal{G}$ whose recognition problem is NP-hard. This is the case of 3-colorable graphs, which is a class closed under taking (induced) subgraphs. In this paper, we focus on a family of graph classes that exhibits a nice behavior with respect to the considered problems (and many others): we consider $\mathcal{G}$ to be a *minor-closed* graph class, i.e., such that every minor of a graph in $\mathcal{G}$ (that is, obtained from a subgraph of a graph in $\mathcal{G}$ by contracting edges; see Section 2 for the formal definition) is also in $\mathcal{G}$. Indeed, it turns out that, for every such a family $\mathcal{G}$, the problems become fixed-parameter tractable, as we proceed to discuss.

The *minor-obstruction set* (in short *obstruction set*) of $\mathcal{G}$ is the set of minor-minimal graphs that do not belong to $\mathcal{G}$, and is denoted by $\mathsf{obs}(\mathcal{G})$. Notice that $\mathsf{obs}(\mathcal{G})$ gives a complete characterization of $\mathcal{G}$ as, for every graph G, it holds that $G \in \mathcal{G}$ if and only if, for every $H \in \mathsf{obs}(\mathcal{G})$, H is not a minor of G. Because of Robertson and Seymour's theorem [49], $\mathsf{obs}(\mathcal{G})$ is *finite* for every minor-closed graph class. As checking whether an h-vertex graph H is a minor of G can be done in time $f(h) \cdot n^2$ [31, 47], the finiteness of $\mathsf{obs}(\mathcal{G})$ along with the above characterization imply that, for every minor-closed graph class $\mathcal{G}$, checking whether $G \in \mathcal{G}$ can be done in time $c \cdot n^2$, where c is a constant depending on the graph class $\mathcal{G}$. This meta-theorem implies the *existence* of FPT-algorithms for a wide family of problems, including Vertex Deletion to $\mathcal{G}$ and Elimination Distance to $\mathcal{G}$. Indeed, this follows by observing that if $\mathcal{G}$ is minor-closed, then for every non-negative integer k, the classes $\mathcal{A}_k(\mathcal{G})$ and $\mathcal{E}_k(\mathcal{G})$ are also minor-closed.

As Robertson and Seymour's theorem [49] does *not* give any way to construct the corresponding obstruction sets, the aforementioned argument is not constructive, i.e., it cannot construct the obstruction sets required for the corresponding FPT-algorithms. Moreover, these algorithms are *non-uniform* in k, meaning that we have a *distinct* algorithm for every value of k. Important steps towards the constructibility of such FPT-algorithms were done by Adler, Grohe, and Kreutzer [1] and Bulian and Dawar [11], who respectively proved that $\mathsf{obs}(\mathcal{A}_k(\mathcal{G}))$ and $\mathsf{obs}(\mathcal{E}_k(\mathcal{G}))$ are effectively computable. Hence, for both problems, it is possible to construct uniform (in k) algorithms running in time $f(k) \cdot n^2$ for some computable function f. However, this does not imply any reasonable, or even explicit, parametric dependence of the obtained algorithms.

The main focus of this paper is on the parametric and polynomial dependence of FPT-algorithms to solve Vertex Deletion to $\mathcal{G}$ and Elimination Distance to $\mathcal{G}$, i.e., for recognizing the classes $\mathcal{A}_k(\mathcal{G})$ and $\mathcal{E}_k(\mathcal{G})$, when $\mathcal{G}$ is a minor-closed graph class.

Concerning Vertex Deletion to $\mathcal{G}$, after a number of articles for particular cases of minor-closed classes $\mathcal{G}$, such as graphs of bounded treewidth [19, 34], planar graphs [27, 42], or graphs of bounded genus [37], an explicit FPT-algorithm for *any* minor-closed graph $\mathcal{G}$ was recently proposed by Sau, Stamoulis, and Thilikos [51], running in time $2^{\mathcal{O}(k^c)} \cdot n^3$, where c is a constant that depends on the maximum size of a graph in the obstruction set of $\mathcal{G}$.

Moreover, in the case where $\mathsf{obs}(\mathcal{G})$ contains some apex-graph (that is, a 1-apex for the class of planar graphs), Sau, Stamoulis, and Thilikos [51] gave an improved running time of $2^{\mathcal{O}(k^c)} \cdot n^2$. Note also that the more general variant where $\mathcal{G}$ is a topological-minor-closed graph class is in FPT as well [20].

As for Elimination Distance to $\mathcal{G}$ when $\mathcal{G}$ is minor-closed, no explicit parametric dependence was known, with the notable exception of treedepth, for which Reidl, Rossmanith, Villaamil, and Sikdar [46] gave an algorithm deciding whether $\mathsf{td}(G) \leq k$ in time $2^{\mathcal{O}(k \cdot \mathsf{tw})} \cdot n$, where $\mathsf{tw} := \mathsf{tw}(G)$ (see also [9]). Using our terminology, and given that $\mathsf{tw}(G) \leq \mathsf{td}(G)$ for every graph G, this yields an FPT-algorithm for Elimination Distance to $\mathcal{G}_\emptyset$, where $\mathcal{G}_\emptyset$ is the class consisting of the empty graph, running in time $2^{\mathcal{O}(k^2)} \cdot n$. Note that this algorithm [46], combined with the fact that $\mathsf{td}(G) \leq \log(n) \cdot \mathsf{tw}(G)$ (see [9]), imply an XP-algorithm for the problem of computing td when parameterized by tw, namely an algorithm that computes the value of $\mathsf{td}(G)$ in time $n^{\mathcal{O}(\mathsf{tw}(G)^2)}$. To the best of our knowledge, it is open whether computing td parameterized by tw is in FPT.

Before describing our results, let us mention some recent relevant results dealing with Elimination Distance to $\mathcal{G}$ for classes $\mathcal{G}$ that are not necessarily minor-closed. Agrawal and Ramanujan [4] (resp. Agrawal, Kanesh, Panolan, Ramanujan, and Saurabh [3]) provided FPT-algorithms, with parameter k, when $\mathcal{G}$ is the class of cliques (resp. graphs of bounded degree). Fomin, Golovach, and Thilikos [18] identified sufficient and necessary conditions for the existence of FPT-algorithms when $\mathcal{G}$ is definable in first-order logic (such as having bounded degree). Jansen, de Kroon, and Włodarczyk [26] proved, among other results, that if $\mathcal{G}$ is a hereditary union-closed graph class and Vertex Deletion to $\mathcal{G}$ can be solved in time $2^{k^{\mathcal{O}(1)}} \cdot n^{\mathcal{O}(1)}$ (as it is the case for every minor-closed class $\mathcal{G}$ by the results of [51]), then there is an algorithm that, given an n-vertex graph G, computes an $\mathcal{O}(\mathsf{ed}_{\mathcal{G}}(G)^3)$-elimination set of G for $\mathcal{G}$ in time $2^{\mathsf{ed}_{\mathcal{G}}(G)^{\mathcal{O}(1)}} \cdot n^{\mathcal{O}(1)}$. Therefore, for union-closed minor-closed graph classes $\mathcal{G}$, the result of [26] yields an FPT-approximation algorithm for Elimination Distance to $\mathcal{G}$.

Agrawal, Kanesh, Lokshtanov, Panolan, Ramanujan, Saurabh, and Zehavi [2] proved that if $\mathcal{G}$ is hereditary, union-closed, and definable in monadic second-order logic, then Vertex Deletion to $\mathcal{G}$ is (non-uniformly) in FPT if, and only if, Elimination Distance to $\mathcal{G}$ is (non-uniformly) in FPT. Incidentally, they also showed that if $\mathcal{G}$ is defined by excluding a finite number of connected topological minors, then Elimination Distance to $\mathcal{G}$ is (uniformly) in FPT. We note that the results of [2] do not provide explicit parametric dependencies for these FPT-algorithms. Also, let us mention that it was conjectured in [2] that Elimination Distance to $\mathcal{G}$ is in FPT parameterized by a generalization of treewidth called $\mathcal{G}$-*treewidth* (see [2, 16, 26]). Note that, if true, this conjecture would answer the open problem mentioned above of whether computing td parameterized by tw is in FPT.

Our results. In this paper, we provide explicit FPT-algorithms for Vertex Deletion to $\mathcal{G}$ and Elimination Distance to $\mathcal{G}$ for *every* fixed minor-closed graph class $\mathcal{G}$. Our first result is the following.

▶ **Theorem 1.** *For every minor-closed graph class $\mathcal{G}$, there exists an algorithm that solves* Vertex Deletion to $\mathcal{G}$ *in time* $2^{\mathsf{poly}(k)} \cdot n^2$.

The degree of the polynomial function poly in the running time of Theorem 1 and of the other results below, as well as the constants hidden in the $\mathcal{O}$-notation in the running time of the algorithms, depend on the maximum size of a graph in $\mathsf{obs}(\mathcal{G})$. Thus, the algorithm of Theorem 1, while being uniformly FPT in k, is *not* uniform in the target class $\mathcal{G}$, as one needs to know an upper bound on the size of the minor-obstructions. This "meta-non-uniformity"

applies to all the algorithms presented in this paper, and it is also the case, among many others, of the FPT-algorithms in [51]. The algorithm of Theorem 1 improves the algorithm of [51] from cubic to quadratic complexity in n while keeping the same parametric dependence on k. This answers positively one of the open problems posed in [51].

Our next algorithmic results concern Elimination Distance to $\mathcal{G}$ and provide, to the authors' knowledge, the first FPT-algorithms for this problem, when $\mathcal{G}$ is minor-closed, with an *explicit parametric dependence*.

▶ **Theorem 2.** *For every minor-closed graph class $\mathcal{G}$, there exists an algorithm that solves* Elimination Distance to $\mathcal{G}$ *in time* $2^{2^{2^{\mathsf{poly}(k)}}} \cdot n^2$. *In the particular case where* $\mathsf{obs}(\mathcal{G})$ *contains an apex-graph, this algorithm runs in time* $2^{2^{\mathcal{O}(k^2 \log k)}} \cdot n^2$.

Examples of classes $\mathcal{G}$ where $\mathsf{obs}(\mathcal{G})$ contains an apex-graph are graphs of bounded Euler genus, such as planar graphs. Our next result improves the parametric dependence of the algorithm of Theorem 2 when $\mathsf{obs}(\mathcal{G})$ contains an apex-graph, with a worse polynomial factor.

▶ **Theorem 3.** *For every minor-closed graph class $\mathcal{G}$ such that* $\mathsf{obs}(\mathcal{G})$ *contains an apex-graph, there exists an algorithm that solves* Elimination Distance to $\mathcal{G}$ *in time* $2^{\mathsf{poly}(k)} \cdot n^3$.

As discussed later, a crucial ingredient in the algorithms of Theorem 2 and Theorem 3 is to solve Elimination Distance to $\mathcal{G}$ parameterized by the treewidth of the input graph. The following result, which may be of independent interest, deals with this case.

▶ **Theorem 4.** *For every minor-closed graph class $\mathcal{G}$, there exists an algorithm that solves* Elimination Distance to $\mathcal{G}$ *in time* $2^{\mathcal{O}(k \cdot \mathsf{tw} + \mathsf{tw} \log \mathsf{tw})} \cdot n$, *where* tw *denotes the treewidth of the input graph.*

The algorithm of Theorem 4 can be seen as a generalization of the algorithm of Reidl, Rossmanith, Villaamil, and Sikdar [46] deciding whether $\mathsf{td}(G) \leq k$ in time $2^{\mathcal{O}(k \cdot \mathsf{tw})} \cdot n$. Since, for any graph G and any graph class $\mathcal{G}$, $\mathsf{ed}_{\mathcal{G}}(G) \leq \mathsf{td}(G) \leq \mathsf{tw}(G) \cdot \log n$, Theorem 4 implies the existence of an XP-algorithm for Elimination Distance to $\mathcal{G}$ parameterized by treewidth, when $\mathcal{G}$ is minor-closed, running in time $n^{\mathcal{O}(\mathsf{tw}^2)}$. Given that the conjecture of [2] is still open, this is the best type of algorithm that one can expect for Elimination Distance to $\mathcal{G}$ parameterized by treewidth.

Finally, for any minor-closed graph class $\mathcal{G}$, we provide an upper bound on the size of the graphs in the obstruction set of $\mathcal{E}_k(\mathcal{G})$.

▶ **Theorem 5.** *For every minor-closed graph class $\mathcal{G}$ and for every positive integer k, each graph in* $\mathsf{obs}(\mathcal{E}_k(\mathcal{G}))$ *has at most* $2^{2^{2^{\mathsf{poly}(k)}}}$ *vertices. Moreover, if* $\mathsf{obs}(\mathcal{G})$ *contains an apex-graph, this bound drops to* $2^{2^{\mathsf{poly}(k)}}$.

The only previously known bound for the graphs in $\mathsf{obs}(\mathcal{E}_k(\mathcal{G}))$ is the one for treedepth by Dvořák, Giannopoulou, and Thilikos [15], who proved that every graph in $\mathsf{obs}(\mathcal{E}_k(\mathcal{G}_\emptyset))$ has size at most $2^{2^{k-1}}$. Theorem 5 can be seen as a generalization of the results of Sau, Stamoulis, and Thilikos [52], who provided similar upper bounds for the graphs in $\mathsf{obs}(\mathcal{A}_k(\mathcal{G}))$.

These two results are, to the authors' knowledge, the first upper bounds on the size of the graphs in the obstruction set for the elimination distance parameter, and give, as an immediate consequence, the first known upper bound for the size of these obstruction sets.

Our techniques. This paper builds heavily on the techniques recently introduced in [51] in order to deal with Vertex Deletion to $\mathcal{G}$, which are based on exploiting the Flat Wall Theorem of Robertson and Seymour [47], namely the version proved by Kawarabayashi, Thomas, and Wollan [32] and its recent restatement by Sau, Stamoulis, and Thilikos [50]. In a nutshell, the idea of Theorem 1, Theorem 2, and Theorem 3 is that, as far as the treewidth of the input graph is sufficiently large as an appropriate function of k, it is possible to either "branch" into a number of subproblems that depends only on k and where the value of the parameter is strictly smaller, or to find an irrelevant vertex (i.e., a vertex that does not change the answer to the considered problem) and remove it from the graph. The irrelevant vertex technique originates from Robertson and Seymour [47] and is further developped in [50–52]. Once the treewidth is bounded, what remains is to apply the most efficient possible algorithm to solve the problem via dynamic programming on tree decompositions.

Let us focus more particularly on the techniques we use to prove Theorem 1. Contrary to the algorithm of [51] that solves Vertex Deletion to $\mathcal{G}$ for any minor-closed class $\mathcal{G}$, we *avoid using iterative compression*. This explains the improvement from cubic to quadratic complexity in n. The algorithm of Theorem 1 can be seen as an extension of the algorithm of [51] that solves Vertex Deletion to $\mathcal{G}$ in the particular case where $\mathsf{obs}(\mathcal{G})$ contains some apex-graph, and uses ideas that date back to the work of Marx and Schlotter [42] for the Planarization problem, that is, when $\mathcal{G}$ is the class of planar graphs. In Section 3 we provide a sketch of the algorithms claimed in Theorem 1, Theorem 2, and Theorem 3, and in Section 4 we present the algorithm of Theorem 1 in full detail, along with a proof of its correctness.

The proof of Theorem 4 consists of a dynamic programming algorithm that combines the framework of [46] for the particular case where $\mathcal{G}$ contains only the empty graph (i.e., for treedepth) with the representative-based techniques introduced in [5]. A bit more precisely, the idea is to encode the partial solutions (called *characteristic*) via sets of annotated trees with some additional properties. Here, the trees correspond to partial elimination trees and the annotations indicate the representatives, in the leaves of the elimination trees, with respect to the canonical equivalence relation defined for the target class $\mathcal{G}$. The size of the characteristic dominates the running time of the whole algorithm. As usual when dealing with dynamic programming, the formal description of the algorithm is quite technical and lengthy, and has been deferred to the full version of the paper.

Finally, to obtain the upper bound on the size of a graph $G \in \mathsf{obs}(\mathcal{E}_k(\mathcal{G}))$ claimed in Theorem 5, we proceed in two steps. First, we bound the treewidth of G by a function of k. To do so, we observe that if the treewidth of G is big enough, then there is a big enough wall in G, and we find an irrelevant vertex v for Elimination Distance to $\mathcal{G}$ in G. However, $G \setminus \{v\} \in \mathcal{E}_k(\mathcal{G})$ and $G \notin \mathcal{E}_k(\mathcal{G})$, hence we reach a contradiction. The second step is to bound the size of a minor-minimal obstruction of small treewidth. This uses the classic technique of Lagergren [39] (see also [21–23, 28, 29, 38, 40, 52]) combined with the encoding of the tables of the dynamic programming algorithm that we use to prove Theorem 4; see the full paper.

2 Preliminaries

In this section we give some basic definitions needed to understand the main body of the paper. Due to space limitations and the length of all the formal definitions, the complete preliminaries are provided in the full version of the paper (definitions and preliminary results regarding treedepth, treewidth and boundaried graphs, and framework of flat walls).

Minors and obstructions. A graph G' is a *minor* of a graph G, denoted by $G' \preceq G$, if G' can be obtained from G by a sequence of vertex removals, edge removals, and edge contractions. Let $\mathcal{G}$ be a graph class that is closed under taking minors. Recall that the *minor obstruction set* of $\mathcal{G}$ is defined as the set of all minor-minimal graphs that are not in $\mathcal{G}$, and is denoted by $\mathsf{obs}(\mathcal{G})$. Given a finite non-empty collection of non-empty graphs $\mathcal{F}$, we denote by $\mathsf{exc}(\mathcal{F})$ the set containing every graph G that excludes all graphs in $\mathcal{F}$ as minors. We call each graph in $\mathsf{exc}(\mathcal{F})$ *$\mathcal{F}$-minor-free*.

Restating the problems. Let $\mathcal{G}$ be a minor-closed graph class and $\mathcal{F}$ be its obstruction set. Clearly, Vertex Deletion to $\mathcal{G}$ is the same problem as asking, given a graph G and some $k \in \mathbb{N}$, for a vertex set $S \subseteq V(G)$ of at most k vertices such that $G \setminus S \in \mathsf{exc}(\mathcal{F})$. Following the terminology of [5–8, 19, 20, 34, 35, 51], we call this problem $\mathcal{F}$-M-Deletion. Likewise, Elimination Distance to $\mathcal{G}$ is the same problem as asking whether $\mathsf{ed}_{\mathsf{exc}(\mathcal{F})}(G) \leq k$. We thus follow a similar notation and call this problem $\mathcal{F}$-M-Elimination Distance. Using the notation, $\{K_1\}$-M-Elimination Distance is the problem of asking whether $\mathsf{td}(G) \leq k$.

Some conventions. In the rest of the paper, we fix $\mathcal{G}$ to be a minor-closed graph class and $\mathcal{F}$ to be the set $\mathsf{obs}(\mathcal{G})$. From Robertson and Seymour's theorem [49], we know that $\mathcal{F}$ is a finite collection of graphs. Given a graph G, we define its *apex number* to be the smallest integer a for which there is a set $A \subseteq V(G)$ of size at most a such that $G \setminus A$ is planar. An *apex-graph* is a graph with apex number one. Also, we define the *detail* of G, denoted by $\mathsf{detail}(G)$, to be the maximum among $|E(G)|$ and $|V(G)|$. We define three constants depending on $\mathcal{F}$ that will be used throughout the paper whenever we consider such a graph family $\mathcal{F}$. We define $a_{\mathcal{F}}$ as the minimum apex number of a graph in $\mathcal{F}$, we set $s_{\mathcal{F}} := \max\{|V(H)| \mid H \in \mathcal{F}\}$, and we set $\ell_{\mathcal{F}} := \max\{\mathsf{detail}(H)| \mid H \in \mathcal{F}\}$. Given a tuple $\mathbf{t} = (x_1, \ldots, x_\ell) \in \mathbb{N}^\ell$ and two functions $\chi, \psi : \mathbb{N} \to \mathbb{N}$, we write $\chi(n) = \mathcal{O}_{\mathbf{t}}(\psi(n))$ in order to denote that there exists a computable function $\phi : \mathbb{N}^\ell \to \mathbb{N}$ such that $\chi(n) = \mathcal{O}(\phi(\mathbf{t}) \cdot \psi(n))$. Notice that $s_{\mathcal{F}} \leq \ell_{\mathcal{F}} \leq s_{\mathcal{F}}(s_{\mathcal{F}} - 1)/2$, and thus $\mathcal{O}_{\ell_{\mathcal{F}}}(\cdot) = \mathcal{O}_{s_{\mathcal{F}}}(\cdot)$. Observe also that $\mathcal{A}_k(\mathcal{G})$ and $\mathcal{E}_k(\mathcal{G})$ are $K_{s_{\mathcal{F}}+k}$-minor-free graph classes, and thus, due to [53], we can always assume that G has $\mathcal{O}_{s_{\mathcal{F}}}(k\sqrt{\log k} \cdot n)$ edges, otherwise we can directly conclude that (G, k) is a no-instance for both problems.

Walls and flat walls. In this paper we extensively deal with walls and flat walls, following the framework of [50]. Unfortunately, more than ten pages are required to provide all the technical notions to correctly present all this framework, that is necessary to use the tools developed in [50–52]. Thus, formal definitions are provided in the full version of the paper. More precisely, we introduce walls and several notions concerning them (just look at Figure 1 to understand what a wall is). We then provide the definitions of a rendition and a painting in order to define flat walls. There are a number of technical terms (such as tilts, influence, regular flatness pairs, ...) that are not the main focus of this work. Let us just mention that the perimeter of a flat wall of a graph G separates $V(G)$ into two sets X and Y with Y containing the wall. The *compass* of a flat wall is $G[Y]$.

We define canonical partitions and the notion of bidimensionality. Informally speaking, a *canonical partition* of a graph with respect to some wall W refers to a partition of the vertex set of a graph in bags that follow the structure of a wall subgraph of the given graph; see Figure 1 for an illustration. The *bidimensionality* of a vertex set X with respect to a wall W of a graph G intuitively expresses the "spread" of a set X in a W-canonical partition of G. The crucial idea is that a set X of small bidimensionality cannot "destroy" a large (flat) wall too much.

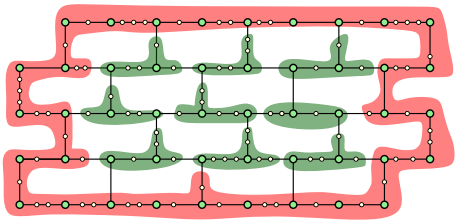

Figure 1 A 5-wall and its canonical partition $\mathcal{Q}$. The red bag is the external bag Q_{ext}.

Finally, we present homogeneous walls. Intuitively, *homogeneous flat walls* are flat walls that allow the routing of the same set of (topological) minors in the augmented flaps (i.e., the flaps together with the apex set) "cropped" by each one of their bricks. Such a homogeneous wall can be detected in a big enough flat wall (Proposition 10) and this "homogeneity" property implies that some central part of a big enough homogeneous wall can be declared irrelevant (Proposition 11).

3 Sketch of the algorithms

In this section we provide a sketch of the algorithms claimed in Theorem 1, Theorem 2 and Theorem 3. As mentioned in the introduction, Theorem 1 can be seen as a generalization of the algorithm of [51] that solves $\mathcal{F}$-M-Vertex Deletion in the particular case where $\mathcal{F}$ contains some apex-graph. While many techniques taken from [51] remain the same, some new ingredients are needed so as to deal with the possible existence of many apices in all graphs in $\mathcal{F}$. On the other hand, Theorem 2 and Theorem 3 can be seen as an adaptation of Theorem 1 to $\mathcal{F}$-M-Elimination Distance. Since these three algorithms follow a common streamline, we sketch all of them simultaneously while pointing out the steps where they differ. Moreover, the full proof of Theorem 1 is given in Section 4, while the proofs of Theorem 2 and Theorem 3 can be found in the full version of the paper.

The first common step is to run the following algorithm that states that a graph G in $\mathcal{A}_k(\mathsf{exc}(\mathcal{F}))$ or $\mathcal{E}_k(\mathsf{exc}(\mathcal{F}))$ either has bounded treewidth or contains a large wall. This result was proved in [51] in the case of $\mathcal{F}$-M-Deletion. The proof in the case of $\mathcal{F}$-M-Elimination Distance, necessary for Theorem 2 and Theorem 3, can be found in the full version of the paper.

▶ **Proposition 6** ([51], full paper)**.** *Let $\mathcal{F}$ be a finite collection of graphs. There exist a function $f_1 : \mathbb{N} \to \mathbb{N}$ and an algorithm with the following specifications:*

`Find-Wall`(G, r, k)
***Input**: A graph G, an odd $r \in \mathbb{N}_{\geq 3}$, and $k \in \mathbb{N}$.*
***Output**: One of the following:*

- **Case 1:** *Either a report that (G, k) is a* no*-instance of $\mathcal{F}$-M-Deletion (resp. $\mathcal{F}$-M-Elimination Distance), or*
- **Case 2:** *a report that G has treewidth at most $f_1(s_{\mathcal{F}}) \cdot r + k$, or*
- **Case 3:** *an r-wall W of G.*

Moreover, $f_1(s_{\mathcal{F}}) = 2^{\mathcal{O}(s_{\mathcal{F}}^2 \cdot \log s_{\mathcal{F}})}$, and the algorithm runs in time $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(r^2+(k+r)\cdot\log(k+r))} \cdot n$ (resp. $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(r^2+k^2)} \cdot n$).

In **Case 1**, we can immediately conclude. In **Case 2**, since the treewidth of G is bounded, we use a dynamic programming algorithm to solve the corresponding problem. Namely, we solve $\mathcal{F}$-M-Deletion on instances of bounded treewidth using the main result from [5].

▶ **Proposition 7** ([5]). *For every finite collection of graphs $\mathcal{F}$, there exists an algorithm that, given a triple (G, tw, k) where G is a graph of treewidth at most tw and k is a non-negative integer, solves $\mathcal{F}$-M-Deletion in time $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(\mathsf{tw}\cdot\log \mathsf{tw})} \cdot n$.*

For $\mathcal{F}$-M-Elimination Distance, we use Theorem 4 to conclude. The proof of this (quite technically involved) dynamic programming algorithm is given in the full version of the paper.

Therefore, it only remains to deal with **Case 3**. Given an r-wall W of G, we want to reduce the size of G. To do so, we observe that we can either:

- **Case 3a:** find a subwall W_a of W and an apex set A_a such that W_a is flat in $G \setminus A_a$ and has a compass of bounded treewidth, or
- **Case 3b:** find a subwall W_b of W that is very "well connected" to an apex set A_b of small size.

The above distinction is done using two algorithmic versions of the Flat Wall Theorem consecutively. The first one comes from [32, Theorem 7.7] and is translated here in the new framework with tilts of [50]. Informally, we say that a graph H is *grasped* by a wall W in a graph G if there is a model of H in G such that the model of every node of H intersects W.

▶ **Proposition 8** ([32]). *There are two functions $f_2, f_3 : \mathbb{N} \to \mathbb{N}$, such that the images of f_2 are odd integers, and an algorithm with the following specifications:*

`Grasped-or-Flat`(G, r, t, W)
***Input**: A graph G, an odd $r \in \mathbb{N}_{\geq 3}$, $t \in \mathbb{N}_{\geq 1}$, and an $f_2(t) \cdot r$-wall W of G.*
***Output**: One of the following:*

- *Either a model of a K_t-minor in G grasped by W, or*
- *a set $A \subseteq V(G)$ of size at most $f_3(t)$ and a flatness pair $(W', \mathfrak{R}')$ of $G \setminus A$ of heigth r such that W' is a $\tilde{W}'$-tilt of some subwall $\tilde{W}'$ of W.*

Moreover, $f_2(t) = \mathcal{O}(t^{26})$, $f_3(t) = \mathcal{O}(t^{24})$, and the algorithm runs in time $\mathcal{O}(t^{24}m + n)$.

We would like to mention that the notion of being grasped by a wall is one of the new main arguments yielding the improvement of the complexity for $\mathcal{F}$-M-Deletion compared to [51].

The second one comes from [51] and adds the condition that W' has a compass of bounded treewidth, at the price of dropping the condition that the model of K_t is grasped by W.

▶ **Proposition 9** ([51]). *There exist a function $f_4 : \mathbb{N} \to \mathbb{N}$ and an algorithm with the following specifications:*

`Clique-Or-twFlat`(G, r, t)
***Input**: A graph G, an odd $r \in \mathbb{N}_{\geq 3}$, and $t \in \mathbb{N}_{\geq 1}$.*
***Output**: One of the following:*

- *Either a report that K_t is a minor of G, or*
- *a tree decomposition of G of width at most $f_4(t) \cdot r$, or*
- *a set $A \subseteq V(G)$ of size at most $f_3(t)$ and a regular flatness pair $(W', \mathfrak{R}')$ of $G \setminus A$ of height r whose $\mathfrak{R}'$-compass has treewidth at most $f_4(t) \cdot r$.*

Moreover, $f_4(t) = 2^{\mathcal{O}(t^2 \log t)}$ and this algorithm runs in time $2^{\mathcal{O}_t(r^2)} \cdot n$. The algorithm can be modified to obtain an explicit dependence on t in the running time, namely $2^{2^{\mathcal{O}(t^2 \log t)} \cdot r^3 \log r} \cdot n$.

`Grasped-or-Flat` is used to find a big enough complete graph "controlled" by the input wall, while we need `Clique-or-twFlat` to find a flat wall whose compass has bounded treewidth. Unfortunately, we cannot obtain both conditions simultaneously, and this is why we need both results. If, after using both algorithms, we obtain a flatness pair $(\tilde{W}', \mathfrak{R}')$ of

$G \setminus A_a$ of heigth r_a whose compass has bounded treewidth, then we are in **Case 3a**. In that case, the following result from [51] provides an algorithm that, given a flatness pair of big enough height, outputs a homogeneous flatness pair.

▶ **Proposition 10** ([51]). *There is a function $f_5 : \mathbb{N}^4 \to \mathbb{N}$, whose images are odd integers, and an algorithm with the following specifications:*

`Homogeneous`$(r, \tilde{a}, a, \ell, t, G, A, W, \mathcal{R})$
***Input**: Five integers $r \in \mathbb{N}_{\geq 3}$, $\tilde{a}, a, \ell, t \in \mathbb{N}$, where $\tilde{a} \leq a$, a graph G, a set $A \subseteq V(G)$ of size at most a, and a flatness pair $(W, \mathfrak{R})$ of $G \setminus A$ of height $f_5(r, a, \tilde{a}, \ell)$ whose $\mathfrak{R}$-compass has treewidth at most t.*
***Output**: A flatness pair $(\breve{W}, \breve{\mathfrak{R}})$ of $G \setminus A$ of height r that is ℓ-homogeneous with respect to $\binom{A}{\leq \tilde{a}}$ and is a W'-tilt of $(W, \mathfrak{R})$ for some subwall W' of W.*
Moreover, $f_5(r, \tilde{a}, a, \ell) = \mathcal{O}(r^{f_6(\tilde{a}, a, \ell)})$ where $f_6(\tilde{a}, a, \ell) = 2^{a^{\tilde{a}} \cdot 2^{\mathcal{O}((\tilde{a}+\ell)\cdot \log(\tilde{a}+\ell))}}$ and the algorithm runs in time $2^{\mathcal{O}(f_6(\tilde{a}, a, \ell) \cdot r \log r + t \log t)} \cdot (n + m)$.

Then we use the next result, that essentially says that the central vertex v of a big enough homogeneous wall is irrelevant, i.e., (G, k) and $(G \setminus v, k)$ are equivalent instances of the corresponding problem. Here, $\mathsf{bid}_{G \setminus A, W}(X)$ denotes the bidimensionality of a set X in the wall W with apex set A.

▶ **Proposition 11** ([52]). *Let $\mathcal{F}$ be a finite collection of graphs. There exist two functions $f_7 : \mathbb{N}^4 \to \mathbb{N}$ and $f_8 : \mathbb{N}^2 \to \mathbb{N}$, and an algorithm with the following specifications:*

`Find-Irrelevant-Vertex`$(k, a, G, A, W, \mathcal{R})$
***Input**: Two integers $k, a \in \mathbb{N}$, a graph G, a set $A \subseteq V(G)$, and a regular flatness pair $(W, \mathcal{R})$ of $G \setminus A$ of height at least $f_7(a, \ell_{\mathcal{F}}, 3, k)$ that is $f_8(a, \ell_{\mathcal{F}})$-homogeneous with respect to $\binom{A}{\leq a}$.*
***Output**: A vertex v of $G \setminus A$ such that for every set $X \subseteq V(G)$ with $\mathsf{bid}_{G \setminus A, W}(X) \leq k$ and $|A \setminus X| \leq a$, it holds that $G \setminus X \in \mathsf{exc}(\mathcal{F})$ if and only if $G \setminus (X \setminus v) \in \mathsf{exc}(\mathcal{F})$.*
Moreover, $f_7(a, \ell_{\mathcal{F}}, q, k) = \mathcal{O}(k \cdot (f_{\mathsf{ul}}(16a + 12\ell_{\mathcal{F}}))^3 + q)$, where f_{ul} is the function of the Unique Linkage Theorem (see [33]) and $f_8(a, \ell_{\mathcal{F}}) = a + \ell_{\mathcal{F}} + 3$, and this algorithm runs in time $\mathcal{O}(n + m)$.

We can prove that both k-apex sets and k-elimination sets have small bidimensionality. If, for every k-apex set S, $G \setminus S \in \mathsf{exc}(\mathcal{F})$ if and only if $G \setminus (S \setminus v) \in \mathsf{exc}(\mathcal{F})$, then it is straightforward to see that v is irrelevant for $\mathcal{F}$-M-Deletion. It is slightly less trivial to prove that, for each k-elimination set S, we can find some superset $X \supseteq S$ of small bidimensionality such that a similar statement holds. Additional details are available in the full paper.

Therefore we can recursively solve the problems on the instance $(G \setminus v, k)$.

If no flatness pair whose compass has bounded treewidth was found, then we are in **Case 3b**. In this case, inspired by [42] and [51], we use the following result of [52] that basically says that if there is a big enough flat wall W and an apex set A' of $a_{\mathcal{F}}$ vertices that are all adjacent to many bags of a canonical partition of W, then each k-apex set or k-elimination set intersects A'.

▶ **Proposition 12** ([52]). *There exist three functions $f_9, f_{10}, f_{11} : \mathbb{N}^3 \to \mathbb{N}$, such that if G is a graph, $k \in \mathbb{N}$, A is a subset of $V(G)$, $(W, \mathfrak{R})$ is a flatness pair of $G \setminus A$ of height at least $f_9(a_{\mathcal{F}}, s_{\mathcal{F}}, k)$, $\tilde{\mathcal{Q}}$ is a W-canonical partition of $G \setminus A$, A' is a subset of vertices of A that are adjacent, in G, to vertices of at least $f_{10}(a_{\mathcal{F}}, s_{\mathcal{F}}, k)$ many $f_{11}(a_{\mathcal{F}}, s_{\mathcal{F}}, k)$-internal bags of $\tilde{\mathcal{Q}}$, and $|A'| \geq a_{\mathcal{F}}$, then for every set $X \subseteq V(G)$ such that $G \setminus X \in \mathsf{exc}(\mathcal{F})$ and $\mathsf{bid}_{G \setminus A, W}(X) \leq k$, it holds that $X \cap A' \neq \emptyset$. Moreover, $f_9(a, s, k) = \mathcal{O}(2^a \cdot s^{5/2} \cdot k^{5/2})$, $f_{10}(a, s, k) = \mathcal{O}(2^a \cdot s^3 \cdot k^3)$, and $f_{11}(a, s, k) = \mathcal{O}((a^2 + k) \cdot s)$, where $a = a_{\mathcal{F}}$ and $s = s_{\mathcal{F}}$.*

For the $\mathcal{F}$-M-Deletion problem, if we find such a set A', then we can branch by guessing which vertex $v \in A'$ belongs to a k-apex set and recursively solving $(G \setminus v, k-1)$. Given that A' has size $a_{\mathcal{F}}$ and that k decreases after each guess, this step is applied at most $a_{\mathcal{F}}^k$ times.

However, for $\mathcal{F}$-M-Elimination Distance, k does not decrease, given that the size of a k-elimination set may not depend on k. Thus, this step may be done $a_{\mathcal{F}}^n$ times, which does not give an FPT-algorithm. To circumvent this problem, we propose two alternatives:

Option 1: The first alternative is to only use **Case 3a**. This is possible given that $(K_{s_{\mathcal{F}}+k}, k)$ is a no-instance of both problems. Thus, when using the algorithms `Grasped-or-Flat` and `Clique-or-twFlat`, we force the outcome to be an apex set A and a flatness pair of $G \setminus A$. However, the bound on the size of A now depends on k, and thus, so does the variable a in the input of the algorithm `Homogeneous`. This explains the triple-exponential parametric dependence on k in Theorem 2. Interestingly, a precise analysis of the time complexity shows that if $a_{\mathcal{F}} = 1$, i.e., when $\mathcal{F}$ contains an apex graph, the parametric dependence is only double-exponential on k (cf. Theorem 2).

Option 2: The second alternative is to restrict ourselves to the case where $a_{\mathcal{F}} = 1$. Thus, in **Case 3b**, we find a vertex v that belongs to every k-elimination set. There is no need to branch, and this step is done at most n times. However, the fact that the time complexity of this step is quadratic in n explains the cubic complexity of the algorithm in Theorem 3.

It remains to show that if no flatness pair whose compass has bounded treewidth was found, then we can find a flatness pair and a set A' satisfying the conditions of Proposition 12. To do so, using flow techniques, we find the set A of vertices with sufficiently many internally-disjoint paths to W, independently from one another. If this set is too large, we can safely declare a no-instance. Otherwise, we extend the canonical partition of W and just check whether $a_{\mathcal{F}}$ vertices of A are adjacent to many vertices of this new canonical partition. If this happens, then we can safely use Proposition 12. The second main improvement with respect to the algorithm in [51] is the new argument that the extension of the canonical partition of W can be done in a totally arbitrary manner. The quadratic complexity of this step stems from the search for internally-disjoint paths for every vertex of the input graph.

4 Vertex deletion to a minor-closed graph class

In this section we prove our main result for the $\mathcal{F}$-M-Deletion problem, namely Theorem 1.

All the propositions necessary for this proof have already been stated in Section 3, aside from the following result proved in [52] that intuitively states that, given a canonical partition $\tilde{\mathcal{Q}}$ of a flat wall $(W, \mathfrak{R})$ of big enough height, we can find a "packing" of subwalls of W that are inside some central part of W and such that the vertex set of every bag of $\tilde{\mathcal{Q}}$ intersects the vertices of at most one of these walls.

▶ **Proposition 13** ([52]). *There exists a function $f_{12} : \mathbb{N}^3 \to \mathbb{N}$ such that if $p, l \in \mathbb{N}_{\geq 1}$, $r \in \mathbb{N}_{\geq 3}$ is an odd integer, G is a graph, $(W, \mathfrak{R})$ is a flatness pair of G of height at least $f_{12}(l, r, p)$, and $\tilde{\mathcal{Q}}$ is a W-canonical partition of G, then there is a collection $\mathcal{W} = \{W^1, \ldots, W^l\}$ of r-subwalls of W such that*

- *for every $i \in [l]$, $\bigcup \mathsf{influence}_{\mathfrak{R}}(W^i)$ is a subgraph of $\bigcup\{Q \mid Q$ is a p-internal bag of $\tilde{\mathcal{Q}}\}$ and*
- *for every $i, j \in [l]$, with $i \neq j$, there is no internal bag of $\tilde{\mathcal{Q}}$ that contains vertices of both $V(\bigcup \mathsf{influence}_{\mathfrak{R}}(W^i))$ and $V(\bigcup \mathsf{influence}_{\mathfrak{R}}(W^j))$.*

Moreover, $f_{12}(l, r, p) = \mathcal{O}(\sqrt{l} \cdot r + p)$ and $\mathcal{W}$ can be constructed in time $\mathcal{O}(n + m)$.

4.1 Description of the algorithm for $\mathcal{F}$-M-Deletion

Our algorithm for $\mathcal{F}$-M-Deletion has three steps. In Step 1, either we can easily conclude with a positive or a negative answer (**Cases 1 and 2**) or we find a big wall. If we can find a large flat wall of bounded treewidth inside this wall, then we go to Step 2 and find an irrelevant vertex (**Case 3a**). Otherwise, we proceed to Step 3 where, by using flow techniques, we find a set of vertices that intersects every solution, and we branch on this set or we report a negative answer (**Case 3b**). The correctness of the algorithm is not trivial and will be justified in Subsection 4.2.

Given a non-negative integer x, we denote by $\mathsf{odd}(x)$ the smallest odd number that is not smaller than x. We define the following constants.

$$
\begin{aligned}
a &= f_3(s_{\mathcal{F}} + a_{\mathcal{F}} - 1), & b &= f_3(s_{\mathcal{F}}),\\
q &= f_{10}(a_{\mathcal{F}}, s_{\mathcal{F}}, k), & p &= f_{11}(a_{\mathcal{F}}, s_{\mathcal{F}}, k),\\
l &= (q-1)\cdot(k+b), & r_6 &= f_7(a+b, \ell_{\mathcal{F}}, 3, k)\\
d &= f_8(a+b, \ell_{\mathcal{F}}) & r_5 &= f_5(r_6, a+b, a+b, d),\\
t &= f_4(s_{\mathcal{F}})\cdot r_5, & r_4 &= \mathsf{odd}(t+3),\\
r_3 &= f_{12}(a_{\mathcal{F}}, r_4, 1), & r_2 &= \mathsf{odd}(2 + f_2(s_{\mathcal{F}} + a_{\mathcal{F}} - 1)\cdot r_3),\\
r_2' &= \mathsf{odd}(\max\{f_9(a_{\mathcal{F}}, s_{\mathcal{F}}, k), f_{12}(l+1, r_2, p)\}), & r_1 &= \mathsf{odd}(f_2(s_{\mathcal{F}})\cdot r_2' + k).
\end{aligned}
$$

Note that $r_6 = \mathcal{O}_{\ell_{\mathcal{F}}}(k)$, $r_5, r_4, r_3, r_2, t = \mathcal{O}_{\ell_{\mathcal{F}}}(k^c)$, and $r_2', r_1 = \mathcal{O}_{\ell_{\mathcal{F}}}(k^{c+2})$ where $c = f_6(a+b, a+b, d)$. Recall from Section 2 that we may assume that G has $\mathcal{O}_{s_{\mathcal{F}}}(k\sqrt{\log k}\cdot n)$ edges.

Step 1. Run the algorithm `Find-Wall` from Proposition 6 with input (G, r_1, k) and, in time $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(r_1^2 + (k+r_1)\log(k+r_1))}\cdot n = 2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^{2(c+2)})}\cdot n$,

- either report a no-instance, or
- conclude that $\mathsf{tw}(G) \leq f_1(s_{\mathcal{F}})\cdot r_1 + k$ and solve $\mathcal{F}$-M-Deletion in time $2^{\mathcal{O}_{\ell_{\mathcal{F}}}((r_1+k)\log(r_1+k))}\cdot n = 2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^{c+2}\cdot\log k)}\cdot n$ using the algorithm of Proposition 7, or
- obtain an r_1-wall W_1 of G.

If the output of Proposition 6 is an r_1-wall W_1, consider all the $\binom{r_1}{r_2}^2 = 2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^c\log k)}$ r_2-subwalls of W_1. For each one of them, say W_2, let W_2^* be the central (r_2-2)-subwall of W_2 and let D_{W_2} be the graph obtained from G after removing the perimeter of W_2 and taking the connected component containing W_2^*. Run the algorithm `Grasped-or-Flat` of Proposition 8 with input $(D_{W_2}, r_3, s_{\mathcal{F}} + a_{\mathcal{F}} - 1, W_2^*)$. This can be done in time $\mathcal{O}_{s_{\mathcal{F}}}(k\sqrt{\log k}\cdot n)$.

If for some of these subwalls the result is a set $A \subseteq V(D_{W_2})$ with $|A| \leq a$ and a flatness pair $(W_3, \mathfrak{R}_3)$ of $D_{W_2}\setminus A$ of height r_3 then, as in Proposition 13, compute a W_3-canonical partition $\tilde{\mathcal{Q}}$ of $D_{W_2}\setminus A$ and a collection $\mathcal{W} = \{W^1, ..., W^{a_{\mathcal{F}}}\}$ of r_4-subwalls of W_3 such that for every $i \in [a_{\mathcal{F}}]$, $\bigcup \mathsf{influence}_{\mathfrak{R}_3}(W^i)$ is a subgraph of $\bigcup\{Q \mid Q \text{ is a } p\text{-internal bag of } \tilde{\mathcal{Q}}\}$ and for every $i, j \in [a_{\mathcal{F}}]$, with $i \neq j$, there is no internal bag of $\tilde{\mathcal{Q}}$ that contains vertices of both $V(\bigcup \mathsf{influence}_{\mathfrak{R}_3}(W^i))$ and $V(\bigcup \mathsf{influence}_{\mathfrak{R}_3}(W^j))$. This can be done in time $\mathcal{O}_{s_{\mathcal{F}}}(k\sqrt{\log k}\cdot n)$.

For $i \in [a_{\mathcal{F}}]$, let W^{i*} be the central (r_4-2)-subwall of W^i and let D_{W^i} be the graph obtained from D_{W_2} after removing A and the perimeter of W^i and taking the connected component containing W^{i*}. Run the algorithm `Clique-or-twFlat` of Proposition 9 with input $(D_{W^i}, r_5, s_{\mathcal{F}})$. This takes time $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(r_5^2)}\cdot n = 2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^{2c})}\cdot n$. If for one of these subwalls the result is a set A' of size at most b and a regular flatness pair $(W_5, \mathfrak{R}_5)$ of $D_{W^i}\setminus A'$ of height r_5 whose $\mathfrak{R}_5$-compass has treewidth at most t, then we proceed to Step 2.

If, for every flatness pair $(W_3, \mathfrak{R}_3)$ and for every $i \in [a_{\mathcal{F}}]$, the result is a report that $K_{s_{\mathcal{F}}}$ is a minor of D_{W^i}, then we proceed to Step 3.

Step 2 (irrelevant vertex case). We obtain a 7-tuple $\mathfrak{R}'_5$ by adding all vertices of $G \setminus V(\mathsf{Compass}_{\mathfrak{R}_5}(W_5))$ to the set in the first coordinate of $\mathfrak{R}_5$, such that $(W_5, \mathfrak{R}'_5)$ is a regular flatness pair of $G \setminus (A \cup A')$ whose $\mathfrak{R}'_5$-compass has treewidth at most t. We apply the algorithm `Homogeneous` of Proposition 10 with input $(r_6, a+b, a+b, d, t, G, A \cup A', W_5, \mathfrak{R}'_5)$, which outputs, in time $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(t \log t + k \log k)} \cdot n = 2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^c \log k)} \cdot n$, a flatness pair $(W_6, \mathfrak{R}_6)$ of $G \setminus (A \cup A')$ of height r_6 that is d-homogeneous with respect to $2^{A \cup A'}$ and is a W^*-tilt of $(W_5, \mathfrak{R}'_5)$ for some subwall W^* of W_5. We apply the algorithm `Find-Irrelevant-Vertex` of Proposition 11 with input $(k, a+b, G, A \cup A', W_6, \mathfrak{R}_6)$, which outputs, in time $\mathcal{O}(n+m) = \mathcal{O}_{\ell_{\mathcal{F}}}(k\sqrt{\log k} \cdot n)$, a vertex v such that (G, k) and $(G \setminus v, k)$ are equivalent instances of $\mathcal{F}$-M-Deletion. Then the algorithm runs recursively on the equivalent instance $(G \setminus v, k)$.

Step 3 (branching case). Consider all the r'_2-subwalls of W_1, which are at most $\binom{r_1}{r'_2}^2 = 2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^{c+2} \log k)}$ many, and for each of them, say W'_2, compute its canonical partition $\mathcal{Q}$. Then, contract each bag Q of $\mathcal{Q}$ to a single vertex v_Q, and add a new vertex v_{all} and make it adjacent to all v_Q's. In the resulting graph G', for every vertex y of $G \setminus V(W'_2)$, check, using a path augmentation algorithm [13], whether there are q internally vertex-disjoint paths from v_{all} to y in time $\mathcal{O}(q \cdot m) = \mathcal{O}_{\ell_{\mathcal{F}}}(k^4\sqrt{\log k} \cdot n)$. Let $\tilde{A}$ be the set of all such y's.

If $|\tilde{A}| < a_{\mathcal{F}}$, then report a no-instance.

If $a_{\mathcal{F}} \leq |\tilde{A}| \leq k+b$, then consider all the $\binom{|\tilde{A}|}{a_{\mathcal{F}}} = 2^{\mathcal{O}_{\ell_{\mathcal{F}}}(\log k)}$ subsets of $\tilde{A}$ of size $a_{\mathcal{F}}$. For each one of them, say A^*, construct $\tilde{\mathcal{Q}}$ by enhancing $\mathcal{Q}$ on $G \setminus A^*$. Then, we distinguish two cases depending on whether for every A^* all its vertices are adjacent to vertices of q p-internal bags of $\tilde{\mathcal{Q}}$.

If each vertex of A^* is adjacent to vertices of q p-internal bags of $\tilde{\mathcal{Q}}$, then (due to Proposition 12) A^* should intersect every solution of $\mathcal{F}$-M-Deletion for the instance (G, k). Therefore, the algorithm runs recursively on each instance $(G \setminus y, k-1)$ for $y \in A^*$. If one of them is a yes-instance with $(k-1)$-apex set S of $G \setminus y$, then (G, k) is a yes-instance with k-apex set $S \cup \{y\}$ of G. If all of them are no-instances, then report a no-instance. This concludes the case where each vertex of A^* is adjacent to vertices of q p-internal bags of $\tilde{\mathcal{Q}}$.

If for every subset A^* of $\tilde{A}$ of size $a_{\mathcal{F}}$, there is a vertex of A^* that is not adjacent to vertices of q p-internal bags of the given $\tilde{\mathcal{Q}}$, then report a no-instance. This concludes the case that $a_{\mathcal{F}} \leq |\tilde{A}| \leq k+b$.

If for every wall, $|\tilde{A}| > k+b$, then report that (G, k) is a no-instance of $\mathcal{F}$-M-Deletion.

Notice that Step 3, when applied, takes time $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^{c+2} \log k)} \cdot n^2$, because we apply the flow algorithms to each of the $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^{c+2} \log k)}$ r'_2-subwalls and for each vertex of G. However, the search tree created by the branching algorithm has at most $a_{\mathcal{F}}$ branches and depth at most k. So Step 3 cannot be applied more than $a_{\mathcal{F}}{}^k$ times during the course of the algorithm. Since Step 1 runs in time $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^{2(c+2)})} \cdot n$, Step 2 runs in time $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^{2c})} \cdot n$, and both may be applied at most n times, the claimed time complexity follows: the algorithm runs in time $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^{2(c+2)})} \cdot n^2$.

4.2 Correctness of the algorithm

Suppose first that (G, k) is a yes-instance and let S be a k-apex set of G. The application of the algorithm `Find-Wall` of Proposition 6 with input (G, r_1, k) either returns a report that $\mathsf{tw}(G) \leq f_1(s_{\mathcal{F}}) \cdot r_1 + k$ or returns an r_1-wall. In the first case, i.e., if $\mathsf{tw}(G) \leq f_1(s_{\mathcal{F}}) \cdot r_1 + k$,

the application of the algorithm of Proposition 7 correctly outputs a k-apex set of G. We will focus on the latter case, i.e., where the algorithm `Find-Wall` returns an r_1-wall of G, say W_1. Since $r_1 \geq f_2(s_{\mathcal{F}}) \cdot r_2' + k$, there is an $(f_2(s_{\mathcal{F}}) \cdot r_2')$-subwall of W_1, say W_1^*, that does not contain vertices of S. Since $G \setminus S$ does not contain $K_{s_{\mathcal{F}}}$ as a minor, there is no model of $K_{s_{\mathcal{F}}}$ grasped by W_1^* and therefore, due to Proposition 8 with input $(G \setminus S, r_2', s_{\mathcal{F}}, W_1^*)$, we know that there is a set $B \subseteq V(G \setminus S)$, with $|B| \leq b$, and a flatness pair $(W_2', \mathfrak{R}_2')$ of $G \setminus (S \cup B)$ of height r_2' such that W_2' is a W''-tilt of some subwall W'' of W_1^*.

Let $\mathcal{Q}$ be the canonical partition of W_2'. Let G' be the graph obtained by contracting each bag Q of $\mathcal{Q}$ to a single vertex v_Q, and adding a new vertex v_{all} and making it adjacent to all v_Q's. Let $\tilde{A}$ be the set of vertices y of $G \setminus V(W_2')$ such that there are q internally vertex-disjoint paths from v_{all} to y in G'. We claim that $\tilde{A} \subseteq S \cup B$. To show this, we first prove that, for every $y \notin S \cup B$, the maximum number of internally vertex-disjoint paths from v_{all} to y in G' is $k + b + 4$. Indeed, if y is a vertex in the $\mathfrak{R}_2'$-compass of W_2', there are at most $k + b$ such paths that intersect the set $S \cup B$ and at most four paths that do not intersect $S \cup B$ (in the graph $G' \setminus (S \cup B)$) due to the fact that $(W_2', \mathfrak{R}_2')$ is a flatness pair of $G \setminus (S \cup B)$. If y is not a vertex in the $\mathfrak{R}_2'$-compass of W_2', then, since by the definition of flatness pairs the perimeter of W_2' together with the set $S \cup B$ separate y from the $\mathfrak{R}_2'$-compass of W_2', every collection of internally vertex-disjoint paths from v_{all} to y in G' should intersect the set $\{v_{Q_{\text{ext}}}\} \cup S \cup B$, where Q_{ext} is the external bag of $\mathcal{Q}$. Therefore, in both cases, if $y \notin S \cup B$, the maximum number of internally vertex-disjoint paths from v_{all} to y in G' is $k + b + 4$. Since $k + b + 4 < q$, we have that $y \notin \tilde{A}$. Hence, $\tilde{A} \subseteq S \cup B$ and therefore $|\tilde{A}| \leq k + b$. Hence, if (G, k) is a yes-instance we cannot have that $|\tilde{A}| > k + b$, so the algorithm correctly reports a no-instance at the end of Step 3.

Let $\tilde{\mathcal{Q}}$ be a W_2'-canonical partition of $G \setminus (S \cup B)$ obtained by enhancing $\mathcal{Q}$ on $G \setminus (S \cup B)$. Let $\tilde{A}'$ be the set of vertices in $S \cup B$ that are adjacent to vertices of at least q p-internal bags of $\tilde{\mathcal{Q}}$ (recall that $\tilde{A}$ is the set of vertices in $S \cup B$ that are adjacent to vertices of at least q internal bags of $\tilde{\mathcal{Q}}$). Note that $\tilde{A}' \subseteq \tilde{A}$ and therefore $|\tilde{A}'| \leq |\tilde{A}|$.

If $|\tilde{A}'| < a_{\mathcal{F}}$, then at most $a_{\mathcal{F}} - 1$ vertices of $S \cup B$ are adjacent to vertices of at least q p-internal bags of $\tilde{\mathcal{Q}}$. This means that the p-internal bags of $\tilde{\mathcal{Q}}$ that contain vertices adjacent to some vertex of $(S \cup B) \setminus \tilde{A}'$ are at most $(q-1) \cdot (k+b) = l$.

Consider a family $\mathcal{W} = \{W^1, \ldots, W^{l+1}\}$ of $l+1$ r_2-subwalls of W_2' such that for every $i \in [l+1]$, $\bigcup \mathsf{influence}_{\mathfrak{R}_2'}(W^i)$ is a subgraph of $\bigcup\{Q \mid Q \text{ is a } p\text{-internal bag of } \tilde{\mathcal{Q}}\}$ and for every $i, j \in [l+1]$, with $i \neq j$, there is no internal bag of $\tilde{\mathcal{Q}}$ that contains vertices of both $V(\bigcup \mathsf{influence}_{\mathfrak{R}_2'}(W^i))$ and $V(\bigcup \mathsf{influence}_{\mathfrak{R}_2'}(W^j))$. The existence of $\mathcal{W}$ follows from Proposition 13 and the fact that $r_2' \geq f_{12}(l+1, r_2, p)$.

The fact that the p-internal bags of $\tilde{\mathcal{Q}}$ that contain vertices adjacent to some vertex of $(S \cup B) \setminus \tilde{A}'$ are at most l implies that there exists an $i \in [l+1]$ such that no vertex of $V(\bigcup \mathsf{influence}_{\mathfrak{R}_2'}(W^i))$ is adjacent, in G, to a vertex in $(S \cup B) \setminus \tilde{A}'$. Let $W_2 := W^i$, let W_2^* be the central $(r_2 - 2)$-subwall of W_2, and let D_{W_2} be the graph obtained from G by removing the perimeter of W_2 and taking the connected component that contains W_2^*. Since no vertex of $V(\bigcup \mathsf{influence}_{\mathfrak{R}_2'}(W^i))$ is adjacent, in G, to a vertex in $(S \cup B) \setminus \tilde{A}'$, any path in D_{W_2} going from a vertex of W_2^* to a vertex in S must intersect a vertex of $\tilde{A}'$. Thus, there is no model of $K_{s_{\mathcal{F}}+a_{\mathcal{F}}-1}$ grasped by W_2^* in D_{W_2}, because otherwise $K_{s_{\mathcal{F}}}$ would be a minor of $G \setminus S$. So, by applying the algorithm `Grasped-or-Flat` of Proposition 8 with input $(D_{W_2}, r_3, s_{\mathcal{F}} + a_{\mathcal{F}} - 1, W_2^*)$, since $r_2 - 2 \geq f_2(s_{\mathcal{F}} + a_{\mathcal{F}} - 1) \cdot r_3$, we should find a set $A \subseteq V(D_{W_2})$ with $|A| \leq a$ and a flatness pair $(W_3, \mathfrak{R}_3)$ of $D_{W_2} \setminus A$ of height r_3, such that W_3 is a tilt of some subwall $\tilde{W}_3$ of W_2.

Let $\tilde{\mathcal{Q}}'$ be a W_3-canonical partition of $D_{W_2} \setminus A$. Let $\mathcal{W}' = \{W^1, ..., W^{a_{\mathcal{F}}}\}$ be a collection of r_4-subwalls of W_3 such that for every $i \in [a_{\mathcal{F}}]$, $\bigcup \mathsf{influence}_{\mathfrak{R}_3}(W^i)$ is a subgraph of $\bigcup\{Q \mid Q \text{ is an internal bag of } \tilde{\mathcal{Q}}'\}$ and for every $i, j \in [a_{\mathcal{F}}]$, with $i \neq j$, there is no internal bag of $\tilde{\mathcal{Q}}'$ that contains vertices of both $V(\bigcup \mathsf{influence}_{\mathfrak{R}_3}(W^i))$ and $V(\bigcup \mathsf{influence}_{\mathfrak{R}_3}(W^j))$. Since $|\tilde{A}'| < a_{\mathcal{F}}$, there is an $i \in [a_{\mathcal{F}}]$ such that $V(\bigcup \mathsf{influence}_{\mathfrak{R}_3}(W^i))$ does not intersect $\tilde{A}'$. The existence of $\mathcal{W}'$ follows from Proposition 13 and the fact that $r_3 \geq f_{12}(a_{\mathcal{F}}, r_4, 1)$.

Let $W_4 := W^i$. Let W_4^* be the central $(r_4 - 2)$-subwall of W_4 and let D_{W_4} be the graph obtained from D_{W_2} after removing A and the perimeter of W_4 and taking the connected component containing W_4^*. Observe that any path between a vertex of S and a vertex of $V(\bigcup \mathsf{influence}_{\mathfrak{R}_3}(W_4))$ in D_{W_2} intersects $\tilde{A}'$. Since $\tilde{A}'$ does not intersect $V(\bigcup \mathsf{influence}_{\mathfrak{R}_3}(W_4))$, it implies that $\tilde{A}'$ does not intersect D_{W_4}, and thus $S \cap D_{W_4} = \emptyset$. Therefore, D_{W_4} is a minor of $G \setminus S$ and $K_{s_{\mathcal{F}}}$ is not a minor of D_{W_4}. Moreover, W_4^* is a wall of D_{W_4} of height $r_4 - 2 \geq t + 1$, so $\mathsf{tw}(D_{W_4}) > t = f_4(s_{\mathcal{F}}) \cdot r_5$. Therefore, by applying the algorithm `Clique-or-twFlat` of Proposition 9 with input $(D_{W_4}, r_5, s_{\mathcal{F}})$, we should obtain a set A' of size at most b and a regular flatness pair $(W_5, \mathfrak{R}_5)$ of $D_{W_4} \setminus A'$ of height r_5 whose $\mathfrak{R}_5$-compass has treewidth at most t. All this is checked in Step 1, and thus, the algorithm should run Step 2.

If $|\tilde{A}'| \geq a_{\mathcal{F}}$, then, due to Proposition 12 and the fact that $r_2' \geq f_9(a_{\mathcal{F}}, s_{\mathcal{F}}, k)$, for any set $X \subseteq V(G)$ such that $\mathsf{bid}_{G\setminus(S\cup B),W_2'}(X) \leq k$ and such that $G \setminus X \in \mathsf{exc}(\mathcal{F})$, it holds that $X \cap \tilde{A}' \neq \emptyset$. In particular, for any k-apex set S', $\mathsf{bid}_{G\setminus(S\cup B),W_2'}(S') \leq |S'| \leq k$, and thus $S' \cap \tilde{A}' \neq \emptyset$. Thus, there is a vertex $y \in \tilde{A}'$ such that $(G \setminus y, k-1)$ is a yes-instance. Hence, if the algorithm runs Step 3, it finds a vertex $y \in \tilde{A}'$ such that $(G \setminus y, k-1)$ is a yes-instance.

Note that the enhancement $\tilde{\mathcal{Q}}$ of the canonical partition $\mathcal{Q}$ is not unique. In particular, $\tilde{A}'$ depends on $\tilde{\mathcal{Q}}$. However, as long as there is such a $\tilde{\mathcal{Q}}$ such that $|\tilde{A}'| < a_{\mathcal{F}}$, the algorithm finds the wanted flatness pair $(W_4, \mathfrak{R}_4)$ in Step 1 and then runs Step 2. Hence, if (G, k) is a yes-instance, the algorithm runs Step 3 only if for all such $\tilde{A}'$, $|\tilde{A}'| \geq a_{\mathcal{F}}$. Note that, since $|\tilde{A}| \geq |\tilde{A}'|$, in this case we have that, for all such $\tilde{A}'$, $|\tilde{A}| \geq a_{\mathcal{F}}$. This justifies the arbitrary canonical partition enhancement in Step 3 and the fact that, if $|\tilde{A}| < a_{\mathcal{F}}$ in Step 3, then the algorithm reports a no-instance.

Let us now show the correctness of Step 2, and for this we do not suppose anymore that (G, k) is a yes-instance since the argument is the same for both types of instances. Suppose that the algorithm finds in Step 1 a set A' of size at most b and a regular flatness pair $(W_5, \mathfrak{R}_5)$ of $D_{W_4} \setminus A'$ of height r_5 whose $\mathfrak{R}_5$-compass has treewidth at most t. We obtain a 7-tuple $\mathfrak{R}_5'$ by adding all vertices of $G \setminus V(\mathsf{Compass}_{\mathfrak{R}_5}(W_5))$ to the set in the first coordinate of $\mathfrak{R}_5$. Since $(W_5, \mathfrak{R}_5)$ is a regular flatness pair of $D_{W_4} \setminus A'$ and since the vertices added in $\mathfrak{R}_5'$ are either in A, or adjacent at most to the perimeter of W_4, then $(W_5, \mathfrak{R}_5')$ is a regular flatness pair of $G \setminus (A \cup A')$. Since $\mathsf{Compass}_{\mathfrak{R}_5}(W_5) = \mathsf{Compass}_{\mathfrak{R}_5'}(W_5)$, $\mathsf{Compass}_{\mathfrak{R}_5'}(W_5)$ has treewidth at most t. Thus, if we apply the algorithm `Homogeneous` of Proposition 10 with input $(r_6, a+b, a+b, d, t, G, A \cup A', W_5, \mathfrak{R}_5')$, we obtain a flatness pair $(W_6, \mathfrak{R}_6)$ of $G \setminus (A \cup A')$ of height r_6 that is d-homogeneous with respect to $2^{A \cup A'}$ and is a W^*-tilt of $(W_5, \mathfrak{R}_5')$ for some subwall W^* of W_5. Since $|A \cup A'| \leq a + b$, for any set $X \subseteq V(G)$, $|A \setminus X| \leq a + b$. Since $G \setminus S \in \mathsf{exc}(\mathcal{F})$ and $\mathsf{bid}_{G\setminus(A\cup A'),W_6}(S) \leq |S| \leq k$, by applying the algorithm `Find-Irrelevant Vertex` of Proposition 11 with input $(k, a+b, G, A \cup A', W_6, \mathfrak{R}_6)$, we obtain a vertex v such that $G \setminus S \in \mathsf{exc}(\mathcal{F})$ if and only if $G \setminus (S \setminus v) \in \mathsf{exc}(\mathcal{F})$. It follows that (G, k) and $(G \setminus v, k)$ are indeed equivalent instances of $\mathcal{F}$-M-Deletion.

We now suppose that (G, k) is a no-instance. In the beginning of Step 1, the algorithm either reports a no-instance or finds a wall. In the latter case, the algorithm either goes to Step 2 or Step 3. If it runs Step 2, the previous paragraph justifies that the algorithm

finds a vertex v such that $(G \setminus v, k)$ is a no-instance. If the algorithm runs Step 3, then it either reports a no-instance or recursively runs on instances $(G \setminus y, k-1)$. If $(G \setminus y, k-1)$ is yes-instance, then so is (G, k). Thus, $(G \setminus y, k-1)$ is a no-instance for every considered vertex y and the algorithm always reports a no-instance. Hence, Theorem 1 follows.

5 Concluding remarks

For a minor-closed graph class $\mathcal{G}$, we proved that Vertex Deletion to $\mathcal{G}$ can be solved in time $2^{\mathsf{poly}(k)} \cdot n^2$ and that Elimination Distance to $\mathcal{G}$ can be solved in time $2^{2^{2^{\mathsf{poly}(k)}}} \cdot n^2$, and in time $2^{2^{c \cdot k^2 \log k}} \cdot n^2$ and $2^{\mathsf{poly}(k)} \cdot n^3$ in the case where the obstruction set of $\mathcal{G}$ contains an apex-graph. Here the degree of poly and c heavily depend on the size of the obstructions of $\mathcal{G}$. An open question is whether $\mathsf{poly}(k)$ could be replaced by $c \cdot k^d$ for some constant c depending on $\mathcal{G}$ and some *universal* constant d (independent of $\mathcal{G}$). We tend to believe that this dependence on $\mathcal{G}$ in the exponent of the polynomial is unavoidable, at least if we want to use the irrelevant vertex technique, and specially our definition of homogeneity.

On the other hand, we are not aware, for any of the two considered problems, of any lower bound, assuming the Exponential Time Hypothesis [25], stronger than $2^{o(k)} \cdot n^{\mathcal{O}(1)}$, which follows quite easily from known results for Vertex Cover. Proving stronger lower bounds seems to be quite challenging.

Another open problem is whether it is possible to drop the time complexity of Elimination Distance to $\mathcal{G}$ to $2^{\mathsf{poly}(k)} \cdot n^2$ for *every* minor-closed graph class $\mathcal{G}$. We tend to believe that this should be possible. However, it seems to require to use branching ingeniously and, in particular, to find equivalent instances of Elimination Distance to $\mathcal{G}$ with a decreasing value of k.

As for the polynomial running time of our FPT-algorithms, a priori, nothing prevents the existence of algorithms running in *linear time*, although we are quite far from achieving this. Kawarabayashi [30] presented such a linear FPT-algorithm for the Planarization problem, heavily relying on the embedding on the resulting planar graph. Extending this technique to general minor-closed classes would require a very compact encoding of the (entangled) structure of minor-free graphs [48] that would be possible to handle in linear time.

Abstract

Spectral hypergraph sparsification, an attempt to extend well-known spectral graph sparsification to hypergraphs, has been extensively studied over the past few years. For undirected hypergraphs, Kapralov, Krauthgamer, Tardos, and Yoshida (2022) have proved an ε-spectral sparsifier of the optimal $O^*(n)$ size, where n is the number of vertices and O^* suppresses the ε^{-1} and $\log n$ factors. For directed hypergraphs, however, the optimal sparsifier size has not been known. Our main contribution is the first algorithm that constructs an $O^*(n^2)$-size ε-spectral sparsifier for a weighted directed hypergraph. Our result is optimal up to the ε^{-1} and $\log n$ factors since there is a lower bound of $\Omega(n^2)$ even for directed graphs. We also show the first non-trivial lower bound of $\Omega(n^2/\varepsilon)$ for general directed hypergraphs. The basic idea of our algorithm is borrowed from the spanner-based sparsification for ordinary graphs by Koutis and Xu (2016). Their iterative sampling approach is indeed useful for designing sparsification algorithms in various circumstances. To demonstrate this, we also present a similar iterative sampling algorithm for undirected hypergraphs that attains one of the best size bounds, enjoys parallel implementation, and can be transformed to be fault-tolerant.

1 Introduction

Graph sparsification is a fundamental idea for developing efficient algorithms and data structures. One of the earliest developments in this context is a cut sparsifier due to Benczúr and Karger [4], which approximately keeps the size of cuts (by adjusting edge weights). Spielman and Teng [24] introduced a generalized notion called a spectral sparsifier, which approximately preserves the spectrum of the Laplacian matrix of a given graph. Since this seminal work, spectral sparsification of graphs has been extensively studied and used in many applications. See, e.g., [27, 26, 23] for more details on spectral graph sparsification.

This paper studies spectral sparsification of undirected/directed hypergraphs. A hypergraph is a standard tool for generalizing graph-theoretic arguments in a set-theoretic setting, and extending a theory for graphs to hypergraphs is a common theoretical interest.

Besides, many hypergraph-based methods [12, 28, 25, 29, 31] have recently been attracting much attention as extensions of graph-based methods, which also increases the demand for advancing the theory of spectral hypergraph sparsification.

An *undirected hypergraph* is defined by a tuple $H = (V, F, z)$, where V is a finite vertex set, F is a set of subsets of V, and $z\colon F \to \mathbb{R}_+$. Each element in F is called a hyperedge and $z_f := z(f)$ is called the weight of $f \in F$ in H. The Laplacian $L_H\colon \mathbb{R}^V \to \mathbb{R}^V$ of H is defined as a nonlinear operator such that

$$x^\top L_H(x) = \sum_{f \in F} z_f \max_{u,v \in f} (x_u - x_v)^2 \quad \text{for all } x \in \mathbb{R}^V.$$

If x is restricted to $\{0,1\}^V$, $x^\top L_H(x)$ represents the cut function of H. In this sense, the above definition gives a proper extension of the ordinary graph Laplacian. (Here, $x^\top L_H(x)$ is an abuse of notation since $L_H(x)$ is not defined uniquely; nevertheless, this notation is widely used in analogy to the case of ordinary graphs.)

A *directed hypergraph* $H = (V, F, z)$ consists of a finite set V, a set F of hyperarcs, and $z\colon F \ni f \mapsto z_f \in \mathbb{R}_+$, where each *hyperarc* $f \in F$ is a pair $(t(f), h(f))$ of non-empty subsets of V, called the *tail* and the *head* (which may not be disjoint). The Laplacian $L_H\colon \mathbb{R}^V \to \mathbb{R}^V$ of H is defined as a nonlinear operator such that

$$x^\top L_H(x) = \sum_{f \in F} z_f \max_{u \in t(f), v \in h(f)} (x_u - x_v)_+^2 \quad \text{for all } x \in \mathbb{R}^V,$$

where $(\cdot)_+ = \max\{\cdot, 0\}$ (and $(\cdot)_+^2 = (\max\{\cdot, 0\})^2$). If $x \in \{0,1\}^V$, the definition of directed hypergraph Laplacian L_H also captures the cut function of H. Importantly, cut functions of directed hypergraphs can represent a large class of submodular functions [10].[1] Directed hypergraphs are also useful for modeling higher-order directional relations that appear in, e.g., propositional logic [11] and causal inference [14], which have constituted a motivation for studying spectral properties of directed hypergraphs [7].

Given an undirected/directed hypergraph $H = (V, F, z)$ and $\varepsilon \in (0, 1)$, a hypergraph $\tilde{H} = (V, \tilde{F}, \tilde{z})$ is called an *ε-spectral sparsifier* of H if it satisfies $\tilde{F} \subseteq F$ and

$$(1-\varepsilon) x^\top L_H(x) \le x^\top L_{\tilde{H}}(x) \le (1+\varepsilon) x^\top L_H(x) \quad \text{for all } x \in \mathbb{R}^V.$$

One of the big motivations for studying spectral sparsification of directed hypergraphs comes from the connection to the representation of submodular functions. Since such a cut-function representation uses $\Omega(2^{|V|})$ hyperarcs in general, a spectral sparsifier of a directed hypergraph can serve as a compact approximate representation (see the full version [20] for more details).

Soma and Yoshida [22] initiated the study of spectral hypergraph sparsification and gave an algorithm for constructing an ε-spectral sparsifier with $O(n^3 \log n/\varepsilon^2)$ hyperedges, where n is the number of vertices. Unlike ordinary graphs, the hypergraph size can be as large as 2^n (and 4^n if directed). Thus, obtaining a polynomial bound is already nontrivial. For undirected hypergraphs, the result by Soma and Yoshida [22] has been improved to $\tilde{O}(nr^3/\varepsilon^2)$ [3] and to $\tilde{O}(nr/\varepsilon^{O(1)})$ [15],[2] where r denotes the maximum size of a hyperedge in the input hypergraph H and is called the *rank* of H. Kapralov et al. [16] has removed the dependence on r and obtained a nearly linear bound of $\tilde{O}(n/\varepsilon^4)$. Very recently, an improved bound of $\tilde{O}(n/\varepsilon^2)$ has been shown in [13, 18] (concurrently to our work). This upper bound is nearly tight since the $\Omega(n/\varepsilon^2)$ lower bound applies even to ordinary graphs [2, 6].

[1] In fact, any set function can be represented as a cut function of some directed hypergraph if negative weights are allowed [10].

[2] We use $\tilde{O}$ to hide $\mathrm{poly}(\log(n/\varepsilon))$ factors.

Table 1 Bounds on sparsification of directed hypergraphs. In the time complexity, additive $\mathrm{poly}(n, 1/\varepsilon)$ terms are omitted. Note that Kapralov et al. [15] assume the unweighted case.

Method	Cut/Spectral	Bound	Time complexity
Soma and Yoshida [22]	Spectral	$O(n^3 \log n/\varepsilon^2)$	$O(mr^2)$
Kapralov et al. [15]	Spectral	$O(n^2 r^3 \log^2 n/\varepsilon^2)$	$O(mr^2)$
Rafiey and Yoshida [21]	Cut	$O(n^2 r^2/\varepsilon^2)$	$O(m2^r)$
This paper	Spectral	$O(n^2 \log^3(n/\varepsilon)/\varepsilon^2)$	$O(mr^2)$

As for spectral sparsification of directed hypergraphs, Soma and Yoshida [22] showed that their algorithm is also applicable, and hence the $O(n^3 \log n/\varepsilon^2)$ bound also holds for directed hypergraphs. Later, Kapralov et al. [15] gave an $O(n^2 r^3 \log^2 n/\varepsilon^2)$ bound for unweighted directed hypergraphs, where the rank r is defined by $r = \max_{f \in F}\{|h(f)| + |t(f)|\}$ in the directed case. Recently, for the case of cut sparsification, Rafiey and Yoshida [21] obtained sparsifiers with $O(n^2 r^2/\varepsilon^2)$ hyperarcs.[3] See Table 1. On the other hand, a well-known $\Omega(n^2)$ lower bound for directed graphs [9] is valid for directed hypergraphs. Therefore, a central open question in this context is: *can we obtain an upper bound of $\tilde{O}(n^2/\varepsilon^{O(1)})$ that has no dependence on the rank r?*

1.1 Main Results and Idea

Our main contribution is the first algorithm that constructs an ε-spectral sparsifier with $\tilde{O}(n^2/\varepsilon^2)$ hyperarcs for a directed hypergraph, thus settling the aforementioned question.

▶ **Theorem 1.** *Let $H = (V, F, z)$ be a directed hypergraph with n vertices. For any $\varepsilon \in (0, 1)$, our algorithm (shown in Algorithm 3) returns an ε-spectral sparsifier $\tilde{H} = (V, \tilde{F}, \tilde{z})$ of H such that $|\tilde{F}| = O\left(\frac{n^2}{\varepsilon^2} \log^3 \frac{n}{\varepsilon}\right)$ with probability at least $1 - O\left(\frac{1}{n}\right)$. Its time complexity is $O(mr^2)$ with probability at least $1 - O\left(\frac{1}{n}\right)$, where $m = |F|$ and r is the rank of H.*

This bound improves the previous results and is optimal up to the ε^{-1} and logarithmic factors due to the presence of the $\Omega(n^2)$ lower bound for directed graphs. We prove Theorem 1 in Section 4 by providing a concrete algorithm and its analysis.

A natural next question would be whether the ε^{-1} term can be deleted. Our new lower bound shows that the ε^{-1} term is indeed necessary, and an ε-spectral sparsifier of size $O(n^2)$ may not exist in general, thus complementing our upper bound.

▶ **Theorem 2.** *Let $n \in \mathbb{Z}_{>0}$. For any $\varepsilon \in \left(\frac{1}{4n}, 1\right)$, there is a directed hypergraph $H = (V, F, z)$ with $2n$ vertices, $\Omega\left(\frac{n^2}{\varepsilon}\right)$ hyperarcs, and the rank three that has no sub-hypergraph $\tilde{H} = (V, \tilde{F}, \tilde{z})$ such that $\tilde{F} \subsetneq F$ and $(1-\varepsilon)x^\top L_H(x) \le x^\top L_{\tilde{H}}(x) \le (1+\varepsilon)x^\top L_H(x)$ for all $x \in \{0, 1\}^V$.*

This gives a lower bound even for the case of cut sparsification and is the first nontrivial lower bound for sparsification of directed hypergraphs. We give the proof in the full version [20].

The basic idea of our algorithm for Theorem 1 comes from a spanner-based sparsification method for undirected graphs by Koutis and Xu [17], in contrast to the method of [16] for nearly tight sparsification of undirected hypergraphs. The analysis of [16] uses a technique called *weight assignment* [8], which crucially depends on linear algebraic arguments on the

[3] This bound follows from their general result on sparsification of submodular functions.

linear Laplacian of some underlying undirected graph. *Directed* hypergraphs, however, do not have such convenient underlying *undirected* graphs, and hence their idea cannot be utilized. We thus take an alternative route and use the algorithmic framework of Koutis and Xu [17] – iteratively select important edges and sample the remaining edges. Due to its combinatorial nature, we can analyze errors via combinatorial arguments instead of linear algebraic tools. Although our algorithm is as simple as theirs, our analysis for proving Theorem 1 involves novel techniques. Specifically, while building on a recent chaining-based analysis [15, 16], we develop a completely new *discretization scheme* based on a non-trivial combinatorial observation to obtain the optimal upper bound. See Section 3 for an overview of our analysis.

1.2 Additional Results

We also present the following additional results in the full version [20].

Undirected hypergraph sparsification. The iterative sampling approach mentioned above indeed has much potential in hypergraph sparsification. We exhibit its power by presenting a natural extension of the spanner-based algorithm by Koutis and Xu [17] to undirected hypergraphs. The concept of spanners in graphs can be naturally extended to undirected hypergraphs, and accordingly, Koutis and Xu's algorithm can also be extended to undirected hypergraphs. Based on a result by Bansal et al. [3], we show that the resulting algorithm constructs an ε-spectral sparsifier with $O\left(\frac{nr^3}{\varepsilon^2}\log^2 n\right)$ hyperedges, which is nearly optimal if r is constant and matches the bound of [3] (up to a $\log n$ factor). Moreover, our algorithm inherits advantages of the spanner-based approach in that it can be implemented in parallel [17] and can be converted to be fault-tolerant [32], demonstrating that the iterative sampling approach can enjoy various useful extensions.

Application to learning of submodular functions. A notable application of directed hypergraph sparsification due to [22] is agnostic learning of submodular functions. We apply our method to this setting and obtain an $\tilde{O}\left(\frac{n^3}{\varepsilon^4}+\frac{1}{\varepsilon^2}\log\frac{1}{\delta}\right)$ sample complexity bound for agnostic learning of nonnegative hypernetwork-type submodular functions on a ground set of size n, improving the previous $\tilde{O}\left(\frac{n^4}{\varepsilon^4}+\frac{1}{\varepsilon^2}\log\frac{1}{\delta}\right)$ bound in [22]. Note that since the rank r of a hypergraph representing a submodular function can be $O(n)$, eliminating the dependence on r in the sparsifier size (i.e., our improvement from [15]) is crucial in this application. It should be mentioned that this application only requires cut sparsifiers. Nevertheless, since our result gives the first near-optimal bound even on the size of cut sparsifiers of directed hypergraphs, this application serves as a good motivation for our result.

1.3 Related Work

Besides the aforementioned application to agnostic learning of submodular functions, there are many other potential applications that involve the quadratic form $x^\top L_H(x)$ (which is sometimes called the *energy* of hypergraphs), e.g., clustering [25], semi-supervised learning [12, 28, 31, 19], and link prediction [29]. For example, Li et al. [19] use the quadratic form as a smoothness regularizer. Our result on spectral sparsification can be useful when dealing with such regularizers on dense directed hypergraphs.

Cohen et al. [9] studied directed graph sparsification under a different definition of approximation based on *Eulerian scaling*. While their definition is compatible with fast Laplacian solvers, how to extend it to directed hypergraphs seems non-trivial. Our definition is based on a general notion called *submodular transformations* [30] and admits a natural interpretation as a generalization of cut sparsification of directed hypergraphs.

2 Preliminaries

We usually denote a directed hypergraph by $H = (V, F, z)$, the numbers of vertices by n, and the numbers of hyperarcs by m. The Laplacian $L_H \colon \mathbb{R}^V \to \mathbb{R}^V$ is defined as a nonlinear operator that satisfies $x^\top L_H(x) = \sum_{f \in F} z_f \max_{u \in t(f), v \in h(f)} (x_u - x_v)_+^2$ for all $x \in \mathbb{R}^V$, where $h(f), t(f) \subseteq V$ are the head and the tail of f, respectively. For each $f \in F$, we denote the contribution of f to $x^\top L_H(x)$ by $Q_H^x(f) = z_f \max_{u \in t(f), v \in h(f)} (x_u - x_v)_+^2$, which we call the *energy* of f. Note that $x^\top L_H(x) = \sum_{f \in F} Q_H^x(f)$ holds. For any subset F' of F, we let $Q_H^x(F') = \sum_{f \in F'} Q_H^x(f)$, i.e., the sum of energies over F'. For a hyperarc $f \in F$, we define its *biclique* as an arc set $C(f) = \{ (u, v) \mid u \in t(f), v \in h(f) \}$. For a subset $F' \subseteq F$, we let $C(F') = \bigcup_{f \in F'} C(f)$. Below, we often take $\operatorname{argmax}_{f \in F'} \zeta(f)$ for a function $\zeta \colon F \to \mathbb{R}$ and a hyperarc subset $F' \subseteq F$. For convenience, we let such argmax (or argmin) operations always return a singleton by using some tie-breaking rule with a pre-defined total order on F. For example, if vertices are labeled by $1, \dots, n$ and each $f \in F$ is labeled by vertices in f, we may use the lexicographical order on F with respect to the labels. Similarly, we break ties when taking argmax/argmin on any $E' \subseteq V \times V$. We will often use the following Chernoff bound.

▶ **Proposition 3** ([1]). *Let $X_1, X_2, \cdots, X_m$ be independent random variables in the range of $[0, a]$. For any $\delta \in [0, 1]$ and $\mu \geq \mathbb{E}[\sum_{i=1}^m X_i]$, we have*

$$\mathbb{P}\left[\left|\sum_{i=1}^m X_i - \mathbb{E}\left[\sum_{i=1}^m X_i\right]\right| > \delta\mu\right] \leq 2\exp\left(-\frac{\delta^2\mu}{3a}\right).$$

3 Technical Overview

Our algorithm is an iterative algorithm whose each step goes as follows: given a hypergraph $H = (V, F, z)$ from a previous iteration, it constructs a set S of heavy hyperarcs, called a *coreset*, which is kept deterministically in this step, and samples the remaining hyperarcs with probability $1/2$, where weights of sampled ones are doubled. This single step yields a hypergraph with fewer hyperarcs, which is taken as input in the next step. We iterate this until a sub-hypergraph of the desired size is obtained. Roughly speaking, the size of the coreset is about $\tilde{O}(n^2/\varepsilon^2)$, and after about $O(\log(m\varepsilon^2/n^2))$ iterations, we obtain a sub-hypergraph of size $\tilde{O}(n^2/\varepsilon^2)$. This algorithmic framework is identical to that of Koutis and Xu [17] for ordinary undirected graph sparsification, which iteratively constructs a bundle of spanners (instead of a coreset) and sample the remaining edges with probability $1/4$.

We then describe how to analyze the sparsification error. Note that if a sub-hypergraph produced in each step is a sparsifier of a hypergraph $H = (V, F, z)$ given from the previous step with a sufficiently large probability, then we can bound the error accumulated over the iterations. Thus, we focus on the analysis of a single step (which is presented in Lemma 6). To bound the sparsification error in $Q_H^x(F) = x^\top L_H(x)$ for all $x \in \mathbb{R}^V$ in each step, we adopted a chaining-type argument [15, 16]; this enables us to derive a desired uniform bound on a continuous domain from a pointwise bound via adaptive scaling of the domain discretization. Here, how to design a discretization scheme crucially affects how sharp the resulting uniform bound is. Therefore, we need to design an appropriate discretization scheme by carefully looking at the structure of directed hypergraphs.

We below sketch our discretization scheme. Inspired by the previous studies [15, 16], we classify hyperarcs $f \in F \setminus S$ based on their energies $Q_H^x(f)$. Here, since the coreset S is always selected, we can exclude it when discussing the following probabilistic arguments. For

each $x \in \mathbb{R}^V$, we consider a partition of $F \setminus S$ into F_i^x $(i \in \mathbb{Z})$ such that each F_i^x consists of hyperarcs f with energies $Q_H^x(f) \approx 2^{-i} Q_H^x(F)$. Then, the Chernoff bound offers the following pointwise guarantee for each $x \in \mathbb{R}^V$:

$$\mathbb{P}\big[|Q_{\tilde{H}}^x(\tilde{F}_i^x) - Q_H^x(F_i^x)| \geq \varepsilon Q_H^x(F)\big] \lesssim \exp\left(-\frac{\varepsilon^2 Q_H^x(F)}{2^{-i} Q_H^x(F)}\right) = \exp\big(-\varepsilon^2 2^i\big),$$

where $\tilde{H}$ is a sparsifier obtained from H and $Q_{\tilde{H}}^x(\tilde{F}_i^x)$ denotes the energy of $\tilde{H}$ with hyperarcs restricted to F_i^x. To obtain a desired uniform bound using this inequality, we need to design a discretization scheme that satisfies the following two requirements:

(R1) the discretization error is $O(\varepsilon)$, and

(R2) the number of possible discretized energies is bounded by about $\exp(\varepsilon^2 2^i)$.

Kapralov et al. [15] obtained such a scheme by looking at underlying clique digraphs. By contrast, we obtain a discretization scheme by directly looking at hypergraphs. This strategy enables us to eliminate the extra r^3 factor in their bound, but it also poses a new challenge.

We explain the challenge when designing such a discretization scheme by directly looking at hypergraphs. Once $x \in \mathbb{R}^V$ is fixed, the number of hyperarcs f with $Q_H^x(f) \approx 2^{-i} Q_H^x(F)$ is bounded by about 2^i; on the other hand, we need to prepare at least $\mathrm{poly}(n, 1/\varepsilon)$ possible discretized energies for each f to satisfy requirement (R1). Thus, naive counting implies that the number of total discretized energies for all $f \in F_i^x$ is $(\mathrm{poly}(n, 1/\varepsilon))^{2^i} \approx \exp(\tilde{O}(2^i))$, which is too large to satisfy requirement (R2). To overcome this problem, we need an additional combinatorial idea: we count the number of discretized energies by focusing on the number of possible critical pairs. We say that $(u, v) \in C(F \setminus S)$ is a *critical pair* of f if $(u, v) = \mathrm{argmax}_{u' \in t(f), v' \in h(f)} (x_{u'} - x_{v'})_+^2$ (see also Figure 1b). Suppose that a lot of hyperarcs in F_i^x share a common critical pair for a given $x \in \mathbb{R}^V$, particularly when F_i^x contains as many as 2^i hyperarcs. Then, since the energy of f is determined by the $(x_u - x_v)_+^2$ value of the critical pair (u, v) of f, we may get a sharper bound on the number of discretized energies by defining a discretization scheme based on $(x_u - x_v)_+^2$ values so that hyperarcs with the same critical pairs share the same discretized energies (up to scaling of weights).

To accomplish the counting based on this idea, we use the existence of a coreset kept in each iteration. As we will see shortly from the definition, a λ-coreset $S \subseteq F$ contains λ heaviest hyperarcs for each $(u, v) \in C(F)$ (see also Figure 1a). Roughly speaking, important properties of λ-coresets are as follows:

(P1) $|S| \leq \lambda n^2$,

(P2) for any fixed $x \in \mathbb{R}^V$, many hyperarcs with large energies are included in S, and

(P3) for any fixed $x \in \mathbb{R}^V$, the number of critical pairs of hyperarcs in F_i^x is at most $2^i/\lambda$.[4]

If we set $\lambda = \tilde{O}(\varepsilon^{-2})$, the size of λ-coreset S is $\tilde{O}(n^2/\varepsilon^2)$ by property (P1), which is small enough that the output size decreases geometrically in each iteration until we obtain an $\tilde{O}(n^2/\varepsilon^2)$ size sparsifier. Property (P2) bounds the range of i such that F_i^x is non-empty. Most importantly, property (P3) implies that if we count possible discretized energies over F_i^x, the total number is at most $(\mathrm{poly}(n, 1/\varepsilon))^{2^i/\lambda} \approx \exp\big(\tilde{O}(\varepsilon^2 2^i)\big)$, satisfying requirement (R2).

In summary, once the coreset is selected, we can categorize the remaining hyperarcs in each F_i^x based on a moderate number of critical pairs, which yields a sharp bound on the number of possible discretized energies of the remaining hyperarcs. This is the key idea of our discretization scheme, which, together with the chaining-type argument, provides the desired uniform bound on the sparsification error.

[4] For ease of exposition, λ is used differently from Section 4. In Section 4.2, we will instead define F_i^x based on $2^{-i} Q_H^x(F)/\lambda$ values and, accordingly, bound the number of critical pairs by 2^i (Lemma 11).

4 Spectral Sparsification of Directed Hypergraphs

We prove Theorem 1 by presenting a concrete algorithm. Section 4.1 presents our algorithm and key lemmas. Section 4.2 focuses on the analysis of a single iteration, and Section 4.3 bounds the overall sparsification error and the resulting sparsifier size, thus proving Theorem 1. Section 4.4 shows the $O(mr^2)$ time complexity bound of our algorithm.

4.1 Algorithm Description

Our algorithm consists of CoresetFinder (Algorithm 1), DH-Onestep (Algorithm 2), and DH-Sparsify (Algorithm 3). DH-Sparsify iteratively calls DH-Onestep, which uses CoresetFinder as a subroutine. We below explain them one by one.

Algorithm 1 CoresetFinder(H, λ): greedy algorithm for coreset construction.

Input: $H = (V, F, z)$ and $\lambda > 0$
Output: $S \subseteq F$
$S \leftarrow \emptyset$ and $S^{uv} \leftarrow \emptyset$ for each $(u, v) \in C(F)$
$A^{uv} \leftarrow \{ f \in F \mid (u, v) \in C(f) \}$ for each $(u, v) \in C(F)$
for each $(u, v) \in C(F)$ **:**
    if $|A^{uv} \setminus S| \geq \lambda$ **:**
        Find the first λ heaviest hyperarcs $f_1^{uv}, f_2^{uv}, \cdots, f_\lambda^{uv} \in A^{uv} \setminus S$
        Add $f_1^{uv}, f_2^{uv}, \cdots, f_\lambda^{uv}$ to S^{uv}
    else
        $S^{uv} \leftarrow A^{uv} \setminus S$
    $S \leftarrow S \cup S^{uv}$
return S

Algorithm 2 DH-Onestep(H, λ): sampling algorithm called in each iteration in Algorithm 3.

Input: $H = (V, F, z)$ and $\lambda > 0$
Output: $\tilde{H} = (V, \tilde{F}, \tilde{z})$
$S \leftarrow$ CoresetFinder(H, λ)
$\tilde{F} \leftarrow S$ and $\tilde{z}_f \leftarrow z_f$ for $f \in S$
for each $f \in F \setminus S$ **:**
    With probability $\frac{1}{2}$, add f to $\tilde{F}$ and set $\tilde{z}_f \leftarrow 2z_f$
return $\tilde{H} = (V, \tilde{F}, \tilde{z})$

The first building block of our algorithm is CoresetFinder(H, λ) given in Algorithm 1. It takes a hypergraph H and a parameter λ as input, constructs a set, S^{uv}, of up to λ hyperarcs for each $(u, v) \in C(F)$, and outputs $S = \bigcup_{(u,v)\in C(F)} S^{uv}$. For each pair (u, v) (in arbitrary order), S^{uv} is obtained by selecting up to the λ heaviest hyperarcs f with $(u, v) \in C(f)$ among those not selected yet. The parameter λ controls the size of output S.

▶ **Lemma 4.** *Let H be a directed hypergraph and λ be a positive integer.* CoresetFinder(H, λ) *returns a set S of at most λn^2 hyperarcs that can be partitioned into disjoints subsets $\{ S^{uv} \mid (u, v) \in C(F) \}$ satisfying the following conditions:*

1. *for any $(u, v) \in C(F)$, every $f \in S^{uv}$ satisfies $(u, v) \in C(f)$,*
2. *if $(u, v) \in C(F \setminus S)$, $|S^{uv}| = \lambda$ holds, and*
3. *for any $(u, v) \in C(F)$, $f \in S^{uv}$, and $f' \in F \setminus S$ such that $(u, v) \in C(f')$, $z_f \geq z_{f'}$ holds.*

Algorithm 3 DH-SPARSIFY(H, ε): iterative algorithm that computes an ε-spectral sparsifier.

Input: $H = (V, F, z)$ with $|V| = n$ and $|F| = m$, and $\varepsilon > 0$
Output: $\tilde{H} = (V, \tilde{F}, \tilde{z})$

$m^* \leftarrow \frac{n^2}{\varepsilon^2} \log^3 \frac{n}{\varepsilon}$ ▷ This is the (asymptotic) target size of the resulting sparsifier.
$T \leftarrow \left\lceil \log_{4/3}\left(\frac{m}{m^*}\right) \right\rceil$
$i \leftarrow 0$, $\tilde{H}_0 = (V, \tilde{F}_0, \tilde{z}_0) \leftarrow H$, and $m_0 \leftarrow |\tilde{F}_0|$
while $i < T$ and $m_i \geq C_2 m^*$ **:** ▷ C_2 is a constant that is explained in Section 4.3.
  $\varepsilon_i \leftarrow \frac{\varepsilon}{4 \log^2_{4/3}\left(\frac{m_i}{m^*}\right)}$ and $\lambda_i \leftarrow \left\lceil \frac{C_1 \log^3 m_i}{\varepsilon_i^2} \right\rceil$ ▷ ε_i is used in the analysis.
  $\tilde{H}_{i+1} = (V, \tilde{F}_{i+1}, \tilde{z}_{i+1}) \leftarrow$ DH-ONESTEP$(\tilde{H}_i, \lambda_i)$
  $m_{i+1} \leftarrow |\tilde{F}_{i+1}|$
  $i \leftarrow i + 1$
$i_{\mathrm{end}} \leftarrow i$ and $\tilde{H} \leftarrow \tilde{H}_{i_{\mathrm{end}}}$
return $\tilde{H} = (V, \tilde{F}, \tilde{z})$

Proof. Since CORESETFINDER(H, λ) constructs S^{uv} for each $(u, v) \in C(F)$ by selecting up to the λ heaviest hyperarcs f with $(u, v) \in C(f)$ among those that have not been selected yet, S^{uv} for $(u, v) \in C(F)$ are mutually disjoint. This also implies $|S| = \sum_{(u,v)\in C(F)} |S^{uv}| \leq \lambda n^2$ and the first and third conditions. After S is constructed, if there is a hyperarc $f' \in F \setminus S$ such that $(u, v) \in C(f')$, then λ hyperarcs must have been added to S^{uv}. Hence $|S^{uv}| = \lambda$ if $(u, v) \in C(F \setminus S)$, implying the second condition. ◀

We call the set S shown in Lemma 4 a *coreset*, which plays a key role in the analysis.

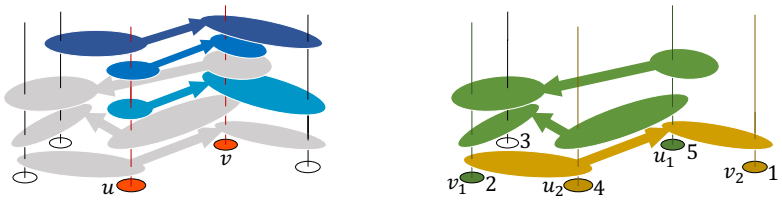
▶ **Definition 5.** *Given a directed hypergraph $H = (V, F, z)$, a subset $S \subseteq F$, and a positive integer λ, we say S is a* λ-coreset *of H if S can be partitioned into disjoints subsets $\{ S^{uv} \mid (u, v) \in C(F) \}$ satisfying the three conditions in the statement of Lemma 4.*

In short, if there is a hyperarc $f' \notin S$ with $(u, v) \in C(f')$, S^{uv} contains (at least) λ hyperarcs that are at least as heavy as $z_{f'}$. Figure 1a illustrates an example of a coreset. We use this coreset as a counterpart of a bundle of spanners in the spanner-based sparsification.

Next, we explain DH-ONESTEP(H, λ) given in Algorithm 2, which is the main subroutine in our algorithm. The algorithm first computes a λ-coreset S by calling CORESETFINDER(H, λ). The hyperarcs in the coreset S are deterministically added to the output. Then, it randomly chooses the remaining hyperarcs with probability $1/2$ and doubles the weights if sampled, thus preserving the expected total weight. The main technical observation is that, under an appropriate choice of λ, the output of DH-ONESTEP(H, λ) is an ε-spectral sparsifier of H. Formally, we can show the following lemma, which is the main technical contribution and will be proved in Section 4.2.

▶ **Lemma 6.** *Let $H = (V, F, z)$ be a directed hypergraph with $|V| = n$ and $|F| = m$. For any $\varepsilon \in (0, 1)$ and $\lambda \geq \frac{C_1 \log^3 m}{\varepsilon^2}$, where C_1 is a sufficiently large constant,* DH-ONESTEP(H, λ) *returns an ε-spectral sparsifier $\tilde{H} = (V, \tilde{F}, \tilde{z})$ of H satisfying $|\tilde{F}| \leq \frac{m}{2} + (3m \log n)^{\frac{1}{2}} + \lambda n^2$ with probability at least $1 - O\left(\frac{1}{n^2}\right)$.*

Finally, we present our sparsification algorithm DH-SPARSIFY(H, ε) in Algorithm 3. In the algorithm description, C_1 denotes the constant given in the statement of Lemma 6, and C_2 is a sufficiently large constant (which we can compute explicitly by carefully expanding the analysis in Section 4.3). The algorithm iteratively calls DH-ONESTEP$(\tilde{H}_i, \lambda_i)$, where $\tilde{H}_i$



(a) Coreset. **(b)** Critical pairs.

Figure 1 Illustration of a coreset and critical pairs on (a part of) a given hypergraph. A circle is a vertex, and a hyperarc is indicated by an arrow and two ellipses representing a head and a tail. A hyperarc contains a vertex if the line originating from the vertex pierces its head or tail. Figure 1a presents an image of a coreset, focusing on a vertex pair (u, v). Suppose that the hyperarcs are aligned in decreasing order of their weights from top to bottom. The blue hyperarcs are the three heaviest ones having u and v as elements of their tails and heads, respectively, and they are included in a subset S^{uv} of a coreset S. We suppose that gray hyperarcs are not in S. While the bottommost gray hyperarc f also satisfies $u \in t(f)$ and $v \in h(f)$, the three blue hyperarcs are heavier than it. Thus, the conditions of the λ-coreset with $\lambda = 3$ are satisfied for (u, v). Figure 1b presents an image of critical pairs of three hyperarcs, which are missed by the coreset S in Figure 1a. Suppose that vertices v have x_v values of 2, 3, 4, 5, and 1 from left to right, respectively, as shown nearby the vertices. Then, the green and yellow hyperarcs have (u_1, v_1) and (u_2, v_2), respectively, as x-ctirical pairs. If the three hyperarcs constitute $F_i^x \subseteq F \setminus S$, we have $E_i^x = \{(u_1, v_1), (u_2, v_2)\}$, and F_i^x is partitioned into F_i^{x,u_1v_1} and F_i^{x,u_2v_2}, shown in green and yellow, respectively.

is the sub-hypergraph obtained in the previous step. Here, the parameter λ_i is defined as in Line 3, which makes $\tilde{H}_{i+1}$ an ε_i-spectral sparsifier of $\tilde{H}_i$ by the condition in Lemma 6.[5] The algorithm repeatedly calls DH-Onestep$(\tilde{H}_i, \lambda_i)$ until the size of $\tilde{H}_i$ becomes $\tilde{O}(n^2/\varepsilon^2)$ or the maximum number of iterations, T, is reached. With this choice of ε_i, we will show that the size of $\tilde{H}_i$ decreases geometrically and that the accumulated sparsification error is bounded by ε. Consequently, the final output is an ε-spectral sparsifier of the desired size, which completes the proof of Theorem 1. We present the analysis in Section 4.3.

4.2 Proof of Lemma 6

We prove Lemma 6, which ensures the correctness of DH-Onestep. In this section, we let $H = (V, F, z)$, $\lambda \geq \frac{C_1 \log^3 m}{\varepsilon^2}$, and $\varepsilon \in (0, 1)$ be as given in the statement of Lemma 6, and let $\tilde{H} = (V, \tilde{F}, \tilde{z})$ be the output of DH-Onestep(H, λ).

To prove Lemma 6, we bound the size and sparsification error of $\tilde{H}$ from above. The former is an easy consequence of the Chernoff bound. We below prove it assuming $m > 12 \log n$; otherwise, an input hypergraph is already sparsified and we do not run DH-Onestep.

▶ **Lemma 7.** *Let $H = (V, F, z)$ be a directed hypergraph with $|V| = n$ and $|F| = m$, and let λ be a positive integer. If $m > 12 \log n$,* DH-Onestep(H, λ) *outputs a sub-hypergraph $\tilde{H} = (V, \tilde{F}, \tilde{z})$ of H satisfying $|\tilde{F}| \leq \frac{m}{2} + (3m \log n)^{\frac{1}{2}} + \lambda n^2$ with probability at least $1 - \frac{2}{n^2}$.*

Proof. Let S be a λ-coreset constructed in Line 2 in DH-Onestep(H, λ). By Lemma 4, S has at most λn^2 hyperarcs. To bound $|\tilde{F} \setminus S|$, for each $f \in F \setminus S$, we let X_f be a random variable that takes 1 if f is sampled and 0 otherwise. Note that $|\tilde{F} \setminus S| = \sum_{f \in F \setminus S} X_f$ holds.

[5] Unlike the existing spanner-based algorithm [17], we need to change ε_i adaptively since fixing $\varepsilon_i = \frac{\varepsilon}{T}$ does not yield a sparsifier of the desired size when the input hypergraph is exponentially large in n.

Since we have $\mathbb{E}\left[\sum_{f\in F\setminus S} X_f\right] = (m-|S|)/2 \le m/2$, for any $t\in(0,1)$, the Chernoff bound (Proposition 3) implies

$$\mathbb{P}\left[\sum_{f\in F\setminus S} X_f - \mathbb{E}\left[\sum_{f\in F\setminus S} X_f\right] > \frac{m}{2}t\right] \le 2\exp\left(-\frac{mt^2}{6}\right).$$

By setting $t = \left(\frac{12\log n}{m}\right)^{\frac{1}{2}}$, which is smaller than 1 due to the lemma assumption, we obtain

$$\mathbb{P}\left[\sum_{f\in F\setminus S} X_f \le \frac{m}{2} + (3m\log n)^{\frac{1}{2}}\right] \ge 1-\frac{2}{n^2}.$$

Thus, we have $|\tilde{F}| = |S| + \sum_{f\in F\setminus S} X_f \le \frac{m}{2} + (3m\log n)^{\frac{1}{2}} + \lambda n^2$ with probability at least $1-\frac{2}{n^2}$. ◀

The rest of this section focuses on showing that $\tilde{H}$ is an ε-spectral sparsifier of H, i.e., $(1-\varepsilon)x^\top L_H(x) \le x^\top L_{\tilde{H}}(x) \le (1+\varepsilon)x^\top L_H(x)$ for any $x\in\mathbb{R}^V$. Since this relation is invariant under scaling of x, it suffices to prove the relation for any x satisfying $x^\top L_H(x) = 1$. Let $\mathbb{S}_H = \left\{ x\in\mathbb{R}^V \;\middle|\; x^\top L_H(x) = 1 \right\}$. A similar normalization is used in [15] with respect to the total energy of the corresponding underlying clique digraphs. By contrast, we directly normalize the total energy of a hypergraph, $x^\top L_H(x)$. This difference is a key to eliminating the extra r^3 factor, while it requires a new discretization scheme, as described later.

Since we analyze the contribution of each hyperarc to the energy of H, it is convenient to use the notation of $Q^x_H(f)$ and $Q^x_H(F')$ for $f\in F$ and $F'\subseteq F$, respectively, defined in Section 2. Our goal is to prove $(1-\varepsilon)Q^x_H(F) \le Q^x_{\tilde{H}}(\tilde{F}) \le (1+\varepsilon)Q^x_H(F)$ for all $x\in\mathbb{S}_H$.

Given $x\in\mathbb{S}_H$ and a λ-coreset $S\subseteq F$, our strategy is to partition $F\setminus S$ into subsets based on the energies and evaluate the error caused by sparsification for each subset. Specifically, we classify hyperarcs $f\in F\setminus S$ into subsets F^x_i defined for each $i\in\mathbb{Z}$ as follows:

$$F^x_i := \left\{ f\in F\setminus S \;\middle|\; Q^x_H(f) \in \left[\frac{1}{2^i\lambda}, \frac{1}{2^{i-1}\lambda}\right) \right\}.$$

We also define $\tilde{F}^x_i := F^x_i \cap \tilde{F}$ for each $i\in\mathbb{Z}$.

Since $Q^x_H(F\setminus S) = \sum_{i\in\mathbb{Z}} Q^x_H(F^x_i)$ and $Q^x_{\tilde{H}}(\tilde{F}\setminus S) = \sum_{i\in\mathbb{Z}} Q^x_{\tilde{H}}(\tilde{F}^x_i)$, our goal is to prove that $|Q^x_{\tilde{H}}(\tilde{F}^x_i) - Q^x_H(F^x_i)|$ is sufficiently small for all $i\in\mathbb{Z}$ and $x\in\mathbb{S}_H$. This is not difficult if i is sufficiently large, as in the following lemma.

▶ **Lemma 8.** *Let $I = \lceil\log_2(9m)\rceil$. For any $x\in\mathbb{S}_H$, $\left|Q^x_H(\cup_{i\ge I+1}F^x_i) - Q^x_{\tilde{H}}\left(\cup_{i\ge I+1}\tilde{F}^x_i\right)\right| \le \frac{\varepsilon}{3}$.*

Proof. Due to the assumption in Lemma 6, $\lambda\varepsilon \ge \frac{C_1\log^3 m}{\varepsilon} \ge 1$ holds for sufficiently large C_1. By the definition of F^x_i, the energy of each hyperarc in $\cup_{i\ge I+1}F^x_i$ is less than $\frac{1}{2^I\lambda}$, which is at most $\frac{\varepsilon}{9m}$ by $I = \lceil\log_2(9m)\rceil$ and $\lambda\varepsilon\ge 1$. Thus, it holds that

$$Q^x_H(\cup_{i\ge I+1}F^x_i) = \sum_{f\in\cup_{i\ge I+1}F^x_i} Q^x_H(f) \le m\cdot\frac{\varepsilon}{9m} \le \frac{\varepsilon}{9}. \tag{1}$$

As for $\tilde{F}\subseteq F$, since the weight of each hyperarc in $\tilde{F}$ is doubled in DH-Onestep, we have

$$Q^x_{\tilde{H}}\left(\cup_{i\ge I+1}\tilde{F}^x_i\right) \le 2\cdot Q^x_H(\cup_{i\ge I+1}F^x_i) \le \frac{2\varepsilon}{9}. \tag{2}$$

Combining eqs. (1) and (2), we obtain the claim. ◀

We then introduce additional definitions for the convenience of describing our discretization scheme and analyzing the sparsification error.

▶ **Definition 9.** *For $x \in \mathbb{S}_H$, we say $(u,v) \in V \times V$ is an x-critical pair of $f \in F$ if we have $(u,v) = \operatorname{argmax}_{(u,v)\in C(f)}(x_u - x_v)_+^2$, breaking ties as in Section 2. For $i \in \mathbb{Z}$ and $x \in \mathbb{S}_H$, let*

$$E_i^x = \{\, (u,v) \in C(F) \mid (u,v) \text{ is an } x\text{-critical pair of some } f \in F_i^x \,\}$$

and, for each $(u,v) \in E_i^x$, let

$$F_i^{x,uv} = \{\, f \in F_i^x \mid (u,v) \text{ is an } x\text{-critical pair of } f \,\}.$$

Note that the collection of $F_i^{x,uv}$ for $(u,v) \in E_i^x$ forms a partition of F_i^x. Figure 1b presents an example of x-critical pairs.

We now discuss how to bound $|Q_{\tilde{H}}^x(\tilde{F}_i^x) - Q_H^x(F_i^x)|$ for i that is not covered in Lemma 8. By using the Chernoff bound, it is easy to evaluate the probability that $|Q_{\tilde{H}}^x(\tilde{F}_i^x) - Q_H^x(F_i^x)|$ is small for each $x \in \mathbb{S}_H$. To convert it to a uniform bound over all $x \in \mathbb{S}_H$, we construct an appropriate discretization scheme, as follows.

Let $\Delta = \frac{\varepsilon}{9m}$. For $(u,v) \in E_i^x$, we define the *discretization width* as $\Delta_i^{uv} \coloneqq \frac{\Delta}{\max_{f\in F_i^{x,uv}} z_f}$. Note that $F_i^{x,uv} \neq \emptyset$ holds for $(u,v) \in E_i$ by the definitions of E_i and $F_i^{x,uv}$, and hence Δ_i^{uv} is well-defined. The denominator plays the role of scaling the width. Given any $x \in \mathbb{S}_H$, we consider discretizing $(x_u - x_v)_+^2$ for each $(u,v) \in E_i^x$, not the energy itself. Specifically, for each $i \in \mathbb{Z}$ and $(u,v) \in E_i^x$, we use $\left\lfloor \frac{(x_u - x_v)_+^2}{\Delta_i^{uv}} \right\rfloor \Delta_i^{uv}$ as a discretized value of $(x_u - x_v)_+^2$. Then, for each $f \in F_i^{x,uv}$ such that $(u,v) \in E_i^x$, we define the *discretized energy* $D_H^x(f)$ by

$$D_H^x(f) \coloneqq z_f \left\lfloor \frac{(x_u - x_v)_+^2}{\Delta_i^{uv}} \right\rfloor \Delta_i^{uv}.$$

It should be noted that the discretized energy of $f \in F_i^{x,uv}$ is defined by first discretizing $(x_u - x_v)_+^2$ and then scaling it by z_f. This somewhat indirect discretization scheme will turn out important when bounding the number of possible discretized energies.

For each sampled hyperarc $f \in F_i^{x,uv} \cap \tilde{F}$ with $(u,v) \in E_i^x$, we define the *discretized energy after sampling* by $D_{\tilde{H}}^x(f) \coloneqq 2D_H^x(f)$. We also let $D_H^x(F_i^x) = \sum_{f\in F_i^x} D_H^x(f)$ and $D_{\tilde{H}}^x(\tilde{F}_i^x) = \sum_{f\in \tilde{F}_i^x} D_{\tilde{H}}^x(f)$. We can ensures that discretization errors are small as follows.

▶ **Lemma 10.** *For any $x \in \mathbb{S}_H$, we have*

$$\sum_{i\in\mathbb{Z}} |D_H^x(F_i^x) - Q_H^x(F_i^x)| \le \frac{\varepsilon}{9} \qquad \text{and} \qquad \sum_{i\in\mathbb{Z}} \left|D_{\tilde{H}}^x(\tilde{F}_i^x) - Q_{\tilde{H}}^x(\tilde{F}_i^x)\right| \le \frac{2\varepsilon}{9}.$$

Proof. Recall that the discretized energy $D_H^x(f)$ of each $f \in F_i^{x,uv}$ is obtained by discretizing $(x_u - x_v)_+^2$ with the width Δ_i^{uv} and scaling it by z_f. Therefore, the discretization error for each f is bounded by $z_f \Delta_i^{uv}$. From the definition of Δ_i^{uv}, we have $z_f \Delta_i^{uv} = z_f \frac{\Delta}{\max_{f\in F_i^{x,uv}} z_f} \le \Delta$. Hence, the total discretization error over all $f \in F \setminus S$ is bounded by $m\Delta$, which is at most $\frac{\varepsilon}{9}$ since $\Delta = \frac{\varepsilon}{9m}$. Thus, we obtain the first inequality. The second inequality follows from the fact that the weights of sampled hyperarcs are doubled. ◀

From Lemma 10, we can bound the sparsification error $|Q_{\tilde{H}}^x(\tilde{F}_i^x) - Q_H^x(F_i^x)|$ for all $x \in \mathbb{S}_H$ by bounding $|D_{\tilde{H}}^x(\tilde{F}_i^x) - D_H^x(F_i^x)|$ for all $x \in \mathbb{S}_H$. Since the number of possible discretized energies is finite, we can use the standard Chernoff bound and union bound to evaluate the sparsification error. Thus, what remains is to prove that the number of discretized energies is

small enough so that we can obtain the desired uniform bound. To this end, we first bound the size of E_i^x and then bound the number of possible discretized values. The following lemma bounds the size of E_i^x, in which the existence of a λ-coreset plays an important role.

▶ **Lemma 11.** *For $i \in \mathbb{Z}$, we have $|E_i^x| < 2^i$.*

Proof. By the definition of E_i^x, for each $(u,v) \in E_i^x$, there is a hyperarc $f^{uv} \in F_i^x \subseteq F \setminus S$ such that (u,v) is an x-critical pair of f^{uv}. Since S is a λ-coreset, S admits a partition $\{ S^{uv} \mid (u,v) \in C(F) \}$ satisfying the three conditions in Lemma 4. Since $f^{uv} \notin S$, the third condition in Lemma 4 implies $z_f \geq z_{f^{uv}}$ for any $f \in S^{uv}$. Hence, for any $f \in S^{uv}$, we have

$$Q_H^x(f^{uv}) = z_{f^{uv}}(x_u - x_v)_+^2 \leq z_f(x_u - x_v)_+^2 \leq \max_{(u',v') \in C(f)} z_f(x_{u'} - x_{v'})_+^2 = Q_H^x(f). \quad (3)$$

Since the second condition in Lemma 4 implies $|S^{uv}| = \lambda$ for $(u,v) \in E_i^x \subseteq C(F \setminus S)$,

$$\begin{aligned} Q_H^x(F) &\geq \sum_{(u,v) \in E_i^x} (Q_H^x(S^{uv}) + Q_H^x(f^{uv})) \quad \text{(since all } S^{uv} \text{ and } f^{uv} \notin S \text{ are disjoint)} \\ &\geq \sum_{(u,v) \in E_i^x} (\lambda + 1) \cdot Q_H^x(f^{uv}) \qquad \text{(by eq. (3) and } |S^{uv}| = \lambda) \\ &\geq \sum_{(u,v) \in E_i^x} (\lambda + 1) \cdot (2^i \lambda)^{-1} \qquad \text{(by } f^{uv} \in F_i^x). \end{aligned}$$

holds, hence $Q_H^x(F) > 2^{-i}|E_i^x|$. Since $Q_H^x(F) = 1$ by $x \in \mathbb{S}_H$, we obtain $|E_i^x| < 2^i$. ◀

From Lemma 11, if $i \leq 0$, we have $|E_i^x| < 2^i \leq 1$, which implies $E_i^x = \emptyset$ and $F_i^x = \emptyset$. Thus, the following corollary holds.

▶ **Corollary 12.** *If $i \leq 0$, we have $F_i^x = \emptyset$.*

Due to Corollary 12 and Lemma 8, we can focus on $i \in \mathbb{Z}$ with $1 \leq i \leq I = \lceil \log_2 9m \rceil$. In this range, we have the following bound on the number of possible discretized values.

▶ **Lemma 13.** *For each positive integer i, let $L_i = \left\{ \left(F_i^x, \{D_H^x(f)\}_{f \in F_i^x} \right) \mid x \in \mathbb{S}_H \right\}$, where $\{D_H^x(f)\}_{f \in F_i^x}$ is the list of the discretized energies over all hyperarcs in F_i^x. If $1 \leq i \leq I = \lceil \log_2 9m \rceil$, we have $|L_i| \leq \left(\frac{648 n^4 m^4}{\lambda \varepsilon} \right)^{2^i}$.*

Since the proof of Lemma 13 is not short, we first complete the proof of Lemma 6 assuming that Lemma 13 is true; then, we prove Lemma 13 in Section 4.2.1.

Proof of Lemma 6. Let $I = \lceil \log_2(9m) \rceil$ as in Lemma 8 and define L_i as in Lemma 13. Fix $i \in \{1, 2, \ldots, I\}$ and consider any element of L_i, which we denote by $(F_i^y, \{D_H^y(f)\}_{f \in F_i^y})$ for some $y \in \mathbb{S}_H$. Since the discretized energy of each hyperarc is obtained by rounding down, we have $D_H^y(f) \leq Q_H^y(f)$. Thus, for every $f \in F_i^y$, it holds that

$$D_H^y(f) \leq Q_H^y(f) < \frac{1}{2^{i-1}\lambda}. \quad (4)$$

For each $f \in F \setminus S$, let X_f be a random variable that takes 1 with probability $1/2$ and 0 otherwise, which represents the randomness of sampling and hence $D_{\tilde{H}}^y(\tilde{F}_i^y) = \sum_{f \in F_i^y} 2X_f D_H^y(f)$. By $D_H^y(f) \leq Q_H^y(f)$ again, we have

$$\mathbb{E}\left[\sum_{f \in F_i^y} 2X_f D_H^y(f) \right] = \sum_{f \in F_i^y} D_H^y(f) = D_H^y(F_i^y) \leq Q_H^y(F_i^y) \leq Q_H^y(F) = 1. \quad (5)$$

Due to eqs. (4) and (5), the Chernoff bound (Proposition 3) with $\mu = 1$, $a = \frac{1}{2^{i-2}\lambda}$, and $\delta = \frac{\varepsilon}{3I}$ implies

$$\mathbb{P}\left[\left|D^y_{\tilde{H}}(\tilde{F}^y_i) - D^y_H(F^y_i)\right| > \frac{\varepsilon}{3I}\right] = \mathbb{P}\left[\left|\sum_{f\in F^y_i} 2X_f D^y_H(f) - \mathbb{E}\left[\sum_{f\in F^y_i} 2X_f D^y_H(f)\right]\right| > \frac{\varepsilon}{3I}\right] \leq 2\exp\left(-\frac{2^i\cdot\varepsilon^2\lambda}{108I^2}\right).$$

This bound is true for each $(F^y_i, \{D^y_H(f)\}_{f\in F^y_i}) \in L_i$, and we can convert it to a uniform bound over all $(F^y_i, \{D^y_H(f)\}_{f\in F^y_i}) \in L_i$ by using Lemma 13 and the union bound as follows:

$$\mathbb{P}\left[\exists (F^y_i, \{D^y_H(f)\}_{f\in F^y_i}) \in L_i, \left|D^y_{\tilde{H}}(\tilde{F}^y_i) - D^y_H(F^y_i)\right| > \frac{\varepsilon}{3I}\right] \leq 2\exp\left(-\frac{2^i\cdot\varepsilon^2\lambda}{108I^2}\right)\cdot\left(\frac{648n^4m^4}{\lambda\varepsilon}\right)^{2^i}.$$

We may assume $nm \geq 648$ (otherwise Lemma 6 is trivial for a sufficiently large C_1). Letting C_1 be sufficiently large, we have $\lambda \geq \frac{C_1\log^3 m}{\varepsilon^2} \geq \frac{108I^2}{\varepsilon^2}(6\log n + 5\log m)$ and $\lambda\varepsilon \geq 1$. Thus, we can further bound the right-hand side from above by

$$2\exp\left(-\frac{2^i\cdot\varepsilon^2\lambda}{108I^2}\right)\cdot\left(n^5m^5\right)^{2^i} \leq 2\exp\left(-2^i\cdot(6\log n + 5\log m)\right)\cdot\left(n^5m^5\right)^{2^i} \leq \frac{2}{n^{2^i}}.$$

Therefore, $\mathbb{P}[\forall (F^y_i, \{D^y_H(f)\}_{f\in F^y_i}) \in L_i, |D^y_{\tilde{H}}(\tilde{F}^y_i) - D^y_H(F^y_i)| \leq \frac{\varepsilon}{3I}] \geq 1 - \frac{2}{n^{2^i}}$ holds. Since $(F^x_i, \{D^x(f)\}_{f\in F^x_i}) \in L_i$ holds for all $x \in \mathbb{S}_H$, we can equivalently rewrite the bound as

$$\mathbb{P}\left[\forall x \in \mathbb{S}_H, \left|D^x_{\tilde{H}}(\tilde{F}^x_i) - D^x_H(F^x_i)\right| \leq \frac{\varepsilon}{3I}\right] \geq 1 - \frac{2}{n^{2^i}}.$$

By the union bound over $1 \leq i \leq I = \lceil\log_2(9m)\rceil$ and $\sum_{i=1}^I \frac{2}{n^{2^i}} \leq \sum_{i=1}^\infty \frac{2}{n^{2i}} \leq \frac{2}{n^2-1} \leq \frac{3}{n^2}$ (for $n \geq 2$), we obtain

$$\mathbb{P}\left[\forall x \in \mathbb{S}_H, \sum_{i=1}^I \left|D^x_{\tilde{H}}(\tilde{F}^x_i) - D^x_H(F^x_i)\right| \leq \frac{\varepsilon}{3}\right] \geq 1 - \frac{3}{n^2}. \tag{6}$$

Thus, for all $x \in \mathbb{S}_H$, we can bound $|x^\top L_{\tilde{H}}(x) - x^\top L_H(x)| = |Q^x_{\tilde{H}}(\tilde{F}) - Q^x_H(F)|$ as follows:

$$\begin{aligned}
&\left|Q^x_{\tilde{H}}(\tilde{F}) - Q^x_H(F)\right| \\
&= \frac{\varepsilon}{3} + \sum_{i=1}^I |Q^x_{\tilde{H}}(\tilde{F}^x_i) - Q^x_H(F^x_i)| \qquad \text{(by Lemma 8 and Corollary 12)} \\
&\leq \frac{\varepsilon}{3} + \sum_{i=1}^I \left[|Q^x_{\tilde{H}}(\tilde{F}^x_i) - D^x_{\tilde{H}}(\tilde{F}^x_i)| + |D^x_{\tilde{H}}(\tilde{F}^x_i) - D^x_H(F^x_i)| + |D^x_H(F^x_i) - Q^x_H(F^x_i)|\right] \\
&\leq \frac{\varepsilon}{3} + \frac{\varepsilon}{9} + \frac{\varepsilon}{3} + \frac{2\varepsilon}{9} \qquad \text{(by Lemma 10 and eq. (6))} \\
&= \varepsilon,
\end{aligned}$$

which holds with probability at least $1 - \frac{3}{n^2}$. Hence, $\tilde{H}$ is an ε-spectral sparsifier of H. Combining this with the size bound in Lemma 7, we obtain Lemma 6. ◀

4.2.1 Proof of Lemma 13

We present the proof of Lemma 13. Our goal is to bound the size of L_i defined in Lemma 13 for $i \in \mathbb{Z}$ with $1 \leq i \leq I = \lceil\log_2 9m\rceil$. To this end, we proceed in two steps: we first bound the number of possible combinations of $(F^x_i, E^x_i, \{F^{x,uv}_i\}_{f\in E^x_i})$ over all $x \in \mathbb{S}_H$, and then bound the number of possible lists $\{D^x_H(f)\}_{f\in F^x_i}$ of discretized energies. For convenience, we define the following notion.

▶ **Definition 14.** *Let $(E, \{f_{uv}\}_{(u,v)\in E}, \pi_E)$ be a tuple such that $E \subseteq V \times V$, $\{f_{uv}\}_{(u,v)\in E}$ is a list of hyperarcs indexed by $(u,v) \in E$, and π_E is a total ordering on E. For $i \in \{1,2,\dots,I\}$, we say $(E, \{f_{uv}\}_{(u,v)\in E}, \pi_E)$ is i-*realized *by $x \in \mathbb{S}_H$ if the following conditions hold:*

1. $E = E_i^x$,
2. $f_{uv} = \operatorname{argmin}_{f\in F_i^{x,uv}} z_f$ *for each* $(u,v) \in E_i^x$, *and*
3. π_E *is the increasing order of the values of* $(x_u - x_v)_+^2$, *i.e.,* (u,v) *is smaller than* (u',v') *in* π_E *if and only if* $(x_u - x_v)_+^2 \le (x_{u'} - x_{v'})_+^2$ *(where the tie-breaking rule explained in Section 2 is used when the equality holds).*

The following lemma says that the i-realizability determines E_i^x, F_i^x, and $F_i^{x,uv}$, implying that we can reduce the problem of counting the number of possible $(F_i^x, E_i^x, \{F_i^{x,uv}\}_{f\in E_i^x})$ to that of counting the number of possible tuples $(E, \{f_{uv}\}_{(u,v)\in E}, \pi_E)$.

▶ **Lemma 15.** *Let $(E, \{f_{uv}\}_{(u,v)\in E}, \pi_E)$ be a tuple as defined in Definition 14 and $x, y \in \mathbb{S}_H$. If both x and y i-realize $(E, \{f_{uv}\}_{(u,v)\in E}, \pi_E)$ and $\bigcup_{j=1}^{i-1} F_j^x = \bigcup_{j=1}^{i-1} F_j^y$ holds, then, for every $(u,v) \in E$, we have $E_i^x = E_i^y$, $F_i^x = F_i^y$, and $F_i^{x,uv} = F_i^{y,uv}$.*

Proof. By the definition of the i-realizability, we have $E_i^x = E = E_i^y$. If we can assume $F_i^{x,uv} = F_i^{y,uv}$ for every $(u,v) \in E$, we have $F_i^x = \bigcup_{(u,v)\in E} F_i^{x,uv} = \bigcup_{(u,v)\in E} F_i^{y,uv} = F_i^y$ since $\{ F_i^{x,uv} \mid (u,v) \in C(F) \}$ and $\{ F_i^{y,uv} \mid (u,v) \in C(F) \}$ are partitions of F_i^x and F_i^y, respectively. Therefore, we below focus on proving $F_i^{x,uv} = F_i^{y,uv}$ for every $(u,v) \in E$.

For a contradiction, suppose $F_i^{x,u_1v_1} \neq F_i^{y,u_1v_1}$ for some $(u_1,v_1) \in E$. Without loss of generality, we assume there is a hyperarc $f^* \in F_i^{x,u_1v_1} \setminus F_i^{y,u_1v_1}$. Since both x and y i-realize $(E, \{f_{uv}\}_{(u,v)\in E}, \pi_E)$ and $(u_1,v_1) \in E$, the second condition of the i-realizability implies

$$\operatorname*{argmin}_{f\in F_i^{x,u_1v_1}} z_f = f_{u_1v_1} = \operatorname*{argmin}_{f\in F_i^{y,u_1v_1}} z_f. \tag{7}$$

In particular, we have $z_{f_{u_1v_1}} \le z_{f^*}$ for $f^* \in F_i^{x,u_1v_1}$. Hence

$$\begin{aligned} Q_H^y(f^*) &= z_{f^*} \max_{(u,v)\in C(f^*)} (y_u - y_v)_+^2 \\ &\ge z_{f_{u_1v_1}} (y_{u_1} - y_{v_1})_+^2 \qquad \big(\text{by } (u_1,v_1) \in C(f^*) \text{ and } z_{f^*} \ge z_{f_{u_1v_1}}\big) \\ &= z_{f_{u_1v_1}} \max_{(u,v)\in C(f_{u_1v_1})} (y_u - y_v)_+^2 \qquad (\text{by } f_{u_1v_1} \in F_i^{y,u_1v_1} \text{ as in eq. (7)}) \\ &\ge \frac{2^{-i}}{\lambda} \qquad (\text{by } f_{u_1v_1} \in F_i^y). \end{aligned}$$

From $Q_H^y(f^*) \ge \frac{2^{-i}}{\lambda}$ and $f^* \in F_i^{x,u_1v_1} \subseteq F \setminus S$, it must hold that $f^* \in \bigcup_{j=1}^{i} F_j^y$. Moreover, since $\bigcup_{j=1}^{i-1} F_j^x = \bigcup_{j=1}^{i-1} F_j^y$ by the lemma assumption and $f^* \notin \bigcup_{j=1}^{i-1} F_j^x$ by $f^* \in F_i^{x,u_1v_1}$, we have $f^* \notin \bigcup_{j=1}^{i-1} F_j^y$, hence $f^* \in F_i^y$. Since the orderings of E with respect to $(x_u - x_v)_+^2$ and $(y_u - y_v)_+^2$ are both equal to π_E and (u_1,v_1) is an x-critical pair of f^*, we have

$$(u_1,v_1) = \operatorname*{argmax}_{(u,v)\in C(f^*)\cap E} (y_u - y_v)_+^2. \tag{8}$$

Since $f^* \in F_i^y$, eq. (8) implies $f^* \in F_i^{y,u_1v_1}$, contradicting the assumption of $f^* \notin F_i^{y,u_1v_1}$. Therefore, $F_i^{x,uv} = F_i^{y,uv}$ holds for every $(u,v) \in E$. ◀

Lemma 15 enables us to bound the number of possible $(F_i^x, E_i^x, \{F_i^{x,uv}\}_{f\in E_i^x})$ for $x \in \mathbb{S}_H$.

▶ **Lemma 16.** *For each $i \ge 1$, $\left|\left\{ (F_i^x, E_i^x, \{F_i^{x,uv}\}_{f\in E_i^x}) \mid x \in \mathbb{S}_H \right\}\right| \le \left(2^i n^2 m\right)^{2^{i+1}}$ holds.*

Proof. First, we suppose that F_j^x for $j = 1, \dots, i-1$ are fixed. Then, due to Lemma 15, we can bound the number of possible combinations of $(F_i^x, E_i^x, \{F_i^{x,uv}\}_{f \in E_i^x})$ for all $x \in \mathbb{S}_H$ by counting the number of possible tuples $(E, \{f_{uv}\}_{(u,v)\in E}, \pi_E)$ that can be i-realized by some $x \in \mathbb{S}_H$. Since $|E| < 2^i$ by Lemma 11, the number of possible E is $\sum_{k=1}^{|E|} \binom{n^2}{k} \le \sum_{k=1}^{2^i-1} \binom{n^2}{k}$. Once E is specified, there are up to m possible choices of f_{uv} for each $(u,v) \in E$. Furthermore, the number of possible total orderings π_E of E is at most $(|E|)! \le (2^i)!$. Thus, the number of possible tuples $(E, \{f_{uv}\}_{(u,v)\in E}, \pi_E)$ that can be i-realized by some $x \in \mathbb{S}_H$ is at most $\left(\sum_{k=1}^{2^i-1} \binom{n^2}{k}\right) \cdot m^{2^i} \cdot (2^i)!$. This is further upper bounded by $\left(2^i n^2 m\right)^{2^i}$ by a simple calculation.

We now remove the assumption that F_j^x for $j = 1, \dots, i-1$ are fixed. By inductively using the above bound in increasing order of j, the number of possible combinations of $(F_i^x, E_i^x, \{F_i^{x,uv}\}_{f\in E_i^x})$ over all $x \in \mathbb{S}_H$ is at most $\prod_{j=1}^{i} \left(2^j n^2 m\right)^{2^j} \le \left(2^i n^2 m\right)^{\sum_{j=1}^{i} 2^j} \le \left(2^i n^2 m\right)^{2^{i+1}}$, thus completing the proof. ◀

We then fix any tuple $(F_i^y, E_i^y, \{F_i^{y,uv}\}_{f\in E_i^y})$ for some representative $y \in \mathbb{S}_H$ and upper bound the number of possible lists of discretized energies, $\{D_H^x(f)\}_{f\in F_i^x}$, over a subspace of $\mathbb{S}_H$ that consists of x with $(F_i^x, E_i^x, \{F_i^{x,uv}\}_{f\in E_i^x}) = (F_i^y, E_i^y, \{F_i^{y,uv}\}_{f\in E_i^y})$.

▶ **Lemma 17.** *Let $i \ge 0$ and fix $y \in \mathbb{S}_H$ arbitrarily. The number of possible lists $\{D_H^x(f)\}_{f\in F_i^x}$ for all $x \in \mathbb{S}_H$ with $(F_i^x, E_i^x, \{F_i^{x,uv}\}_{(u,v)\in E_i^x}) = (F_i^y, E_i^y, \{F_i^{y,uv}\}_{(u,v)\in E_i^y})$ is at most $\left(\frac{9m}{2^{i-2}\lambda\varepsilon}\right)^{2^i}$.*

Proof. Let $x \in \mathbb{S}_H$ satisfy the condition in the lemma statement and fix $(u,v) \in E_i^x$. Since every $f \in F_i^{x,uv} \subseteq F_i^x$ satisfies $z_f (x_u - x_v)_+^2 = Q_H^x(f) < \frac{1}{2^{i-1}\lambda}$, the range of $(x_u - x_v)_+^2$ is restricted to $\left[0, \frac{1}{2^{i-1}\lambda \min_{f\in F_i^{x,uv}} z_f}\right)$. Hence, the number of possible discretized $(x_u - x_v)_+^2$ values, $\left\lfloor (x_u - x_v)_+^2 / \Delta_i^{uv} \right\rfloor \Delta_i^{uv}$, over all $x \in \mathbb{S}_H$ under the lemma condition is at most

$$\frac{1}{\Delta_i^{uv} 2^{i-1}\lambda \min_{f\in F_i^{x,uv}} z_f} = \frac{1}{\Delta 2^{i-1}\lambda} \cdot \frac{\max_{f\in F_i^{x,uv}} z_f}{\min_{f\in F_i^{x,uv}} z_f} \le \frac{1}{\Delta 2^{i-2}\lambda}, \tag{9}$$

where the equality is due to $\Delta_i^{uv} = \Delta / \max_{f\in F_i^{x,uv}} z_f$ and the inequality comes from $z_f (x_u - x_v)_+^2 = Q_H^x(f) \in \left[\frac{1}{2^i\lambda}, \frac{1}{2^{i-1}\lambda}\right)$ for $f \in F_i^{x,uv} \subseteq F_i^x$, i.e., $\max_{f\in F_i^{x,uv}} z_f \le 2 \min_{f\in F_i^{x,uv}} z_f$.

Since the discretized energy of $f \in F_i^{x,uv}$ is defined by $D_H^x(f) = z_f \left\lfloor (x_u - x_v)_+^2 / \Delta_i^{uv} \right\rfloor \Delta_i^{uv}$, fixing the discretization of $(x_u - x_v)_+^2$ determines discretized energies of all $f \in F_i^{x,uv}$. Therefore, the number of possible lists $\{D_H^x(f)\}_{f\in F_i^{x,uv}}$ is also bounded by eq. (9) for each $(u,v) \in E_i^x$. Since $|E_i^x| < 2^i$ by Lemma 11, the number of possible lists $\{D_H^x(f)\}_{f\in F_i^x}$ is at most $\left(\frac{1}{\Delta 2^{i-2}\lambda}\right)^{2^i}$. By substituting $\Delta = \frac{\varepsilon}{9m}$ into it, we obtain the lemma. ◀

We are now ready to prove Lemma 13.

Proof of Lemma 13. We can uniquely specify any element of L_i by first fixing $(F_i^x, E_i^x, \{F_i^{x,uv}\}_{f\in E_i^x})$ and then $\{D_H^x(f)\}_{f\in F_i^x}$. Therefore, we have $|L_i| \le (2^i n^2 m)^{2^{i+1}} \cdot \left(\frac{9m}{2^{i-2}\lambda\varepsilon}\right)^{2^i} = \left(\frac{36 \cdot 2^i n^4 m^3}{\lambda\varepsilon}\right)^{2^i}$ by Lemmas 16 and 17. Combining this with $i \le I = \lceil \log_2 9m \rceil$ completes the proof. ◀

4.3 Proof of Theorem 1

Let $H = (V, F, z)$ be a directed hypergraph with $|V| = n$ and $|F| = m$, $\varepsilon \in (0,1)$, and $\tilde{H} = (V, \tilde{F}, \tilde{z})$ the output of DH-Sparsify(H, ε). Our goal is to prove that $\tilde{H}$ is an ε-spectral sparsifier of H and $|\tilde{F}| = O\left(\frac{n^2}{\varepsilon^2} \log^3 \frac{n}{\varepsilon}\right)$. We here use m^*, T, i_{end}, $(\tilde{H}_i = (V, \tilde{F}_i, \tilde{z}_i), \lambda_i)$, m_i,

and ε_i given in the description of DH-Sparsify(H,ε) (Algorithm 3), where $m^* = \frac{n^2}{\varepsilon^2}\log^3\frac{n}{\varepsilon}$ is the target sparsifier size, $T = \left\lceil \log_{4/3}\left(\frac{m}{m^*}\right)\right\rceil$ is the maximum number of iterations, i_{end} is the number of iterations performed, $(\tilde{H}_i = (V, \tilde{F}_i, \tilde{z}_i), \lambda_i)$ is the input of DH-Onestep at the ith iteration, $m_i = |\tilde{F}_i|$, and $\varepsilon_i = \frac{\varepsilon}{4\log^2_{4/3}\left(\frac{m_i}{m^*}\right)}$, as in Line 3 of Algorithm 3.

We first show that the number of hyperarcs decreases geometrically in each step.

▶ **Lemma 18.** *Let m_i be the number of hyperarcs in $\tilde{H}_i$. Assume $m_i \geq C_2 m^* = C_2\frac{n^2}{\varepsilon^2}\log^3\frac{n}{\varepsilon}$ for a sufficiently large constant C_2. Then, we have $(3m_i\log n)^{\frac{1}{2}} + \lambda_i n^2 \leq \frac{m_i}{4}$.*

Proof. It is easy to show that $(3m_i\log n)^{\frac{1}{2}} \leq \frac{m_i}{8}$ holds if $m_i \geq 192\log n$, which is true if C_2 is sufficiently large. Hence, the desired inequality holds if $\lambda_i n^2 \leq \frac{m_i}{8}$, which we show below.

By Line 3 in Algorithm 3, we have $\varepsilon_i = \frac{\varepsilon}{4\log^2_{4/3}\frac{m_i}{m^*}}$ and $\lambda_i = \left\lceil \frac{C_1\log^3 m_i}{\varepsilon_i^2}\right\rceil$. Hence,

$$\frac{m_i}{8} - \lambda_i n^2 \geq \frac{m_i}{8} - \frac{2500C_1 n^2}{\varepsilon^2}\log^3 m_i \log^4\frac{m_i}{m^*} \qquad (\text{by } 4^2/\log^4(4/3) < 2500).$$

Let $m_i = \alpha m_*$ and $g(\alpha)$ be the right-hand side of the above inequality, which we regard as a function of α. Since $m^* = (n/\varepsilon)^2\log^3(n/\varepsilon)$, we have

$$\begin{aligned} g(\alpha) &= m_*\left(\frac{\alpha}{8} - \frac{2500C_1}{\log^3(n/\varepsilon)}\log^3(\alpha m_*)\log^4\alpha\right) \\ &\geq m_*\left(\frac{\alpha}{8} - \frac{10000C_1}{\log^3(n/\varepsilon)}(\log^3\alpha + \log^3 m_*)\log^4\alpha\right) \quad (\text{by } (a+b)^3 \leq 4(a^3+b^3)) \\ &\geq m_*\left(\frac{\alpha}{8} - 10000C_1\left(\frac{\log^3\alpha}{\log^3(n/\varepsilon)} + 125\right)\log^4\alpha\right) \quad \left(\text{by } m_* = \frac{n^2}{\varepsilon^2}\log^3\frac{n}{\varepsilon} \leq \left(\frac{n}{\varepsilon}\right)^5\right). \end{aligned}$$

Thus, there exists a sufficiently large constant C_2, which is independent of n and ε, such that $g(\alpha) \geq 0$ holds for all $\alpha \geq C_2$. Using this constant C_2, for all $m_i \geq C_2 m^*$, we have $\lambda_i n^2 \leq \frac{m_i}{8}$ as desired. ◀

Proof of Theorem 1. We say DH-Onestep(H_i,λ_i) is *successful* if $\tilde{H}_{i+1}$ is an ε_i-spectral sparsifier of $\tilde{H}_i$ and $m_{i+1} \leq \frac{3}{4}m_i$ holds. DH-Sparsify(H,ε) calls DH-Onestep(H_i,λ_i) only when $m_i \geq C_2 m^*$ and $i \leq T$. Therefore, by Lemmas 6 and 18, with probability at least $1 - O\left(\frac{T}{n^2}\right) \gtrsim 1 - O\left(\frac{1}{n}\right)$, DH-Onestep$(H_i,\lambda_i)$ is successful for all i with $0 \leq i \leq i_{\mathrm{end}}$. Hence, assuming all DH-Onestep(H_i,λ_i) to be successful, we below prove that the output hypergraph $\tilde{H}$ has $O\left(\frac{n^2}{\varepsilon^2}\log^3\frac{n}{\varepsilon}\right)$ hyperarcs and that $\tilde{H}$ is an ε-spectral sparsifier of H.

We first discuss the size of $\tilde{H}$. If $m_i \leq C_2 m^* = \frac{C_2 n^2\log^3(n/\varepsilon)}{\varepsilon^2}$ occurs for some $i \leq T-1$, then m_i gives the size of $\tilde{H}$ by the termination rule of DH-Sparsify, which is already small enough. Hence we below assume $m_i \geq C_2 m^*$ for all $i < T$. Since every DH-Onestep(H_i,λ_i) is successful, $m_{i+1} \leq \frac{3}{4}m_i$ holds for all $i = 0, 1, \cdots, T-1$. Thus, it holds that

$$m_T \leq m\cdot\left(\frac{3}{4}\right)^T \leq m\cdot\left(\frac{3}{4}\right)^{\log_{4/3}\frac{m\varepsilon^2}{n^2\log^3(n/\varepsilon)}} = \frac{n^2\log^3(n/\varepsilon)}{\varepsilon^2}.$$

Therefore, we have $|\tilde{F}| = O\left(\frac{n^2}{\varepsilon^2}\log^3\frac{n}{\varepsilon}\right)$.

We then show that $\tilde{H}$ is an ε-spectral sparsifier of H. Since $\tilde{H}_{i+1}$ is an ε_i-spectral sparsifier of $\tilde{H}_i$ for all $i = 0, 1, \cdots, i_{\mathrm{end}}-1$, the output hypergraph $\tilde{H} = \tilde{H}_{i_{\mathrm{end}}}$ is an $\tilde{\varepsilon}$-spectral sparsifier of H, where

$$\tilde{\varepsilon} = \max\left\{\prod_{i=0}^{i_{\mathrm{end}}-1}(1+\varepsilon_i) - 1, 1 - \prod_{i=0}^{i_{\mathrm{end}}-1}(1-\varepsilon_i)\right\}.$$

A simple calculation yields the following upper bound on $\tilde{\varepsilon}$:

$$\tilde{\varepsilon} \le \sum_{j=1}^{i_{\mathrm{end}}} \sum_{0 \le i_1 < \cdots < i_j \le i_{\mathrm{end}}-1} \varepsilon_{i_1}\varepsilon_{i_2}\cdots\varepsilon_{i_j} \le \sum_{j=1}^{i_{\mathrm{end}}} \left(\sum_{i=0}^{i_{\mathrm{end}}-1} \varepsilon_i \right)^j. \tag{10}$$

Since $m_{i+1} \le \frac{3}{4} m_i$ and $m_{i_{\mathrm{end}}-1} \ge C_2 m^*$, we have $m_{i_{\mathrm{end}}-j} \ge \left(\frac{4}{3}\right)^{j-1} C_2 m^* \ge \left(\frac{4}{3}\right)^j m^*$ for sufficiently large $C_2 \ge \frac{4}{3}$, hence $\log_{4/3}\left(\frac{m_{i_{\mathrm{end}}-j}}{m^*}\right) \ge j$. Using $\sum_{j=1}^{\infty} \frac{1}{j^2} \le \frac{\pi^2}{6}$, we obtain

$$\sum_{i=0}^{i_{\mathrm{end}}-1} \varepsilon_i = \sum_{i=0}^{i_{\mathrm{end}}-1} \frac{\varepsilon}{4 \log_{4/3}^2\left(\frac{m_i}{m^*}\right)} \le \sum_{j=1}^{\infty} \frac{\varepsilon}{4j^2} \le \frac{\varepsilon}{4} \cdot \frac{\pi^2}{6} \le \frac{\varepsilon}{2}.$$

Putting this into the right-hand side of eq. (10), we have

$$\sum_{j=1}^{i_{\mathrm{end}}} \left(\sum_{i=0}^{i_{\mathrm{end}}-1} \varepsilon_i \right)^j \le \sum_{j=1}^{i_{\mathrm{end}}} \left(\frac{\varepsilon}{2}\right)^j \le \frac{\frac{\varepsilon}{2}}{1-\frac{\varepsilon}{2}} \le \varepsilon. \tag{11}$$

By eqs. (10) and (11), $\tilde{H} = \tilde{H}_{i_{\mathrm{end}}}$ is an ε-spectral sparsifier of H.

To conclude, with probability at least $1 - O\left(\frac{1}{n}\right)$, DH-Sparsify$(H, \varepsilon)$ outputs an ε-spectral sparsifier of H with $O\left(\frac{n^2}{\varepsilon^2} \log^3 \frac{n}{\varepsilon}\right)$ hyperarcs. ◀

4.4 Total Time Complexity

We show that our algorithm runs in $O(r^2 m)$ time with probability at least $1 - O(1/n)$.

▶ **Theorem 19.** *For any directed hypergraph $H = (V, F, z)$ with the rank r and m hyperarcs and $\varepsilon \in (0, 1)$,* DH-Sparsify(H, ε) *runs in $O(r^2 m)$ time with probability at least $1 - O(1/n)$.*

Proof. We first discuss the running time of DH-Onestep$(\tilde{H}_i, \lambda_i)$, where $\tilde{H}_i = (V, \tilde{F}_i, \tilde{z}_i)$ and $|\tilde{F}_i| = m_i$. It first constructs a λ_i-coreset by calling CoresetFinder$(\tilde{H}_i, \lambda_i)$. CoresetFinder first constructs $A^{uv} = \{ f \in F \mid C(f) \ni (u, v) \}$ for $(u, v) \in C(F)$, which is done in $O(r^2 m_i)$ time since we have $|C(f)| = O(r^2)$ for each $f \in \tilde{F}_i$. Then, for each $(u, v) \in C(F)$, it selects the λ_i heaviest hyperarcs from $A^{uv} \setminus S$ in $O(|A^{uv} \setminus S|)$ time by using a selection algorithm [5], thus taking $O\left(\sum_{(u,v)\in C(F)} |A^{uv} \setminus S|\right) = O(r^2 m_i)$ time in total. Therefore, CoresetFinder$(\tilde{H}_i, \lambda_i)$ takes $O(r^2 m_i)$ time. After that, DH-Onestep samples the remaining hyperarcs in $O(m_i)$ time. Thus, DH-Onestep$(\tilde{H}_i, \lambda_i)$ takes $O(r^2 m_i)$ time.

We then bound the total time complexity. Since DH-Sparsify(H, ε) calls DH-Onestep$(\tilde{H}_i, \lambda_i)$ for $i = 0, 1, \ldots, T-1$ (or stops earlier), the total time complexity is at most $O\left(r^2 \sum_{i=0}^{T-1} m_i\right)$. From Lemmas 7 and 18, whenever DH-Onestep is called, we have $m_{i+1} \le \frac{3}{4} m_i$ with probability at least $1 - O(1/n^2)$. This implies that $\sum_{i=0}^{T-1} m_i \le m \sum_{i=0}^{T-1} \left(\frac{3}{4}\right)^i \le 4m$ holds with probability at least $1 - O(T/n^2) \gtrsim 1 - O(1/n)$. Therefore, the total time complexity is bounded by $O(r^2 m)$ with probability at least $1 - O(1/n)$. ◀

The Communication Complexity of Set Intersection Under Product Distributions

Abstract

We consider a multiparty setting where k parties have private inputs $X_1, \ldots, X_k \subseteq [n]$ and wish to compute the intersection $\bigcap_{\ell=1}^{k} X_\ell$ of their sets, using as little communication as possible. This task generalizes the well-known problem of set disjointness, where the parties are required only to determine whether the intersection is empty or not. In the worst-case, it is known that the communication complexity of finding the intersection is the same as that of solving set disjointness, regardless of the size of the intersection: the cost of both problems is $\Omega(n \log k + k)$ bits in the shared blackboard model, and $\Omega(nk)$ bits in the coordinator model.

In this work we consider a realistic setting where the parties' inputs are independent of one another, that is, the input is drawn from a product distribution. We show that this makes finding the intersection significantly easier than in the worst-case: only $\tilde{\Theta}((n^{1-1/k}(\mathrm{H}(S)+1)^{1/k}) + k)$ bits of communication are required, where $\mathrm{H}(S)$ is the Shannon entropy of the intersection S. We also show that the parties do not need to know the exact underlying input distribution; if we are given in advance $O(n^{1/k})$ samples from the underlying distribution μ, we can learn enough about μ to allow us to compute the intersection of an input drawn from μ using expected communication $\tilde{\Theta}((n^{1-1/k}\,\mathbb{E}[|S|]^{1/k}) + k)$, where $|S|$ is the size of the intersection.

1 Introduction

Communication complexity is concerned with understanding the communication cost of computing on data that is partitioned between $k \geq 2$ parties, with each party holding a private input $\boldsymbol{X}^i$.[1] The parties would like to jointly compute some function $f(\boldsymbol{X}^1, \ldots, \boldsymbol{X}^k)$ of their data, using as little communication as possible. Two models of communication are typically studied: in the *shared blackboard* model, the parties communicate by writing messages on a "board" that all the other parties can read (essentially, they communicate by broadcast); in the *private-channel* model, the parties communicate over private channels. For both models, there is a wealth of protocols and lower bounds characterizing the cost of computing different functions, and obtaining applications in areas ranging from distributed graph algorithms (see [30, 10, 6, 8, 9] and many more), to streaming algorithms (e.g., [1, 3, 15])

[1] This is called *number-in-hand* because each party holds its own private input; in the *number-on-forehead* model, each party can see the inputs of all the other parties, but not its own input. The number-on-forehead model has compelling applications in circuit complexity, but it is not a realistic model of a distributed system.

and beyond. We focus on the *distributional setting*, where the inputs $\boldsymbol{X}^1, \ldots, \boldsymbol{X}^k$ are drawn from a distribution μ, and our goal is to compute $f(\boldsymbol{X}^1, \ldots, \boldsymbol{X}^k)$ with a low error probability over μ.

In this paper we study the cost of computing an intersection: each party holds a set $\boldsymbol{X}^i \subseteq [n]$, and our goal is to output the intersection, $\boldsymbol{S} = \bigcap_{i=1}^n \boldsymbol{X}^i$. This fundamental problem has many applications, including computing joins for distributed databases [10, 16]; computing the Jaccard similarity of data sets, the number of distinct elements, and rarity [10]; and algebraic function computation on reconciled data [19]. Recently this problem also found applications in online advertising [14], notably at Google [18].

Computing the intersection of sets $\boldsymbol{X}^1, \ldots, \boldsymbol{X}^k$ is as at least as hard as solving the *set disjointness* problem, where we are required to determine whether $\cap_{i=1}^k \boldsymbol{X}^i = \emptyset$. Set disjointness is known to require $\Omega(n)$ bits of communication for two-parties [26, 24], $\Omega(n \log k)$ bits of communication for k parties on the shared blackboard [8], and $\Omega(kn)$ bits of communication for k parties with private channels [6]. However, all of these hardness results hold only when the parties' inputs are highly-correlated; if the input is drawn from a *product distribution* (i.e., the parties' inputs are independent of one another), then two-party set disjointness requires only $\Theta(\sqrt{n})$ bits [2, 5], and this was recently extended to the multi-party setting, where it was shown that the communication cost is $\tilde{\Theta}(n^{1-1/k})$ in both the shared blackboard and the coordinator models [12]. We note that all the lower bounds mentioned above hold even for input distributions where the intersection is of small constant size – that is, either the input sets do not intersect at all, or they have a non-empty but constant-sized intersection, and our goal is to distinguish between these two cases.

Our main question in this paper is whether under product distributions we can efficiently compute the full intersection of the parties' inputs, rather than merely determining whether it is empty or not. We show that the answer is *yes*, at least when the intersection is not too large: if the expected intersection size is $\mathbb{E}[\boldsymbol{S}] = s$, then we can compute the full intersection using $\tilde{\Theta}(n^{1-1/k} s^{1/k})$ bits of communication in expectation, in both the shared blackboard and the coordinator models. This can be viewed as a natural extension of the tight bound for set disjointness in the product case, which is $\tilde{\Theta}(n^{1-1/k})$, even when $s = \Theta(1)$ [12]. Our protocol and lower bound bear some similarities to [12]. We generalize our result in two ways, motivated by practical applications.

"Learning" the input distribution. In this scenario, instead of being told the input distribution μ, we are given iid *samples* from μ, and must "learn" whatever we can about μ before running the protocol on the actual input (which is also drawn from μ). Can we learn enough about μ to exploit its product structure, without requiring a prohibitive number of samples? In Section 4.1 we show that the answer is *yes*: $\tilde{O}(n^{1/k})$ sample suffice to learn enough about μ to solve any future instance with optimal communication cost.

▶ **Theorem 1.** *Let $\delta > 0$, and assume we have access to $O\left(n^{1/k} \log(nk/\delta)\right)$ iid samples from an unknown product distribution μ. Then we can construct a zero-error two-round protocol Π for computing the intersection, such that with probability at least $1-\delta$ over the samples, the protocol Π that we constructed has expected communication cost $O\left(kn^{1-1/k}\, \mathbb{E}\left[|\boldsymbol{S}|+1\right]^{1/k} \log n\right)$ on inputs drawn from μ.*

In particular, when $k \geq \log n$, we require only a single sample from μ. This is perhaps surprising, since it is known that in order to fully learn a distribution over kn bits – that is, in order to output a distribution μ' that is ϵ-close to μ in statistical distance – the number of samples required is $\Omega\left(2^{nk}/(nk)\right)$ [28]. The key is that instead of learning the entire distribution, we show that it suffices to estimate the marginal expectation of each input bit, which is a much easier task.

It remains open whether $\Omega(n^{1/k})$ samples are truly necessary to obtain the optimal communication complexity, and more generally, what is the tradeoff between the number of samples we have and the communication complexity we can obtain. However, we show in Section 5 that if we do not have *any* prior information about the distribution μ (i.e., no samples), then the fact that μ is a product distribution is not helpful at all: for any function f, computing f under an unknown product distribution is as hard as computing f under non-product distributions.

Large but predictable intersections. Although we assume that the parties have independent inputs, we do not assume that the elements inside a given party's input are independent of one another: for example, if each party's input is a list of items purchased by some set of customers, then the elements may be highly correlated, as one item purchased by a customer is likely to tell us a lot about other items the same customer is likely to purchase. Correlations between elements can lead to a situation where the intersection is "large but fairly predictable", in the sense that while the intersection S has large expected size, its Shannon entropy $\mathrm{H}(S)$ is much smaller. As an extreme example, if we have two parties with inputs X, Y that are each either $[n]$ or $\emptyset$ with probability $1/2$, then the expected size of the intersection is $n/2$, but its Shannon entropy is only 1.

In Section 4.3 we show that it is not the size of the intersection but its entropy that matters: when the distribution μ is known, we can replace the size $|\boldsymbol{S}|$ of the intersection with its entropy, $\mathrm{H}(\boldsymbol{S})$, and obtain the following.

▶ **Theorem 2.** *Let μ be a product distribution known to all the parties. Then in the coordinator model, there is an $O(\log n)$-round zero-error deterministic protocol for finding the intersection, with expected communication cost at most $O\left(k^2 n^{1-1/k} \left(\mathrm{H}(\boldsymbol{S})+1\right)^{1/k} \log n + k\right)$, where the expectation is with respect to the input distribution μ.*

We remark that for non-product distributions this is not possible: in the hard distribution of Razborov [24] for two-party set disjointness, the intersection has entropy $O(\log n)$, as it is always either empty or contains a single element which is uniformly random over $[n]$. Nevertheless, even determining whether the intersection is empty or not requires $\Omega(n)$ bits of communication, and this of course implies that *finding* the intersection also requires $\Omega(n)$ communication.

Lower bounds. To complement our protocols above, in Section 5 we prove a matching lower bound, up to polylogarithmic factors:

▶ **Theorem 3.** *For every $n, k \in \mathbb{N}$ with $2 \le k \le \log n$, and for every $s \in [1, n/2]$, there exists a product distribution μ over $\{0,1\}^{n \times k}$ such that*

- $\mathbb{E}_\mu [\, |\boldsymbol{S}| \,] = s$,
- $s \le \mathrm{H}(\boldsymbol{S}) \le (s+1)\log n$, *and*
- *Any deterministic protocol for computing the intersection with error probability at most $1/10$ over μ has expected communication complexity $\Omega(n^{1-1/k} s^{1/k}/k^2)$.*

Although the lower bound is stated only for $k \le \log n$ parties, we can "stretch" the lower bound from $k = \log n$ to larger k by generating the inputs of the first $\log n$ parties using the hard distribution from the theorem, and giving the remaining parties the set $[n]$. As a result, for $k > \log n$, we obtain a lower bound of $\tilde{\Omega}(n)$ regardless of the intersection size s, and this is tight up to polylogarithmic factors.

Our lower bound actually applies to a weak output model, where every element of the intersection can be output by a different party: at the end of the protocol, each party ℓ outputs a list of decisions of the form "$i \in \boldsymbol{S}$" or "$i \notin \boldsymbol{S}$". We require that for every coordinate $i \in [n]$, one party must output a decision for i, but the identity of the party that output a decision for i need not be known in advance (that is, it may be a function of the transcript). The party j that outputs a decision for i may rely on its own input $\boldsymbol{X}^j$ when making the decision. This output model is quite weak compared to the standard output model that we assume in our protocols, where the output to the computation must be computable from the transcript of the protocol. Making the lower bound work in this weak model is technically challenging: our lower bound uses information-theoretic arguments, which typically rely on the fact that an *external observer* must learn a lot of information about the inputs, but this is not necessarily true in the weak output model.

We also remark that all of the results discussed up to this point (both upper and lower bounds) assume that the protocol must output the *entire* intersection correctly with high probability: if we output a set that differs from the true intersection in even a single element, this is considered an error. One can also consider a weaker notion, which is more appealing for lower bounds, where for every $i \in [n]$, we only need to determine whether $i \in \boldsymbol{S}$ with good *marginal* error probability, independent of the other elements. This weaker notion is only meaningful when many coordinates have constant probability bounded away from 0 and 1 of being in the intersection, otherwise we can simply guess independently for each coordinate whichever outcome is more likely for that coordinate; e.g., if $\Pr[i \in \boldsymbol{S}] = 1/\sqrt{n}$ for every i, we can guess that the intersection is empty, and still be correct on every element with marginal probability $1 - 1/\sqrt{n}$. However, if every element has probability between $1/3$ and $1/2$ of being in the intersection, then we can also prove a tight lower bound even for the case where the protocol only needs to succeed with good marginal probability on each element (see the full version of this paper for a proof of this theorem).

2 Related Work

Set disjointness has been studied extensively, in many versions and models; we refer to the surveys [11, 27] for more background. The problem of computing the intersection, or of finding an element in the intersection, has also been studied, for two parties [7, 25, 10, 13, 29, 4, 17] and for more than two parties [10, 23]; to our knowledge, all previously mentioned prior work is for either worst-case hardness (that is, a non-distributional setting, where the inputs are chosen adversarially), or for non-product distributions, and is thus not directly relevant to the current paper. In addition, [20, 21, 22] studied a different scenario where two parties wish to compute the bitwise-AND of their input vectors (as well as other functions), assuming the coordinates of the vectors are iid, in the regime where the input length goes to infinity and the error is vanishing. In contrast, here we consider multi-party intersection with a fixed input length and constant error, and we do not assume that the coordinates are iid.

The hardness of set disjointness under product distributions was first studied in [2], which proved a lower bound of $\Omega(\sqrt{n})$ and an upper bound of $O(\sqrt{n}\log n)$ on the communication complexity of the problem. Later, [5] eliminated the log-factor and improved the upper bound to $O(\sqrt{n})$, and showed that in general, when the parties' inputs have mutual information I with one another, the communication cost of set disjointness is $\tilde{\Theta}(\sqrt{n(I+1)})$ (the product case is the case where $I = 0$). It turns out that the techniques of [2, 5] do not scale to more than 2 parties, but in [12], using different techniques, it was shown that $\tilde{\Theta}(n^{1-1/k})$ bits are necessary and sufficient in the k-player setting.

The protocols of [2, 5, 12] for set disjointness share the following feature: at any point in the protocol, if we identify that given what we have learned so far the probability that the inputs are disjoint is bounded by some small threshold ϵ, then we halt and output "not disjoint". If the probability of disjointness is greater than ϵ, we rely on this fact to make progress: in [2, 5], we use it to efficiently sample a large set that is disjoint from one player's input, and those elements are then discarded from consideration; in [12], we exploit the fact that no single element is likely to be in the intersection to show that each element $i \in [n]$ is probably missing from the input of some specific player $p(i)$. We then ask each player j to say only the elements $X_j \cap \{i : p(i) = j\}$, as this set is likely to be small, but at the same time it helps us learn of many elements that are definitely not in the intersection. If we want to find the intersection in full, the basic approach of [12] continues to work if we know that we have a *small* intersection, but it breaks down when the intersection is large.

Our work generalizes the basic approach of [12] to handle larger intersection sizes. This yields a protocol for finding the intersection that depends on the *entropy* of the intersection instead of its expected size (as already noted in the introduction, the former may be much smaller than the latter). We also show that the basic protocol of [12] can be made *robust*, in the sense that the players do not need to know the exact underlying input distribution.

When the number of players is $k \geq \log n$, [12] gives a different protocol that actually finds the entire intersection, and has communication cost $\tilde{O}(n)$. We show that this protocol can be made robust as well, and in fact a *single* sample from the underlying product distribution is enough, with high probability, for the players to be able to successfully execute the protocol.

As for lower bounds, [12] gave a lower bound on finding the intersection under a product distribution, for the case where the expected intersection size is 1 (which coincides with the set disjointness problem), when the transcript reveals the intersection to an *external observer*. In this work, we generalize this lower bound in two ways. First, our lower bound must handle larger intersections, up to linear in n. This large range of intersection sizes implies, naturally, that the lower bound proof must handle both very small and very large probabilities, which requires delicate handling. Secondly, our bound is proven in the weaker model where for each coordinate, one of the players must decide whether this coordinate is in the intersection or not, and the identity of this player may not even be known in advance.

3 Preliminaries

Notation. We use boldface letters to denote random variables. Given a vector v indexed by $\{1, \ldots, m\}$ and a subset of coordinates $J = \{j_1, \ldots, j_\ell\}$, we denote by $v_J = v_{j_1,\ldots,j_\ell}$ coordinates J of v. If $\boldsymbol{A}$ is a random variable and $\mathcal{E}$ is an event, then $\boldsymbol{A}|_{\mathcal{E}}$ denotes the distribution of $\boldsymbol{A}$ conditioned on $\mathcal{E}$.

The input to the k players is denoted $\boldsymbol{X}^1, \ldots, \boldsymbol{X}^k \in \{0,1\}^n$. It is convenient to sometimes view the inputs to the players as sets, and sometimes as the characteristic vectors of their sets. We use $\boldsymbol{X}_i^\ell$ to denote the i-th coordinate of player ℓ's input, when viewed as a characteristic vector. The intersection of the players' inputs is denoted $\boldsymbol{S} = \bigcap_{\ell \in [k]} \boldsymbol{X}^\ell$, and for each $i \in [n]$, $\boldsymbol{S}_i$ is an indicator for the event "$i \in \boldsymbol{S}$". We refer to $\boldsymbol{S}_1, \ldots, \boldsymbol{S}_n$ as the *bits of the intersection*.

We sometimes abuse notation by conflating Bernoulli distributions with their expected value: for example, if the input distribution is μ, we use μ_i^ℓ to denote both the marginal distribution of $\boldsymbol{X}_i^\ell$, and the expected value of $\boldsymbol{X}_i^\ell$.

The shared blackboard model. In this classical model of multiparty communication, we have k players, with private inputs $\boldsymbol{X}^1, \ldots, \boldsymbol{X}^k$. The players communicate by writing on a *shared blackboard* that all players can see. At any point in the protocol, the identity of

the next player to write on the board is determined by the current contents of the board. We refer to the contents of the board as the *transcript* of the protocol, and denote it by the random variable $\boldsymbol{\Pi}$.

The coordinator model. In the coordinator model of multiparty computation, in addition to the k players, we also have a *coordinator*, who has no input. The players communicate with the coordinator over private channels, but players cannot communicate directly with one another. The order of communication is governed by the coordinator, and the *transcript* of the protocol consists of all messages sent and received by the coordinator.

Set intersection. In the k-player set intersection problem, our goal is to compute:

$$\mathrm{INT}_{n,k}(X^1, \ldots, X^k) = \cap_{\ell=1}^{k} X^\ell.$$

Since the intersection can be very large, it is crucial that we do not charge the players for "writing" the output at the end of the protocol. Instead, we assume one of the following two output models:

- In our upper bounds, the output is some predetermined function of the transcript; in other words, an external observer can learn the intersection just by observing the transcript of the protocol, without knowing any of the inputs.
- In our lower bounds, the output is jointly produced by the players, with each player j choosing at the end of the protocol a set of indices I_j, and outputting the bits $\{\boldsymbol{S}_i : i \in I_j\}$. The index set I_j may depend on the transcript of the protocol, but not on player j's input. However, the *values* that player j outputs for the bits $\{\boldsymbol{S}_i : i \in I_j\}$ may depend on player j's input. Thus, an external observer that sees only the transcript of the protocol is able to learn which player will output which bits, but not the values of the output bits. We require that every bit $\boldsymbol{S}_i$ must be output by some player; if more than one player outputs the bit $\boldsymbol{S}_i$, and the players disagree, this is considered an error.

Information theory and entropy. The *Shannon entropy* of a random variable $\boldsymbol{A} \sim \mu$ is given by

$$\mathrm{H}_\mu(\boldsymbol{A}) = \sum_{a \in supp(\mu)} \mu(a) \log \frac{1}{\mu(a)},$$

where $supp(\mu)$ denotes the support of the distribution μ. We omit the subscript μ when the distribution is clear from the context.

Given jointly-distributed variables $(\boldsymbol{A}, \boldsymbol{B}) \sim \mu$, with marginal distributions $\mu_{\boldsymbol{A}}$ and $\mu_{\boldsymbol{B}}$ respectively, the *conditional entropy* of $\boldsymbol{A}$ given $\boldsymbol{B}$ is

$$\mathrm{H}_\mu(\boldsymbol{A}|\boldsymbol{B}) = \mathop{\mathbb{E}}_{b \sim \mu_{\boldsymbol{B}}} \left[\mathrm{H}_{\mu|_{\boldsymbol{B}=b}}(\boldsymbol{A})\right].$$

We sometimes abuse notation by writing $\mathrm{H}_\mu(\boldsymbol{A}|\mathcal{E})$ to denote $\mathrm{H}_{\mu|_{\mathcal{E}}}(\boldsymbol{A})$ (here, $\mathcal{E}$ is an event, not a random variable).

We rely on the following basic properties of the entropy:

1. Entropy is non-negative: $\mathrm{H}(\boldsymbol{A}) \geq 0$.
2. Conditioning does not increase entropy: $\mathrm{H}(\boldsymbol{A}|\boldsymbol{B}) \leq \mathrm{H}(\boldsymbol{A})$.
3. The chain rule for entropy: $\mathrm{H}(\boldsymbol{A}_1, \ldots, \boldsymbol{A}_m) = \sum_{i=1}^{m} \mathrm{H}(\boldsymbol{A}_i|\boldsymbol{A}_{i-1}, \ldots, \boldsymbol{A}_1)$.
4. Subadditivity: $\mathrm{H}(\boldsymbol{A}_1, \ldots, \boldsymbol{A}_m) \leq \sum_{i=1}^{m} \mathrm{H}(\boldsymbol{A}_i)$, with equality iff $\boldsymbol{A}_1, \ldots, \boldsymbol{A}_m$ are independent.

For $p \in [0,1]$, we use $\mathrm{H}(p)$ as short-hand notation for the Shannon entropy of a Bernoulli random variable with probability p of being 1. In our lower bound, we use the following fact:

▶ **Fact 4.** *Let $p \in [0,1]$, Then* $\min\{p, 1-p\} \leq \mathrm{H}(p)$.

To measure the amount of information a protocol reveals about its inputs, we use *mutual information*. The *mutual information* between random variables $\boldsymbol{A}$ and $\boldsymbol{B}$ is given by $\mathsf{I}(\boldsymbol{A}\,;\,\boldsymbol{B}) := H(\boldsymbol{A}) - H(\boldsymbol{A} \mid \boldsymbol{B})$. For random variables $\boldsymbol{A}, \boldsymbol{B}, \boldsymbol{C}$, the *conditional mutual information* between $\boldsymbol{A}$ and $\boldsymbol{B}$ given $\boldsymbol{C}$ is $\mathsf{I}(\boldsymbol{A}\,;\,\boldsymbol{B} \mid \boldsymbol{C}) := H(\boldsymbol{A} \mid \boldsymbol{C}) - H(\boldsymbol{A} \mid \boldsymbol{B}, \boldsymbol{C})$.

The following Lemma will be useful in our lower bound:

▶ **Lemma 5.** *Let $\boldsymbol{A}, \boldsymbol{B}, \boldsymbol{\Pi}$ be random variables, such that $\boldsymbol{A}$ and $\boldsymbol{B}$ are independent. Then* $\mathsf{I}(\boldsymbol{A}\,;\,\boldsymbol{\Pi} \mid \boldsymbol{B}) = \mathsf{I}(\boldsymbol{A}\,;\,\boldsymbol{\Pi}) + \mathsf{I}(\boldsymbol{A}\,;\,\boldsymbol{B} \mid \boldsymbol{\Pi})$.

For an event $\mathcal{E}$, we sometimes abuse notation and denote $\mathsf{I}(\boldsymbol{A}\,;\,\boldsymbol{B} \mid \mathcal{E}) := \mathsf{I}(\boldsymbol{A}|_{\mathcal{E}}\,;\,\boldsymbol{B}|_{\mathcal{E}})$.

To measure the difference between two distributions, we use KL divergence:

▶ **Definition 6** (KL divergence)**.** *For two distributions μ,μ' supported over a set χ, the* KL divergence *of μ from μ' is:*

$$D(\mu \,||\, \mu') := \sum_{x \in \chi} \mu(x) \log \frac{\mu(x)}{\mu'(x)}.$$

We sometimes use $D(p \,||\, p')$ as short-hand notation for the divergence between the Bernoulli distributions with probability p and p' (resp.) of being 1.

KL divergence has the following monotonicity property, which will be useful in our upper bound:

▶ **Lemma 7.** *Let $0 < p < q \leq a < 1/100$ be constants, then $D(p+a \,||\, p) \geq D(q+a \,||\, q)$.*

The proof of Lemma 7 will appear in the full version of this paper.

Our lower bound also uses *Pinsker's inequality*, which asserts that for any $p, p' \in (0,1)$ we have $|p - p'| \leq \sqrt{D(p \,||\, p') \ln 2/2}$.

The mutual information between two variables $\boldsymbol{A}, \boldsymbol{B}$ is equal to the *expected divergence* of $\boldsymbol{A}$'s posterior distribution given $\boldsymbol{B}$, from $\boldsymbol{A}$'s prior distribution (or vice-versa):

▶ **Fact 8.** *For any random variables $\boldsymbol{A}, \boldsymbol{B}$ we have* $\mathsf{I}(\boldsymbol{A}\,;\,\boldsymbol{B}) = \mathbb{E}_{b \sim \boldsymbol{B}}\left[D\left(\boldsymbol{A}|_{\boldsymbol{B}=b} \,||\, \boldsymbol{A}\right)\right]$.

The following technical lemmas will be useful in our lower bound. The first bounds the "difference" between two Bernoulli random variables, in terms of their KL divergence:

▶ **Lemma 9.** *Let p, q be constants in $(0,1)$, and let $\alpha \in (0, 1/2)$, such that $D(q \,||\, p) < p\alpha^2/(4 \ln 2)$. Then we have $q/p \in ((1-\alpha)p, (1+\alpha)p)$.*

In Section 4.2 we use the tight version of the additive Chernoff bound, which is stated in terms of KL divergence: for a sum $\boldsymbol{Y} = \sum_{i=1}^{m} \boldsymbol{Y}_i$ of iid Bernoulli random variables with $\mathbb{E}[\boldsymbol{Y}_i] = p$, we have

$$\Pr\left[\sum_{i=1}^{n} \boldsymbol{Y}_i/n \geq p + \epsilon\right] \leq e^{-D(p+\epsilon \,||\, p)}, \qquad \text{and} \qquad \Pr\left[\sum_{i=1}^{n} \boldsymbol{Y}_i/n \leq p - \epsilon\right] \leq e^{-D(p-\epsilon \,||\, p)}.$$

4 Upper Bounds

In this section we give three upper bounds. The first two address the case where the number of parties is $k \leq \log n$: we first give a protocol with expected communication $\tilde{O}(n^{1-1/k}\,\mathbb{E}\,[\boldsymbol{S}]^{1/k})$, which can also handle input distributions that are known only approximately, and then build on it to construct a protocol with expected communication $\tilde{O}(n^{1-1/k}\mathrm{H}\,(\boldsymbol{S})^{1/k})$, replacing the expected size of the intersection with its entropy. These two protocols can be used in either the shared blackboard model or the coordinator model, since one model can simulate the other with multiplicative cost at most $O(k) = O(\log n)$.

The third protocol is for the case where $k > \log n$, in the coordinator model, which is the harder of the two models when k is large. This final protocol relies on advance access to only a single sample from the input distribution, and computes the intersection with expected communication $\tilde{O}(n + k)$.

Approximate knowledge of a distribution. As explained above, some of our protocols assume that the players do not exactly know the underlying input distribution, and instead are provided advanced access to samples from the distribution. We use these samples to approximate the marginal distribution of every bit $\boldsymbol{X}_i^j$ in the input. It is crucial to allow both multiplicative and additive approximation error, as allowing only one type of error would make it costlier to obtain the approximation (in terms of the number of samples required; see Section 4.2 below).

▶ **Definition 10.** *Let $\epsilon \geq 0, \alpha \in [0,1)$ and let $b \in [0,1]$. We say that a value $a \in [0,1]$ is an* (α,ϵ)-approximation *of b if $(1-\alpha)a - \epsilon \leq b \leq (1+\alpha)a + \epsilon$ and also $(1-\alpha)(1-a) - \epsilon \leq 1 - b \leq (1+\alpha)(1-a) + \epsilon$.*

We extend this definition to a distribution μ over $\{0,1\}^{n\times k}$ by saying that a collection of values $\left(a_i^\ell\right)_{i\in[n],\ell\in[k]} \subseteq [0,1]^{n\times k}$ is an (α,ϵ)-*approximation for the marginals of* μ if a_i^ℓ is an (α,ϵ)-approximation of the marginal μ_i^ℓ for every $i \in [n]$ and $\ell \in [k]$.

4.1 Basic Protocol for Computing Intersections ($k \leq \log n$)

In this section we give our protocol for computing the intersection of the players' inputs assuming approximate knowledge of the marginals of the input distribution. We assume that the number of players is $k \leq \log n$.

▶ **Theorem 11.** *Suppose all players know values $\left(a_i^\ell\right)_{i\in[n],\ell\in[k]}$ that* (α,ϵ)-approximate *the marginals of a product distribution μ. Then there is a zero-error two-round protocol in the coordinator model for finding the intersection, with expected communication cost*

$$O\left(\left(\frac{1+\alpha}{1-\alpha}\right)\left(kn^{1-1/k}\,\mathbb{E}\,[|\boldsymbol{S}|]^{1/k} + 2\epsilon kn\right)\log n + k\right),$$

where the expectation is over the input distribution μ.

From here on, we will refer to this protocol as Π_{base}.

High-level overview. We begin with a high-level overview of Π_{base}, assuming for simplicity that the players know the true marginals $\left(\mu_i^\ell\right)_{i\in[n],\ell\in[k]}$ of the input distribution.

For each coordinate $i \in [n]$, the protocol checks whether i is in the intersection using one of the following two strategies:

- "The 1-strategy": this strategy is appropriate for coordinates i where some player ℓ has a very small probability that $\boldsymbol{X}_i^\ell = 1$. In this case we can make good progress at little expected cost by asking player ℓ to speak up only if it has $\boldsymbol{X}_i^\ell = 1$: with good probability, player ℓ says nothing, and we learn that coordinate i is not in the intersection.
  Concretely, we find the player ℓ that has the smallest probability that $\boldsymbol{X}_i^\ell = 1$, that is, the smallest value of μ_i^ℓ (breaking ties arbitrarily), and ask this player to send index i iff $\boldsymbol{X}_i^\ell = 1$. If player ℓ did not send index i, we learn that $\boldsymbol{X}_i^\ell = 0$, and therefore coordinate i is not in the intersection. However, if player i did send index i, then $\boldsymbol{X}_i^\ell = 1$, and coordinate i might be in the intersection; to check, we simply ask all players $\ell' \neq \ell$ to send $\boldsymbol{X}_i^{\ell'}$, and then we check if they all sent 1.
  The expected communication cost of this strategy is at most $k \log n \min_{\ell \in [k]} \mu_i^\ell$: with probability $1 - \mu_i^\ell$ we have $\boldsymbol{X}_i^\ell = 0$, and in this case no bits are sent.[2] With probability $\min_{\ell \in [k]} \mu_i^\ell$, the player that has the minimum μ_i^ℓ sends index i, and the other players ℓ' follow suit by announcing $\boldsymbol{X}_i^{\ell'}$, for a total cost of at most $k \log n$ bits.
- "The 0-strategy": this strategy is appropriate for coordinates i where all players $\ell \in [k]$ are fairly likely to have $\boldsymbol{X}_i^\ell = 1$ (i.e., μ_i^ℓ is fairly large). In this case, we ask each player ℓ to announce index i iff $\boldsymbol{X}_i^\ell = 0$, and we then know that i is in the intersection iff no player sent index i.
  The expected communication cost of this strategy is $\log n \cdot \sum_{\ell \in [k]} \left(1 - \mu_i^\ell\right)$.

To choose which strategy to pursue for a given coordinate i, we simply compare the expected cost of the two strategies, and choose the strategy with the smaller expected cost; however, since we do not have access to the true marginals $\left(\mu_i^\ell\right)_{i \in [n], \ell \in [k]}$, we use the estimates $\left(a_i^\ell\right)_{i \in [n], \ell \in [k]}$ in their place. Thus, we estimate the cost of the 1-strategy to be $k \min_{\ell \in [k]} a_i^\ell$, and the cost of the 0-strategy to be $\sum_{\ell \in [k]} (1 - a_i^\ell)$ (ignoring the $\log n$ factor), and we choose to follow the 1-strategy for coordinate i iff $k \min_{\ell \in [k]} a_i^\ell < \sum_{\ell \in [k]} (1 - a_i^\ell)$.

We remark that this protocol generalizes a protocol for set disjointness that appeared in [12], but in [12] only the 1-strategy was required, because we could assume that no single coordinate had high probability of being in the intersection – otherwise we could simply guess that the intersection is not empty.

Detailed description of the protocol. The players first partition the coordinates into two sets, I_1 (for the 1-strategy) and I_0 (for the 0-strategy), defined as follows:

$$I_1 := \left\{ i \in [n] \;\middle|\; k \min_{\ell \in [k]} a_i^\ell \leq \sum_{\ell \in [k]} (1 - a_i^\ell) \right\}, \qquad \text{and} \qquad I_0 := [n] \setminus I_1.$$

Note that this is done with no communication, as all players know $(a_i^\ell)_{i \in [n], \ell \in [k]}$.

Next, for any $i \in I_1$, let $owner(i)$ be the player ℓ believed to be most likely to have $i \notin X_i^\ell$ (if there are several such players, we choose the first one):

$$owner(i) := \min \left\{ \ell \in [k] \;\middle|\; a_i^\ell = \min_{m \in [k]} a_i^m \right\}.$$

[2] Technically, players are not allowed to convey information by staying silent. In our implementation below, this is handled by having the players announce all their indices as a set, rather than going over the coordinates one-by-one as we do in our informal overview here. The sets are encoded using a variable-length encoding, and "no bits are sent for coordinate i" technically means that index i does not appear in any player's set.

We partition I_1 into subsets $I_1^1, \ldots, I_1^k$ by owner, with $I_1^\ell := \{i \in I_1 \mid owner(i) = \ell\}$ for each $i \in [k]$. The protocol proceeds as follows.

1. Each player $\ell \in [k]$ announces $\overline{X^\ell} \cap I_0$ and $X^\ell \cap I_1^\ell$.
2. The coordinator can now deduce the intersection in the I_0 coordinates, as it holds that $\cup_{\ell \in [k]} \left(\overline{X^\ell} \cap I_0\right) = I_0 \setminus \cap_{\ell \in [k]} X^\ell$. The coordinator also sets $T := \cup_{\ell \in [k]} \left(X^\ell \cap I_1^\ell\right)$, and announces T to all players.
3. Each player $\ell \in [k]$ sends $X^\ell \cap T$ to the coordinator. The coordinator declares that the intersection in I_1 is $\left(\cap_{\ell \in [k]} X^\ell\right) \cap T$.

Expected communication cost. We prove a tighter bound than the one claimed in Theorem 11, as the tighter bound will be useful to us in Section 4.3:

▷ Claim 12. When executed with an (α, ϵ)-approximation of the marginals of μ, the expected communication cost of Π_{base} is

$$O\left(\left(\frac{1+\alpha}{1-\alpha}\right)\left(k\sum_{i=1}^{n}\min\left\{\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k}, \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k}\right\} + 2\epsilon k n\right)\log n + k\right). \tag{1}$$

To obtain Theorem 11 from the claim, we apply Hölder's inequality to the inner sum:

$$\sum_{i=1}^{n}\min\left\{\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k}, \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k}\right\} \le \sum_{i=1}^{n}\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k} \le n^{1-1/k}\,\mathbb{E}\left[|\boldsymbol{S}|\right]^{1/k}.$$

Plugging this into (1) yields the theorem.

The proof of Claim 12 is given in the full version of this paper, but we give a sketch here. We begin by considering an idealized version of the protocol, where the coordinates are partitioned into subsets J_0, J_1 based on their true marginals (which are not known the players):

$$J_1 := \left\{ i \in [n] \;\middle|\; k\min_{\ell \in [k]}\mathbb{E}\left[\boldsymbol{X}_i^\ell\right] \le \sum_{\ell \in [k]}\left(1-\mathbb{E}\left[\boldsymbol{X}_i^\ell\right]\right)\right\} \qquad \text{and} \qquad J_0 := [n] \setminus J_1.$$

For each $i \in J_1$, the idealized protocol follows the 1-strategy, paying $k\min_{\ell \in [k]}\mathbb{E}\left[\boldsymbol{X}_i^\ell\right]$ in expected communication; for each $i \in J_0$, the idealized protocol follows the 0-strategy, paying $\sum_{\ell \in [k]}\left(1-\mathbb{E}\left[\boldsymbol{X}_i^\ell\right]\right)$ in expected communication.

Due to the way in which J_0, J_1 are defined, we are able to show that the idealized protocol pays an expected cost per coordinate of at most $k\min\left\{\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k}, \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k}\right\}$:

▶ **Lemma 13.** *Let $i \in [n]$. If $i \in J_0$, then*

$$\sum_{\ell \in [k]}\mathbb{E}\left[1-\boldsymbol{X}_i^\ell\right] \le k\min\left\{E\left[\boldsymbol{S}_i\right]^{1/k}, \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k}\right\},$$

and if $i \in J_1$, then

$$k\min_{\ell \in [k]}\mathbb{E}\left[\boldsymbol{X}_i^\ell\right] \le k\min\left\{E\left[\boldsymbol{S}_i\right]^{1/k}, \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k}\right\}.$$

Proof. Fix a coordinate $i \in [n]$. Observe that since μ is a product distribution,

$$\min_{\ell\in[k]} \mathbb{E}\left[\boldsymbol{X}_i^\ell\right] \le \left(\prod_{\ell\in[k]} \mathbb{E}\left[\boldsymbol{X}_i^\ell\right]\right)^{1/k} = \left(\mathbb{E}\left[\prod_{\ell\in[k]} \boldsymbol{X}_i^\ell\right]\right)^{1/k} = \mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k}.$$

Hence if $\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k} \le \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k}$ and $i \in J_1$, then we have:

$$\min_{\ell\in[k]} \mathbb{E}\left[\boldsymbol{X}_i^\ell\right] \le \mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k} = \min\left\{E\left[\boldsymbol{S}_i\right]^{1/k}, \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k}\right\}.$$

Similarly, if $\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k} \le \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k}$ and $i \in J_0$, then we have:

$$\sum_{\ell\in[k]} \mathbb{E}\left[1-\boldsymbol{X}_i^\ell\right] < k \min_{\ell\in[k]} \mathbb{E}\left[\boldsymbol{X}_i^\ell\right] \le k\,\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k} = k\min\left\{\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k}, \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k}\right\}.$$

Now, if $\left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k} < \mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k}$, i.e., $\mathbb{E}\left[\boldsymbol{S}_i\right] > 1/2$, then observe that this implies that $i \in J_0$, as we have that:

$$1/2 < \mathbb{E}\left[\boldsymbol{S}_i\right] = \mathbb{E}\left[\prod_{\ell\in[k]} \boldsymbol{X}_i^\ell\right] = \prod_{\ell\in[k]} \mathbb{E}\left[\boldsymbol{X}_i^\ell\right] \le \min_{\ell\in[k]} \mathbb{E}\left[\boldsymbol{X}_i^\ell\right],$$

where the last inequality is since all the expectations are upper bounded by 1. This in turn implies that:

$$\sum_{\ell\in[k]} \mathbb{E}\left[1-\boldsymbol{X}_i^\ell\right] \le \frac{k}{2} < k \min_{\ell\in[k]} \mathbb{E}\left[\boldsymbol{X}_i^\ell\right],$$

and hence $i \in J_0$. Now we have that:

$$\begin{aligned}
&\sum_{\ell\in[k]} \mathbb{E}\left[1-\boldsymbol{X}_i^\ell\right] \\
&= k\left(1-(1/k)\sum_{\ell\in[k]} \mathbb{E}\left[\boldsymbol{X}_i^\ell\right]\right) \\
&\le k\left(1-\left(\prod_{\ell\in[k]} \mathbb{E}\left[\boldsymbol{X}_i^\ell\right]\right)^{1/k}\right) && \text{(AM-GM inequality.)} \\
&= k\left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k}\right).
\end{aligned}$$

Finally, observe that

$$1-\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k} \le 1-\mathbb{E}\left[\boldsymbol{S}_i\right] \le \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k} = \min\left\{\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k}, \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k}\right\}. \quad \blacktriangleleft$$

Since the idealized protocol pays $k\min\left\{\mathbb{E}\left[\boldsymbol{S}_i\right]^{1/k}, \left(1-\mathbb{E}\left[\boldsymbol{S}_i\right]\right)^{1/k}\right\}$ per coordinate i, its total cost matches the bound from Claim 12 with $\alpha = \epsilon = 0$. To prove the claim for the actual protocol, we relate it to the idealized protocol, and show that its communication cost is similar. The key here is to show that even if we "misclassify" a coordinate i by placing it in I_1 when the idealized protocol has it in J_0 or vice-versa, the penalty is not too large: the partition into I_1 vs. I_0 is based on the estimates $\left(a_i^\ell\right)_{i\in[n],\ell\in[k]}$, which are close to the true

marginals $\left(\mu_i^\ell\right)_{i\in[n],\ell\in[k]}$ on which the partition into J_1 vs. J_0 is based. If $i \in I_1$ but $i \in J_0$ or vice-versa, then we must be close to the threshold where one strategy becomes preferable to the other, and therefore it does not matter too much which strategy we choose to pursue. For example, consider the case where $i \in I_1$ but $i \in J_0$. Then our actual protocol communicates $k\,\mathbb{E}\left[\boldsymbol{X}_i^{owner(i)}\right]$ bits in expectation for coordinate i, while an idealized protocol (where the players use J_0, J_1) communicates $\sum_{\ell\in[k]}\mathbb{E}\left[1-\boldsymbol{X}_i^\ell\right]$ bits in expectation. Now, since $i \in I_1$, we have $k\min_{\ell\in[k]} a_i^\ell \le \sum_{\ell\in[k]}(1-a_i^\ell)$. Hence:

$$\begin{aligned}
k\,\mathbb{E}\left[\boldsymbol{X}_i^{owner(i)}\right] &\le k\left((1+\alpha)a_i^{owner(i)}+\epsilon\right) = (1+\alpha)k\min_{\ell\in[k]} a_i^\ell + \epsilon k \\
&\le (1+\alpha)\sum_{\ell\in[k]}(1-a_i^\ell)+\epsilon k \\
&\le (1+\alpha)\sum_{\ell\in[k]}\frac{(1-\mathbb{E}\left[\boldsymbol{X}_i^\ell\right])+\epsilon}{1-\alpha}+\epsilon k \\
&\le \frac{1+\alpha}{1-\alpha}\left(\sum_{\ell\in[k]}\mathbb{E}\left[1-\boldsymbol{X}_i^\ell\right]+2\epsilon k\right).
\end{aligned}$$

Finally, showing a similar bound on the other possible types of misclassification, summing over all coordinates and applying Lemma 13 completes the proof for Claim 12.

4.2 Approximating the Marginals

In this section we show how to compute an $(1/4, n^{1/k})$-approximation of a value $b \in [0,1]$, given access to $\tilde{\Theta}(n^{1/k})$ iid samples from a Bernoulli distribution with probability b of returning 1. We then apply this procedure to obtain the estimates $\left(a_i^\ell\right)_{i\in[n],\ell\in[k]}$ that are used in the protocol of the previous section.

In general, to obtain an (α,ϵ)-approximation of a value $b \in [0,1]$, it suffices to take $\tilde{\Theta}(1/(\alpha^2\epsilon))$ samples from Bernoulli(b). In fact, we can provide a stronger guarantee: with high probability, our estimate $\boldsymbol{a}$ is either

- Purely additive: a $(0,\epsilon)$-approximation of b, that is, $\boldsymbol{a}-\epsilon \le b \le \boldsymbol{a}+\epsilon$; or,
- Purely multiplicative: an $(\alpha,0)$-approximation of b, that is, $(1-\alpha)\boldsymbol{a} \le b \le (1+\alpha)\boldsymbol{a}$ and $(1-\alpha)(1-\boldsymbol{a}) \le 1-b \le (1+\alpha)(1-\boldsymbol{a})$.

However, we do not know in advance (or even in hindsight) whether the estimate that we get will be purely additive or purely multiplicative. We note that if we were to insist on always having a purely additive estimate or on always having a purely multiplicative estimate, then we would require significantly more samples. For example, to obtain an purely additive $\pm\epsilon$ approximation of a value b close to $1/2$, we would require $\Omega(1/\epsilon^2)$ samples rather than $\Omega(1/\epsilon)$, which is important in our case, since ϵ is very small (roughly $n^{-1/k}$); to obtain a purely multiplicative $(1\pm\alpha)$-approximation of a value b close to 0 we require $\Omega(1/b)$ samples (i.e., an unbounded number of samples when b is unknown). Thus, it is important that our protocol can handle the type of estimate that we produce here, which can have both types of approximation error.

Obtaining the estimate is very simple, but the analysis is somewhat delicate:

▶ **Lemma 14.** *For any $\alpha,\epsilon,\delta \in (0,1)$ and $b \in (0,1)$, given access to $O(\frac{1}{\alpha^2\epsilon}\log(1/\delta))$ iid samples of Bernoulli(b), with probability $1-\delta$ we can compute a value a that is either an $(\alpha,0)$-approximation or a $(0,\epsilon)$-approximation to b (or both).*

Proof. Let $m = (100/(\alpha^2\epsilon))\log(4/\delta)$. Given samples $\boldsymbol{B}_1, \ldots, \boldsymbol{B}_m \sim \text{Bernoulli}(b)$, the estimate we output is $\boldsymbol{a} = \sum_{i=1}^{m} \boldsymbol{B}_i/m$. We claim that this estimate (α, ϵ)-approximates b with probability $1-\delta$. We divide into cases based on the values of ϵ and b.

Case 1: $\epsilon > \frac{1}{100}$. In this case we prove that $\boldsymbol{a}$ is a $(0, \epsilon)$-approximation to b with probability $1-\delta$. By the additive Chernoff bound,

$$\Pr\left(\boldsymbol{a} > b + \epsilon\right) \leq e^{-m \cdot D(b+\epsilon \,||\, b)} \leq e^{-m\cdot\epsilon^2} \leq e^{-m\cdot\epsilon/100},$$

where the second step uses Pinsker's inequality, and the last step uses the fact that $\epsilon > 1/100$. Similarly, $\Pr\left(\boldsymbol{a} < b - \epsilon\right) \leq e^{-m\cdot D(b-\epsilon \,||\, b)} \leq e^{-m\cdot\epsilon^2} \leq e^{-m\cdot\epsilon/100}$. Since $m \geq (100/\epsilon)\log(4/\delta)$ we have $e^{-m\cdot\epsilon/100} \leq \delta/4$, so the probability that either $\boldsymbol{a} > b+\epsilon$ or $\boldsymbol{a} < b-\epsilon$ is less than δ. In other words, with probability at least $1-\delta$, we have $\boldsymbol{a} - \epsilon \leq b \leq \boldsymbol{a} + \epsilon$, as required.

Case 2: $\epsilon < b < 1-\epsilon$. In this case we prove that $\boldsymbol{a}$ is an $(\alpha, 0)$-approximation to b with probability $1-\delta$. By the multiplicative Chernoff bound, $\Pr\left(\boldsymbol{a} \notin (1 \pm \alpha/2)b\right) \leq 2e^{-(\alpha/2)^2 bm/3} \leq 2e^{-\alpha^2\epsilon m/12}$. Similarly, $\Pr\left(1-\boldsymbol{a} \notin (1 \pm (\alpha/2))(1-b)\right) \leq 2e^{-(\alpha/2)^2(1-b)m/3} \leq 2e^{-\alpha^2\epsilon m/12}$. Since $m = (100/(\alpha^2\epsilon))\log(4/\delta)$, we have $e^{-\alpha^2\epsilon m/3} \leq \delta/4$, and thus the probability that either $\boldsymbol{a} \notin (1\pm\alpha/2)b$ or $1-\boldsymbol{a} \notin (1\pm\alpha/2)(1-b)$ is at most δ. Note that if $(1-\alpha/2)b \leq \boldsymbol{a} \leq (1+\alpha/2)b$, then we also have $b \leq \boldsymbol{a}/(1-\alpha/2) \leq (1+\alpha)\boldsymbol{a}$ and $b \geq \boldsymbol{a}/(1+\alpha/2) \geq (1-\alpha)\boldsymbol{a}$, as required, and similarly for $1-b$ and $1-\boldsymbol{a}$.

Case 3: $b \leq \epsilon \leq 1/100$ or $1-b \leq \epsilon \leq 1/100$. In this case we prove that $\boldsymbol{a}$ is a $(0, \epsilon)$-approximation to b with probability $1-\delta$. Let us assume that $b \leq \epsilon \leq 1/100$, as the other case is symmetric. First, observe that $\Pr\left(\boldsymbol{a} < b - \epsilon\right) = 0$, as $b - \epsilon < 0$. For the other side, by the additive Chernoff bound, $\Pr\left[\boldsymbol{a} > b + \epsilon\right] \leq e^{-m\cdot D(b+\epsilon \,||\, b)}$. Using Lemma 7 and the fact that $b \leq \epsilon$, we can bound the divergence from below by $D\left(b+\epsilon \,||\, b\right) \geq D\left(2\epsilon \,||\, \epsilon\right)$; and using a technical lemma from [9] and the fact that $\epsilon \leq 1/100$, we have $D\left(2\epsilon \,||\, \epsilon\right) \geq 2\epsilon/10$. All together, we see that $\Pr\left[\boldsymbol{a} > b + \epsilon\right] \leq e^{-2\epsilon m/10} \leq \delta$. ◀

Plugging in $\epsilon = n^{-1/k}$ and $\alpha = 1/4$, we see that $O(n^{1/k})$ samples suffice to estimate a single marginal μ_i^ℓ with sufficient accuracy, and $O(n^{1/k}\log(nk))$ samples suffice to approximate the entire distribution.

4.3 Entropy-Based Protocol ($k \leq \log n$)

In this section we refer to the protocol of Section 4.1 as *the base protocol*, Π_{base}. We show how to build on the base protocol to obtain a better protocol in the case where the intersection has small entropy. For convenience, we describe the new protocol in the shared blackboard model (the protocol can be adapted to the coordinator model with a multiplicative overhead of $O(k) = O(\log n)$ by having the coordinator forward every message to all players).

High-level overview. In this overview we assume for simplicity that $\Pr\left[\boldsymbol{S}_i = 1\right] \leq 1/2$ for each i, which means that $\mathrm{H}(\boldsymbol{S}_i) \geq \mathbb{E}\left[\boldsymbol{S}_i\right]$. This suffices to convey the main ideas; in the actual protocol, we work with $\min\left(\mathbb{E}\left[\boldsymbol{S}_i\right], 1 - \mathbb{E}\left[\boldsymbol{S}_i\right]\right)$ instead of $\mathbb{E}\left[\boldsymbol{S}_i\right]$, and rely on the fact that $\mathrm{H}(p) \geq \min(p, 1-p)$ for every $p \in [0,1]$.

Our protocol is motivated by the observation that the base protocol from Section 4.1 already has the desired communication cost of $\tilde{O}(n^{1-1/k}\mathrm{H}(\boldsymbol{S})^{1/k})$ in the special case where the intersection bits $\boldsymbol{S}_1, \ldots, \boldsymbol{S}_n$ are *independent*: by our assumption that $\mathrm{H}(\boldsymbol{S}_i) \geq \mathbb{E}\left[\boldsymbol{S}_i\right]$ for each i, we can use Claim 12 and Hölder's inequality to see that the base protocol computes

the intersection with expected communication cost $\tilde{O}\left(n^{1-1/k}\left(\sum_{i=1}^{n}\mathrm{H}\left(\boldsymbol{S}_i\right)\right)^{1/k}\right)$. In general, $\sum_{i=1}^{n}\mathrm{H}(\boldsymbol{S}_i)$ can be much greater than $\mathrm{H}(\boldsymbol{S})$ (e.g., if $\boldsymbol{S}_1 = \ldots = \boldsymbol{S}_n$). However, if $\boldsymbol{S}_1, \ldots, \boldsymbol{S}_n$ are independent, then $\sum_{i=1}^{n}\mathrm{H}\left(\boldsymbol{S}_i\right) = \mathrm{H}(\boldsymbol{S})$, and we are done.

What should we do when $\boldsymbol{S}_1, \ldots, \boldsymbol{S}_n$ are not independent? In this case we show that we can *exploit* the correlation between the bits. Given a set of coordinates $I \subseteq [n]$, let us say that the bits of $\boldsymbol{S}_I$ are *nearly-independent* if

$$\sum_{i\in I}\mathrm{H}\left(\boldsymbol{S}_i\right) \leq 2\mathrm{H}\left(\boldsymbol{S}_I\right). \tag{2}$$

Intuitively, (2) requires that the bits of $\boldsymbol{S}_I$ behave "almost as nicely" as independent bits, in that the sum of their marginal entropies is not much greater than their joint entropy (where for truly independent bits these would be equal).

Our protocol finds a maximal subset of coordinates $I \subseteq [n]$ such that the bits $\boldsymbol{S}_I$ are nearly-independent, and uses the base protocol to compute $\boldsymbol{S}_I$. By (2), the communication cost is $\tilde{O}\left(n^{1-1/k}\left(\sum_{i\in I}\mathrm{H}\left(\boldsymbol{S}_i\right)\right)^{1/k}\right) = \tilde{O}\left(n^{1-1/k}\mathrm{H}\left(\boldsymbol{S}_I\right)^{1/k}\right)$. Each remaining coordinate $j \notin I$ is "somewhat dependent" on $\boldsymbol{S}_I$, otherwise we could add j to I and obtain a larger set, contradicting the maximality of I. Intuitively, this means that our uncertainty about $\boldsymbol{S}_j$ should decrease after learning $\boldsymbol{S}_I$, and indeed we can prove that $\mathrm{H}\left(\boldsymbol{S}_j \mid \boldsymbol{S}_I\right) \leq (1/2)\mathrm{H}\left(\boldsymbol{S}_j\right)$ (see Lemma 15 in the next section). We now recurse on the remaining coordinates.

After $O(\log n)$ iterations, for each coordinate j that we have not yet solved, the entropy of $\boldsymbol{S}_j$ is reduced to at most $1/2^{\log n} = 1/n$. We can now afford to simply call the base protocol to solve all the remaining coordinates: if $F \subseteq [n]$ is the set of remaining coordinates, then the cost of solving all of them using the base protocol is roughly $\tilde{O}\left(n^{1-1/k}\left(\sum_{i\in F}\mathrm{H}\left(\boldsymbol{S}_i\right)\right)^{1/k}\right) = \tilde{O}\left(n^{1-1/k}\cdot\left(\sum_{i\in F}(1/n)\right)^{1/k}\right) = \tilde{O}\left(n^{1-1/k}\cdot 1\right)$.

Detailed description of the protocol. Throughout the protocol, the players maintain a subset $J \subseteq [n]$ of coordinates in which the intersection was already computed, and a distribution μ', which is the posterior input distribution given what the protocol has learned so far. All entropies computed during the run of the protocol are with respect to the updated distribution, μ'. The protocol is as follows.

1. Initialize $J \leftarrow \emptyset, \mu' \leftarrow \mu$.
2. Repeat $R = \lceil \log n \rceil$ times, or until $J = [n]$:
   - 2.1. Let $I \subseteq [n] \setminus J$ be a maximal set of nearly-independent coordinates (see (2) above). If there is more than one possible choice for I, we choose the lexicographically-smallest one. This step does not require communication.
   - 2.2. Execute the base protocol Π_{base} on the coordinates of I, using the distribution μ'. Let τ be the transcript of Π_{base}, and let $\mu'|_\tau$ be the distribution μ' conditioned on the event that the transcript of Π_{base} is τ.
   - 2.3. Update $J \leftarrow J \cup I, \mu' \leftarrow \mu'|_\tau$.
3. Finally, if $J \neq [n]$, call the protocol Π_{base} on the remaining coordinates $[n] \setminus J$, using the distribution μ'.

At the end, we output all intersection elements found during any of the calls to Π_{base}.

Expected communication cost. In the analysis we rely on the finer bound given in Claim 12 for the communication cost of Π_{base}. The bound is stated in terms of the expectations $\mathbb{E}\left[\boldsymbol{S}_i\right]$, but since $\mathrm{H}(p) \geq \min\{p, 1-p\}$ for every $p \in [0,1]$, Claim 12 and Hölder's inequality imply that the expected cost of Π_{base} when $\alpha = \epsilon = 0$ is

$$O\left(k\sum_{i=1}^{n}\mathrm{H}(\boldsymbol{S}_i)^{1/k}+k\right)=O\left(kn^{1-1/k}\left(\sum_{i=1}^{n}\mathrm{H}(\boldsymbol{S}_i)\right)^{1/k}\right). \tag{3}$$

Our goal now is essentially to replace the term $\sum_{i=1}^{n}\mathrm{H}(\boldsymbol{S}_i)$ in the bound above by $\mathrm{H}(\boldsymbol{S})$.

The full analysis will be given in the full version of this paper. The main idea is that in every iteration $r \le \lceil \log n \rceil$, if $\boldsymbol{I}_r$ is the set of coordinates on which we call Π_{base} in iteration r, then by choice of $\boldsymbol{I}_r$ we have $\sum_{i\in\boldsymbol{I}_r}\mathrm{H}_{\mu_r}(\boldsymbol{S}_i) \le 2\mathrm{H}_{\mu_r}(\boldsymbol{S}_{\boldsymbol{I}_r})$. Note that the expectation here is taken with respect to the distribution μ_r, which is the input distribution conditioned on the transcript up to iteration r (exclusive). Together with (3), this means that the cost of calling Π_{base} on $\boldsymbol{I}_r$ is $O(kn^{1-1/k}\mathrm{H}_{\mu_r}(\boldsymbol{S}_{\boldsymbol{I}_r})^{1/k})$.

When we reach the last step of the protocol, the set of remaining coordinates may not be nearly-independent. However, we claim that for every coordinate $i \in [n]$, given the transcript of the entire protocol so far, the conditional entropy of $\boldsymbol{S}_i$ is reduced to at most $1/n$. This is because in every iteration, the protocol either determines $\boldsymbol{S}_i$, reducing its entropy to zero, or solves a set of coordinates on which $\boldsymbol{S}_i$ depends strongly, which also reduces its entropy.

▶ **Lemma 15.** *Let $\boldsymbol{\Pi}_{<r}$ denote the transcript of the protocol up to iteration r, exclusive. For every $i \in [n]$ and iteration $r \le R$, $\mathrm{H}_\mu(\boldsymbol{S}_i \mid \boldsymbol{\Pi}_{<r+1}) \le \frac{1}{2}\mathrm{H}_\mu(\boldsymbol{S}_i \mid \boldsymbol{\Pi}_{<r})$.*

Proof. We prove that for every iteration $r \le R$ and transcript $\tau_{<r}$,

$$\mathrm{H}_\mu(\boldsymbol{S}_i \mid \boldsymbol{\Pi}_{<r+1}, \boldsymbol{\Pi}_{<r}=\tau_{<r}) \le \frac{1}{2}\mathrm{H}_\mu(\boldsymbol{S}_i \mid \boldsymbol{\Pi}_{<r}=\tau_{<r}).$$

The lemma then follows by taking the expectation over $\tau_{<r}$.

The transcript $\tau_{<r}$ determines the sets $I_1,\ldots,I_r$ on which Π_{base} is called in every iteration $1,\ldots,r$, as well as $\boldsymbol{S}_{\boldsymbol{I}_1}=S_{I_1},\ldots,\boldsymbol{S}_{\boldsymbol{I}_{r-1}}=S_{I_{r-1}}$. The value of $\boldsymbol{S}_{\boldsymbol{I}_r}$ is not determined by $\tau_{<r}$, but it is determined by $\Pi_{<r+1}$, as it is computed in iteration r itself. Therefore,

$$\mathrm{H}(\boldsymbol{S}_i \mid \boldsymbol{\Pi}_{<r+1}, \tau_{<r}) = \mathrm{H}(\boldsymbol{S}_i \mid \boldsymbol{\Pi}_{<r+1}, \tau_{<r}, \boldsymbol{S}_{I_1},\ldots,\boldsymbol{S}_{I_r}) \le \mathrm{H}(\boldsymbol{S}_i \mid \tau_{<r}, \boldsymbol{S}_{I_1},\ldots,\boldsymbol{S}_{I_r}),$$

where the last step uses the fact that conditioning does not increase entropy.

If there is some iteration $t \le r$ such that $i \in I_t$, then clearly $\mathrm{H}(\boldsymbol{S}_i \mid \tau_{<r}, \boldsymbol{S}_{I_1},\ldots,\boldsymbol{S}_{I_r}) = 0$, and the lemma follows from the non-negativity of entropy. Otherwise, i is not an element of any set $I_1,\ldots,I_r$, and in particular $i \notin I_r$. We claim that $\mathrm{H}(\boldsymbol{S}_i \mid \tau_{<r}, \boldsymbol{S}_{I_r}) \le (1/2)\mathrm{H}(\boldsymbol{S}_i \mid \tau_{<r})$, which proves the claim, as $\mathrm{H}(\boldsymbol{S}_i \mid \tau_{<r}, \boldsymbol{S}_{I_r}) = \mathrm{H}\left(\boldsymbol{S}_i \,\middle|\, \tau_{<r}, \boldsymbol{S}_{I_r}, \boldsymbol{S}_{I_1},\ldots,\boldsymbol{S}_{I_{r-1}}\right)$ and similarly $\mathrm{H}(\boldsymbol{S}_i \mid \tau_{<r}) = \mathrm{H}\left(\boldsymbol{S}_i \,\middle|\, \tau_{<r}, \boldsymbol{S}_{I_1},\ldots,\boldsymbol{S}_{I_{r-1}}\right)$ (as $\boldsymbol{S}_{I_1},\ldots,\boldsymbol{S}_{I_{r-1}}$ are all determined by $\tau_{<r}$).

Suppose for the sake of contradiction that

$$\mathrm{H}(\boldsymbol{S}_i \mid \tau_{<r}, \boldsymbol{S}_{I_r}) > (1/2)\mathrm{H}(\boldsymbol{S}_i \mid \tau_{<r}). \tag{4}$$

Then we can write

$$\begin{aligned}\sum_{j\in I_r\cup\{i\}}\mathrm{H}(\boldsymbol{S}_j \mid \tau_{<r}) &= \mathrm{H}(\boldsymbol{S}_i \mid \tau_{<r}) + \sum_{j\in I_r}\mathrm{H}(\boldsymbol{S}_j \mid \tau_{<r})\\ &\le 2\mathrm{H}(\boldsymbol{S}_i \mid \tau_{<r}, \boldsymbol{S}_{I_r}) + 2\mathrm{H}(\boldsymbol{S}_{I_r} \mid \tau_{<r}) \qquad \text{(by (4) and by choice of } I_r)\\ &= 2\mathrm{H}\left(\boldsymbol{S}_{I_r\cup\{i\}} \,\middle|\, \tau_{<r}\right),\end{aligned}$$

which contradicts the maximality of I_r. ◀

▶ **Corollary 16.** *For every $i \in [n]$ we have $\mathrm{H}_\mu(\boldsymbol{S}_i \mid \boldsymbol{\Pi}_{<R+1}) \le 1/n$.*

By the corollary, we can simply use (3) to bound the cost of calling Π_{base} on all the remaining coordinates by $O\left(kn^{1-1/k} \cdot \left(\sum_{i=1}^{n}(1/n)\right)^{1/k}\right) = O\left(kn^{1-1/k}\right)$. The final step in the proof is to carefully sum the costs of all the iterations, using Hölder's inequality and the chain rule for entropy to obtain the final bound of Theorem 2.

4.4 Upper Bound for Large k

For the case where we have $k \geq \log n$ players, we show that a single sample from the input distribution suffices to later compute the intersection on new inputs with expected communication cost $\tilde{O}(n+k)$. To do so, we modify a protocol from [12].

High-level overview. The protocol from [12] handles coordinates differently based on whether they have a non-negligible probability of being in the intersection or not. Let us say that a coordinate i is *negligible* if $\Pr[\boldsymbol{S}_i = 1] < \delta/n$. For negligible coordinates i, the protocol simply guesses that $\boldsymbol{S}_i = 0$, without trying to actually compute $\boldsymbol{S}_i$. By union bound, this contributes a total of at most $O(\delta)$ to our error probability. For non-negligible coordinates i, it is observed in [12] that since μ is a product distribution, the expected number of players ℓ that have $\boldsymbol{X}_i^\ell = 0$ must be very small; otherwise, $\Pr[\boldsymbol{S}_i = 1] = \prod_{\ell\in[k]} \Pr\left[\boldsymbol{X}_i^\ell = 1\right]$ would be very small, but we assumed that $\Pr[\boldsymbol{S}_i = 1] \geq \delta/n$. This means we can afford to have every player ℓ that has $\boldsymbol{X}_i^\ell = 0$ announce this fact to the coordinator, who then determines that $\boldsymbol{S}_i = 1$ iff no player ℓ announced that $\boldsymbol{X}_i^\ell = 0$.

In our setting we do not know the input distribution exactly, which can lead to two types of mistakes:

- Classifying a coordinate i as negligible when it is in fact non-negligible: we cannot afford to make even one such mistake, because for such coordinates we always output $\boldsymbol{S}_i = 0$, even though there is non-negligible probability that $\boldsymbol{S}_i = 1$. Thus, when we classify a coordinate as negligible, it must truly be negligible under the unknown input distribution.
- Classifying a coordinate i as non-negligible when it is in fact negligible: this type of mistake does not lead to incorrect outputs, but it can increase our expected communication cost, depending on the expected players that have 0 in coordinate i. Unlike the previous case, here we can afford to make some mistakes, but we should avoid classifying a coordinate i as non-negligible if $\sum_{i=1}^{k} \mathbb{E}\left[1 - \boldsymbol{X}_i^\ell\right]$ is large.

We show that when $k \geq \log n$, a single sample from the input distribution suffices to classify coordinates well enough for our purposes. Let $z_i = \sum_{\ell\in[k]}\left(1 - \mathbb{E}\left[\boldsymbol{X}_i^\ell\right]\right)$ be the expected number of zeroes in coordinate $i \in [n]$, under the unknown input distribution. Given one sample $\boldsymbol{A} \sim \mu$, we estimate z_i by $v_i := \sum_{\ell\in[k]}\left(1 - \boldsymbol{A}_i^\ell\right)$. Since $k \geq \log n$, the value $\sum_{\ell\in[k]}\left(1 - \boldsymbol{A}_i^\ell\right)$ is concentrated about its mean, which is z_i. This allows us to simultaneously estimate $z_1, \ldots, z_n$ with enough precision that no non-negligible coordinate is classified as negligible, and at the same time, every coordinate i that is classified as non-negligible has small z_i.

Detailed description of the protocol. As outlined above, we first take a sample $\boldsymbol{A} \sim \mu$, compute the estimates $v_i := \sum_{\ell\in[k]}\left(1 - \boldsymbol{A}_i^\ell\right)$, and then choose the following set of coordinates $N \subseteq [n]$ to classify as non-negligible: $N = \{i \in [n] : v_i \leq \beta \ln(n/\delta)\}$, where $\beta \geq 1$ is a constant whose value will be fixed later.

The protocol then proceeds as follows: given input $\boldsymbol{X} \sim \mu$,

1. For each coordinate $i \notin N$, the coordinator declares that $\boldsymbol{S}_i = 0$, that is, $i \notin \bigcap_{\ell\in[k]} \boldsymbol{X}^\ell$.
2. Simultaneously, each player ℓ sends $\boldsymbol{N}^\ell := N \cap \left([n] \setminus \boldsymbol{X}^\ell\right)$ to the coordinator.
3. The coordinator outputs $N \setminus \bigcup_{\ell\in[k]} \boldsymbol{N}^\ell$ as its estimate for the intersection $\boldsymbol{S}$.

Correctness and expected communication cost. Let $z_i = \sum_{\ell \in [k]} \left(1 - \mathbb{E}\left[\boldsymbol{X}_i^\ell\right]\right)$ be the expected number of zeroes in coordinate $i \in [n]$, and let $\mathcal{E}$ be the event that for every coordinate $i \in [n]$,

- If $z_i < \ln(n/\delta)$ then $i \in N$ (that is, $v_i \leq \beta \ln(n/\delta)$), and
- If $z_i > \beta^2 \ln(n/\delta)$ then $i \notin N$ (that is, $v_i > \beta \ln(n/\delta)$).

Intuitively, $\mathcal{E}$ is the event that we have classified every coordinate "well enough". Using Chernoff, it is easy to see that when β is large enough (say, $\beta \geq 8$), the event $\mathcal{E}$ occurs with probability $\geq 1 - \delta$ over the sample $\boldsymbol{A} \sim \mu$. This implies the correctness of the protocol: whenever $\mathcal{E}$ occurs, every coordinate $i \in [n]$ where $z_i < \beta \ln(n/\delta)$ is identified as non-negligible, $i \in N$. The coordinates in N are correctly solved by the protocol, since every player that has a zero in such a coordinate informs the coordinator. As for coordinates $i \notin N$, these coordinates must have $z_i \geq \beta \ln(n/\delta)$. By Lemma 4 in [12], this implies that $\Pr[\boldsymbol{S}_i = 1] \leq \delta/n$. By union bound, the probability that any such coordinate is in the intersection is at most δ. The error probability of the protocol is therefore bounded by $\Pr\left[\overline{\mathcal{E}}\right] + \Pr[\mathcal{E}] \cdot \delta \leq 2\delta$.

To bound the expected communication, we again condition on the event $\mathcal{E}$, which implies that every coordinate $i \in N$ that we actually solve has $z_i \leq \beta^2 \ln(n/\delta)$. Since $\log n \cdot z_i = \log n \sum_{\ell \in [k]} \left(1 - \mathbb{E}\left[\boldsymbol{X}_i^\ell\right]\right)$ is the expected communication cost of solving i, this means we send an expected $O(\log(n) \log(n/\delta))$ bits per coordinate in N, for a total of $O(n \log(n) \log(n/\delta))$.

5 Lower Bounds

We begin by observing that when we know nothing about the input distribution other than the fact that it is a product distribution, the distributional communication complexity of computing any function f is the same as the worst-case cost. This justifies our need for taking samples from the distribution before constructing the protocols of Sections 4.1, 4.4.

▶ **Observation 17.** *Let f be a function over $\{0,1\}^{n \times k}$, and let C be the worst-case randomized communication complexity[3] of f with error probability $1/3$ (on any input). Let Π be a (possibly randomized) protocol for computing f, such that under* any product distribution *μ over $\{0,1\}^{n \times k}$ we have $\Pr_{\boldsymbol{X} \sim \mu}[\Pi$ correctly computes $f(\boldsymbol{X})] \geq 2/3$. Then there is a product distribution μ such that the expected communication cost of Π under μ is C.*

Proof. For each input $X \in \{0,1\}^{n \times k}$, let μ_X be the product distribution μ_X that assigns to each player ℓ the input X^ℓ (this is a deterministic assignment, but it still qualifies as a product distribution). Because μ_X is a product distribution, and Π can handle any product distribution, when we run Π on inputs drawn from μ_X it has success probability at least $2/3$, which means that it correctly computes $f(X)$ with probability at least $2/3$. Thus, Π is in fact a protocol for computing f with worst-case error probability at most $1/3$ on any input. Therefore there must exist some input X, and hence some product distribution μ_X, on which Π sends C bits in expectation. ◀

Lower bound on the expected communication cost. To prove the lower bound of Theorem 3, we follow the information-theoretic lower bound technique of [12]. We note that the common information-theoretic strategy of using a *direct sum* argument, where we lower-bound

[3] The randomized communication complexity of a function f is the minimum over all protocols that compute f with worst-case error $\leq 1/3$ of the expected number of bits sent in the worst case (i.e., on any input) by the protocol. The error probability and the expectation are taken with respect to the protocol's internal randomness.

the cost of solving each bit of the problem correctly and then sum over the costs, cannot be used in this context: it yields lower bounds on the cost of solving each coordinate with small marginal error, but as we explained in Section 1, computing each bit $\boldsymbol{S}_i$ of the intersection with small marginal error is easy when the marginal probabilities that $\boldsymbol{S}_i = 1$ tend to be small:

▶ **Proposition 18.** *Let $\alpha \in (0,1)$, $\epsilon \in (0,1]$ be constants, $n > (1/\epsilon)^{2/\alpha}$, $k \geq 2$, and let μ be a product distribution over $(\{0,1\}^n)^k$, with expected intersection size $s \leq n^{1-\alpha}$. Then there exists a deterministic protocol that reveals the intersection to an external observer, with per-coordinate error at most ϵ and expected communication cost at most $\tilde{O}\left(n^{(1-\alpha/2)(1-1/k)}(s+1)^{1/k}\right)$.*

Proof. First, observe that the average coordinate $i \in [n]$ has expected intersection size $s/n = n^{-\alpha}$. Denote by I the set of coordinates $i \in [n]$ that have expected intersection size $\mathbb{E}[\boldsymbol{S}_i] > n^{-\alpha/2}$. Note that by Markov's inequality $|I| \leq n^{-\alpha/2} \cdot n = n^{1-\alpha/2}$. Now, if $k \leq \log n$, then the players execute the basic protocol of Theorem 11 on the coordinates of I. Note that the protocol reveals the intersection in coordinates I to an external observer with zero error. Since the overall expected intersection size for the coordinates is at most s, the protocol has expected communication cost $\tilde{O}\left(n^{(1-\alpha/2)(1-1/k)}(s+1)^{1/k}\right)$.

Similarly, if $k > \log n$, the players execute our protocol for $k > \log n$ (described at 4.4) on the coordinates of I. Note that the protocol reveals the intersection to an external observer with per-coordinate error at most $\epsilon/n^{1-\alpha/2} < \epsilon$ and expected communication cost at most $\tilde{O}\left(n^{(1-\alpha/2)(1-1/k)} + k\right)$.

For any remaining coordinate $i \notin I$, the external observer simply declares that $i \notin \cap_{\ell \in [k]} X^\ell$, and has a per-coordinate error at most $n^{-\alpha/2} < \epsilon$. ◀

Fix an expected intersection size s. Our lower bound uses the distribution where each bit of the input has iid probability $(s/n)^{1/k}$ of being 1 (that is, the distribution is also a product distribution over the elements, not just the players). It is not hard to see that this yields the desired expected intersection size of s, and also that the entropy of the intersection is $\tilde{\Theta}(s)$.

Now suppose we are given a protocol Π that sends $o\left(n^{1-1/k}s^{1/k}\right)$ bits in expectation. Following [12], we first show that for the average coordinate $i \in [n]$ and transcript τ of the protocol, for each player ℓ, the distribution of $\boldsymbol{X}_i^\ell$ conditioned on $\boldsymbol{\Pi} = \tau$ is very close to its prior: intuitively, to rule out an event with prior probability p, the protocol must spend $\Omega(p)$ of its information budget; in our case the event is $\boldsymbol{X}_i^\ell = 1$, and $p = (s/n)^{1/k}$. The protocol expends $o\left(n^{1-1/k}s^{1/k}/n\right) = o\left((s/n)^{1/k}\right)$ of its total information budget on the average coordinate, so the event $\boldsymbol{X}_i^\ell = 1$ remains roughly as likely as it was originally.

Consider a specific coordinate $i \in [n]$, and assume that for all the coordinates $j < i$, the bits $\boldsymbol{S}_i$ have been computed correctly; we denote this event by $\mathcal{E}_{<i}$. Since the protocol computes the entire intersection correctly w.h.p., the event $\mathcal{E}_{<i}$ has high probability. Assume w.l.o.g. that player 1 is the one that outputs $\boldsymbol{S}_i$ given the transcript τ: given on the transcript τ, the event $\mathcal{E}$, and the event $\boldsymbol{X}_i^1 = 1$, player 1 must decide whether to output $\boldsymbol{S}_i = 0$ or $\boldsymbol{S}_i = 1$ (if $\boldsymbol{X}_i^1 = 0$ then player 1 knows that $\boldsymbol{S}_i = 0$ and does not need to work to learn the answer). However, we can show that even conditioned on $\tau, \mathcal{E}$, and $\boldsymbol{X}_i^1 = 1$, the distribution of $\boldsymbol{S}_i$ is still very close to its prior, and therefore player 1 has roughly the same uncertainty about whether or not $\boldsymbol{S}_i = 1$ as it had originally, $\mathrm{H}(\boldsymbol{S}_i) = \tilde{\Theta}(s/n)$.

After analyzing the uncertainty about the output in each coordinate $i \in [n]$ conditioned on $\tau, \mathcal{E}$ and the event that the player ℓ deciding this coordinate has $\boldsymbol{X}_i^\ell = 1$, we carefully "collect" these uncertainties and add them up, to show that the players jointly have too much uncertainty about the entire intersection and cannot output it correctly with sufficiently high

probability. We note that unlike [12], in this process we need to handle conditioning on some fairly high-probability events (e.g., the event that $\boldsymbol{X}_i^\ell = 1$ has probability $(s/n)^{1/k}$, which is constant when $s = \Omega(n)$). This has the potential of distorting the distributions we work with by a lot if not handled properly.

An Optimal Separation Between Two Property Testing Models for Bounded Degree Directed Graphs

Abstract

We revisit the relation between two fundamental property testing models for bounded-degree *directed* graphs: the *bidirectional* model in which the algorithms are allowed to query both the outgoing edges and incoming edges of a vertex, and the *unidirectional* model in which only queries to the outgoing edges are allowed. Czumaj, Peng and Sohler [STOC 2016] showed that for directed graphs with both maximum indegree and maximum outdegree upper bounded by d, any property that can be tested with query complexity $O_{\varepsilon,d}(1)$ in the bidirectional model can be tested with $n^{1-\Omega_{\varepsilon,d}(1)}$ queries in the unidirectional model. In particular, if the proximity parameter ε approaches 0, then the query complexity of the transformed tester in the unidirectional model approaches n. It was left open if this transformation can be further improved or there exists any property that exhibits such an extreme separation.

We prove that testing *subgraph-freeness* in which the subgraph contains k source components, requires $\Omega(n^{1-\frac{1}{k}})$ queries in the unidirectional model. This directly gives the first explicit properties that exhibit an $O_{\varepsilon,d}(1)$ vs $\Omega(n^{1-f(\varepsilon,d)})$ separation of the query complexities between the bidirectional model and unidirectional model, where $f(\varepsilon,d)$ is a function that approaches 0 as ε approaches 0. Furthermore, our lower bound also resolves a conjecture by Hellweg and Sohler [ESA 2012] on the query complexity of testing k-star-freeness.

1 Introduction

Graph property testing is a framework for studying extremely fast (randomized) algorithms for solving a relaxation of classical decision problems on graphs. Given a graph property P, we are interested in designing an algorithm, called a *property tester*, that with high constant probability, accepts any graph G that satisfies P, and rejects any graph that is "far" from satisfying P, i.e., one needs to modify a significant fraction of the representation (e.g., adjacency matrix or adjacency list) of the graph to make it satisfy P. It is assumed that the algorithm is given oracle access to the representation of the graph and the goal of a property tester is to solve the above problem by making as few queries to the oracle as possible. Since the seminal works by Rubinfeld and Sudan [20] (on algebraic property testing)

and Goldreich, Goldwasser and Ron [11] (on combinatorial and graph property testing), a lot of efforts have been made on studying which properties can be tested within a sublinear (e.g., constant) number of queries in several classical models, e.g., the dense graph model [11, 1] and bounded-degree graph model [12]. In particular, we have see a rapid development of property testing on *undirected* graphs in the past two decades. We refer to the recent book [10] for a survey.

On the other hand, we still do not know much about property testing in *directed graphs (digraphs)* so far. Bender and Ron [3] introduced two fundamental models for studying directed graph property testing. The first is called *bidirectional* model, where the algorithm is allowed to query both outgoing and incoming edges of a vertex; the second is called *unidirectional* model, where the algorithm is only allowed to query the outgoing edges, while not incoming edges. The latter model seems more realistic for some applications. For example, consider the webgraphs. It is much easier to query the outgoing edges (u, v) (which corresponds to a hyperlink from webpage u to webpage v) than querying the incoming edges. In this paper, we focus on bounded-degree directed graphs. A digraph G is said to be *d-bounded*, if both the maximum outdegree and maximum indegree of G are upper bounded by d, which is assumed to be a constant.

Bender and Ron gave an algorithm for testing strong connectivity with $\tilde{O}(1/\varepsilon)$ queries in the bidirectional model, and showed that there is a lower bound of $\Omega(\sqrt{n})$ queries for any algorithm with two-sided error[1] in the unidirectional model. Goldreich [9], and Hellweg and Sohler [16] gave a lower bound of $\Omega(n)$ queries for testing strong connectivity with one-sided error in the unidirectional model. The works [9, 16] also gave testers for strong connectivity with $n^{1-1/(d+1/\varepsilon)}$ queries with two-sided error in the unidirectional model. In [16], the authors gave testers for subgraph-freeness with $O(n^{1-\frac{1}{k}})$ queries in the unidirectional model, where k is the number of connected components in the subgraph that have no incoming edges. It is known that a few properties can be tested with a constant number of queries in the bidirectional model, including Eulerianity [18], k-edge connectivity [18, 23, 8], k-vertex connectivity [18, 8].

Towards a deeper understanding of testing properties of bounded degree directed graphs (digraphs), Czumaj, Peng and Sohler [5] studied the relation between these two models and provided a generic transformation that converts testers with constant query complexity in the bidirectional model, to testers with sublinear query complexity in the unidirectional model. Specifically, in [5], it was shown that any property P that can be tested with[2] $q = O_{\varepsilon,d}(1)$ queries in the bidirectional model can be tested with $n^{1-d^{-\Theta(q)}} = n^{1-\Omega_{\varepsilon,d}(1)}$ queries in the unidirectional model (with two-sided error). In particular, if the proximity parameter ε approaches 0, then the query complexity of the transformed tester in the unidirectional model approaches n (as the term $d^{-\Theta(q)}$ approaches 0).

One natural question that is left open is that *is the above the transformation tight*? Or equivalently, *can we achieve a much better query complexity, say $n^{c-\Omega_{\varepsilon,d}(1)}$, in the latter model, for some universal constant $c < 1$*? Indeed, currently, the best known lower bound for this transformation is for testing 3-*star-freeness*, where a 3-star is a 4-vertex directed graph such that there exists one center vertex v, and for any other three vertices u, there is an edge from u to v, and no other edges exist. Hellweg and Sohler [16] have shown that 3-star-freeness can be tested with a constant number of queries in bidirectional model, while

[1] A tester for a property P is said to have *one-sided error* if it accepts every (di)graph satisfying P, and it errs if the graph is far from having P. It is said to have *two-sided error* if it errs in both cases.

[2] Throughout the paper, we use the notation $O_{\varepsilon,d}()$ (resp. $\Omega_{\varepsilon,d}()$) to describe a function in the Big-O (resp. Big-Omega) notation assuming that ε and d are constant.

the query complexity of a tester for this property in the unidirectional model is $\Theta(n^{2/3})$ for any constant $\varepsilon > 0$. Therefore, there is still a significant gap between the upper bound (i.e., $n^{1-\Omega_{\varepsilon,d}(1)}$) in the bidirectional model in the transformation and the current best-known lower bound (i.e., $\Omega(n^{2/3})$).

Before we state our result, we formally introduce the definition of property testing in both directional and unidirectional models. Let $P = (P_n)_{n\in\mathbb{N}}$ be a d-bounded digraph property, where P_n is a property of d-bounded digraphs with n vertices. An n-vertex graph G is said to be ε-far from satisfying P_n if one needs to modify more than εdn edges to make it a d-bounded digraph with property P_n, where $\varepsilon > 0$ is called the proximity parameter. We say that P is *q-query testable* (or that P *can be tested with query complexity* q) if for every n, ε and d, there exists a tester that makes $q = q(n, \varepsilon, d)$ queries and with probability at least $\frac{2}{3}$, accepts any n-vertex d-bounded digraph G satisfying P, and rejects any n-vertex d-bounded digraph G that is ε-far from satisfying P. We call such a tester an *ε-tester* for P.

We show that there exists a property that exhibits an $O_{\varepsilon,d}(1)$ vs $\Omega(n^{1-\Theta_{\varepsilon,d}(1)})$ separation of the query complexities between the bidirectional model and unidirectional model, which implies that the transformation of [5] is essentially tight.

▶ **Theorem 1.** *For any sufficiently small constant $\varepsilon > 0$, there exists a digraph property $P = P_{\varepsilon,d}$ such that P can be tested with $O_{\varepsilon,d}(1)$ queries in the bidirectional model, while any ε-tester for P in the unidirectional model requires $n^{1-f(\varepsilon,d)}$ queries, where $f(\varepsilon, d)$ is a function that approaches 0 when ε approaches 0.*

The above theorem is a direct corollary from the following result regarding testing subgraph-freeness. Let H be a directed graph. A strongly connected component[3] W is called a *source component* of H, if there is no edge from $V(H) \setminus W$ to W. A directed graph H is said to be *weakly connected* if its underlying undirected graph (i.e., the graph that is obtained by ignoring all the directions of the edges) is connected. For example, we note that k-star is just a weakly connected digraph with k source components, where a directed graph H with $k + 1$ vertices is called a *k-star* if there is a vertex v such that each of the other k vertices has exactly one edge pointing to v, and H does not contain any other edges. Let G and H be two directed graphs. The graph G is said to be *H-free* if H does not appear as a subgraph in G. We have the following theorem on testing H-freeness for any (constant-size) H with k source components.

▶ **Theorem 2.** *Let k be any integer such that $k \geq 2$. Let d be some constant. Let H be a weakly connected*[4] *directed graph with k source components. There exists an $\varepsilon_0 = \Theta_{d,k}(1)$ such that any ε_0-tester for testing H-freeness of an n-vertex d-bounded graph requires at least $\Omega(n^{1-\frac{1}{k}})$ queries in the unidirectional model.*

We remark that it has been shown by Hellweg and Sohler [16] that for any H with k source components, H-freeness can be tested with query complexity $O_{\varepsilon,d,k}(1)$ in the bidirectional model, and also can be tested with query complexity $O_{\varepsilon,d,k}(n^{1-\frac{1}{k}})$ in the unidirectional model[5]. Given the above result, we can easily prove Theorem 1.

[3] We call $W \subseteq V(H)$ a *strongly connected component* of H if the subgraph $H[W]$ of H induced by W is strongly connected, and there does not exist any set of vertices $X \subseteq V(H) \setminus W$ such that the subgraph of H induced by $W \cup X$ is strongly connected. That is, the subgraph of $H[W]$ is a strongly connected and maximal.

[4] For graphs H that is not weakly connected, we can handle each of its weakly connected components separately.

[5] On the high level, their algorithms use the following observation: if a bounded-degree directed graph G

Proof of Theorem 1. Let $\eta > 0$ and define property P_η to be the property of being H-free, for any H that is weakly connected digraph with $k = \lceil 1/\eta \rceil$ source components. According to Theorem 2, any ε_0-tester for P_η requires at least $\Omega(n^{1-\frac{1}{k}}) > \Omega(n^{1-\eta})$ queries in the unidirectional model, where $\varepsilon_0 = \varepsilon_0(d, \eta)$ is a function of d, η. Now given any sufficiently small constant $\varepsilon > 0$, let η' be a number satisfying that $\varepsilon = \varepsilon_0(d, \eta')$. Then Theorem 1 follows by taking $P = P_{\eta'}$ and $f(\varepsilon, d) = \eta'$. ◀

Furthermore, it was conjectured in [16] that testing k-star-freeness requires $\Omega(n^{1-\frac{1}{k}})$ queries in the unidirectional model. Since k-star is a directed subgraph with k-source components, our Theorem 2 resolves this conjecture.

1.1 Discussions of previous ideas and our techniques

We first sketch the main ideas of the lower bound for testing 3-star-freeness given by Hellweg and Sohler [16]. Their proof makes use of a problem called *testing* 3-*occurrence-freeness*[6] of a sequence[7]. Let A be a length-n sequence of integers such that each element in A is from $[\ell] := \{1, \cdots, \ell\}$ and occurs at most 3 times. We say A is 3-*occurrence-free* if no integer in A occurs exactly 3 times in A. We say A is ε-*far from being* 3-*occurrence-free* if one needs to change[8] more than εn elements of A to obtain a 3-occurrence-free sequence. [16] gave a local reduction from the problem of testing 3-occurrence-freeness of a sequence to the problem of testing 3-star-freeness. That is, given an instance A with m elements of 3-occurrence-freeness, they constructed a graph G with $\Theta(m)$ vertices, such that

1) if A is 3-occurrence-free, then G is 3-star-free; if A is ε-far from being 3-occurrence-free then G is $\Theta(\varepsilon)$-far from being 3-star-free;

2) every query to G can be answered by performing $O(1)$ queries to A.

To obtain a lower bound for testing 3-occurrence-freeness, [16] constructed two classes $\mathcal{C}_A$, $\mathcal{C}_B$ of length-n sequences such that $\mathcal{C}_A$ is a class of 3-occurrence-free sequences and $\mathcal{C}_B$ is a class of sequences that are $\Omega(1)$-far from being 3-occurrence-free, and the *frequency variables*, denoted by X_A and X_B, of the sequences from these two different classes have 2 proportional moments, i.e.,

$$\frac{\mathbf{E}[X_B]}{\mathbf{E}[X_A]} = \frac{\mathbf{E}[X_B^2]}{\mathbf{E}[X_A^2]}.$$

Then the lower bound $\Omega(n^{2/3})$ for testing 3-occurrence-freeness follows from a lower bound for distinguishing random variables with 2-proportional moments given in [19].

Now we note that to obtain a lower bound for testing H-freeness for any H with k source components, it suffices to give a lower bound for testing k-occurrence-freeness for general k in the way similar as above. That is, we construct two classes $\mathcal{C}_A$, $\mathcal{C}_B$ of length-n sequences such that $\mathcal{C}_A$ is a class of k-occurrence-free sequences and $\mathcal{C}_B$ is a class of sequences that are $\Omega_k(1)$-far from being k-occurrence-free, and the *frequency variables*, denoted by X_A and X_B, of the sequences from these two different classes have $k-1$ proportional moments, i.e.,

$$\frac{\mathbf{E}[X_B]}{\mathbf{E}[X_A]} = \frac{\mathbf{E}[X_B^2]}{\mathbf{E}[X_A^2]} = \cdots = \frac{\mathbf{E}[X_B^{k-1}]}{\mathbf{E}[X_A^{k-1}]}.$$

---

is ε-far from H-freeness, then G contains $\Omega(\varepsilon n)$ vertex-disjoint copies of H. Then in the bidirectional model, one can sample a constant number of vertices and perform BFS from each sampled vertex to find a copy of H; in the unidirectional model, one can sample many edges to see if some copy of H is formed.

[6] In [16], the same problem was called 3-value freeness.

[7] We use "sequence" rather than "multiset" as the position of each element affects our construction.

[8] It is allowed to use integers that are larger than ℓ to change the elements of A.

However, the main difficulty is to construct two classes of sequences satisfying the above equations for general $k \geq 3$, which was also pointed out in [16]. Besides the aforementioned construction in [16] which only works for $k = 3$, we also note that in [19], a special pair of random variables with $k-1$ proportional moments is also constructed (for establishing their lower bound for Distinct-Elements). That is, their random variables take values of the form $(B+3)^i$, for any integers $B > 1, k > 1$ and $i = 0, \ldots, k-1$. This leads to a large gap between the expectations of the corresponding variables. To show a lower bound for testing k-occurrence-freeness, we need to construct random variables taking values $1, 2, \ldots, k$, for any integer $k > 1$. This is more challenging as it corresponds to a much smaller gap (which is arbitrarily close to 1) between the expectations of the corresponding variables (see Lemma 10). To construct such two random variables, we establish some identities related to binomial coefficients, and use them to define two distributions satisfying a number of linear equations which in turn are necessary conditions for two variables having proportional moments.

We then give a local reduction from testing k-occurrence-freeness to testing H-freeness for H with k-source components. The reduction also non-trivially generalizes the one for 3-star-free in [16], as 3-star is a special subgraph with a nice symmetric property, while an arbitrary subgraph H might contain different types of asymmetric structures. Our main idea is as follows. Given a sequence S, we construct a graph G on the fly such that each element in the sequence corresponds to a source component of H in G; an element in S appears k times if and only if a copy of H is added in G. For the latter, we carefully add k source components of H to G and add edges from these components to one center component (which is the rest part of H after removing all the source components). Finally, we show that this construction preserves the distance to the properties and each query to G can be answered by querying at most 1 position in S.

1.2 Other Related work

Ito, Khoury and Newman [17] recently gave a characterization of monotone and hereditary properties that can be tested with constant query complexity and one-sided error in both bounded-degree bidirectional model and bounded-degree unidirectional model. For testing acyclicity in the bidirectional model, Bender and Ron [3] gave a lower bound of $\Omega(n^{1/3})$ queries for algorithms with two-sided error and a lower bound $\Omega(n^{1/2})$ queries for algorithms with one-sided error. The latter lower bound has been improved to $\tilde{\Omega}(n^{5/9})$ queries by Chen, Randolph, Servedio and Sun [4].

In the dense directed graph model (with different types of queries and notion of "ε-far"), Alon and Shapira [2] gave an algorithm with constant query complexity for testing subgraph-freeness.

There exists a class of properties which can be tested with constant number of queries by the so-called *proximity-oblivious testers* [13]. Goldreich and Ron [14] showed that any property that can be tested by a proximity-oblivious tester that makes q uniformly distributed queries with constant detection probability can be tested by a sample-based testers of sample complexity $O(n^{1-1/q})$, where a sample-based tester only samples elements independently from some distribution of the tested object. Building upon [7, 15], Dall'Agnol, Tom and Lachish [6] recently showed that any property that is testable with q queries admits a sample-based tester with sample complexity $n^{1-1/O(q^2 \log^2 q)}$. Their algorithms are defined over a constant-size output alphabet, which is very different from the bounded degree (directed) graph model, in which a super constant alphabet is needed.

Valiant developed a wishful thinking theorem in [22], telling that two distributions whose so-called *k-based moments* have small gap are indistinguishable by k-Poissonized samples. This is a tool for establishing lower bounds of testing symmetric properties on distributions.

On a very high level, both [22] and our work are constructing far distributions with the same collision, while the details for the constructions differ significantly. For example, our proof is built upon Corollary 5.7 of [19], which requires to carefully construct two distributions that have proportional moments. In [22], it is required to construct two distributions whose k-based moments have small gap. It is unclear if two distributions with small gap between k-based moments have proportional moments, or vice versa. In addition, we are using very different properties of Vandermonde matrix from those used in [22].

2 A Lower Bound for Testing k-Occurrence-freeness

In this section, we will prove the lower bound on the query complexity for testing k-occurrence-freeness, which is defined as follows. Given a sequence A of n integers such that each entry of A is from $[n] := \{1, \ldots, n\}$ and each element $i \in [n]$ occurs at most k times, the problem is to distinguish if A is *k-occurrence-free*, i.e., no element occurs in k positions of A, or A is *ε-far from k-occurrence-free*, i.e., more than εn elements of A needs to be changed to make it k-occurrence-free. We assume that the algorithm can query the element (or the value) of any position of the sequence in constant time. The goal is to solve the problem by making as few queries as possible. We will show the following result.

▶ **Theorem 3.** *Any algorithm for testing k-occurrence-freeness with parameter $\varepsilon = \Omega_k(1)$ requires at least $\Omega(n^{1-1/k})$ queries, where n is the length of the input sequence.*

2.1 Basic tools and notions

To prove the above theorem, we will make use of a lower bound by Raskhodnikova et al. [19] for distinguishing two sequences satisfying some property. We first introduce two definitions.

▶ **Definition 4** (Frequency variable)**.** *Let A be a sequence of integers. We define its* frequency variable X_A *as follows. Choose a number uniformly at random from the set of distinct elements that occur in A and then let X_A denote its* frequency[9]*, i.e., the number of times it occurs.*

Take the following sequence $S = \{1, 2, 1, 3, 2, 1, 4\}$ as an example. There are 4 distinct elements (or values) in S: value 1 occurs 3 times, value 2 occurs twice, value 3 and 4 each occurs once. Thus the frequency variable X_S of S satisfies that $\Pr[X_S = 1] = 0.5$, $\Pr[X_S = 2] = 0.25$, $\Pr[X_S = 3] = 0.25$.

▶ **Definition 5** (Proportional moments)**.** *Two random variables X_1 and X_2 are said to have $k-1$* proportional moments*, if $\frac{\mathbf{E}[X_2]}{\mathbf{E}[X_1]} = \frac{\mathbf{E}[X_2^2]}{\mathbf{E}[X_1^2]} = \cdots = \frac{\mathbf{E}[X_2^{k-1}]}{\mathbf{E}[X_1^{k-1}]}$. We say that two sequences have $k-1$ proportional moments if their frequency variables have $k-1$ proportional moments.*

Let P denote a property defined on sequence of integers such that it is invariant under any permutation of indices and values. [19] has shown that any tester for P that makes t queries can be simulated by a *Poisson-s* algorithm that only looks at the histogram of the samples as its input, and $s = O(t)$. Relevant definitions are as follows.

▶ **Definition 6** (*Poisson-s* algorithm)**.** *An algorithm is called a* Poisson-s *algorithm if the number of samples of the algorithm is determined by a Poisson distribution with the expectation s.*

[9] We directly adopt the notion "frequency" from [19].

▶ **Definition 7** (Histogram). *Given a sequence S, the histogram H of S is a function defined as follows:*

$$H(i) := |\{s \in S | s \text{ occurs exactly } i \text{ times in } S\}|$$

In [19], Raskhodnikova et al. proved that if two sequences have $k-1$ proportional moments and $s = o(n^{1-\frac{1}{k}})$, then any *Poisson-s* algorithm can't distinguish their histograms.Formally, based on Lemma 5.3 and Corollary 5.7 in [19], we have the following Lemma.

▶ **Lemma 8** ([19]). *Let X_A and X_B be two random variables with $k-1$ proportional moments. And let D_{X_A} and D_{X_B} be two length-n sequences of integers, whose frequency variables are X_A and X_B, respectively. Let P be a property of sequences that is invariant under permutations of indices and values, and let $\varepsilon > 0$ be a constant.*

1. *If $\mathcal{A}'$ is a tester for P with t queries, i.e., $\mathcal{A}'$ accepts the input sequence that satisfies P with probability at least $\frac{2}{3}$; it rejects any sequence that is ε-far from satisfying P, with probability at least $\frac{2}{3}$.*
   Then there must be a Poisson-s *algorithm $\mathcal{A}$ that gets only the histogram of the samples, where $s = O(t)$, satisfiying the following: if the input sequence satisfies P, $\mathcal{A}$ accepts with probability at least $\frac{2}{3} - o(1)$; if the input sequence is ε-far from satisfying P, $\mathcal{A}$ rejects with probability at least $\frac{2}{3} - o(1)$.*
2. *For any* Poisson-s *algorithm $\mathcal{A}$ with $s = o(n^{1-\frac{1}{k}})$, if $\mathcal{A}$ gets only access to the histogram of samples, then we have*

$$|\Pr[\mathcal{A}(D_{X_A}) = \text{True}] - \Pr[\mathcal{A}(D_{X_B}) = \text{True}]| = o(1).$$

Note that by the above Lemma, for a property P that is invariant under permutation of indices and values, any tester for P can be well simulated by a *Poisson-s* algorithm, which only accesses to the histogram of samples. Thus it suffices to only consider such *Poisson-s* algorithms. Furthermore, if there exist two instances of P with proportional moments, then it is hard to distinguish these two instances, for any *Poisson-s* algorithm that only accesses to the histogram of samples.

2.2 Proof of Theorem 3

Now we give the proof of Theorem 3. We first note that k-occurrence-freeness is a property that is invariant under permutation of indices and values. Suppose that there exist two families of sequence instances, denoted by $\mathcal{C}_A$ and $\mathcal{C}_B$, respectively, such that 1) $\mathcal{C}_A$ and $\mathcal{C}_B$ have $k-1$ proportional moments; 2) sequences in $\mathcal{C}_A$ are k-occurrence-free, and sequences in $\mathcal{C}_B$ are far from k-occurrence-freeness. Now assume that there exist a tester $\mathcal{A}'$ for k-occurrence-freeness with $s = o(n^{1-\frac{1}{k}})$ queries. Then, according to Lemma 8, there must be a *Poisson-s* algorithm $\mathcal{A}$ that gets only access to the histogram of samples. For such algorithm $\mathcal{A}$, we have

$$|\Pr[\mathcal{A}(D_{X_A}) = \text{True}] - \Pr[\mathcal{A}(D_{X_B}) = \text{True}]| = (\frac{2}{3} - o(1)) - (\frac{1}{3} + o(1)) \geq \frac{1}{6},$$

which contradicts to the second part of Lemma 8 and thus implies the $\Omega(n^{1-\frac{1}{k}})$ lower bound. Therefore, to prove Theorem 3, it suffices to construct two families of sequences with the above desired properties.

Proof of Theorem 3. We first construct two classes, denoted by $\mathcal{C}_A, \mathcal{C}_B$, of length-$n$ sequences, such that for any sequences $A \in \mathcal{C}_A$ and $B \in \mathcal{C}_B$, it holds that 1) A is k-occurrence-free and B is ε-far from k-occurrence-free, and 2) the frequency variables X_A, X_B of these two instances A, B have $k-1$ proportional moments.

To do so, we first prove the claim.

▷ Claim 9. It holds that

$$\begin{pmatrix} 1 & 1 & \cdots & 1 \\ 1 & 2 & \cdots & k \\ 1 & 2^2 & \cdots & k^2 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 2^{k-1} & \cdots & k^{k-1} \end{pmatrix} \cdot \begin{pmatrix} (-1)^1\binom{k}{1} \\ (-1)^2\binom{k}{2} \\ (-1)^3\binom{k}{3} \\ \vdots \\ (-1)^k\binom{k}{k} \end{pmatrix} = \begin{pmatrix} -1 \\ 0 \\ 0 \\ \vdots \\ 0 \end{pmatrix}. \tag{1}$$

Proof. We define a sequence of helper functions $f_j(x)$ to prove (1).

$$f_j(x) = \begin{cases} (1+x)^k, & j = 0 \\ x \cdot f_{j-1}^{'}(x), & j = 1, 2, \cdots, k-1 \end{cases} \tag{2}$$

To prove the claim, we note that it suffices to show the following:

$$f_0(-1) \;=\; 1 + \sum_{i=1}^{k} (-1)^{\cdot} \tbinom{k}{j} = 0, \tag{3}$$

$$f_j(-1) \;=\; \sum_{i=1}^{k} i^j \cdot (-1)^i \cdot \tbinom{k}{i} = 0, \text{ for any } j = 1, \ldots, k-1. \tag{4}$$

Note that if the above are true, then each line of Equations (1) holds, which finishes the proof of the claim. In the following, we prove Equations (3) and (4).

Let us first consider the binomial expansion of $f_0(x)$. We have that

$$f_0(x) = (1+x)^k = \sum_{i=0}^{k} x^i \cdot \tbinom{k}{i} = 1 + \sum_{i=1}^{k} x^i \cdot \tbinom{k}{i}. \tag{5}$$

Thus, $f_0(-1) = (1-1)^k = 1 + \sum_{i=1}^{k} (-1)^i \cdot \binom{k}{i} = 0$. That is, Equation (3) holds.

To prove Equation (4), we show that for any $1 \le j \le k-1$, it holds that

(a) $f_j(x) = \sum_{i=1}^{k} i^j \cdot x^i \cdot \binom{k}{i}$,

(b) $f_j(x) = \sum_{i=1}^{j} a_i \cdot x^i \cdot (1+x)^{k-i}$, for some numbers $a_1, \ldots, a_j \ge 0$.

Note that by the above two items, we have that $f_j(-1) = 0 = \sum_{i=1}^{k} i^j \cdot x^i \cdot \binom{k}{i}$, for each $j = 1, \ldots, k-1$, which finishes the proof of Equation (4) (and the claim).

In the following, we prove the above two items (a) and (b) by induction. Consider the case $j = 1$. By definition of function $f_j(x)$ given by (2) and the expansion (5), it holds that

$$f_0'(x) = k \cdot (1+x)^{k-1} = \sum_{i=1}^{k} i \cdot x^{i-1} \cdot \tbinom{k}{i},$$

which implies that

$$f_1(x) = x \cdot f_0^{'}(x) = x \cdot k \cdot (1+x)^{k-1} = \sum_{i=1}^{k} i \cdot x^i \cdot \tbinom{k}{i}$$

Now we assume that the items (a) and (b) hold for $j \leq k-2$, and we prove it for $j+1$.

For item (a), since $f_j(x) = \sum_{i=1}^{k} i^j \cdot x^i \cdot \binom{k}{i}$, we have that $f'_j(x) = \sum_{i=1}^{k} i^{j+1} \cdot x^{i-1} \cdot \binom{k}{i}$. Thus,

$$f_{j+1}(x) = \sum_{i=1}^{k} i^{j+1} \cdot x^i \cdot \binom{k}{i}$$

by Definition (2).

For item (b), since $f_j(x) = \sum_{i=1}^{j} a_i \cdot x^i \cdot (1+x)^{k-i}$, for some numbers $a_1, \ldots, a_j \geq 0$, it holds that

$$f'_j(x) = \sum_{i=1}^{j} (a_i \cdot i \cdot x^{i-1} \cdot (1+x)^{k-i} + a_i \cdot x^i \cdot (k-i) \cdot (1+x)^{k-i-1}).$$

Thus, by Definition (2),

$$f_{j+1}(x) = \sum_{i=1}^{j} (a_i \cdot i \cdot x^i \cdot (1+x)^{k-i} + a_i \cdot x^{i+1} \cdot (k-i) \cdot (1+x)^{k-i-1}) = \sum_{i=1}^{j+1} a'_i \cdot x^i \cdot (1+x)^{k-i},$$

for some numbers $a'_1, \cdots, a'_{j+1} \geq 0$.

Therefore, both items (a) and (b) hold and this finishes the proof the claim. ◁

Now we define two distributions $\mathbf{p}, \mathbf{q}$ over $[k]$ as follows.

1. if k is even, define

$$\mathbf{p}_i = \begin{cases} 0, & \text{if } i \text{ is even} \\ \frac{1}{2^{k-1}} \cdot \binom{k}{i}, & \text{if } i \text{ is odd} \end{cases} \qquad \mathbf{q}_i = \begin{cases} \frac{1}{2^{k-1}-1} \cdot \binom{k}{i}, & \text{if } i \text{ is even} \\ 0, & \text{if } i \text{ is odd} \end{cases}$$

2. if k is odd, define

$$\mathbf{p}_i = \begin{cases} \frac{1}{2^{k-1}-1} \cdot \binom{k}{i}, & \text{if } i \text{ is even} \\ 0, & \text{if } i \text{ is odd} \end{cases} \qquad \mathbf{q}_i = \begin{cases} 0, & \text{if } i \text{ is even} \\ \frac{1}{2^{k-1}} \cdot \binom{k}{i}, & \text{if } i \text{ is odd} \end{cases}$$

Now we show the following Lemma.

▶ **Lemma 10.** *Let $\mathbf{p}, \mathbf{q}$ be defined as above. There exists $d > 0$ such that*

$$\begin{pmatrix} \mathbf{q}_1 \\ \mathbf{q}_2 \\ \mathbf{q}_3 \\ \vdots \\ \mathbf{q}_k \end{pmatrix} = d \cdot \begin{pmatrix} \mathbf{p}_1 \\ \mathbf{p}_2 \\ \mathbf{p}_3 \\ \vdots \\ \mathbf{p}_k \end{pmatrix} + (d-1) \cdot \begin{pmatrix} (-1)^1 \binom{k}{1} \\ (-1)^2 \binom{k}{2} \\ (-1)^3 \binom{k}{3} \\ \vdots \\ (-1)^k \binom{k}{k} \end{pmatrix} \tag{6}$$

Proof. For the case that k is even, we let $d = 1 + \frac{1}{2^{k-1}-1}$.

First note that $\mathbf{p}_k = 0$ and $\mathbf{q}_k = (d-1) \cdot \binom{k}{k}$. Thus, the last equation holds. For even $i \in \{2, 4, \ldots, k\}$, $\mathbf{p}_i = 0$ and $\mathbf{q}_i = d \cdot \mathbf{p}_i + (d-1) \cdot \binom{k}{i}$. For odd $i \in \{1, 3, \ldots, k-1\}$, $\mathbf{p}_i = \frac{d-1}{d} \cdot \binom{k}{i}$ and $\mathbf{q}_i = d \cdot \mathbf{p}_i + (d-1) \cdot (-1) \cdot \binom{k}{i} = 0$. Thus, Equation (6) holds.

For the case that k is odd, we let $d = 1 - \frac{1}{2^{k-1}}$.

Note that $\mathbf{p}_k = 0$ and $\mathbf{q}_k = (1-d) \cdot \binom{k}{k}$. Thus, the last equation holds. For odd $i \in \{1, 3, \ldots, k\}$, $\mathbf{p}_i = 0$ and $\mathbf{q}_i = d \cdot \mathbf{p}_i + (1-d) \cdot \binom{k}{i}$. For even $i \in \{2, 4, \ldots, k-1\}$, $\mathbf{p}_i = \frac{1-d}{d} \cdot \binom{k}{i}$ and $\mathbf{q}_i = d \cdot \mathbf{p}_i + (d-1) \cdot \binom{k}{i} = 0$. Thus, Equation (6) holds. ◀

▶ **Lemma 11.** *Let k be any integer with $k \geq 2$. Let $\mathbf{p}, \mathbf{q}$ be distributions over $[k]$ defined as above. It holds that*

1. $\mathbf{p}_k = 0$ *and* $\mathbf{q}_k \geq \frac{1}{2^k}$*;*
2. *for any two random variables X_A and X_B with distributions $\mathbf{p}$ and $\mathbf{q}$, respectively, it holds that X_A and X_B have $k-1$ proportional moments.*

Proof. The first item follows from the definitions of $\mathbf{p}$ and $\mathbf{q}$.

Now prove the second item. Let $d > 0$ be the number from Lemma 10. We will show that

$$\frac{\mathbf{E}[X_B]}{\mathbf{E}[X_A]} = \frac{\mathbf{E}[X_B^2]}{\mathbf{E}[X_A^2]} = \cdots = \frac{\mathbf{E}[X_B^{k-1}]}{\mathbf{E}[X_A^{k-1}]} = d,$$

or equivalently,

$$\begin{pmatrix} 1 \\ \mathbf{E}[X_B] \\ \mathbf{E}[X_B^2] \\ \vdots \\ \mathbf{E}[X_B^{k-1}] \end{pmatrix} = d \cdot \begin{pmatrix} 1/d \\ \mathbf{E}[X_A] \\ \mathbf{E}[X_A^2] \\ \vdots \\ \mathbf{E}[X_A^{k-1}] \end{pmatrix}. \tag{7}$$

By the definition X_A, it holds that for any $0 \leq i \leq k-1$, $\mathbf{E}[X_A^i] = \sum_{j=1}^{k} p_j \cdot j^i$. That is,

$$\begin{pmatrix} 1 \\ \mathbf{E}[X_A] \\ \mathbf{E}[X_A^2] \\ \vdots \\ \mathbf{E}[X_A^{k-1}] \end{pmatrix} = \begin{pmatrix} 1 & 1 & \cdots & 1 \\ 1 & 2 & \cdots & k \\ 1 & 2^2 & \cdots & k^2 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 2^{k-1} & \cdots & k^{k-1} \end{pmatrix} \begin{pmatrix} \mathbf{p}_1 \\ \mathbf{p}_2 \\ \mathbf{p}_3 \\ \vdots \\ \mathbf{p}_k \end{pmatrix} \tag{8}$$

Similarly, it holds that

$$\begin{pmatrix} 1 \\ \mathbf{E}[X_B] \\ \mathbf{E}[X_B^2] \\ \vdots \\ \mathbf{E}[X_B^{k-1}] \end{pmatrix} = \begin{pmatrix} 1 & 1 & \cdots & 1 \\ 1 & 2 & \cdots & k \\ 1 & 2^2 & \cdots & k^2 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 2^{k-1} & \cdots & k^{k-1} \end{pmatrix} \begin{pmatrix} \mathbf{q}_1 \\ \mathbf{q}_2 \\ \mathbf{q}_3 \\ \vdots \\ \mathbf{q}_k \end{pmatrix} \tag{9}$$

By Equations (8) and (9), we know that to prove Equation (7), it suffices to show that

$$\begin{pmatrix} 1 & 1 & \cdots & 1 \\ 1 & 2 & \cdots & k \\ 1 & 2^2 & \cdots & k^2 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 2^{k-1} & \cdots & k^{k-1} \end{pmatrix} \begin{pmatrix} \mathbf{q}_1 \\ \mathbf{q}_2 \\ \mathbf{q}_3 \\ \vdots \\ \mathbf{q}_k \end{pmatrix} = d \cdot \begin{pmatrix} 1/d & 1/d & \cdots & 1/d \\ 1 & 2 & \cdots & k \\ 1 & 2^2 & \cdots & k^2 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 2^{k-1} & \cdots & k^{k-1} \end{pmatrix} \begin{pmatrix} \mathbf{p}_1 \\ \mathbf{p}_2 \\ \mathbf{p}_3 \\ \vdots \\ \mathbf{p}_k \end{pmatrix}. \tag{10}$$

Recall that by Lemma 10, it holds that

$$\begin{pmatrix} \mathbf{q}_1 \\ \mathbf{q}_2 \\ \mathbf{q}_3 \\ \vdots \\ \mathbf{q}_k \end{pmatrix} = d \cdot \begin{pmatrix} \mathbf{p}_1 \\ \mathbf{p}_2 \\ \mathbf{p}_3 \\ \vdots \\ \mathbf{p}_k \end{pmatrix} + (d-1) \cdot \begin{pmatrix} (-1)^1 \binom{k}{1} \\ (-1)^2 \binom{k}{2} \\ (-1)^3 \binom{k}{3} \\ \vdots \\ (-1)^k \binom{k}{k} \end{pmatrix}$$

Substituting $\mathbf{q}_i$ from the above equation to the left hand side of equation (10) gives us that

$$d \cdot \begin{pmatrix} 1 & 1 & \cdots & 1 \\ 1 & 2 & \cdots & k \\ 1 & 2^2 & \cdots & k^2 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 2^{k-1} & \cdots & k^{k-1} \end{pmatrix} \cdot \begin{pmatrix} \mathbf{p}_1 \\ \mathbf{p}_2 \\ \mathbf{p}_3 \\ \vdots \\ \mathbf{p}_k \end{pmatrix} + (d-1) \cdot \begin{pmatrix} 1 & 1 & \cdots & 1 \\ 1 & 2 & \cdots & k \\ 1 & 2^2 & \cdots & k^2 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 2^{k-1} & \cdots & k^{k-1} \end{pmatrix} \cdot \begin{pmatrix} (-1)^1\binom{k}{1} \\ (-1)^2\binom{k}{2} \\ (-1)^3\binom{k}{3} \\ \vdots \\ (-1)^k\binom{k}{i} \end{pmatrix}$$

$$= d \cdot \begin{pmatrix} 1 \\ \mathbf{E}[X_A] \\ \mathbf{E}[X_A^2] \\ \vdots \\ \mathbf{E}[X_A^{k-1}] \end{pmatrix} + (d-1) \cdot \begin{pmatrix} 1 & 1 & \cdots & 1 \\ 1 & 2 & \cdots & k \\ 1 & 2^2 & \cdots & k^2 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 2^{k-1} & \cdots & k^{k-1} \end{pmatrix} \cdot \begin{pmatrix} (-1)^1\binom{k}{1} \\ (-1)^2\binom{k}{2} \\ (-1)^3\binom{k}{3} \\ \vdots \\ (-1)^k\binom{k}{i} \end{pmatrix} = d \cdot \begin{pmatrix} 1/d \\ \mathbf{E}[X_A] \\ \mathbf{E}[X_A^2] \\ \vdots \\ \mathbf{E}[X_A^{k-1}] \end{pmatrix},$$

where the last equation follows from Claim 1.

On the other hand, by Equation (8), we know that the right hand side of (10) is,

$$d \cdot \begin{pmatrix} 1/d & 1/d & \cdots & 1/d \\ 1 & 2 & \cdots & k \\ 1 & 2^2 & \cdots & k^2 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 2^{k-1} & \cdots & k^{k-1} \end{pmatrix} \begin{pmatrix} \mathbf{p}_1 \\ \mathbf{p}_2 \\ \mathbf{p}_3 \\ \vdots \\ \mathbf{p}_k \end{pmatrix} = d \cdot \begin{pmatrix} 1/d \\ \mathbf{E}[X_A] \\ \mathbf{E}[X_A^2] \\ \vdots \\ \mathbf{E}[X_A^{k-1}] \end{pmatrix}.$$

Therefore, Equation (10) holds and thus X_A and X_B have $k-1$ proportional moments. This finishes the proof of the Lemma. ◀

Now we construct class $\mathcal{C}_A$ as follows: $\mathcal{C}_A$ is a class of sequences, and the frequency variable X_A of every sequence A is $\Pr[X_A = i] = p_i$. That is, for every sequence A, the fraction of elements that occur i times is exactly p_i. We can construct $\mathcal{C}_B$ analogously by substituting p_i with q_i.

By construction, sequence A is k-occurrence-free. Consider the sequence B. Suppose that there are l distinct values in B, then at least $q_k \cdot l$ values occur k times in B, which means that B is at least $\frac{q_k \cdot l}{n}$-far from k-occurrence-free. As every value in B occurs in at most k positions, there are at least $\frac{n}{k}$ distinct values, i.e., $l \geq \frac{n}{k}$. Thus, B is at least $\frac{q_k}{k}$-far from k-occurrence-free. According to previous analysis, A and B have $k-1$ proportional moments. The theorem then follows from Lemma 8. ◀

3 A Lower Bound for Testing Subgraph-Freeness

In this section, we give the proof of the lower bound on the query complexity for testing subgraph-freeness, i.e., prove Theorem 2.

Proof of Theorem 2. We give a reduction from the problem of testing k-occurrence of a sequence to the problem of testing H-freeness in the unidirectional model. That is, given an instance of the former problem, i.e., a length-n sequence S such that each element is promised to occur at most k times, we will construct an instance of the H-freeness testing problem, i.e., a directed graph G with $n' = \Theta(n)$ vertices and bounded degree. Then we show that this construction preserves the distances of the properties and any algorithm $\mathcal{A}'$ for testing H-freeness in the unidirectional model can be invoked on G to test if S is

k-occurrence-freeness. In particular, if $\mathcal{A}'$ has query complexity $o(n'^{1-\frac{1}{k}})$, then this implies an algorithm for testing k-occurrence-freeness with query complexity $o(n^{1-\frac{1}{k}})$, contradicting to Theorem 3.

Preprocessing the subgraph H. Since H has k source components, we denote these components by $\{C_1, \cdots, C_k\}$. Note that each C_i is a subgraph of H. We use N_{comp} to denote the maximum number of vertices in $\{C_1, C_2, \cdots, C_k\}$, i.e., $N_{\text{comp}} = \max_{i=1,\cdots,k} |V(C_i)|$ where $V(C)$ denotes the vertex set of the graph C. We use C_0 to denote the subgraph induced by the remainder of vertices in $V(H)$ and we call C_0 the center component of H. Let $N_{\text{center}} = |V(C_0)| = |V(H)| - \sum_{i=1}^{k} |V(C_i)|$. Note that since $C_1, \cdots, C_k$ are source components, by definition, no edge exists between different such components. All the edges leaving C_i (for $i = 1, \cdots, k$) are entering C_0. We can first decompose H into source components and the center component (e.g., by using Tarjan's algorithm [21]), index them, and identify all the edges crossing different components in constant time (as the size of H is constant).

We illustrate such a decomposition of a subgraph $\tilde{H}$ in Figure 1. Note that $\tilde{H}$ has 3 source components and 1 center component (see Figure 2). It can be partitioned into four parts such $V(\tilde{C}_0) = \{v_2, v_7\}$, $V(\tilde{C}_1) = \{v_1\}$, $V(\tilde{C}_2) = \{v_3, v_4, v_5\}$, $V(\tilde{C}_3) = \{v_6\}$ as follows. In this example, $N_{\text{comp}} = 3$, $N_{\text{center}} = 2$.

In the construction of the graph G, we will treat each component C_i, $1 \le i \le k$, as a subgraph with N_{comp} vertices. That is, for each such C_i, we add $(N_{\text{comp}} - |V(C_i)|)$ isolated vertices to C_i to obtain a new component C'_i so that $|V(C'_i)| = N_{\text{comp}}$. We can reassemble these new components $\{C'_1, C'_2, \cdots, C'_k\}$ with C_0 to obtain a graph H'.

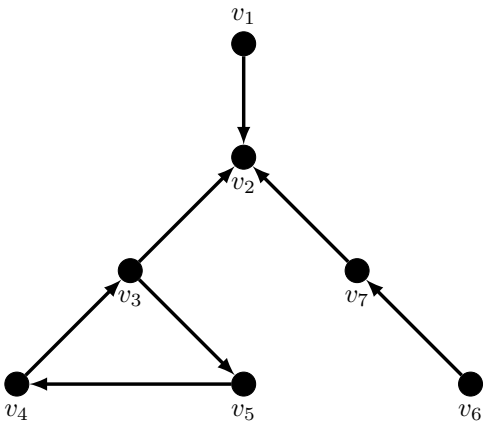

Figure 1 A subgraph $\tilde{H}$.

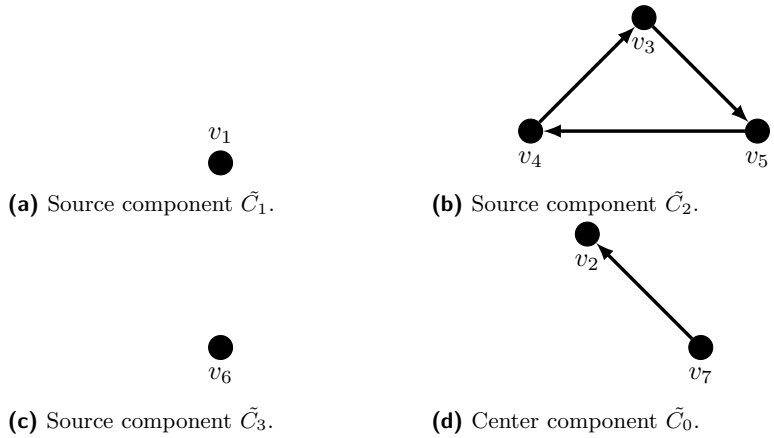
Now we index each vertex of H' by some integer in $\{1, \cdots, N_{\text{center}} + k \cdot N_{\text{comp}}\}$ as follows. The index set of $V(C'_0)$ is $[1, N_{\text{center}}]$, and the index set of $V(C'_i)$ is $[N_{\text{center}} + (i-1) \cdot N_{\text{comp}} + 1, N_{\text{center}} + i \cdot N_{\text{comp}}]$, for each $1 \le i \le k$. Furthermore, for each component C'_i with $0 \le i \le k$, we sequentially index the vertices using the corresponding index set according to the lexicographical ordering of the vertices in the aforementioned component decomposition.

Now we describe the reduction. Given a length-n sequence S, the directed graph $G = (V, E)$ can be constructed as follows. We first add n disjoint copies of the subgraph C_0 to G. Then we will add n copies of source components and add some edges from source components to some copy of C_0 constructed before. That is, each element in the sequence corresponds to a source component. Note that there are no edges between different copies of source components. The offline construction is formally described as follows.



(a) Source component $\tilde{C}_1$. **(b)** Source component $\tilde{C}_2$.

(c) Source component $\tilde{C}_3$. **(d)** Center component $\tilde{C}_0$.

Figure 2 Decomposing $\tilde{H}$ into 3 source components and 1 center component.

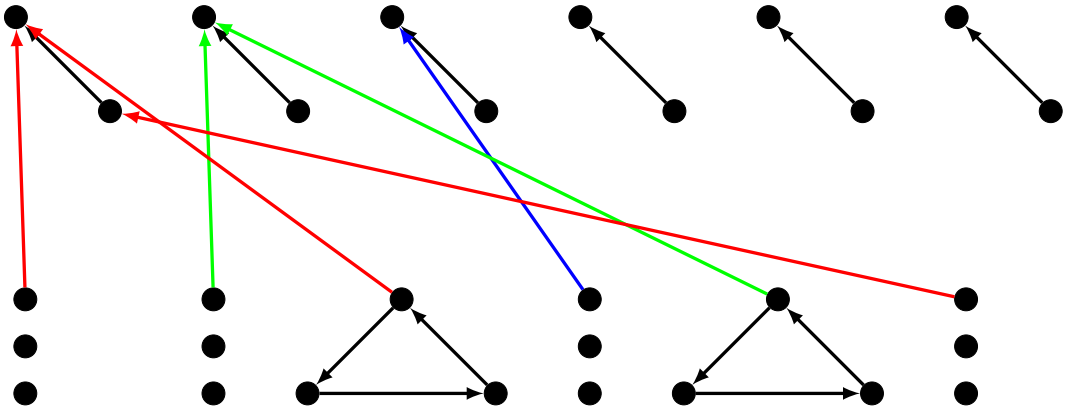


Figure 3 Constructing $\tilde{G}$ from the sequence $\tilde{S}$ and the decomposition of $\tilde{H}$.

Vertex set and vertex indices. We index vertices in G from 1 to $n \cdot (N_{\text{center}} + N_{\text{comp}})$. The vertex set is decomposed into two parts: the *center part* and the *source part*. More precisely, the source part contains n potential source components with vertex indices from 1 to $n \cdot N_{\text{comp}}$, and the center part contains n disjoint copies of the center component C_0 with vertex indices from $n \cdot N_{\text{comp}} + 1$ to $n \cdot (N_{\text{comp}} + N_{\text{center}})$. Furthermore, the vertices in the i-th copy of the source component are indexed from $(i-1) \cdot N_{\text{comp}} + 1$ to $i \cdot N_{\text{comp}}$, while the vertices of the j-th copy of the center component are indexed from $n \cdot N_{\text{comp}} + (j-1) \cdot N_{\text{center}} + 1$ to $n \cdot N_{\text{comp}} + j \cdot N_{\text{center}}$.

Adding components and edges. Add n disjoint copies of C_0 to G. Initialize a size-n array T such that $T_a = 0$ for each $1 \le a \le n$. For each $a = 1, 2, \cdots, n$:

1. let b be the value (or element) of S at position a
2. If b is a new value that algorithm sees for the first time, define an array $R_b = \{1, 2, \cdots, k\}$.
3. Uniformly sample a number t from R_b. Add an copy of C'_t. Ignoring isolated vertices in C'_t, add edges between this copy of C'_t and the b-th copy of C_0 in the same way as the connections between their counterparts in the subgraph H. Delete t from R_b. Set $T_a = t$, i.e., the a-th position of S is mapped to a source component C'_t.

Note that by construction, the graph G is d-bounded, and its maximum (in- or out-) degree the same as the maximum (in- or out-) degree of H.

We give an illustration of the above construction in Figure 3. Given a sequence $\tilde{S} = \{1, 2, 1, 3, 2, 1\}$, and a subgraph $\tilde{H}$ as shown in Figure 1. The graph $\tilde{G}$ from the above reduction is shown Figure 3. In this figure, edges of the same color correspond to positions of the same value (or element) in $\tilde{S}$. For example, the 3 red edges correspond to the 3 occurrences of value 1. Together with the corresponding source and center components, these red edges form an copy of $\tilde{H}$.

Construction on the fly. We show that the above construction of G can be done on the fly and each query to G can be answered by querying at most 1 position in S. More precisely, let $\mathcal{A}'$ be an algorithm for testing H-freeness. When $\mathcal{A}'$ queries the i-th outgoing neighbor of a vertex v, we consider the following cases.

If $v > n \cdot N_{\text{comp}}$, then v belongs to a copy of C_0, then we do not need to query sequence S, and we can simply locate the vertex $v' = (v - n \cdot N_{\text{comp}}) \bmod N_{\text{center}}$ in C_0. And by our index in H', we know the corresponding vertex index in H' is also v'. Then we can check the i-th neighbor of v' in H', denoted by v''. Thus we just return $v - v' + v''$.

If $1 \leq v \leq n \cdot N_{\text{comp}}$, then v belongs to a copy of some source component. Calculate $a = \lceil v/N_{\text{comp}} \rceil$ and query the a-th position of S. Let b denote the query answer. If $T_a = 0$, which means that this element is queried for the first time, uniformly sample a type t from the rest of types R_b for value b, and update $T_a = t$; otherwise simply set $t = T_a$. Note that R and T are maintained as described in the construction. Then calculate $v' = v \bmod N_{\text{comp}}$. Now we know that the queried vertex v corresponds to the v'-th vertex in a C'_t component, which is adjacent to the b-th copy of C_0. We can look up vertex $N_{\text{center}} + (t-1) \cdot N_{\text{comp}} + v'$ in H', which is isomorphic to vertex v in G. We use v'' to denote the i-th neighbor of $N_{\text{center}} + (t-1) \cdot N_{\text{comp}} + v'$ in H'. If v'' belongs to the C'_t part in H, we just return $v - v' + v''$. Otherwise, if v'' belongs to a C_0 part, we return $n \cdot N_{\text{comp}} + (b-1) \cdot N_{\text{center}} + v''$.

Thus, any query for a vertex v with $v > n \cdot N_{\text{comp}}$ can be answered without querying S; query for a vertex v with $1 \leq v \leq n \cdot N_{\text{comp}}$ can be answered by making one query to S.

Note that our construction generates a graph G from a distribution $\mathcal{D} = \{G_1, G_2, \cdots\}$. We will show that if S is k-occurrence-free, then any graph from $\mathcal{D}$ is H-free; if S is far from being k-occurrence-free, then every graph in $\mathcal{D}$ is far from H-freeness.

Preserving the distances. Note that in the above construction, if there exists some value occurring k times in S, then these k occurrences of the same value results in k different source components covering $\{C_1, C_2, \cdots, C_k\}$, and they are adjacent to the same center. That is, each element occurring k times in the sequence result in an occurrence of H in G. For each element occurring less than k times, the center corresponding to this value will be adjacent to less than k source components, which in turn implies that H does not occur in this case. We mention that the auxiliary isolated vertices also do not contribute to any occurrence of H.

Thus, if S is k-occurrence-free, then there can not be any occurrence of H, and thus G must be H-free. If S is ε-far from being k-occurrence-free, then there will be at least εn occurrences of H in G. This implies that G is at least ε'-far from H-freeness, for $\varepsilon' = \frac{\varepsilon n}{d(N_{\text{center}} + N_{\text{comp}})n} = \frac{\varepsilon}{d(N_{\text{center}} + N_{\text{comp}})}$.

Putting things together. Let $\mathcal{A}'$ be an algorithm for testing H-freeness with proximity parameter $\varepsilon = \Theta_{k,d}(1)$. Suppose that the query complexity is $o(n'^{1-\frac{1}{k}})$ on an n'-vertex digraph. Now we invoke the algorithm $\mathcal{A}'$ on the graph G that was constructed as before.

As we have seen, each query in G can be answered by making at most 1 query to the sequence S. Furthermore, if S is k-occurrence-free, then G is H-free and if S is ε-far from being k-occurrence-free, then G is ε'-far from H-free, for $\varepsilon' = \frac{\varepsilon}{d\cdot(N_{\text{center}}+N_{\text{comp}})} = \Theta_{k,d}(1)$. Thus, the algorithm $\mathcal{A}'$, together with the construction, also solves the problem of testing k-occurrence-freeness with $o(n^{1-\frac{1}{k}})$ queries, which contradicts Theorem 3. Thus, the query complexity of $\mathcal{A}'$ is $\Omega(n^{1-\frac{1}{k}})$. This finishes the proof of the theorem. ◀

Abstract

This paper considers the decidability of fully quantum nonlocal games with noisy maximally entangled states. Fully quantum nonlocal games are a generalization of nonlocal games, where both questions and answers are quantum and the referee performs a binary POVM measurement to decide whether they win the game after receiving the quantum answers from the players. The quantum value of a fully quantum nonlocal game is the supremum of the probability that they win the game, where the supremum is taken over all the possible entangled states shared between the players and all the valid quantum operations performed by the players. The seminal work $\mathrm{MIP}^* = \mathrm{RE}$ [16, 17] implies that it is undecidable to approximate the quantum value of a fully nonlocal game. This still holds even if the players are only allowed to share (arbitrarily many copies of) maximally entangled states. This paper investigates the case that the shared maximally entangled states are noisy. We prove that there is a computable upper bound on the copies of noisy maximally entangled states for the players to win a fully quantum nonlocal game with a probability arbitrarily close to the quantum value. This implies that it is decidable to approximate the quantum values of these games. Hence, the hardness of approximating the quantum value of a fully quantum nonlocal game is not robust against the noise in the shared states.

This paper is built on the framework for the decidability of non-interactive simulations of joint distributions [12, 7, 11] and generalizes the analogous result for nonlocal games in [26]. We extend the theory of Fourier analysis to the space of super-operators and prove several key results including an invariance principle and a dimension reduction for super-operators. These results are interesting in their own right and are believed to have further applications.

1 Introduction

Nonlocal games are a core model in the theory of quantum computing, which has found wide applications in quantum complexity theory, quantum cryptography, and the foundation of quantum mechanics. A nonlocal game is executed by three parties, a referee and two

non-communicating players, which are usually named Alice and Bob. Before the game starts, the players may share an arbitrary bipartite quantum state. The referee samples a pair of questions and sends each of them to the players, separately. Each player is supposed to reply with a classical answer to the referee. They win the game if the questions and the answers satisfy a given predicate. The distribution of the questions and the predicate is known to the players. The *quantum value* is the supremum of the probability that the players win the game. It is a central topic in quantum computing to understand the computational complexity of computing the quantum value of a nonlocal game. After decades of efforts [6, 21, 20, 14, 15, 24, 9], it has been finally settled by the seminal work $\mathrm{MIP}^* = \mathrm{RE}$ [16, 17], where Ji, Natarajan, Vidick, Wright and Yuen proved that it is undecidable to approximately compute the quantum value of a nonlocal game with constant precision. This result implies that there is no computable upper bound on the preshared entanglement for the players to win the game with a probability close to the quantum value. Otherwise, the probability of success can be obtained by ε-netting all possible quantum strategies and brute-force searching for the optimal value. Ji et al. essentially proved that it is still uncomputable even if the players are only allowed to share (arbitrarily many) EPR states.

In [26], the authors investigated the robustness of the hardness of the nonlocal games under noise. More specifically, they considered a variant of nonlocal games, where the preshared quantum states are corrupted. It is shown that the quantum value of a nonlocal game is computable if the players are allowed to share arbitrarily many copies of *noisy maximally entangled states* (MES). Hence, the hardness of the nonlocal games collapses in the presence of noise from the preshared entangled states.

In this paper, we consider *fully quantum nonlocal games*, which are a broader class of games where both questions and answers are quantum and the predicates are replaced by quantum measurements with binary outcomes: win and loss. More specifically, a fully quantum nonlocal game

$$\mathfrak{G} = \left(\mathcal{P}, \mathcal{Q}, \mathcal{R}, \mathcal{A}, \mathcal{B}, \phi_{\mathsf{in}}^{\mathcal{PQR}}, \left\{P_{\mathsf{win}} = M^{\mathcal{ABR}}, P_{\mathsf{loss}} = \mathbb{1} - M^{\mathcal{ABR}}\right\}\right)$$

consists of a referee and two non-communicating players: Alice and Bob, where $\mathcal{P}, \mathcal{Q}, \mathcal{R}, \mathcal{A}, \mathcal{B}$ are quantum systems, $\phi_{\mathsf{in}}^{\mathcal{PQR}}$ is a tripartite quantum state in $\mathcal{P} \otimes \mathcal{Q} \otimes \mathcal{R}$ and $\{P_{\mathsf{win}}, P_{\mathsf{loss}}\}$ is a measurement acting on $\mathcal{A} \otimes \mathcal{B} \otimes \mathcal{R}$. Alice, Bob, and the referee share the input state $\phi_{\mathsf{in}}^{\mathcal{PQR}}$, where Alice, Bob, and the referee hold $\mathcal{P}, \mathcal{Q}, \mathcal{R}$, respectively, at the beginning of the game. Alice and Bob are supposed to perform quantum operations mapping $\mathcal{P}$ to $\mathcal{A}$ and $\mathcal{Q}$ to $\mathcal{B}$, and then send the quantum states in $\mathcal{A}$ and $\mathcal{B}$ to the referee, respectively. After receiving the quantum messages from the players, the referee performs the POVM measurement $\{P_{\mathsf{win}}, P_{\mathsf{loss}}\}$. Again, the players are allowed to share arbitrary quantum states before the game starts. Both players know the description of ϕ_{in} and the POVM. The quantum value of the game G is the supremum of the probability that the players win the game. The supremum is over all possible preshared quantum states and the quantum operations that can be implemented by both parties. It is not hard to see if $\phi_{\mathsf{in}} = \sum_{x,y} \mu(x,y) |x\rangle\langle x|^{\mathcal{P}} \otimes |y\rangle\langle y|^{\mathcal{Q}} \otimes |xy\rangle\langle xy|^{\mathcal{R}}$ and both P_{win} and P_{loss} are projectors on computational basis, where μ is a bipartite distribution, then it boils down to a nonlocal game.

Fully quantum nonlocal games also capture the complexity class of two-prover one-round quantum multi-prover interactive proof systems $\mathsf{QMIP}(2,1)$. The variants of nonlocal games, where either the questions or the answers are replaced by quantum messages have occurred in much literature [3, 22, 27, 5, 10, 4, 2, 18]. In [3], Buscemi introduced the so-called semi-quantum nonlocal games, which are nonlocal games with quantum questions and classical answers, and proved that semi-quantum nonlocal games can be used to characterize LOSR (local operations and shared randomness) paradigm. Such games are further used to study

the entanglement verification in the subsequent work [4, 2]. In a different context, Regev and Vidick in [27] proposed quantum XOR games, where the questions are quantum and the answers are still classical. In [22], Leung, Toner, and Watrous introduced a communication task: coherent state exchange and its analogue in the setting of nonlocal games, where both questions and answers are quantum. In [10], Fitzsimons and Vidick demonstrated an efficient reduction that transforms a local Hamiltonian into a 5-players nonlocal game allowing classical questions and quantum answers. They showed that approximating the value of this game to a polynomial inverse accuracy is QMA-complete. In [5], Chung, Wu, and Yuen further proved a parallel repetition for nonlocal games where again questions are classical and answers are quantum.

As fully quantum nonlocal games are a generalization of nonlocal games, Ji et al.'s result [16, 17] implies that it is also undecidable to approximately compute the quantum value of a fully quantum nonlocal game, even if they are only allowed to share MESs.

In this paper, we continue the line of research in [26] to investigate whether the hardness of fully quantum nonlocal games can be maintained against the noise. More specifically, we consider the games where the players share arbitrarily many copies of noisy MES's $\psi^{\mathcal{ST}}$. Each $\psi^{\mathcal{ST}}$ is a bipartite state in quantum system $\mathcal{S}\otimes\mathcal{T}$, where Alice and Bob hold $\mathcal{S}$ and $\mathcal{T}$, respectively. The value of a game can be written as

$$\mathrm{val}_Q(\mathfrak{G},\psi)=\lim_{n\to\infty}\max_{\Phi_{\mathsf{Alice}},\Phi_{\mathsf{Bob}}}\mathrm{Tr}\left[P_{\mathsf{win}}\left(\left(\Phi_{\mathsf{Alice}}\otimes\Phi_{\mathsf{Bob}}\right)\left(\phi_{\mathsf{in}}^{\mathcal{PQR}}\otimes\left(\psi^{\mathcal{ST}}\right)^{\otimes n}\right)\right)\right].$$

where the maximum is taken over all quantum operations $\Phi_{\mathsf{Alice}}:\mathcal{P}\otimes\mathcal{S}^{\otimes n}\to\mathcal{A}$ and $\Phi_{\mathsf{Bob}}:\mathcal{Q}\otimes\mathcal{T}^{\otimes n}\to\mathcal{B}$. Noisy MESs were introduced in [26], which will be defined later. They include depolarized EPR states $(1-\varepsilon)\left|\Psi\right\rangle\!\left\langle\Psi\right|+\varepsilon\mathbb{1}/2\otimes\mathbb{1}/2$, where $\varepsilon>0$ and $\left|\Psi\right\rangle=\left(\left|00\right\rangle+\left|11\right\rangle\right)/\sqrt{2}$ is an EPR state. [16, 17] proved that it is undecidable to approximate $\mathrm{val}_Q(\mathfrak{G},\left|\Psi\right\rangle)$ within constant precision.

Main results

In this paper, we prove that it is computable to approximate $\mathrm{val}_Q(\mathfrak{G},\psi)$ within arbitrarily small precision if ψ is a noisy MES.

▶ **Theorem 1** (Main result, informal). *Given integer $m\geq 2$, $\delta\in(0,1)$ and a fully quantum nonlocal game $\mathfrak{G}$, where players are allowed to share arbitrarily many copies m-dimensional noisy MESs ψ, there exists an explicitly computable bound $D=D\left(\varepsilon,\delta,m,\mathfrak{G}\right)$ such that it suffices for the players to share D copies of ψ to achieve the winning probability at least $\mathrm{val}_Q(\mathfrak{G},\psi)-\delta$. Thus it is feasible to approximate the quantum value of the game $(\mathfrak{G},\psi)$ to arbitrarily precision.*

As mentioned above, the class of noisy MESs includes $(1-\varepsilon)\left|\Psi\right\rangle\!\left\langle\Psi\right|+\varepsilon\mathbb{1}/2\otimes\mathbb{1}/2$, where $\varepsilon>0$ and Ψ is an EPR state. It is as hard as Halting problem to approximate $\mathrm{val}_Q(\mathfrak{G},\left|\Psi\right\rangle)$ proved by [16, 17]. Therefore, our result implies that the hardness of fully quantum nonlocal games is also not robust against the noise in the preshared states.

This result generalizes [26] where the authors proved that it is feasible to approximate the values when both questions and answers are classical. Both works are built on the series of works for the decidability of *non-interactive simulations of joint distributions* [12, 11, 7]. In the setting of non-interactive simulations of joint distributions, two non-communicating players Alice and Bob are provided a sequence of independent samples $(x_1,y_1),(x_2,y_2),\ldots$ from a joint distribution μ, where Alice observes $x_1,x_2,\ldots$ and Bob observes $y_1,y_2,\ldots$. The question is to decide what joint distribution ν Alice and Bob can sample. The research on this problem has a long history and fruitful results (see, for example [19] and the references

therein). The quantum analogue was first studied by Delgosha and Beigi [8], which is referred to as *local state transformation*. The decidability of local state transformation is still widely open. In this work, we prove that the local state transformation is decidable when the source states are noisy MESs.

1.1 Contributions

The main contribution in this paper is developing a Fourier-analytic framework for the study of the space of super-operators. Here we list some conceptual or technical contributions, which are believed to be interesting in their own right and have further applications in quantum information science.

1. Analysis in the space of super-operators.
   The space of super-operators is difficult to understand in general. In this paper, we make a crucial observation that the quantum value of a fully quantum nonlocal game can be reformulated in terms of the *Choi representations* of the adjoint maps of the quantum operations. Instead of the space of super-operators, we apply Fourier analysis to the space spanned by those Choi representations. Then we prove an invariance principle for super-operators as well as a dimension reduction for quantum operations, which generalize the analogous results in [26].
   Our understanding of Fourier analysis in the space of super-operators is still very limited, although Boolean analysis has been studied extensively in both mathematics and theoretical computer science for decades. The approach taken in this paper may pave the way for the theory of Fourier analysis in the space of super-operators.
2. Invariance principle for super-operators.
   The classical invariance principle is a central limit theorem for polynomials [23], which asserts that the distribution of a low-degree and flat polynomial with random inputs uniformly drawn from $\{\pm 1\}^n$ is close to the distribution which is obtained by replacing the inputs with i.i.d. standard normal distributions. Here a polynomial is flat means that no variable has high influence on the value of the polynomial. In [26], the authors established an invariance principle for matrix spaces. This paper further proves an invariance principle for super-operators. This is essential to reduce the number of shared noisy MESs.
3. Dimension reduction for quantum operations.
   An important step in our proof is a dimension reduction for quantum operations, which enables us to reduce the dimensions of both players' quantum operations. It, in turn, reduces the number of noisy MESs shared between the players. Dimension reductions for quantum operations are usually difficult and sometimes even impossible [13, 28]. In this paper, we prove a dimension reduction via an invariance principle for super-operators and the dimension reduction for polynomials in Gaussian spaces [11]. we adopt the techniques in [11] with a delicate analysis. It leads to an exponential upper bound in the main theorem. which also improves the doubly exponential upper bound in [26].

1.2 Comparison with [26]

In [26], the authors applied Fourier analysis to the Hilbert space where both players' measurements stay, and proved hypercontractive inequalities, quantum invariance principles and dimension reductions for matrices and random matrices. In a fully quantum nonlocal game, both players perform quantum operations. Hence, a natural approach is to further extend the framework in [12, 26] to the space of super-operators.

The first difficulty occurs as the answers are quantum. In [26], the authors applied the framework to each pair of POVM elements (one from Alice and one from Bob). Further taking a union bound, the result concludes. Hence, it suffices to work on the space where the POVM elements stay, which is a tensor product of identical Hilbert spaces. This approach fails when considering fully quantum nonlocal games as the answers are quantum. Hence, we need to have a convenient representation of super-operators to work on. It is known that there are several equivalent representations of super-operators [29]. In this paper, we choose the Choi representations of super-operators, which view a super-operator as an operator in the tensor product of the input space and the output space. Hence, the underlying Hilbert space is a tensor product of a number of identical Hilbert spaces and the output Hilbert space. Thus, the analysis in [26] cannot be generalized here directly.

The second difficulty occurs as the questions are quantum. In [26], the authors essentially proved an upper bound on the number of noisy MESs for each pair of inputs. If the precision of the approximation is good enough, then we can obtain an upper bound for all inputs again by a union bound because the questions are finite in a nonlocal game. This argument cannot be directly generalized to fully nonlocal games as the questions are the marginal state of the input state with Alice and Bob. Fortunately, this difficulty can be avoided as the input state is in a bounded-dimensional space and thus it suffices to prove the theorem for each basis element from a properly chosen basis in the space, and then take a union bound.

The last difficulty is that the rounding argument in [26] does not apply to fully quantum nonlocal games. In the end of the construction, the new super-operators are no longer valid quantum operations. In [26], the construction gives a number of Hermitian operators in the end. The rounding argument proves that it is possible to round these Hermitian operators to valid POVMs with small deviation. For fully quantum nonlocal games we need a new rounding argument which is able to round super-operators to valid quantum operations with small deviation in the end of the construction.

1.3 Proof overview

The proof is built on the framework in [12, 11, 7] for the decidability of non-interactive simulation of joint distributions. To explain the high-level idea of our proof, we start with the decidability of a particular task of local state transformation. Then we explain how to generalize it to nonlocal games.

Local state transformation

We are interested in the decidability of the following local state transformation problem.

Given $\delta > 0$, a bipartite state σ and a noisy MES ψ, suppose Alice and Bob share arbitrarily many copies of ψ.

- **Yes**. Alice and Bob are able to jointly generate a bipartite state σ' using only local operations such that σ' is δ-close to σ, i.e., $\|\sigma - \sigma'\|_1 \leq \delta$.
- **No**. Any quantum state σ' that Alice and Bob can jointly generate using only local operations is 2δ-far from σ, i.e., $\|\sigma - \sigma'\|_1 \geq 2\delta$.

As there is no upper bound on the number of copies of ψ, the decidability of this question is unclear. If it were proved that any quantum operation could be simulated by a quantum operation in a bounded dimension, then the problem would be decidable as we could search

all possible quantum operations in a bounded-dimensional space via an ε-net and brute force. More specifically, suppose Alice and Bob share n copies of noisy MESs ψ and they perform quantum operations Φ_{Alice} and Φ_{Bob}. For any precision parameter $\delta \in (0,1)$, we need to construct quantum operations $\widetilde{\Phi_{\mathsf{Alice}}}$ and $\widetilde{\Phi_{\mathsf{Bob}}}$ acting on D copies of ψ, where D is independent of n, such that

$$\left(\Phi_{\mathsf{Alice}} \otimes \Phi_{\mathsf{Bob}}\right)\left(\psi^{\otimes n}\right) \approx \left(\widetilde{\Phi_{\mathsf{Alice}}} \otimes \widetilde{\Phi_{\mathsf{Bob}}}\right)\left(\psi^{\otimes D}\right). \tag{1}$$

To explain the high-level ideas, we assume that ψ is a 2-qubit quantum state for simplicity. Let $\{\mathcal{X}_a\}_{a\in\{0,1,2,3\}}$ be an orthonormal basis in the space of 2×2 matrices. We observe that the left hand side of Equation (1) is determined by the following 4^{2n} values:

$$\left\{\mathrm{Tr}\left[\left(\mathcal{X}_a \otimes \mathcal{X}_b\right)\left(\left(\Phi_{\mathsf{Alice}} \otimes \Phi_{\mathsf{Bob}}\right)\left(\psi^{\otimes n}\right)\right)\right]\right\}_{a,b\in\{0,1,2,3\}^n},$$

where $\mathcal{X}_a = \mathcal{X}_{a_1} \otimes \cdots \otimes \mathcal{X}_{a_n}$. Notice that

$$\mathrm{Tr}\left[\left(\mathcal{X}_a \otimes \mathcal{X}_b\right)\left(\left(\Phi_{\mathsf{Alice}} \otimes \Phi_{\mathsf{Bob}}\right)\left(\psi^{\otimes n}\right)\right)\right] = \mathrm{Tr}\left[\left(\left(\Phi_{\mathsf{Alice}}\right)^*\left(\mathcal{X}_a\right) \otimes \left(\Phi_{\mathsf{Bob}}\right)^*\left(\mathcal{X}_b\right)\right)\left(\psi^{\otimes n}\right)\right],$$

where $\left(\Phi_{\mathsf{Alice}}\right)^*$ and $\left(\Phi_{\mathsf{Bob}}\right)^*$ are the adjoints of Φ_{Alice} and Φ_{Bob}, respectively. Hence, Equation (1) is equivalent to

$$\mathrm{Tr}\left[\left(\left(\Phi_{\mathsf{Alice}}\right)^*\left(\mathcal{X}_a\right) \otimes \left(\Phi_{\mathsf{Bob}}\right)^*\left(\mathcal{X}_b\right)\right)\psi^{\otimes n}\right] \approx \mathrm{Tr}\left[\left(\left(\widetilde{\Phi_{\mathsf{Alice}}}\right)^*\left(\mathcal{X}_a\right) \otimes \left(\widetilde{\Phi_{\mathsf{Bob}}}\right)^*\left(\mathcal{X}_b\right)\right)\psi^{\otimes D}\right]. \tag{2}$$

Equation (2) resembles the setting considered in [26]. It is proved in [26] that for any POVM $\{M_i \otimes N_j\}_{i,j}$ acting on $\psi^{\otimes n}$, there exists POVM $\left\{M'_i \otimes N'_j\right\}_{i,j}$ acting on $\psi^{\otimes D}$ such that

$$\mathrm{Tr}\left[\left(M_i \otimes N_j\right)\psi^{\otimes n}\right] \approx \mathrm{Tr}\left[\left(M'_i \otimes N'_j\right)\psi^{\otimes D}\right],$$

for all i,j. However, $\left(\Phi_{\mathsf{Alice}}\right)^*\left(\mathcal{X}_a\right)$ and $\left(\Phi_{\mathsf{Bob}}\right)^*\left(\mathcal{X}_b\right)$ are not positive. It is even not clear how to characterize $\left(\Phi_{\mathsf{Alice}}\right)^*\left(\mathcal{X}_a\right)$ and $\left(\Phi_{\mathsf{Bob}}\right)^*\left(\mathcal{X}_b\right)$ for valid quantum operations Φ_{Alice} and Φ_{Bob}. Thus we cannot directly apply the results in [26]. Instead of working on each of $\left(\Phi_{\mathsf{Alice}}\right)^*\left(\mathcal{X}_a\right)$ and $\left(\Phi_{\mathsf{Bob}}\right)^*\left(\mathcal{X}_b\right)$, we work on the Choi representations $J\left(\left(\Phi_{\mathsf{Alice}}\right)^*\right)$ and $J\left(\left(\Phi_{\mathsf{Bob}}\right)^*\right)$, which include the information of $\left(\Phi_{\mathsf{Alice}}\right)^*\left(\mathcal{X}_a\right)$ and $\left(\Phi_{\mathsf{Bob}}\right)^*\left(\mathcal{X}_b\right)$ for all a,b. One more advantage of Choi representations is that we have a neat characterization of the Choi representations of quantum operations. Thus it is more convenient to bound the deviations of the intermediate super-operators from valid quantum operations throughout the construction. We consider the Fourier expansions of $J\left(\left(\Phi_{\mathsf{Alice}}\right)^*\right)$ and $J\left(\left(\Phi_{\mathsf{Bob}}\right)^*\right)$, and reduce the dimensions of the super-operators via the framework for the decidability of non-interactive simulations of joint distributions in [12, 11, 7, 26]. To this end, we prove an invariance principle for super-operators, and combine it with the dimension reduction for polynomials in Gaussian spaces [11]. There are several prerequisites for the invariance principle. Firstly, the Choi representation should have low degree. Secondly, all but a constant number of systems are of low influence, that is, all but a constant number of subsystems do not influence the super-operators much. The construction takes several steps to adjust the Fourier coefficients of $J\left(\left(\Phi_{\mathsf{Alice}}\right)^*\right)$ and $J\left(\left(\Phi_{\mathsf{Bob}}\right)^*\right)$ to meet those prerequisites. Meanwhile, the new super-operators still need to be close to valid quantum operations so that the value of the game does not change much. Once these prerequisites are satisfied, the basis elements in those subsystems with low influence are replaced by properly chosen Gaussian variables, which only causes a small deviation by the invariance principle.

Each step is sketched as follows.

1. **Smoothing**

   This step is aimed to obtain bounded-degree approximations of $J\left((\Phi_{\mathsf{Alice}})^*\right)$ and $J\left((\Phi_{\mathsf{Bob}})^*\right)$. We apply a noise operator Δ_γ for some $\gamma \in (0,1)$ defined in Definition 10 to both $J\left((\Phi_{\mathsf{Alice}})^*\right)$ and $J\left((\Phi_{\mathsf{Bob}})^*\right)$ on the input spaces. Note that both Choi representations are positive operators. After smoothing the operation and truncating the high-degree parts, we get bounded-degree approximations $M^{(1)}$ and $N^{(1)}$, of $J\left((\Phi_{\mathsf{Alice}})^*\right)$ and $J\left((\Phi_{\mathsf{Bob}})^*\right)$, respectively. Though the bounded-degree approximations may no longer be positive, the deviation can be proved to be small.

2. **Regularity**

   This step is aimed to prove that the number of subsystems having high influence is bounded. The influence of a subsystem of a multipartite Hermitian operator is defined in Definition 3. Informally speaking, the influence measures how much the subsystem can affect the operator. For a bounded operator, the total influence, which is the summation of the influences of all subsystems, is upper bounded by the degree of the operator. This is a generalization of a standard result in Boolean analysis. Note that we have bounded-degree approximations after the first step. The desired result follows by a Markov inequality.

3. **Invariance principle**

   In this step, we use correlated Gaussian variables to substitute the basis elements in all the subsystems with low influence in $M^{(1)}$ and $N^{(1)}$, after which we get random operators $\mathbf{M}^{(2)}$ and $\mathbf{N}^{(2)}$, whose Fourier coefficients are low-degree multilinear polynomials in Gaussian variables. We also need to prove that, $\mathbf{M}^{(2)}$ and $\mathbf{N}^{(2)}$ are close to positive operators in expectation.

4. **Dimension reduction**

   This step is aimed to reduce the number of Gaussian variables. After applying a dimension reduction to $\mathbf{M}^{(2)}$ and $\mathbf{N}^{(2)}$, we get random operators $\mathbf{M}^{(3)}$ and $\mathbf{N}^{(3)}$ containing a bounded number of Gaussian random variables. Unlike [26], we get an upper bound independent of the number of quantum subsystems via a more delicate analysis. However, the Fourier coefficients of $\mathbf{M}^{(3)}$ and $\mathbf{N}^{(3)}$ are no longer low-degree polynomials after the dimension reduction.

5. **Smooth random operators**

   The remaining steps are mainly concerned with removing the Gaussian variables. This step is aimed to get low-degree approximations of the Fourier coefficients of $\mathbf{M}^{(3)}$ and $\mathbf{N}^{(3)}$. We apply the Ornstein-Uhlenbeck operator (aka noise operators in Gaussian space) to the Gaussian variables in $\mathbf{M}^{(3)}$ and $\mathbf{N}^{(3)}$ and truncate the high-degree parts to get $\mathbf{M}^{(4)}$ and $\mathbf{N}^{(4)}$. We should note that the Fourier coefficients of $\mathbf{M}^{(4)}$ and $\mathbf{N}^{(4)}$ are polynomials, but not multilinear.

6. **Multilinearization**

   This step is aimed to get multilinear approximations of the Fourier coefficients of $\mathbf{M}^{(4)}$ and $\mathbf{N}^{(4)}$. To this end, We apply the multilinearization lemma in [11] to get random operators $\mathbf{M}^{(5)}$ and $\mathbf{N}^{(5)}$. Now we are ready to use the invariance principle again to convert random operators back to operators.

7. **Invariance to operators**

   In this step we substitute the Gaussian variables with properly chosen basis elements, to get operators $M^{(6)}$ and $N^{(6)}$, which have a bounded number of quantum subsystems. Again, we need to apply a quantum invariance principle to ensure that $M^{(6)}$ and $N^{(6)}$ are close to positive operators.

8. **Rounding**
   We now have operators $M^{(6)}$ and $N^{(6)}$ that are close to positive operators. The last thing to do is to round them to the Choi representations of the adjoints of some quantum operations. After the rounding, the whole construction is done.

2 Preliminary

Given $n \in \mathbb{Z}_{>0}$, let $[n]$ and $[n]_{\geq 0}$ represent the sets $\{1, \ldots, n\}$ and $\{0, \ldots, n-1\}$, respectively. For all $a \in \mathbb{Z}_{\geq 0}^n$, we define $|a| = |\{i : a_i > 0\}|$. In this paper, the lower-cased letters in bold $\mathbf{g}, \mathbf{h}, \ldots$ are reserved for random variables, and the capital letters in bold $\mathbf{M}, \mathbf{N}$ are reserved for random operators.

2.1 Quantum mechanics

We denote the set of Hermitian operators in a quantum system $\mathcal{S}$ by $\mathcal{H}_\mathcal{S}$. The identity operator is denoted by $\mathbb{1}_\mathcal{S}$. We use the shorthand $\mathcal{SA}$ to represent $\mathcal{S} \otimes \mathcal{A}$. The Hermitian space of the composition of n Hermitian space $\mathcal{H}_\mathcal{S}$ is denoted by $\mathcal{H}_\mathcal{S}^{\otimes n}$, or $\mathcal{H}_\mathcal{S}^n$ for short.

Given quantum systems $\mathcal{S}, \mathcal{A}$, let $\mathcal{L}(\mathcal{S}, \mathcal{A})$ denote the set of all linear maps from $\mathcal{M}_\mathcal{S}$ to $\mathcal{M}_\mathcal{A}$ A quantum operation from the input system $\mathcal{S}$ to the output system $\mathcal{A}$ is represented by a CPTP (completely positive and trace preserving) map $\Phi \in \mathcal{L}(\mathcal{S}, \mathcal{A})$. We define $\psi^\mathcal{S} = \mathrm{Tr}_\mathcal{A}\, \psi^{\mathcal{SA}}$ to represent the state obtained by tracing out system $\mathcal{A}$ from $\psi^{\mathcal{SA}}$.

For a given map $\Phi \in \mathcal{L}(\mathcal{S}, \mathcal{A})$, the adjoint of Φ is defined to be the unique map $\Phi^* \in \mathcal{L}(\mathcal{A}, \mathcal{S})$ that satisfies

$$\mathrm{Tr}\ \Phi^*(Q)^\dagger P = \mathrm{Tr}\ Q^\dagger \Phi(P) \quad \text{for all } P \in \mathcal{L}(\mathcal{S}) \text{ and } Q \in \mathcal{L}(\mathcal{A}). \tag{3}$$

Given $\Psi \in \mathcal{L}(\mathcal{A}, \mathcal{S})$, the Choi representation of Ψ is a linear map $J : \mathcal{L}(\mathcal{A}, \mathcal{S}) \to \mathcal{H}(\mathcal{SA})$ defined as follows:

$$J(\Psi) = \sum_a \Psi\left(\widetilde{\mathcal{A}_a}\right) \otimes \widetilde{\mathcal{A}_a}, \tag{4}$$

where $\widetilde{\mathcal{A}_a} = \mathcal{A}_a / \sqrt{|\mathcal{A}|}$[1], and $\left\{\mathcal{A}_a : a \in \left[|\mathcal{A}|^2\right]_{\geq 0}\right\}$ is an orthonormal basis in $\mathcal{A}$. J is a linear bijection. Ψ can be recovered from its Choi representation $J(\Psi)$ as follows.
