$$\Psi(P) = \mathrm{Tr}_\mathcal{A}\left(J(\Psi)\left(\mathbb{1}_\mathcal{S} \otimes P^\dagger\right)\right). \tag{5}$$

▶ **Fact 2.** *$\Phi \in \mathcal{L}(\mathcal{S}, \mathcal{A})$ is a quantum operation if and only if $J(\Phi^*) \geq 0$ and $\mathrm{Tr}_\mathcal{A} J(\Phi^*) = \mathbb{1}_\mathcal{S}$.*

2.2 Fourier analysis in Gaussian space

Given $n \in \mathbb{Z}_{>0}$, let γ_n represent a standard n-dimensional normal distribution. A function $f : \mathbb{R}^n \to \mathbb{R}$ is in $L^2(\mathbb{R}, \gamma_n)$ if $\int_{\mathbb{R}^n} f(x)^2 \gamma_n(\mathrm{d}x) < \infty$.

All the functions involved in this paper are in $L^2(\mathbb{R}, \gamma_n)$. We equip $L^2(\mathbb{R}, \gamma_n)$ with an inner product $\langle f, g \rangle_{\gamma_n} = \mathbb{E}_{x \sim \gamma_n}[f(x)g(x)]$.

[1] The denominator is because of the demoninator in the definition of the inner product $\frac{1}{\mathsf{s}}\mathrm{Tr}\ P^\dagger Q$.

The set of *Hermite polynomials* forms an orthonormal basis in $L^2(\mathbb{R}, \gamma_1)$ with respect to the inner product $\langle \cdot, \cdot \rangle_{\gamma_1}$. The Hermite polynomials $H_r : \mathbb{R} \to \mathbb{R}$ for $r \in \mathbb{Z}_{\geq 0}$ are defined as

$$H_0(x) = 1; H_1(x) = x; H_r(x) = \frac{(-1)^r}{\sqrt{r!}} e^{x^2/2} \frac{\mathrm{d}^r}{\mathrm{d}x^r} e^{-x^2/2}.$$

For any $\sigma \in (\sigma_1, \ldots, \sigma_n) \in \mathbb{Z}^n_{\geq 0}$, define $H_\sigma : \mathbb{R}^n \to \mathbb{R}$ as $H_\sigma(x) = \prod_{i=1}^n H_{\sigma_i}(x_i)$.

The set $\left\{H_\sigma : \sigma \in \mathbb{Z}^n_{\geq 0}\right\}$ forms an orthonormal basis in $L^2(\mathbb{R}, \gamma_n)$. Every function $f \in L^2(\mathbb{R}, \gamma_n)$ has an *Hermite expansion* as

$$f(x) = \sum_{\sigma \in \mathbb{Z}^n_{\geq 0}} \widehat{f}(\sigma) \cdot H_\sigma(x),$$

where $\widehat{f}(\sigma)$'s are the *Hermite coefficients* of f, which can be obtained by $\widehat{f}(\sigma) = \langle H_\sigma, f \rangle_{\gamma_n}$.

We say $f \in L^2(\mathbb{R}, \gamma_n)$ is *multilinear* if $\widehat{f}(\sigma) = 0$ for $\sigma \notin \{0,1\}^n$.

▶ **Definition 3.** *The* influence *of the i-th coordinate(variable) on f, denoted by* $\mathrm{Inf}_i(f)$*, is defined by*

$$\mathrm{Inf}_i(f) = \mathop{\mathbb{E}}_{\mathbf{x} \sim \gamma_n} \left[\mathrm{Var}_{\mathbf{x}'_i \sim \gamma_1} [f(\mathbf{x}_1, \ldots, \mathbf{x}_{i-1}, \mathbf{x}'_i, \mathbf{x}_{i+1}, \ldots \mathbf{x}_n)] \right].$$

The following fact summarizes some basic properties of variance and influence.

▶ **Fact 4** ([25, Proposition 8.16 and Proposition 8.23])**.** *Given $f \in L^2(\mathbb{R}, \gamma_n)$, it holds that*

1. $\mathrm{Var}[f] = \sum_{\sigma \neq 0^n} \widehat{f}(\sigma)^2 \leq \sum_\sigma \widehat{f}(\sigma)^2 = \|f\|_2^2$.
2. $\mathrm{Inf}_i(f) = \sum_{\sigma_i \neq 0} \widehat{f}(\sigma)^2 \leq \mathrm{Var}[f]$.

2.3 Fourier analysis in matrix space

Given $1 \leq m, p \leq \infty$, and $H \in \mathcal{H}_m$, the p-norm of H is defined to be

$$\|H\|_p = \left(\mathrm{Tr} \left(H^2 \right)^{p/2} \right)^{1/p}.$$

The *normalized p-norm* of H is defined as

$$|||H|||_p = \left(\frac{1}{m} \mathrm{Tr} \left(H^2 \right)^{p/2} \right)^{1/p}.$$

Given $P, Q \in \mathcal{H}_m$, we define an inner product over $\mathbb{R}$:

$$\langle P, Q \rangle = \frac{1}{m} \mathrm{Tr}\, PQ.$$

We need the following particular classes of bases in $\mathcal{H}_m$ on which our Fourier analysis is based.

▶ **Definition 5.** *Let $\{\mathcal{B}_i\}_{i \in [m^2]_{\geq 0}}$ be an orthonormal basis in $\mathcal{H}_m$ over $\mathbb{R}$. We say $\{\mathcal{B}_i\}_{i \in [m^2]_{\geq 0}}$ is a standard orthonormal basis if $\mathcal{B}_0 = \mathbb{1}_m$.*

▶ **Fact 6.** *Let $\{\mathcal{B}_i\}_{i=0}^{m^2-1}$ be a standard orthonormal basis in $\mathcal{H}_m$. Then the set $\left\{\mathcal{B}_\sigma = \otimes_{i=1}^n \mathcal{B}_{\sigma_i} : \sigma \in [m^2]^n_{\geq 0}\right\}$ is a standard orthonormal basis in $\mathcal{H}_m^{\otimes n}$.*

Given a standard orthonormal basis $\{\mathcal{B}_i\}_{i=0}^{m^2-1}$ in $\mathcal{H}_m$, every $H \in \mathcal{H}_m^{\otimes n}$ has a Fourier expansion:

$$H = \sum_{\sigma \in [m^2]_{\geq 0}^n} \widehat{H}(\sigma) \mathcal{B}_\sigma,$$

where $\widehat{H}(\sigma) \in \mathbb{R}$ are the Fourier coefficients. The basic properties of $\widehat{H}(\sigma)$'s are summarized in the following fact, which can be easily derived from the orthonormality of $\{\mathcal{B}_\sigma\}_{\sigma \in [m^2]_{\geq 0}^n}$.

▶ **Fact 7** ([26, Fact 2.11]). *Given a standard orthonormal basis $\{\mathcal{B}_i\}_{i \in [m^2]_{\geq 0}}$ in $\mathcal{H}_m$ and $M, N \in \mathcal{H}_m$, it holds that*

1. $\langle M, N \rangle = \sum_\sigma \widehat{M}(\sigma) \widehat{N}(\sigma)$.
2. $\|\|M\|\|_2^2 = \langle M, M \rangle = \sum_\sigma \widehat{M}(\sigma)^2$.
3. $\langle \mathbb{1}_m, M \rangle = \widehat{M}(0)$.

▶ **Definition 8.** *Let $\mathcal{B} = \{\mathcal{B}_i\}_{i \in [m^2]_{\geq 0}}$ be a standard orthonormal basis in $\mathcal{H}_m$, $P, Q \in \mathcal{H}_m^{\otimes n}$*

1. *The degree of P is defined to be* $\deg P = \max\left\{|\sigma| : \widehat{P}(\sigma) \neq 0\right\}$.
2. *For any $i \in [n]$, the influence of i-th coordinate is defined to be*

$$\mathrm{Inf}_i(P) = \|\|P - \mathbb{1}_m \otimes \mathrm{Tr}_i P\|\|_2^2,$$

   where $\mathbb{1}_m$ is in the i'th quantum system, and Tr_i means tracing out the i'th system.
3. *The total influence of P is defined to be* $\mathrm{Inf}(P) = \sum_i \mathrm{Inf}_i(P)$.

▶ **Fact 9** ([26, Lemma 2.16]). *Given $P \in \mathcal{H}_m^{\otimes n}$, a standard orthonormal basis $\mathcal{B} = \{\mathcal{B}_i\}_{i \in [m^2]_{\geq 0}}$ in $\mathcal{H}_m$, it holds that*

1. $\mathrm{Inf}_i(P) = \sum_{\sigma : \sigma_i \neq 0} \left|\widehat{P}(\sigma)\right|^2$.
2. $\mathrm{Inf}(P) = \sum_\sigma |\sigma| \left|\widehat{P}(\sigma)\right|^2 \leq \deg P \cdot \|\|P\|\|_2^2$.

▶ **Definition 10.** *Given a quantum system $\mathcal{S}$ with dimension $|\mathcal{S}| = \mathsf{s}$, $\gamma \in [0,1]$, the depolarizing operation $\Delta_\gamma : \mathcal{H}_\mathcal{S} \to \mathcal{H}_\mathcal{S}$ is defined as follows. For any $P \in \mathcal{H}_\mathcal{S}$,*

$$\Delta_\gamma(P) = \gamma P + \frac{1-\gamma}{\mathsf{s}} (\mathrm{Tr}\ P) \cdot \mathbb{1}_\mathcal{S}.$$

▶ **Fact 11** ([26, Lemma 3.6 and Lemma 6.1]). *Given $n, m \in \mathbb{Z}_{>0}$, $\gamma \in [0,1]$, a standard orthonormal basis of $\mathcal{H}_m$: $\mathcal{B} = \{\mathcal{B}_i\}_{i=0}^{m^2-1}$, the following holds:*

1. *For any $P \in \mathcal{H}_m^{\otimes n}$ with a Fourier expansion $P = \sum_{\sigma \in [m^2]_{\geq 0}^n} \widehat{P}(\sigma) \mathcal{B}_\sigma$, it holds that*

$$\Delta_\gamma(P) = \sum_{\sigma \in [m^2]_{\geq 0}^n} \gamma^{|\sigma|} \widehat{P}(\sigma) \mathcal{B}_\sigma.$$

2. *For any $P \in \mathcal{H}_m^{\otimes n}$, $\|\|\Delta_\gamma(P)\|\|_2 \leq \|\|P\|\|_2$.*
3. *Δ_γ is a quantum operation.*
4. *For any $d \in \mathbb{Z}_{>0}, P \in \mathcal{H}_m^{\otimes n}$, it holds that $\left\|\left|(\Delta_\gamma(P))^{>d}\right|\right\|_2 \leq \gamma^d \|\|P\|\|_2$.*

▶ **Definition 12** (Maximal correlation). *[1] Given quantum systems $\mathcal{S}, \mathcal{T}$ with dimensions $\mathsf{s} = |\mathcal{S}|$ and $\mathsf{t} = |\mathcal{T}|$, $\psi^{\mathcal{S}\mathcal{T}} \in \mathcal{H}_{\mathcal{S}\mathcal{T}}$ with $\psi^\mathcal{S} = \mathbb{1}_\mathcal{S}/\mathsf{s}, \psi^\mathcal{T} = \mathbb{1}_\mathcal{T}/\mathsf{t}$, the maximal correlation of $\psi^{\mathcal{S}\mathcal{T}}$ is defined to be*

$$\rho\left(\psi^{\mathcal{S}\mathcal{T}}\right) = \sup\left\{ \begin{smallmatrix} \left|\mathrm{Tr}\left((P \otimes Q)\psi^{\mathcal{S}\mathcal{T}}\right)\right| : P \in \mathcal{H}_\mathcal{S}, Q \in \mathcal{H}_\mathcal{T}, \\ \mathrm{Tr}\ P = \mathrm{Tr}\ Q = 0, \|\|P\|\|_2 = \|\|Q\|\|_2 = 1 \end{smallmatrix} \right\}.$$

2.4 Random operators

In this subsection, we introduce random operators defined in [26], which unifies Gaussian variables and operators.

▶ **Definition 13** ([26]). *Given $p, h, n, m \in \mathbb{Z}_{>0}$, we say $\mathbf{P}$ is a random operator if it can be expressed as*

$$\mathbf{P} = \sum_{\sigma \in [m^2]_{\geq 0}^h} p_\sigma(\mathbf{g}) \mathcal{B}_\sigma,$$

where $\{\mathcal{B}_i\}_{i \in [m^2]_{\geq 0}}$ is a standard orthonormal basis in $\mathcal{H}_m$, $p_\sigma : \mathbb{R}^n \to \mathbb{R}$ for all $\sigma \in [m^2]_{\geq 0}^h$ and $\mathbf{g} \sim \gamma_n$. $\mathbf{P} \in L^p\left(\mathcal{H}_m^{\otimes h}, \gamma_n\right)$ if $p_\sigma \in L^p(\mathbb{R}, \gamma_n)$ for all $\sigma \in [m^2]_{\geq 0}^h$.

We say $\mathbf{P}$ is multilinear if $p_\sigma(\cdot)$ is multilinear for all $\sigma \in [m^2]_{\geq 0}^h$.

▶ **Fact 14** ([26, Lemma 2.23]). *Given $n, h, m \in \mathbb{Z}_{>0}$, let $\mathbf{P} \in L^2\left(\mathcal{H}_m^{\otimes h}, \gamma_n\right)$ with an associated vector-valued function p under a standard orthonormal basis. It holds that $\mathbb{E}\left[\|\mathbf{P}\|_2^2\right] = \|p\|_2^2$.*

2.5 Rounding maps

Define a function $\zeta : \mathbb{R} \to \mathbb{R}$ as follows.

$$\zeta(x) = \begin{cases} x^2 & \text{if } x \leq 0 \\ 0 & \text{otherwise} \end{cases}. \tag{6}$$

The function ζ measures the distance between an Hermitian operator and the set of positive semi-definite operators in 2-norm.

▶ **Fact 15** ([26, Lemma 9.1]). *Given $m \in \mathbb{Z}_{>0}$, $H \in \mathcal{H}_m$, it holds that*

$$\operatorname{Tr} \zeta(H) = \min\left\{\|H - X\|_2^2 : X \geq 0\right\}.$$

3 Main results

▶ **Theorem 16.** *Given $\epsilon \in (0,1)$, $n, s \in \mathbb{Z}_{>0}$, and quantum systems $\mathcal{P}, \mathcal{Q}, \mathcal{R}, \mathcal{S}, \mathcal{T}, \mathcal{A}, \mathcal{B}$ with dimensions $\mathsf{p} = |\mathcal{P}|, \mathsf{q} = |\mathcal{Q}|, \mathsf{r} = |\mathcal{R}|, \mathsf{s} = |\mathcal{S}|, \mathsf{t} = |\mathcal{T}|, \mathsf{a} = |\mathcal{A}|, \mathsf{b} = |\mathcal{B}|$. Let $\{\mathcal{A}_a\}_{a \in [\mathsf{a}^2]_{\geq 0}}$, $\{\mathcal{B}_b\}_{b \in [\mathsf{b}^2]_{\geq 0}}$, $\{\mathcal{R}_r\}_{r \in [\mathsf{r}^2]_{\geq 0}}$ be orthonormal bases in $\mathcal{H}_\mathcal{A}$, $\mathcal{H}_\mathcal{B}$ and $\mathcal{H}_\mathcal{R}$, respectively. Let $\psi^{\mathcal{ST}} \in \mathcal{H}_{\mathcal{ST}}$ be a noisy MES with the maximal correlation $\rho = \rho\left(\psi^{\mathcal{ST}}\right) < 1$, which is defined in Definition 12. Let $\phi_{in}^{\mathcal{PQR}} \in \mathcal{H}_{\mathcal{PQR}}$ be an arbitrary tripartite quantum state. Then there exists an explicitly computable $D = D(\rho, \epsilon, s, \mathsf{p}, \mathsf{q}, \mathsf{r}, \mathsf{s}, \mathsf{t}, \mathsf{a}, \mathsf{b})$, such that for all quantum operations $\Phi_{Alice} \in \mathcal{L}\left(\mathcal{S}^n\mathcal{P}, \mathcal{A}\right)$, $\Phi_{Bob} \in \mathcal{L}\left(\mathcal{T}^n\mathcal{Q}, \mathcal{B}\right)$, there exist quantum operations $\widetilde{\Phi_{Alice}} \in \mathcal{L}\left(\mathcal{S}^D\mathcal{P}, \mathcal{A}\right)$, $\widetilde{\Phi_{Bob}} \in \mathcal{L}\left(\mathcal{T}^D\mathcal{Q}, \mathcal{B}\right)$ such that for all $a \in \left[\mathsf{a}^2\right]_{\geq 0}$, $b \in \left[\mathsf{b}^2\right]_{\geq 0}$, $r \in \left[\mathsf{r}^2\right]_{\geq 0}$,* [2]

$$\left|\operatorname{Tr}\left[\left(\Phi_{Alice}^*\left(\widetilde{\mathcal{A}_a}\right) \otimes \Phi_{Bob}^*\left(\widetilde{\mathcal{B}_b}\right) \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{in}^{\mathcal{PQR}} \otimes \left(\psi^{\mathcal{ST}}\right)^{\otimes n}\right)\right]\right.$$
$$\left. - \operatorname{Tr}\left[\left(\widetilde{\Phi_{Alice}^*}\left(\widetilde{\mathcal{A}_a}\right) \otimes \widetilde{\Phi_{Bob}^*}\left(\widetilde{\mathcal{B}_b}\right) \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{in}^{\mathcal{PQR}} \otimes \left(\psi^{\mathcal{ST}}\right)^{\otimes D}\right)\right]\right| \leq \epsilon.$$

In particular, one may choose

$$D = \exp\left(\operatorname{poly}\left(\mathsf{a}, \mathsf{b}, \mathsf{p}, \mathsf{q}, \mathsf{r}, \log \mathsf{s}, \log \mathsf{t}, \frac{1}{1-\rho}, \frac{1}{\epsilon}\right)\right).$$

[2] Remind that $\widetilde{\mathcal{A}_a} = \mathcal{A}_a/\sqrt{\mathsf{a}}$, $\widetilde{\mathcal{B}_b} = \mathcal{B}_b/\sqrt{\mathsf{b}}$ and $\widetilde{\mathcal{R}_r} = \mathcal{R}_r/\sqrt{\mathsf{r}}$.

▶ **Theorem 17.** *Given parameters $0 < \epsilon, \rho < 1$, and a fully quantum nonlocal game*

$$\mathfrak{G} = \left(\mathcal{P}, \mathcal{Q}, \mathcal{R}, \mathcal{A}, \mathcal{B}, \phi_{in}, \left\{M^{\mathcal{ABR}}, \mathbb{1} - M^{\mathcal{ABR}}\right\}\right),$$

with dimensions $\mathsf{p} = |\mathcal{P}|, \mathsf{q} = |\mathcal{Q}|, \mathsf{r} = |\mathcal{R}|, \mathsf{s} = |\mathcal{S}|, \mathsf{t} = |\mathcal{T}|, \mathsf{a} = |\mathcal{A}|, \mathsf{b} = |\mathcal{B}|$, suppose the two players are restricted to share an arbitrarily finite number of noisy MES states $\psi^{\mathcal{ST}}$, i.e., $\psi^{\mathcal{S}} = \mathbb{1}_{\mathcal{S}}/\mathsf{s}$, $\psi^{\mathcal{T}} = \mathbb{1}_{\mathcal{T}}/\mathsf{t}$ with the maximal correlation $\rho < 1$ as defined in Definition 12. Let $\mathrm{val}_Q(\mathfrak{G}, \psi^{\mathcal{ST}})$ be the supremum of the winning probability that the players can achieve. Then there exists an explicitly computable bound $D = D(\rho, \epsilon, \mathsf{p}, \mathsf{q}, \mathsf{r}, \mathsf{s}, \mathsf{t}, \mathsf{a}, \mathsf{b})$ such that it suffices for the players to share D copies of $\psi^{\mathcal{ST}}$ to achieve the winning probability at least $\mathrm{val}_Q(\mathfrak{G}, \psi^{\mathcal{ST}}) - \epsilon$. In particular, one may choose

$$D = \exp\left(\mathrm{poly}\left(\mathsf{a}, \mathsf{b}, \mathsf{p}, \mathsf{q}, \mathsf{r}, \log \mathsf{s}, \log \mathsf{t}, \frac{1}{1-\rho}, \frac{1}{\epsilon}\right)\right).$$

Proof. To keep the notations short, the superscripts will be omitted whenever it is clear from the context. Suppose the players share n copies of $\psi^{\mathcal{ST}}$ and employ the strategy $(\Phi_{\mathsf{Alice}}, \Phi_{\mathsf{Bob}})$ with the winning probability $\mathrm{val}_Q(\mathfrak{G}, \psi^{\mathcal{ST}})$. We apply Theorem 16 to $(\Phi_{\mathsf{Alice}}, \Phi_{\mathsf{Bob}})$ with $\epsilon \leftarrow \epsilon/(\mathsf{abr})^{3/2}$ to obtain $\left(\widetilde{\Phi_{\mathsf{Alice}}}, \widetilde{\Phi_{\mathsf{Bob}}}\right)$. We claim that the strategy $\left(\widetilde{\Phi_{\mathsf{Alice}}}, \widetilde{\Phi_{\mathsf{Bob}}}\right)$ wins the game with probability at least $\mathrm{val}_Q(\mathfrak{G}, \psi^{\mathcal{ST}}) - \epsilon$.

Let $\{\mathcal{A}_a\}_{a \in [\mathsf{a}^2]_{\geq 0}}$, $\{\mathcal{B}_b\}_{b \in [\mathsf{b}^2]_{\geq 0}}$, $\{\mathcal{R}_r\}_{r \in [\mathsf{r}^2]_{\geq 0}}$ be orthonormal bases in $\mathcal{H}_{\mathcal{A}}$, $\mathcal{H}_{\mathcal{B}}$ and $\mathcal{H}_{\mathcal{R}}$, respectively. From Theorem 16, for all $a \in \left[\mathsf{a}^2\right]_{\geq 0}$, $b \in \left[\mathsf{b}^2\right]_{\geq 0}$, $r \in \left[\mathsf{r}^2\right]_{\geq 0}$, we have

$$\begin{aligned}\Big|\mathrm{Tr}\Big[\Big(\Phi^*_{\mathsf{Alice}}\left(\widetilde{\mathcal{A}_a}\right) \otimes \Phi^*_{\mathsf{Bob}}\left(\widetilde{\mathcal{B}_b}\right) \otimes \widetilde{\mathcal{R}_r}\Big)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes n}\right)\Big] \\ - \mathrm{Tr}\Big[\Big(\widetilde{\Phi^*_{\mathsf{Alice}}}\left(\widetilde{\mathcal{A}_a}\right) \otimes \widetilde{\Phi^*_{\mathsf{Bob}}}\left(\widetilde{\mathcal{B}_b}\right) \otimes \widetilde{\mathcal{R}_r}\Big)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes D}\right)\Big]\Big| \leq \epsilon/(\mathsf{abr})^{3/2}.\end{aligned}$$

By Equation (3), it is equivalent to

$$\begin{aligned}\Big|\mathrm{Tr}\Big[\left(\left(\Phi_{\mathsf{Alice}} \otimes \Phi_{\mathsf{Bob}}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes n}\right)\right)\left(\widetilde{\mathcal{A}_a} \otimes \widetilde{\mathcal{B}_b} \otimes \widetilde{\mathcal{R}_r}\right)\Big] \\ -\mathrm{Tr}\Big[\left(\left(\widetilde{\Phi_{\mathsf{Alice}}} \otimes \widetilde{\Phi_{\mathsf{Bob}}}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes D}\right)\right)\left(\widetilde{\mathcal{A}_a} \otimes \widetilde{\mathcal{B}_b} \otimes \widetilde{\mathcal{R}_r}\right)\Big]\Big| \leq \epsilon/(\mathsf{abr})^{3/2}.\end{aligned}$$

We finally get the desired result:

$$\begin{aligned}&\left|\mathrm{Tr}\left[M^{\mathcal{ABR}}\left(\left(\Phi_{\mathsf{Alice}} \otimes \Phi_{\mathsf{Bob}}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes n}\right) - \left(\widetilde{\Phi_{\mathsf{Alice}}} \otimes \widetilde{\Phi_{\mathsf{Bob}}}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes D}\right)\right)\right]\right| \\ \overset{(\star)}{\leq}\ & \left\|M^{\mathcal{ABR}}\right\| \cdot \left\|\left(\Phi_{\mathsf{Alice}} \otimes \Phi_{\mathsf{Bob}}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes n}\right) - \left(\widetilde{\Phi_{\mathsf{Alice}}} \otimes \widetilde{\Phi_{\mathsf{Bob}}}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes D}\right)\right\|_1 \\ \leq\ & (\mathsf{abr})^{1/2}\left\|\left(\Phi_{\mathsf{Alice}} \otimes \Phi_{\mathsf{Bob}}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes n}\right) - \left(\widetilde{\Phi_{\mathsf{Alice}}} \otimes \widetilde{\Phi_{\mathsf{Bob}}}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes D}\right)\right\|_2 \\ =\ & \Bigg(\mathsf{abr}\sum_{a,b,r}\Big(\mathrm{Tr}\Big[\left(\left(\Phi_{\mathsf{Alice}} \otimes \Phi_{\mathsf{Bob}}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes n}\right)\right)\left(\widetilde{\mathcal{A}_a} \otimes \widetilde{\mathcal{B}_b} \otimes \widetilde{\mathcal{R}_r}\right)\Big] \\ & -\mathrm{Tr}\Big[\left(\left(\widetilde{\Phi_{\mathsf{Alice}}} \otimes \widetilde{\Phi_{\mathsf{Bob}}}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes D}\right)\right)\left(\widetilde{\mathcal{A}_a} \otimes \widetilde{\mathcal{B}_b} \otimes \widetilde{\mathcal{R}_r}\right)\Big]\Big)^2\Bigg)^{1/2} \leq \epsilon,\end{aligned}$$

where $(\star)$ is by Hölder's inequality. ◀

3.1 Notations and setup

The proof of Theorem 16 involves a number of notations. To keep the proof succinct, we introduce the setup and the notations that are used frequently in the rest of the paper.

▶ **Setup 18.** *Given quantum systems* $\mathcal{P}, \mathcal{Q}, \mathcal{R}, \mathcal{S}, \mathcal{T}, \mathcal{A}, \mathcal{B}$ *with dimensions*

$$\mathsf{p} = |\mathcal{P}|, \mathsf{q} = |\mathcal{Q}|, \mathsf{r} = |\mathcal{R}|, \mathsf{s} = |\mathcal{S}|, \mathsf{t} = |\mathcal{T}|, \mathsf{a} = |\mathcal{A}|, \mathsf{b} = |\mathcal{B}|,$$

let $\phi_{in}^{\mathcal{PQR}}$ *be the input state in* $\mathcal{P} \otimes \mathcal{Q} \otimes \mathcal{R}$ *shared among Alice, Bob and the referee, where Alice, Bob and the referee hold* $\mathcal{P}$, $\mathcal{Q}$ *and* $\mathcal{R}$, *respectively. Let* $\psi^{\mathcal{ST}} \in \mathcal{H}_{\mathcal{ST}}$ *be the noisy MES shared between Alice and Bob, where Alice has* $\mathcal{S}$ *and Bob has* $\mathcal{T}$. *Let* $\rho < 1$ *be the maximal correlation of* $\psi^{\mathcal{ST}}$. *Let* $\mathcal{A}$ *and* $\mathcal{B}$ *be the answer registers of Alice and Bob, respectively.*

Let $\{\mathcal{S}_s\}_{s\in[\mathsf{s}^2]_{\geq 0}}, \{\mathcal{T}_t\}_{t\in[\mathsf{t}^2]_{\geq 0}}$ *be standard orthonormal bases in* $\mathcal{H}_{\mathcal{S}}, \mathcal{H}_{\mathcal{T}}$, *respectively. Let* $\{\mathcal{A}_a\}_{a\in[\mathsf{a}^2]_{\geq 0}}, \{\mathcal{B}_b\}_{b\in[\mathsf{b}^2]_{\geq 0}}, \{\mathcal{P}_p\}_{p\in[\mathsf{p}^2]_{\geq 0}}, \{\mathcal{Q}_q\}_{q\in[\mathsf{q}^2]_{\geq 0}}, \{\mathcal{R}_r\}_{r\in[\mathsf{r}^2]_{\geq 0}}$ *be orthonormal bases (not necessary to be standard orthonormal) in* $\mathcal{H}_{\mathcal{A}}, \mathcal{H}_{\mathcal{B}}, \mathcal{H}_{\mathcal{P}}, \mathcal{H}_{\mathcal{Q}}, \mathcal{H}_{\mathcal{R}}$, *respectively. For convenience, we denote* $\widetilde{\mathcal{A}_a}$ *to be* $\mathcal{A}_a/\sqrt{\mathsf{a}}$. *The same for* $\widetilde{\mathcal{B}_b}$, $\widetilde{\mathcal{P}_p}$, $\widetilde{\mathcal{Q}_q}$, $\widetilde{\mathcal{R}_r}$.

When we use universal quantifiers, we omit the ranges of the variables whenever they are clear in the context. For example, we say "for all a, b*" to mean "for all* $a \in [\mathsf{a}^2]_{\geq 0}$, $b \in [\mathsf{b}^2]_{\geq 0}$*".*

Given $M \in \mathcal{H}_{\mathcal{S}^n\mathcal{PA}}$, *for all* p, a, *we define* M_a *to be* $\mathrm{Tr}_{\mathcal{A}}\left[\left(\mathbb{1}_{\mathcal{S}^n\mathcal{P}} \otimes \widetilde{\mathcal{A}_a}\right) M\right]$, *and* $M_{p,a}$ *to be* $\mathrm{Tr}_{\mathcal{P}}\left[\left(\mathbb{1}_{\mathcal{S}^n} \otimes \widetilde{\mathcal{P}_p}\right) M_a\right]$. *Similar for* $N, N_b, N_{q,b}$. *In other words,*

$$M = \sum_{a\in[\mathsf{a}^2]_{\geq 0}} M_a \otimes \widetilde{\mathcal{A}_a}, \quad N = \sum_{b\in[\mathsf{b}^2]_{\geq 0}} N_b \otimes \widetilde{\mathcal{B}_b}. \tag{7}$$

and

$$M_a = \sum_{p\in[\mathsf{p}^2]_{\geq 0}} M_{p,a} \otimes \widetilde{\mathcal{P}_p}, \quad N_b = \sum_{q\in[\mathsf{q}^2]_{\geq 0}} N_{q,b} \otimes \widetilde{\mathcal{Q}_q}. \tag{8}$$

3.2 Proof of Theorem 16

Proof of Theorem 16. Let δ, θ be parameters which are chosen later. The proof is composed of several steps.

- **Smoothing**

  We apply a noise operator defined in Definition 10 to $J\left(\Phi^*_{\mathsf{Alice}}\right)$ and $J\left(\Phi^*_{\mathsf{Bob}}\right)$, and truncate the high-degree parts to get $M^{(1)}$ and $N^{(1)}$, respectively. [3] They satisfy the following.

1. For all a, b, $\left\|\left\|M_a^{(1)}\right\|\right\|_2 \leq 1$ and $\left\|\left\|N_b^{(1)}\right\|\right\|_2 \leq 1$, where $M_a^{(1)}$ and $N_b^{(1)}$ are defined in Equation (7).
2. For all a, b, r:

$$\left|\mathrm{Tr}\left[\left(\Phi^*_{\mathsf{Alice}}\left(\widetilde{\mathcal{A}_a}\right) \otimes \Phi^*_{\mathsf{Bob}}\left(\widetilde{\mathcal{B}_b}\right) \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes n}\right)\right] - \mathrm{Tr}\left[\left(M_a^{(1)} \otimes N_b^{(1)} \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes n}\right)\right]\right| \leq \delta.$$

[3] Readers may refer to the full version for details.

3. For all a, b, p, q, $M^{(1)}_{p,a}$ and $N^{(1)}_{q,b}$ have degree at most d_1, where $M^{(1)}_{p,a}$ and $N^{(1)}_{q,b}$ are defined in Equation (8).
4. $$\frac{1}{\mathsf{s}^n}\mathrm{Tr}\,\zeta\left(M^{(1)}\right) \le \delta \quad \text{and} \quad \frac{1}{\mathsf{t}^n}\mathrm{Tr}\,\zeta\left(N^{(1)}\right) \le \delta,$$
   where ζ is defined in Equation (6).
5. $M^{(1)}_0 = \mathbb{1}_{\mathcal{S}^n\mathcal{P}}/\sqrt{\mathsf{a}}$ and $N^{(1)}_0 = \mathbb{1}_{\mathcal{T}^n\mathcal{Q}}/\sqrt{\mathsf{b}}$.

Here $d_1 = O\left(\frac{\mathsf{a}^2\mathsf{b}^2\mathsf{pq}}{\delta(1-\rho)}\right)$.

- **Regularization**
  We denote $H \subseteq [n]$ to be the set of registers with high influence, satisfying $h = |H| \le d_1(\mathsf{a}+\mathsf{b})/\theta$ such that for all $i \notin H$:
  $$\mathrm{Inf}_i(M) \le \theta, \quad \mathrm{Inf}_i(N) \le \theta.$$
- **Invariance to random operators**
  Substituting the basis elements in the subsystems with low influence in $M^{(1)}$ and $N^{(1)}$, we obtain joint random operators $\mathbf{M}^{(2)}$ and $\mathbf{N}^{(2)}$ satisfying the following.

1. For all a, b, p, q:
   $$\mathbb{E}\left[\left|\left|\left|\mathbf{M}^{(2)}_{p,a}\right|\right|\right|_2^2\right]^{1/2} = \left|\left|\left|M^{(1)}_{p,a}\right|\right|\right|_2 \quad \text{and} \quad \mathbb{E}\left[\left|\left|\left|\mathbf{N}^{(2)}_{q,b}\right|\right|\right|_2^2\right]^{1/2} = \left|\left|\left|N^{(1)}_{q,b}\right|\right|\right|_2.$$
2. For all a, b, r:
   $$\mathbb{E}\left[\mathrm{Tr}\left[\left(\mathbf{M}^{(2)}_a \otimes \mathbf{N}^{(2)}_b \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes h}\right)\right]\right] = \mathrm{Tr}\left[\left(M^{(1)}_a \otimes N^{(1)}_b \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes n}\right)\right].$$
3. $$\left|\frac{1}{\mathsf{s}^h}\mathbb{E}\left[\mathrm{Tr}\,\zeta\left(\mathbf{M}^{(2)}\right)\right] - \frac{1}{\mathsf{s}^n}\mathrm{Tr}\,\zeta\left(M^{(1)}\right)\right| \le O\left(\mathsf{p}^{10/3}\mathsf{a}^4\left(3^{d_1}\mathsf{s}^{d_1/2}\sqrt{\theta}d_1\right)^{2/3}\right)$$
   and
   $$\left|\frac{1}{\mathsf{t}^h}\mathbb{E}\left[\mathrm{Tr}\,\zeta\left(\mathbf{N}^{(2)}\right)\right] - \frac{1}{\mathsf{t}^n}\mathrm{Tr}\,\zeta\left(N^{(1)}\right)\right| \le O\left(\mathsf{q}^{10/3}\mathsf{b}^4\left(3^{d_1}\mathsf{t}^{d_1/2}\sqrt{\theta}d_1\right)^{2/3}\right).$$
4. $\mathbf{M}^{(2)}_0 = \mathbb{1}_{\mathcal{S}^h\mathcal{P}}/\sqrt{\mathsf{a}}$ and $\mathbf{N}^{(2)}_0 = \mathbb{1}_{\mathcal{T}^h\mathcal{Q}}/\sqrt{\mathsf{b}}$.

- **Dimension Reduction**
  We then reducing the number of Gaussian variables in $\left(\mathbf{M}^{(2)}, \mathbf{N}^{(2)}\right)$ randomly. With probability at least $3/4 - \delta/2 > 0$, we get joint random operators $\left(\mathbf{M}^{(3)}, \mathbf{N}^{(3)}\right)$ such that the following holds:

1. For all a, b, p, q:
   $$\mathbb{E}\left[\left|\left|\left|\mathbf{M}^{(3)}_{p,a}\right|\right|\right|_2^2\right] \le (1+\delta)\,\mathbb{E}\left[\left|\left|\left|\mathbf{M}^{(2)}_{p,a}\right|\right|\right|_2^2\right] \quad \text{and} \quad \mathbb{E}\left[\left|\left|\left|\mathbf{N}^{(3)}_{q,b}\right|\right|\right|_2^2\right] \le (1+\delta)\,\mathbb{E}\left[\left|\left|\left|\mathbf{N}^{(2)}_{q,b}\right|\right|\right|_2^2\right].$$

2. $$\mathop{\mathbb{E}}_{\mathbf{x}}\left[\operatorname{Tr}\zeta\left(\mathbf{M}^{(3)}\right)\right] \le 8\mathop{\mathbb{E}}_{\mathbf{g}}\left[\operatorname{Tr}\zeta\left(\mathbf{M}^{(2)}\right)\right] \text{ and } \mathop{\mathbb{E}}_{\mathbf{y}}\left[\operatorname{Tr}\zeta\left(\mathbf{N}^{(3)}\right)\right] \le 8\mathop{\mathbb{E}}_{\mathbf{h}}\left[\operatorname{Tr}\zeta\left(\mathbf{N}^{(2)}\right)\right].$$

3. For all a, b, r:

$$\left|\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{y}}\left[\operatorname{Tr}\left[\left(\mathbf{M}_a^{(3)}\otimes\mathbf{N}_b^{(3)}\otimes\widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}}\otimes\left(\psi^{\mathcal{S}\mathcal{T}}\right)^{\otimes h}\right)\right]\right] - \mathop{\mathbb{E}}_{\mathbf{g},\mathbf{h}}\left[\operatorname{Tr}\left[\left(\mathbf{M}_a^{(2)}\otimes\mathbf{N}_b^{(2)}\otimes\widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}}\otimes\left(\psi^{\mathcal{S}\mathcal{T}}\right)^{\otimes h}\right)\right]\right]\right| \le \delta.$$

4. $\mathbf{M}_0^{(3)} = \mathbb{1}_{\mathcal{S}^h\mathcal{P}}/\sqrt{\mathsf{a}}$ and $\mathbf{N}_0^{(3)} = \mathbb{1}_{\mathcal{T}^h\mathcal{Q}}/\sqrt{\mathsf{b}}$.

Here $n_0 = O\left(\frac{(\mathsf{abr})^{12}(\mathsf{pq})^{20}d_1^{O(d_1)}}{\delta^6}\right)$.

Smoothing random operators

To get low-degree approximations of the Fourier coefficients of $\mathbf{M}^{(3)}$ and $\mathbf{N}^{(3)}$, we obtain joint random operators $\left(\mathbf{M}^{(4)}, \mathbf{N}^{(4)}\right)$ satisfying the following.

1. For all a, b, p, q:

$$\deg\left(\mathbf{M}_{p,a}^{(4)}\right) \le d_2 \quad \text{and} \quad \deg\left(\mathbf{N}_{q,b}^{(4)}\right) \le d_2.$$

2. For all a, b, p, q:

$$\mathbb{E}\left[\left\|\left\|\mathbf{M}_{p,a}^{(4)}\right\|\right\|_2^2\right]^{1/2} \le \mathbb{E}\left[\left\|\left\|\mathbf{M}_{p,a}^{(3)}\right\|\right\|_2^2\right]^{1/2} \quad \text{and} \quad \mathbb{E}\left[\left\|\left\|\mathbf{N}_{q,b}^{(4)}\right\|\right\|_2^2\right]^{1/2} \le \mathbb{E}\left[\left\|\left\|\mathbf{N}_{q,b}^{(3)}\right\|\right\|_2^2\right]^{1/2}.$$

3. $$\mathbb{E}\left[\operatorname{Tr}\zeta\left(\mathbf{M}^{(4)}\right)\right] \le \mathbb{E}\left[\operatorname{Tr}\zeta\left(\mathbf{M}^{(3)}\right)\right] + \delta \text{ and } \mathbb{E}\left[\operatorname{Tr}\zeta\left(\mathbf{N}^{(4)}\right)\right] \le \mathbb{E}\left[\operatorname{Tr}\zeta\left(\mathbf{N}^{(3)}\right)\right] + \delta.$$

4. For all a, b, r:

$$\left|\mathbb{E}\left[\operatorname{Tr}\left[\left(\mathbf{M}_a^{(4)}\otimes\mathbf{N}_b^{(4)}\otimes\widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}}\otimes\psi^{\otimes h}\right)\right]\right] - \mathbb{E}\left[\operatorname{Tr}\left[\left(\mathbf{M}_a^{(3)}\otimes\mathbf{N}_b^{(3)}\otimes\widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}}\otimes\psi^{\otimes h}\right)\right]\right]\right| \le \delta.$$

5. $\mathbf{M}_0^{(4)} = \mathbb{1}_{\mathcal{S}^h\mathcal{P}}/\sqrt{\mathsf{a}}$ and $\mathbf{N}_0^{(4)} = \mathbb{1}_{\mathcal{T}^h\mathcal{Q}}/\sqrt{\mathsf{b}}$.

Here $d_2 = O\left(\frac{\mathsf{a}^2\mathsf{b}^2\mathsf{pq}}{\delta(1-\rho)}\right)$.

Multilinearization

Suppose that

$$\mathbf{M}_{p,a}^{(4)} = \sum_{s\in[\mathsf{s}^2]_{\ge 0}^h} m_{s,p,a}^{(4)}(\mathbf{x})\,\mathcal{S}_s \quad \text{and} \quad \mathbf{N}_{q,b}^{(4)} = \sum_{t\in[\mathsf{t}^2]_{\ge 0}^h} n_{t,q,b}^{(4)}(\mathbf{y})\,\mathcal{T}_t.$$

To get multilinear approximations of the Fourier coefficients of $\mathbf{M}^{(4)}$ and $\mathbf{N}^{(4)}$, we obtain multilinear random operators $\left(\mathbf{M}^{(5)}, \mathbf{N}^{(5)}\right)$ such that the following holds:

1. For all a, b, p, q, $\mathbf{M}^{(5)}_{p,a}$ and $\mathbf{N}^{(5)}_{q,b}$ are degree-d_2 multilinear random operators.
2. Suppose that

$$\mathbf{M}^{(5)}_{p,a} = \sum_{s \in [\mathsf{s}^2]^h_{\geq 0}} m^{(5)}_{s,p,a}(\mathbf{x})\, \mathcal{S}_s \quad \text{and} \quad \mathbf{N}^{(5)}_{q,b} = \sum_{t \in [\mathsf{t}^2]^h_{\geq 0}} n^{(5)}_{t,q,b}(\mathbf{y})\, \mathcal{T}_t,$$

   where $(\mathbf{x}, \mathbf{y}) \sim \mathcal{G}_\rho^{\otimes n_0 \cdot n_1}$. For all $(i,j) \in [n_0] \times [n_1], a, b, p, q, s, t$,

$$\mathrm{Inf}_{(i-1)n_1+j}\left(m^{(5)}_{s,p,a}\right) \leq \theta \cdot \mathrm{Inf}_i\left(m^{(4)}_{s,p,a}\right) \quad \text{and} \quad \mathrm{Inf}_{(i-1)n_1+j}\left(n^{(5)}_{t,q,b}\right) \leq \theta \cdot \mathrm{Inf}_i\left(n^{(4)}_{t,q,b}\right).$$

3. For all a, b:

$$\mathbb{E}\left[\left|\left|\left|\mathbf{M}^{(5)}_a\right|\right|\right|_2^2\right] \leq \mathbb{E}\left[\left|\left|\left|\mathbf{M}^{(4)}_a\right|\right|\right|_2^2\right] \quad \text{and} \quad \mathbb{E}\left[\left|\left|\left|\mathbf{N}^{(5)}_b\right|\right|\right|_2^2\right] \leq \mathbb{E}\left[\left|\left|\left|\mathbf{N}^{(4)}_b\right|\right|\right|_2^2\right].$$

4.

$$\frac{1}{\mathsf{s}^h}\left|\mathbb{E}\left[\mathrm{Tr}\,\zeta\left(\mathbf{M}^{(5)}\right)\right] - \mathbb{E}\left[\mathrm{Tr}\,\zeta\left(\mathbf{M}^{(4)}\right)\right]\right| \leq \delta$$

   and

$$\frac{1}{\mathsf{t}^h}\left|\mathbb{E}\left[\mathrm{Tr}\,\zeta\left(\mathbf{N}^{(5)}\right)\right] - \mathbb{E}\left[\mathrm{Tr}\,\zeta\left(\mathbf{N}^{(4)}\right)\right]\right| \leq \delta.$$

5. For all a, b, r:

$$\left|\mathbb{E}\left[\mathrm{Tr}\left[\left(\mathbf{M}^{(5)}_a \otimes \mathbf{N}^{(5)}_b \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes h}\right)\right]\right] - \mathbb{E}\left[\mathrm{Tr}\left[\left(\mathbf{M}^{(4)}_a \otimes \mathbf{N}^{(4)}_b \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes h}\right)\right]\right]\right| \leq \delta.$$

6. $\mathbf{M}^{(5)}_0 = \mathbb{1}_{\mathcal{S}^h \mathcal{P}}/\sqrt{\mathsf{a}}$ and $\mathbf{N}^{(5)}_0 = \mathbb{1}_{\mathcal{T}^h \mathcal{Q}}/\sqrt{\mathsf{b}}$.

Here $n_1 = O\left(\frac{\mathsf{a}^4\mathsf{b}^4\mathsf{p}^2\mathsf{q}^2 d_2^2}{\theta^2}\right)$.

Invariance to operators

Applying item 2 above, Fact 4 and Fact 14, we have

$$\sum_{s,p,a} \mathrm{Inf}_i\left(m^{(5)}_{s,p,a}\right) \leq \theta \cdot \mathsf{p} \cdot \mathsf{a} \cdot \mathbb{E}\left[\left|\left|\left|\mathbf{M}^{(4)}\right|\right|\right|_2^2\right].$$

Similarly, we have

$$\sum_{t,q,b} \mathrm{Inf}_i\left(n^{(5)}_{t,q,b}\right) \leq \theta \cdot \mathsf{q} \cdot \mathsf{b} \cdot \mathbb{E}\left[\left|\left|\left|\mathbf{N}^{(4)}\right|\right|\right|_2^2\right].$$

Let

$$\theta_0 = \max\left\{\theta\,\mathbb{E}\left[\left|\left|\left|\mathbf{M}^{(4)}\right|\right|\right|_2^2\right], \theta\,\mathbb{E}\left[\left|\left|\left|\mathbf{N}^{(4)}\right|\right|\right|_2^2\right]\right\}.$$

Substituting the Gaussian variables in $\left(\mathbf{M}^{(5)}, \mathbf{N}^{(5)}\right)$ with matrix basis elements to get $\left(M^{(6)}, N^{(6)}\right)$ satisfying that:

1. For all a, b, p, q:
$$\left\|\left\|M^{(6)}_{p,a}\right\|\right\|_2 = \mathbb{E}\left[\left\|\left\|\mathbf{M}^{(5)}_{p,a}\right\|\right\|_2^2\right]^{1/2} \quad \text{and} \quad \left\|\left\|N^{(6)}_{q,b}\right\|\right\|_2 = \mathbb{E}\left[\left\|\left\|\mathbf{N}^{(5)}_{q,b}\right\|\right\|_2^2\right]^{1/2}.$$
2. For all a, b, r:
$$\mathrm{Tr}\left[\left(M^{(6)}_a \otimes N^{(6)}_b \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes n_0 n_1 + h}\right)\right] = \mathbb{E}\left[\mathrm{Tr}\left[\left(\mathbf{M}^{(5)}_a \otimes \mathbf{N}^{(5)}_b \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes h}\right)\right]\right].$$
3. $$\left|\frac{1}{\mathsf{s}^{n_0 n_1 + h}}\mathrm{Tr}\,\zeta\left(M^{(6)}\right) - \frac{1}{\mathsf{s}^h}\mathbb{E}\left[\mathrm{Tr}\,\zeta\left(\mathbf{M}^{(5)}\right)\right]\right| \le O\left(\mathsf{p}^{10/3}\mathsf{a}^4\left(3^{d_2}\mathsf{s}^{d_2/2}\sqrt{\theta_0}d_2\right)^{2/3}\right)$$
and
$$\left|\frac{1}{\mathsf{t}^{n_0 n_1 + h}}\mathrm{Tr}\,\zeta\left(N^{(6)}\right) - \frac{1}{\mathsf{t}^h}\mathbb{E}\left[\mathrm{Tr}\,\zeta\left(\mathbf{N}^{(5)}\right)\right]\right| \le O\left(\mathsf{q}^{10/3}\mathsf{b}^4\left(3^{d_2}\mathsf{t}^{d_2/2}\sqrt{\theta_0}d_2\right)^{2/3}\right).$$
4. $M^{(6)}_0 = \mathbb{1}_{\mathcal{S}^{n_0 n_1 + h}\mathcal{P}}/\sqrt{\mathsf{a}}$ and $N^{(6)}_0 = \mathbb{1}_{\mathcal{T}^{n_0 n_1 + h}\mathcal{Q}}/\sqrt{\mathsf{b}}$.

Rounding

At last, we round $M^{(6)}$ and $N^{(6)}$ to the Choi representations of the adjoints of some quantum operations, $\widetilde{M}$ and $\widetilde{N}$, satisfying

$$\sum_a \left\|\left\|M^{(6)}_a - \widetilde{M_a}\right\|\right\|_2^2 = \mathsf{a}\cdot\left\|\left\|M^{(6)} - \widetilde{M}\right\|\right\|_2^2 \le O\left(\left(\frac{\mathsf{a}^7}{\mathsf{p}\mathsf{s}^{\mathsf{D}}}\mathrm{Tr}\,\zeta\left(M^{(6)}\right)\right)^{1/2}\right), \tag{9}$$

$$\sum_b \left\|\left\|N^{(6)}_b - \widetilde{N_b}\right\|\right\|_2^2 = \mathsf{b}\cdot\left\|\left\|N^{(6)} - \widetilde{N}\right\|\right\|_2^2 \le O\left(\left(\frac{\mathsf{b}^7}{\mathsf{q}\mathsf{t}^{\mathsf{D}}}\mathrm{Tr}\,\zeta\left(N^{(6)}\right)\right)^{1/2}\right). \tag{10}$$

Let $D = h + n_0 n_1$. Then

$$\begin{aligned}
&\left|\mathrm{Tr}\left[\left(M^{(6)}_a \otimes N^{(6)}_b \otimes \widetilde{\mathcal{R}_r} - \widetilde{M_a} \otimes \widetilde{N_b} \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes D}\right)\right]\right| \\
\le\ &\left|\mathrm{Tr}\left[\left(M^{(6)}_a \otimes \left(N^{(6)}_b - \widetilde{N_b}\right) \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes D}\right)\right]\right| \\
&+ \left|\mathrm{Tr}\left[\left(\left(M^{(6)}_a - \widetilde{M_a}\right) \otimes \widetilde{N_b} \otimes \widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}} \otimes \psi^{\otimes D}\right)\right]\right| \\
\le\ &(\mathsf{pq})^{1/2}\left(\left\|\left\|M^{(6)}_a\right\|\right\|_2\left\|\left\|N^{(6)}_b - \widetilde{N_b}\right\|\right\|_2 + \left\|\left\|M^{(6)}_a - \widetilde{M_a}\right\|\right\|_2\left\|\left\|\widetilde{N_b}\right\|\right\|_2\right) \\
\le\ &(\mathsf{pq})^{1/2}\left(\left\|\left\|M^{(6)}_a\right\|\right\|_2\left(\sum_b\left\|\left\|N^{(6)}_b - \widetilde{N_b}\right\|\right\|_2^2\right)^{1/2} + \left(\sum_a\left\|\left\|M^{(6)}_a - \widetilde{M_a}\right\|\right\|_2^2\right)^{1/2}\left\|\left\|\widetilde{N_b}\right\|\right\|_2\right) \\
\overset{(\star)}{\le}\ &\left\|\left\|M^{(6)}_a\right\|\right\|_2 O\left(\left(\frac{\mathsf{b}^7\mathsf{p}^2\mathsf{q}}{\mathsf{t}^D}\mathrm{Tr}\,\zeta\left(N^{(6)}\right)\right)^{1/4}\right) \\
&+ \left\|\left\|\widetilde{N_b}\right\|\right\|_2 O\left(\left(\frac{\mathsf{a}^7\mathsf{p}\mathsf{q}^2}{\mathsf{s}^D}\mathrm{Tr}\,\zeta\left(M^{(6)}\right)\right)^{1/4}\right),
\end{aligned}$$

where $(\star)$ is by Equation (9) and Equation (10).

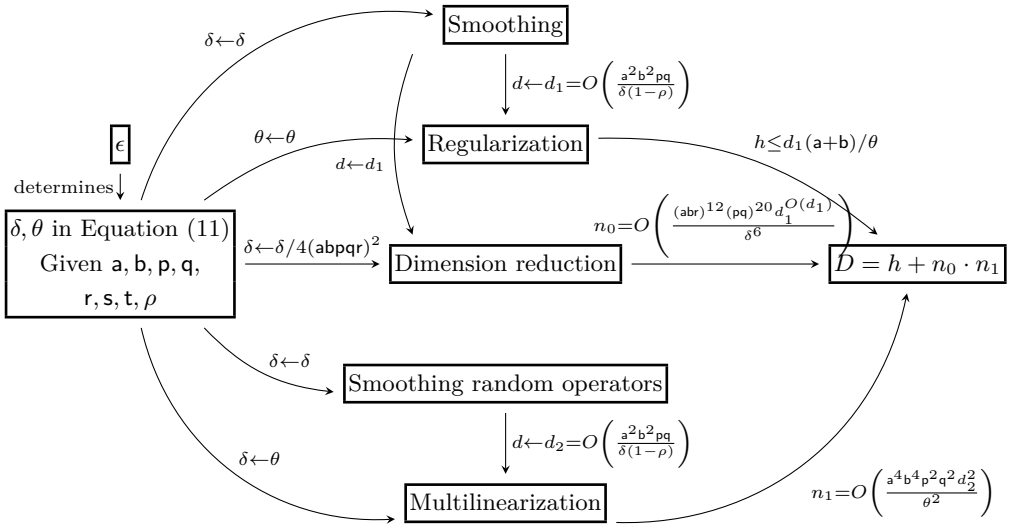

Figure 1 Dependency of parameters in the proof of Theorem 16.

Keeping track of the parameters in the construction, we are able to upper bound $\operatorname{Tr}\zeta\left(M^{(6)}\right)/\mathsf{s}^D$ and $\operatorname{Tr}\zeta\left(N^{(6)}\right)/\mathsf{t}^D$. Finally, by the triangle inequality we are able to upper bound

$$\left|\operatorname{Tr}\left[\left(\Phi^*_{\mathsf{Alice}}\left(\widetilde{\mathcal{A}_a}\right)\otimes\Phi^*_{\mathsf{Bob}}\left(\widetilde{\mathcal{B}_b}\right)\otimes\mathcal{R}_r\right)\left(\phi_{\mathsf{in}}\otimes\psi^{\otimes n}\right)\right]-\operatorname{Tr}\left[\left(\widetilde{M_a}\otimes\widetilde{N_b}\otimes\mathcal{R}_r\right)\left(\phi_{\mathsf{in}}\otimes\psi^{\otimes D}\right)\right]\right|$$

The dependency of the parameters is pictorially described in Figure 1.

We define $\Psi_{\mathsf{Alice}}\in\mathcal{L}\left(\mathcal{A},\mathcal{S}^D\mathcal{P}\right)$, $\Psi_{\mathsf{Bob}}\in\mathcal{L}\left(\mathcal{B},\mathcal{T}^D\mathcal{Q}\right)$ as follows:

$$\Psi_{\mathsf{Alice}}(X)=\operatorname{Tr}_{\mathcal{A}}\left(\widetilde{M}\left(\mathbb{1}_{\mathcal{S}^D\mathcal{P}}\otimes X^\dagger\right)\right),\quad \Psi_{\mathsf{Bob}}(Y)=\operatorname{Tr}_{\mathcal{B}}\left(\widetilde{N}\left(\mathbb{1}_{\mathcal{T}^D\mathcal{Q}}\otimes Y^\dagger\right)\right),$$

just as Equation (5). Let $\widetilde{\Phi_{\mathsf{Alice}}}=\Psi^*_{\mathsf{Alice}}$ and $\widetilde{\Phi_{\mathsf{Bob}}}=\Psi^*_{\mathsf{Bob}}$. Then by Fact 2, $\widetilde{\Phi_{\mathsf{Alice}}}$ and $\widetilde{\Phi_{\mathsf{Bob}}}$ are quantum operations. Furthermore,

$$\begin{aligned}&\operatorname{Tr}\left[\left(\left(\widetilde{\Phi_{\mathsf{Alice}}}\right)^*\left(\widetilde{\mathcal{A}_a}\right)\otimes\left(\widetilde{\Phi_{\mathsf{Bob}}}\right)^*\left(\widetilde{\mathcal{B}_b}\right)\otimes\widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}}\otimes\psi^{\otimes D}\right)\right]\\&\qquad=\operatorname{Tr}\left[\left(\widetilde{M_a}\otimes\widetilde{N_b}\otimes\widetilde{\mathcal{R}_r}\right)\left(\phi_{\mathsf{in}}\otimes\psi^{\otimes D}\right)\right].\end{aligned}$$

Choosing

$$\delta=O(\epsilon),\quad \theta=\frac{\epsilon^{12}}{\exp\left(\frac{\mathsf{a}^2\mathsf{b}^2\mathsf{pq}\log\mathsf{s}\log\mathsf{t}}{\epsilon(1-\rho)}\right)},\tag{11}$$

we finally conclude the result. ◀

Abstract

We study the problem of scheduling precedence-constrained jobs on heterogenous machines in the presence of non-uniform job and machine communication delays. We are given a set of n unit size precedence-ordered jobs, and a set of m related machines each with size m_i (machine i can execute at most m_i jobs at any time). Each machine i has an associated in-delay ρ_i^{in} and out-delay ρ_i^{out}. Each job v also has an associated in-delay ρ_v^{in} and out-delay ρ_v^{out}. In a schedule, job v may be executed on machine i at time t if each predecessor u of v is completed on i before time t or on any machine j before time $t - (\rho_i^{\text{in}} + \rho_j^{\text{out}} + \rho_u^{\text{out}} + \rho_v^{\text{in}})$. The objective is to construct a schedule that minimizes makespan, which is the maximum completion time over all jobs.

We consider schedules which allow duplication of jobs as well as schedules which do not. When duplication is allowed, we provide an asymptotic polylog(n)-approximation algorithm. This approximation is further improved in the setting with uniform machine speeds and sizes. Our best approximation for non-uniform delays is provided for the setting with uniform speeds, uniform sizes, and no job delays. For schedules with no duplication, we obtain an asymptotic polylog(n)-approximation for the above model, and a true polylog(n)-approximation for symmetric machine and job delays. These results represent the first polylogarithmic approximation algorithms for scheduling with non-uniform communication delays.

Finally, we consider a more general model, where the delay can be an arbitrary function of the job and the machine executing it: job v can be executed on machine i at time t if all of v's predecessors are executed on i by time $t-1$ or on any machine by time $t - \rho_{v,i}$. We present an approximation-preserving reduction from the Unique Machines Precedence-constrained Scheduling (UMPS) problem, first defined in [15], to this job-machine delay model. The reduction entails logarithmic hardness for this delay setting, as well as polynomial hardness if the conjectured hardness of UMPS holds.

This set of results is among the first steps toward cataloging the rich landscape of problems in non-uniform delay scheduling.

1 Introduction

With the increasing scale and complexity of scientific and data-intensive computations, it is often necessary to process workloads with many dependent jobs on a network of heterogeneous computing devices with varying computing capabilities and communication delays. For instance, the training and evaluation of neural network models, which involves iterations of precedence constrained jobs, is often distributed over diverse devices such as CPUs, GPUs, or other specialized hardware. This process, commonly referred to as *device placement*, has gained significant interest [18, 21, 32, 33]. Similarly, many scientific workflows are best modeled precedence constrained jobs, and the underlying high-performance computing system as a heterogeneous networked distributed system with communication delays [3, 44, 49].

Optimization problems associated with scheduling under communication delays have been studied extensively, but provably good approximation bounds are few and several challenging open problems remain [1, 4, 14, 23, 26, 34, 35, 37, 39, 40, 43]. With a communication delay, scheduling a set of precedence constrained uniform size jobs on identical machines is already NP-hard [40, 43], and several inapproximability results are known [4, 23]. However, the field is still underexplored and scheduling under communication delay was listed as one of the top ten open problems in scheduling surveys [5, 45]. While there has been progress on polylogarithmic-approximation algorithms for the case of uniform communication delays [16, 26, 29, 31], little is known for more general delay models.

This paper considers the problem of scheduling precedence-constrained jobs on machines connected by a network with *non-uniform* communication delays. In general, the delay incurred in communication between two machines could vary with the machines as well as with the data being communicated, which in turn may depend on the jobs being excuted on the machines. For many applications, however, simpler models suffice. For instance, the machine delays model, where the communication between two machines incurs a delay given by the sum of latencies associated with the two machines, is suitable when the bottleneck is primarily at the machine interfaces. On the other hand, job delays model scenarios where the delay incurred in the communication between two jobs running on two different machines is a function primarily of the two jobs. This is suitable when the communication is data-intensive. Recent work in [15] presents a hardness result for a model in which jobs are given as a DAG and any edge of the DAG separating two jobs running on different machines causes a delay, providing preliminary evidence that obtaining sub-polynomial approximation factors for this model may be intractable. Given polylogarithmic approximations for uniform delays, a natural question is which, if any, non-uniform delay models are tractable.

1.1 Overview of our results

A central contribution of this paper is to explore and catalog a rich landscape of problems in non-uniform delay scheduling. We present polylogarithmic approximation algorithms for several models with non-uniform delays, and a hardness result in the mold of [15] for a different non-uniform delay model. Figure 2 organizes various models in this space, with pointers to results in this paper and relevant previous work.

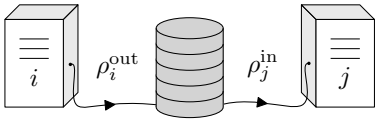

Figure 1 Communicating a result from i to j takes $\rho_i^{\text{out}} + \rho_j^{\text{in}}$ time.

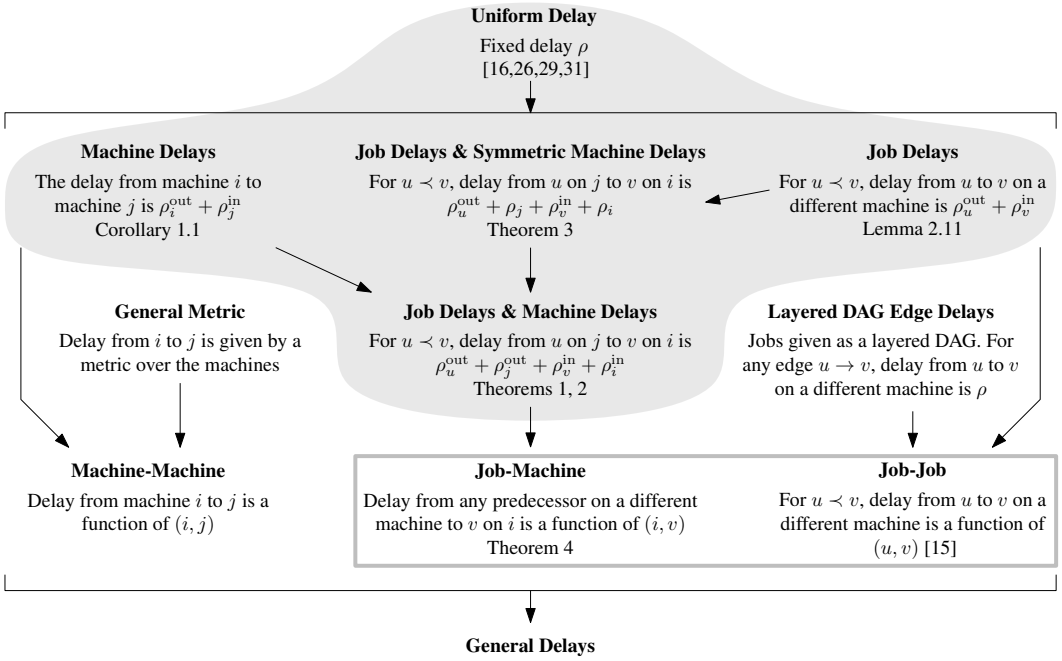

Figure 2 Selection of scheduling models with communication delays. $a \twoheadrightarrow b$ indicates that a is a special case of b. We present approximation algorithms for models with machine delays and job delays, and a hardness of approximation result for the job-machine delays model. Theorems and citations point to results in this paper and in previous work, respectively. Those problems backed in gray are ones for which approximation algorithms are known. Those in the gray box are ones for which hardness results have been proven.

Machine delays and job delays (Section 2). We begin with a natural model where the delay incurred in communication from one machine to another is the sum of delays at the two endpoints. Under machine delays, each machine i has an in-delay ρ_i^{in} and out-delay ρ_i^{out}, and the time taken to communicate a result from i to j is $\rho_i^{\text{out}} + \rho_j^{\text{in}}$. This model, illustrated in Figure 1, is especially suitable for environments where data exchange between jobs occurs via the cloud, an increasingly common mode of operation in modern distributed systems [28,30,50]; ρ_i^{in} and ρ_i^{out} represent the cloud download and upload latencies, respectively, for machine i.

The machine delays model does not account for heterogeneity among jobs, where different jobs may be producing or consuming different amounts of data, which may impact the delay between the processing of one job and that of another dependent job on a different machine. To model this, we allow each job u to have an in-delay ρ_u^{in} and an out-delay ρ_u^{out}.

▶ **Definition 1** (Scheduling under Machine Delays and Job Delays). *We are given as input a set of n precedence ordered jobs and a set of m machines. For any jobs u and v with $u \prec v$, machine i, and time t, u is available to v on i at time t if u is completed on i before time t or on any machine j before time $t - (\rho_j^{\text{out}} + \rho_u^{\text{out}} + \rho_i^{\text{in}} + \rho_v^{\text{in}})$. (This model is illustrated in Figure 3.) If job v is scheduled at time t on machine i, then all of its predecessors must be available to v on i at time t. We define $\rho_{\max} = \max_{x \in V \cup M}\{\rho_x^{\text{in}} + \rho_x^{\text{out}}\}$. The objective is to construct a schedule that minimizes makespan.*

Remark. In our model of Definition 1, communication delay is defined over all pairs of precedence ordered jobs. An alternate model defines communication delay only over those pairs that are adjacent in the job DAG. The two settings differ in general but are equivalent

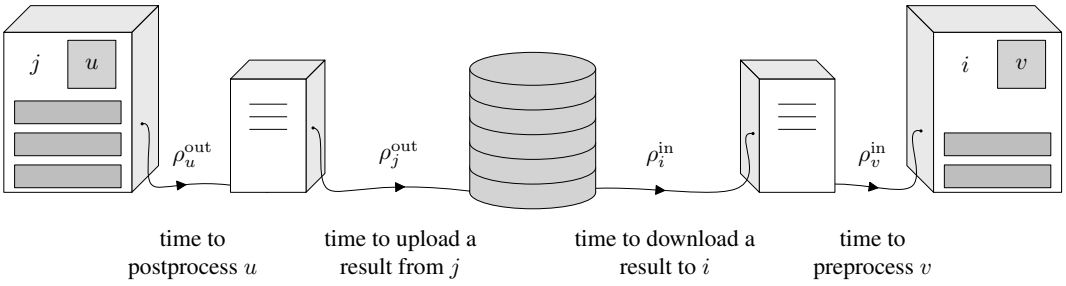

Figure 3 Communicating the result of job u on machine j to execute job v on machine i.

in many scenarios, for instance, when the delays are given by an underlying metric space over the machines, or when communication delays are uniform. The models are equivalent if all delays are machine delays, so our machine delay results hold in the alternate model. The models differ in the presence of general job delays but are equivalent in several special cases, for instance in the setting where the job DAG is transitively closed, which has been extensively studied and proved useful in several important applications [2,19,46]. Transitively closed DAGs capture scenarios where each job may be generating data used by upstream jobs, and an upstream job may need to check the results of any of its predecessors. Examples of such graphs arising in scheduling include interval orders [38], as well as Solution Order Graphs in the context of SAT solvers [8].

We present the first approximation algorithms for scheduling under non-uniform communication delays. In the presence of delays, a natural approach to hide latency and reduce makespan is to duplicate some jobs (for instance, a job that is a predecessor of many other jobs) [1,39]. We consider both schedules that allow duplication (which we assume by default) and those that do not. Our first result is a polylogarithmic asymptotic approximation for scheduling under machine and job delays when duplication is allowed.

▶ **Theorem 1.** There exists a polynomial time algorithm for scheduling unit length, precedence constrained jobs with duplication under machine and job delays, that produces a schedule with makespan $O((\log^9 n)(\text{OPT} + \rho_{\max}))$.

We emphasize that if the makespan of any schedule includes the delays incurred in distributing the problem instance and collecting the output of the jobs, then the algorithm of Theorem 1 is, in fact, a *true polylogarithmic approximation* for makespan. (From a practical standpoint, in order to account for the time incurred to distribute the jobs and collect the results, it is natural to include in the makespan the in- and out-delays of every machine used in the schedule.)

We note that when delays are uniform and duplication is not allowed, it is easy to check if $\text{OPT} < \rho$ since any connected component of the job DAG must be placed on the same machine. This is demonstrated in our true approximation without duplication in Theorem 3. In the presence of duplication, the problem is closely related to the Min k-Union problem, for which conditional hardness proofs are known [12]. This motivates the additive $\rho_{\max}$ in our approximation guarantee.

Related machines and multiprocessors. Theorem 1 is based on a new linear programming framework for addressing non-uniform job and machine delays. We demonstrate the power and flexibility of this approach by incorporating two more aspects of heterogeneity: speed and number of processors. Each machine i has a number m_i of processors and a speed s_i at which each processor processes jobs. We generalize Theorem 1 to obtain the following result.

▶ **Theorem 2.** There exists a polynomial time algorithm for scheduling unit length, precedence constrained jobs with duplication on related multiprocessor machines under machine and job delays, that yields a schedule with makespan $\text{polylog}(n)(\text{OPT} + \rho_{\max})$.

The exact approximation factor obtained depends on the non-uniformity of the particular model. For the most general model we consider in Theorem 2, our proof achieves a $O(\log^{15} n)$ bound. We obtain improved bounds when any of the three defining parameters – size, speed, and delay – are uniform. For instance, we obtain an approximation factor of $O(\log^5 n)$ for scheduling uniform speed and uniform size machines under machine delays alone, i.e., when there are no job delays (Corollary 12 of Section 2). Further, with only job delays and uniform machine delays, we provide a combinatorial asymptotic $O(\log^6 n)$ approximation (Lemma 15 of Section 2) which is improved to an asymptotic $O(\log n)$ approximation if the input contains no out-delays. We note that despite some uniformity, special cases can model certain two-level non-uniform network hierarchies with processors at the leaves, low delays at the first level, and high delays at the second level.

No-duplication schedules. We next consider the problem of designing schedules that do not allow duplication. We obtain a polylogarithmic asymptotic approximation via a reduction to scheduling with duplication. Furthermore, if the delays are symmetric (i.e., $\rho_i^{\text{out}} = \rho_i^{\text{in}}$ for all i, and $\rho_v^{\text{out}} = \rho_v^{\text{in}}$ for all v) we are able to find a *true* polylogarithmic-approximate no-duplication schedule. To achieve this result, we present an approximation algorithm to estimate if the makespan of an optimal no-duplication schedule is at least the delay of any given machine; this enables us to identify machines that cannot communicate in the desired schedule.[1]

▶ **Theorem 3.** There exists a polynomial time algorithm for scheduling unit length, precedence constrained jobs on related multiprocessor machines under machine delays and job delays, which produces a no-duplication schedule with makespan $\text{polylog}(n)(\text{OPT} + \rho_{\max})$. If $\rho_i^{\text{in}} = \rho_i^{\text{out}}$ for all i, then there exists a polynomial time $\text{polylog}(n)$-approximation algorithm for no-duplication schedules.

Pairwise delays. All of the preceding results concern models where the communication associated with a precedence relation $u \prec v$ when u and v are executed on different machines i and j is an *additive* combination of delays at u, v, i, and j. Additive delays are suitable for capturing independent latencies incurred by various components of the system. A more general class of models considers *pairwise* delays where the delay is an *arbitrary function* of i and j (machine-machine), u and v (job-job), or either job and the machine on which it executes (job-machine). The machine-machine delay model captures classic networking scenarios, where the delay across machines is determined by the network links connecting them. Job-job delays model applications where the data that needs to be communicated from one job to another descendant job depends arbitrarily on the two jobs. The job-machine model is well-suited for applications where the delay incurred for communicating the data consumed or produced by a job executing on a machine is an arbitrary function of the size of

[1] We note that the corresponding problem for duplication schedules is a min-max partitioning variant of the Minimum k-Union problem and related to the Min-Max Hypergraph k-Partitioning problem, both of which have been shown to be Densest-k-Subgraph-hard [9, 11]; this might suggest a similar hardness result for deriving a *true* approximation when duplication is allowed.

the data and the bandwidth of the machine. Recent work in [15] shows that scheduling under job-job delays is as hard as the Unique Machine Precedence Scheduling (UMPS) problem, providing preliminary evidence that obtaining sub-polynomial approximation factors may be intractable. We show that UMPS also reduces to scheduling under job-machine delays, suggesting a similar inapproximability for this model.

▶ **Theorem 4 (umps reduces to scheduling under job-machine delays).** There is a polynomial-time approximation-preserving reduction from UMPS to the scheduling precedence constrained jobs under job-machine delays.

1.2 Overview of our techniques

Our approximation algorithms for scheduling under job delays and machine delays (Theorem 1 proved in Section 2) and the generalization to related machines and multiprocessors (Theorem 2 proved in [42]) rely on a framework composed of a carefully crafted linear programming relaxation and a series of reductions that help successively reduce the level of heterogeneity in the problem. While each individual component of the framework refines established techniques or builds on prior work, taken together they offer a flexible recipe for designing approximation algorithms for scheduling precedence-ordered jobs on a distributed system of heterogeneous machines with non-uniform delays. Given the hardness conjectures of [15] for the job-job delay setting (and for the job-machine setting via Theorem 4), we find it surprising that a fairly general model incorporating both job delays and machine delays on related machines is tractable.

Previous results on scheduling under (uniform) communication delays are based on three different approaches: (a) a purely combinatorial algorithm of [26] that works only for uniform delay machines; (b) an LP-based approach of [31] that handles related machines and uniform delays, assuming jobs can be duplicated, and then extends to no-duplication via a reduction; and (c) an approach of [16] based on a Sherali-Adams hierarchy relaxation followed by a semi-metric clustering, which directly tackles the no-duplication model. At a very high level, our main challenge, which is not addressed in any of the previous studies, is to tackle the *multi-dimensional heterogeneity* of the problem space: in the nature of delays (non-uniform values, in- and out-delays, job delays, machine delays) as well as the machines (delay, speed, and size).

We pursue an LP-based framework, which significantly refines the approach of [31]. Their algorithm organizes the computation in phases, each phase corresponding to a (uniform) delay period, and develops a linear program that includes delay constraints capturing when jobs have to be phase-separated and phase constraints bounding the amount of computation within a phase. In non-uniform delay models, the delay constraints for a job v executing on a machine i depend not only on the predecessors of v, but also on the machines on which they may be scheduled. While there is a natural way to account for non-uniform in-delays in the LP, incorporating out-delays or even symmetric delays poses technical difficulties. We overcome this hurdle by first showing that out-delays can be eliminated by suitably adjusting in-delays, at the expense of a polylogarithmic factor in approximation, thus allowing us to focus on in-delays.

Despite the reduction to in-delays, extending the LP of [31] by replacing the uniform delay parameter by the non-uniform delay parameters of our models fails and yields a high integrality gap. This is because their algorithm crucially relies on an ordering of the machines (on the basis of their speeds), which is exploited both in the LP (in the delay and phase constraints) as well as how jobs get assigned and moved in the computation of the final

schedule. Given the multi-dimensional heterogeneity of the problems we study, there is no such natural ordering of the machines. To address the above hurdle, we organize the machines and jobs into groups based on their common characteristics (delay, speed, size), and introduce new variables for assigning jobs to groups without regard to any ordering among them. This necessitates new load and delay constraints and a change in rounding and schedule construction. We now elaborate on these ideas, as we discuss our new framework in more detail.

Reduction to in-delays. The first ingredient of our recipe is an argument that any instance of the problem with machine delays and job delays can be reduced to an instance in which all out-delays are 0, meaning that in the new instance delays depend only on the machine and job receiving the data, at the expense of a polylogarithmic factor in approximation. This reduction is given in Lemma 37 and Algorithm 2 in [42]. To convert from a given schedule with out-delays to one without, we subtract $\rho_i^{\text{out}} + \rho_v^{\text{out}}$ from the execution time of every job v on machine i. However, in order to avoid collisions, we expand the given schedule into phases of different length, organized in particular sequence so that the execution times within each phase may be reduced without colliding with prior phases. This transforms the schedule into one where the in-delay of every machine i is $\rho_i^{\text{in}} + \rho_i^{\text{out}}$ and every job v is $\rho_v^{\text{in}} + \rho_v^{\text{out}}$. This transformation comes at a constant factor cost for machine delays and an $O(\log^2 \rho_{max})$ cost for job delays. A similar procedure converts from an in-delay schedule to one with in- and out-delays, completing the desired reduction.

The linear program (Sections 2.1–2.2). Before setting up the linear program, we partition the machines and the jobs into groups of uniform machines and jobs, respectively; i.e. each machine in a group can be treated as having the same in-delay, speed, and size (to within a constant factor), and each job in a group can be treated as having the same in-delay. The final approximation factor for the most general model grows as K^3 and L, where L is the number of job groups and K is the number of machine groups, which depends on the extent of heterogeneity among the machines. We bound K by $O(\log^3 n)$ in the case when the speeds, sizes, and delays of machines are non-uniform. We emphasize that, even with the machines partitioned in this way, we must carefully design our LP to judiciously distribute jobs among the groups depending on the precedence structure of the jobs and the particular job and machine parameters.

Our LP is inspired by that of [31], though significant changes are necessary to allow for non-uniform delays. The key constraints of each LP are presented below (with the constraints from [31] rewritten to include machine group variables). Here, C^* represents the makespan of the schedule and C_v represents the earliest execution time of job v. $x_{v,k}$ indicates if v is placed on a machine in group $\langle k \rangle$ $(= 1)$ or not $(= 0)$. $z_{u,v,k}$ indicates whether $x_{v,k} = 1$ and $C_v - C_u$ is less the time it takes to communicate the result of u from a different machine. $y_{v,k}$ takes the maximum of $x_{v,k}$ and $\max_u\{z_{v,u,k}\}$ to indicate whether some copy of v is executed on a machine in group $\langle k \rangle$ $(= 1)$ or not $(= 0)$. Other notation used in the linear program is explained in Section 2.

One main difference between our LP and that of [31] is in the constraint that regulates the completion time of precedence ordered jobs in the presence of communication delay.

Delay Constraint in [31]		New Delay Constraint
$C_v \geq C_u + \rho\Big(\sum_{k' \leq k} x_{v,k'} - z_{u,v,k}\Big)$	$\Rightarrow$	$C_v \geq C_u + (\bar{\rho}_k + \bar{\rho}_\ell)(x_{v,k} - z_{u,v,k})$
$\forall u, v, k : u \prec v$		$\forall u, v, k, \ell : u \prec v$ and $v \in [\![\ell]\!]$

The constraint of [31] states that if $u \prec v$ and v is executed on a machine in speed group k, then the completion time of v is at least ρ greater than the completion time of u unless some duplicate of u is executed on group k. The summation over machine groups orders the groups by increasing speeds (similar to [13]). It turns out that the rounding technique which uses this ordering of machine groups, which is used to eliminate a log factor in [13, 31], does not straightforwardly work in our context. The new constraint has an interpretation similar to that of the delay constraint in [31]: if $u \prec v$ and v is executed on delay group k, then the completion time of v is at least the in-delay of k plus the in-delay of v greater than the completion time of u, unless some duplicate of u is also executed on group k. However, in the new constraint, the summation over machine groups has been replaced by a single machine group assignment variable.

The next change to the linear program regards the constraint which governs how many jobs can be duplicated within a communication phase for a single job.

Phase Constraint in [31]			New Phase Constraint	
$\rho \geq \sum_{u \prec v} z_{u,v,k}$	$\forall v, k$	$\Rightarrow$	$(\bar{\rho}_k + \bar{\rho}_\ell) \sum_u z_{u,v,k}$	$\forall v, k, \ell : v \in [\![\ell]\!]$

Both the old and new constraints state that the amount of duplication that can be performed for a single job within a single communication phase on a given group of machines is at most the length of the phase. The new constraint also incorporates the machine and job in-delays.

The final change is to the constraints which lower bound the makespan of the schedule by the total load placed on a single machine.

Load Constraint in [31]			New Load Constraints	
$C^* \cdot \lvert\langle k \rangle\rvert \geq \sum_v x_{v,k}$	$\forall k$	$\Rightarrow$	$C^* \cdot \lvert\langle k \rangle\rvert \geq \sum_v y_{v,k}$	$\forall k$
			$y_{v,k} \geq x_{v,k}$	$\forall v, k$
			$y_{u,k} \geq z_{u,v,k}$	$\forall u, v, k$

Both constraints state that the makespan is at least the total number of jobs placed on any group divided by the size of the group. The old constraint uses $x_{v,k}$ as the sole indicator of whether or not a job is placed on machine group k, and does not need to account for duplicates because of the optimized rounding scheme which utlizes the ordering of job groups by increasing speed. Because the new constraint cannot rely on this ordering, we use the y-variables to account for all duplicates as well.

In [31], the ordering of the groups was leveraged to construct the final schedule by always placing a job on higher capacity groups than the one to which it is assigned by the LP. Since the LP assigns all jobs to some group, we can infer that the total load over all groups does not increase by more than a constant factor. With multidimensional heterogenous machines, there is no clear ordering of machine groups to achieve a similar property (e.g. one set of jobs may be highly parallelizable, while another requires a single fast machine). Using the new LP, our solution is to place all jobs on those groups to which the LP assigns them, along with any predecessors indicated by the z-variables. However, such a construction could vastly exceed the value of the LP unless the load contributed by the z-variables is counted toward the LP makespan. To this end, we introduce the y-variables and associated constraints, which account for this additional, duplicated load. In the most general setting, we also introduce constraints which govern the amount of duplication possible within a single communication phase. These additional constrains model an optimal schedule of the duplicated jobs on the uniform machines within a single group.

Rounding the LP solution and determining final schedule (Sections 2.3–2.4). The next component rounds an optimal LP solution to an integer solution by placing each job on the group for which the job's LP mass is maximized. We also place duplicate predecessors of each job v on its group according to the z-variables for v's predecessors. This indicates a key difference with [31], where the load contributed by duplicates was handled by the ordering of the machines. A benefit of our simple rounding is that it accommodates many different machine and job properties as long as the number of groups can be kept small. Finally, we construct a schedule using the integer LP solution. This subroutine divides the set of jobs assigned to each group into phases and constructs a schedule for each phase by invoking a schedule for the uniform machines case, appending each schedule to the existing schedule for the entire instance.

No-duplication schedules. The proof of the first part of Theorem 3 extends an asympototic polylogarithmic approximation to no-duplication schedules for machine delays and job delays. The theorem follows from the structure of the schedule designed in Theorem 2 and a general reduction in [31] from duplication to no-duplication schedules in the uniform delay case. Avoiding the additive delay penalty of the first part of Theorem 3 to achieve a true approximation is much more difficult. When delays are symmetric (i.e., in-delays equal out-delays), we can distinguish those machines whose delay is low enough to communicate with other machines from those machines with high delay. One of the central challenges is then to distribute jobs among the high-delay machines. We overcome this difficulty by revising the LP in the framework of Theorem 2 to partition the jobs among low- and high-delay machines, and rounding the corresponding solutions separately.

We then must distinguish between those jobs with delay low enough to communicate with other jobs from those with high delay. We note that any predecessor or successor of a high delay job must be executed on the same machine as that job. We leverage this fact to construct our schedule, first placing all high delay jobs with their predecessors and successors on individual machines. We then run our machine and job delay algorithm with the remaining jobs on the low delay machines. This schedule is placed after the execution of the downward closed high-delay components, and before the upward closed high-delay components, ensuring that the schedule is valid.

We note that the design of no-duplication schedules via a reduction to duplication schedules incurs a loss in approximation factor of an additional polylogarithmic factor. While this may not be desirable in a practical implementation, our results demonstrate the flexibility of the approach and highlight its potential for more general delay models.

Hardness for job-machine delay model. The algorithmic framework outlined above incorporates non-uniform job and machine delays that combine additively. It is natural to ask if the techniques extend to other delay combinations or more broadly to pairwise delay models. In the job-machine delay model we study, when a job u executed on machine i precedes job v executed on machine j, then a delay $\rho_{v,j}$ between the two executions is incurred. Our reduction from UMPS to the job-machine delay problem follows the approach of [15] by introducing new jobs with suitable job-machine delay parameters that essentially force each job to be executed on a particular machine. This reduction does not require the flexibility of assigning different delays for different job-job pairs, but it is unclear if the same technique can be applied to machine-machine delay models. Delineating the boundary between tractable models and those for which polylogarithmic approximations violate conjectured complexity lower bounds is a major problem of interest.

1.3 Related work

Precedence constrained scheduling. The problem of scheduling precedence-constrained jobs was initiated in the classic work of Graham who gave a constant approximation algorithm for uniform machines [20]. Jaffe presented an $O(\sqrt{m})$ makespan approximation for the case with related machines [24]. This was improved upon by Chudak and Shmoys who gave an $O(\log m)$ approximation [13], then used the work of Hall, Schulz, Shmoys, and Wein [22] and Queyranne and Sviridenko [41] to generalize the result to an $O(\log m)$ approximation for weighted completion time. Chekuri and Bender [10] proved the same bound as Chudak and Shmoys using a combinatorial algorithm. In subsequent work, Li improved the approximation factor to $O(\log m/\log\log m)$ [27]. The problem of scheduling precedence-constrained jobs is hard to approximate even for identical machines, where the constant depends on complexity assumptions [6, 25, 47]. Also, Bazzi and Norouzi-Fard [7] showed a close connection between structural hardness for k-partite graph and scheduling with precedence constraints.

Precedence constrained scheduling under communication delays. Scheduling under communication delays has been studied extensively [39, 43, 48]. For unit size jobs, identical machines, and unit delay, a (7/3)-approximation is given in [35], and [23] proves the NP-hardness of achieving better than a 5/4-approxmation. Other hardness results are given in [4, 40, 43]. More recently, Davies, Kulkarni, Rothvoss, Tarnawski, and Zhang [16] give an $O(\log\rho\log m)$ approximation in the identical machine setting using an LP approach based on Sherali-Adams hierarchy, which is extended to include related machines in [17]. Concurrently, Maiti, Rajaraman, Stalfa, Svitkina, and Vijayaraghavan [31] provide a polylogarithmic approximation for uniform communication delay with related machines as a reduction from scheduling with duplication. The algorithm of [31] is combinatorial in the case with identical machines.

Davies, Kulkarni, Rothvoss, Sandeep, Tarnawski, and Zhang [15] consider the problem of scheduling precedence-constrained jobs on uniform machine in the presence of non-uniform, job-pairwise communication delays. That is, if $u \prec v$ and u and v are scheduled on different machines, then the time between their executions is at least $\rho_{u,v}$. The authors reduce to this problem from Unique-Machines Precedence-constrained Scheduling (UMPS) in which there is no communication delay, but for each job there is some particular machine on which that job must be placed. The authors show that UMPS is hard to approximate to within a logarithmic factor by a reduction from job-shop scheduling, and conjecture that UMPS is hard to approximate within a polynomial factor.

Precedence constrained scheduling under communication delays with job duplication. Using duplication with communication delay first studied by Papadimitriou and Yannakakis [39], who give a 2-approximation for DAG scheduling with unbounded processors and fixed delay. Improved bounds for infinite machines are given in [1, 14, 36, 37]. Approximation algorithms are given by Munier and Hanen [34, 35] for special cases in which the fixed delay is very small or very large, or the DAG restricted to a tree. The first bounds for a bounded number of machines are given by Lepere and Rapine [26] who prove an asymptotic $O(\log\rho/\log\log\rho)$ approximation. Recent work has extended their framework to other settings: [31] uses duplication to achieve an $O(\log\rho\log m/\log\log\rho)$ approximation for a bounded number of related machines, and Liu, Purohit, Svitkina, Vee, and Wang [29] improve on the runtime of [26] to a near linear time algorithm with uniform delay and identical machines.

1.4 Discussion and open problems

Our results indicate several directions for further work. First, we conjecture that our results extend easily to the setting with non-uniform job sizes. We believe the only barriers to such a result are the techinical difficulties of tracking the completion times of very large jobs that continue executing long after they are placed on a machine. Also, while our approximation ratios are the first polylogarithmic guarantees for scheduling under non-uniform delays, we have not attempted to optimize logarithmic factors. There are obvious avenues for small reductions in our ratio, e.g. the technique used in [26] to reduce the ratio by a factor of $\log \log \rho$. More substantial reduction, however, may require a novel approach. Additionally, in the setting without duplication, we incur even more logarithmic factors owing to our reduction to scheduling with duplication. These factors may be reduced by using a more direct method, possibly extending the LP-hierarchy style approach taken in [16, 17].

Aside from improvements to our current results, our techniques suggest possible avenues to solve related non-uniform delay scheduling problems. A special case of general machine metrics is a machine hierarchy, where machines are given as leaves in a weighted tree. Our incorporation of parallel processors allows our results to apply to a two-level machine hierarch. We would like to explore extensions of our framework to constant-depth hierarchies and tree metrics. More generally, scheduling under metric and general machine-machine delays remains wide open (see Figure 2).

We also believe there are useful analogs to these machine delay models in the job-pairwise regime. A job v with in-delay ρ_v^{in} and out-delay ρ_v^{out} has the natural interpretation of the data required to execute a job, and the data produced by a job. A job tree hierarchy could model the shared libraries required to execute certain jobs: jobs in different subtrees require different resources to execute, and downloading these additional resources incurs a delay. Given the hardness conjectures of [15] and our hardness result for the job-machine delay model, further refining Figure 2 and exploring the tractability boundary would greatly enhance our understanding of scheduling under non-uniform delays.

Finally, recall that our notion of job delays is defined in terms of the precedence relation over the jobs. Another natural notion of job delay may be to consider a DAG defined over the jobs, with a delay incurred only if there is a directed edge $u \to v$ (rather than $u \prec v$). In this setting, while our results do not hold in the presence of general job delays, they do hold for some significant special cases. These include instances where the job DAG is transitively closed, or where job delays are uniform, or where job delays of predecessors are at most that of their successors (i.e. $u \prec v$ implies $\rho_u^{\text{out}} \leq \rho_v^{\text{out}}$ and $\rho_u^{\text{in}} \leq \rho_v^{\text{in}}$), or where there are only machine delays. However, resolving the most general case is an interesting open problem since this family of delay models provides an intuitive and important set of problems.

2 Machine Delays and Job Delays

In this section, we present an asymptotic approximation algorithm for scheduling under machine delays and job delays for unit speed and size machines. As discussed in Section 1.2, we can focus on the setting with no out-delays, at the expense of a polylogarithmic factor in approximation; Lemma 37 of [42] presents the reduction to in-delays. Therefore, in this section, we assume that $\rho_i^{\text{out}} = 0$ for all machines i and $\rho_v^{\text{out}} = 0$ for all jobs v. For convenience, we use ρ_i to denote the in-delay ρ_i^{in} of machine i and ρ_v to denote the in-delay ρ_v^{in} of machine v. Let $\rho_{\max} = \max\{\max_v\{\rho_v\}, \max_i\{\rho_i\}\}$.

2.1 Partitioning machines and jobs into groups

In order to simplify our exposition and analysis, we introduce a new set of machines M' with rounded delays. For each $i \in M$, if $2^{k-1} \leq \rho_i < 2^k$, we introduce $i' \in M'$ with $\rho_{i'} = 2^k$. We then partition M' according to machine delays: machine $i \in M'$ is in $\langle k \rangle$ if $\rho_i = 2^k$; we set $\bar{\rho}_k = 2^k$. We also introduce a new set of jobs V' with rounded delays. For each $v \in V$, if $2^{\ell-1} \leq \rho_v < 2^\ell$, we introduce $v' \in V'$ with $\rho_{v'} = 2^\ell$. We then partition V' according to job delays: job $v \in V'$ is in $[\![\ell]\!]$ if $\rho_v = 2^\ell = \bar{\rho}_\ell$. For the remainder of the section, we work with the machine set M' and the job set V', ensuring that all machines or jobs within a group have identical delays. As shown in the following lemma, this partitioning is at the expense of at most a constant factor in approximation.

▶ **Lemma 2.** *The optimal makespan over the machine set V', M' is no more than a factor of 2 greater than the optimal solution over V, M.*

Proof. Consider any schedule σ on the machine set M. We first show that increasing the delay of each machine by a factor of 2 increases the makespan of the schedule by at most a factor of 2. We define the schedule σ' as follows. For every i, t, if $(i, t) \in \sigma(v)$, then $(i, 2t) \in \sigma'(v)$. It is easy to see that σ' maintains the precedence ordering of jobs, and that the time between the executions of any two jobs has been doubled. Therefore, σ' is a valid schedule with all communication delays doubled, and with the makespan doubled. ◀

We can assume that $\max_k\{\bar{\rho}_k\} \leq n$ since if we ever needed to communicate to a machine with delay greater than n we could schedule everything on a single machine in less time. Therefore, we have $K \leq \log n$ machine groups. Similarly, $\max_\ell\{\bar{\rho}_\ell\} \leq n$, implying that we have $L \leq \log n$ job groups.

2.2 The linear program

In this section, we design a linear program LP_α – Equations (1-11) – parametrized by $\alpha \geq 1$, for machine delays. Following Section 2.1, we assume that the machines and jobs are organized in groups, where each group $\langle k \rangle$ (resp., $[\![\ell]\!]$) is composed of machines (resp., jobs) that have identical delay.

$$C^*_\alpha \geq C_v \qquad \forall v \qquad (1)$$

$$C^*_\alpha \cdot |\langle k \rangle| \geq \sum_v y_{v,k} \qquad \forall k \qquad (2)$$

$$C_v \geq C_u + (\bar{\rho}_k + \bar{\rho}_\ell)(x_{v,k} - z_{u,v,k}) \qquad \forall u, v, k, \ell : u \prec v, v \in [\![\ell]\!] \qquad (3)$$

$$C_v \geq C_u + 1 \qquad \forall u, v : u \prec v \qquad (4)$$

$$\alpha(\bar{\rho}_k + \bar{\rho}_\ell) \geq \sum_u z_{u,v,k} \qquad \forall v, k, \ell : v \in [\![\ell]\!] \qquad (5)$$

$$\sum_k x_{v,k} = 1 \qquad \forall v \qquad (6)$$

$$C_v \geq 0 \qquad \forall v \qquad (7)$$

$$x_{v,k} \geq z_{u,v,k} \qquad \forall u, v, k \qquad (8)$$

$$y_{v,k} \geq x_{v,k} \qquad \forall v, k \qquad (9)$$

$$y_{u,k} \geq z_{u,v,k} \qquad \forall u, v, k \qquad (10)$$

$$z_{u,v,k} \geq 0 \qquad \forall u, v, k \qquad (11)$$

Variables. C^*_α represents the makespan of the schedule. For each job v, C_v represents the earliest completion time of v. For each job v and group $\langle k \rangle$, $x_{v,k}$ indicates whether or not v is first executed on a machine in group $\langle k \rangle$. For each $\langle k \rangle$ and pair of jobs u, v such that $u \prec v$ and $v \in [\![\ell]\!]$, $z_{u,v,k}$ indicates whether v is first executed on a machine in group $\langle k \rangle$ and the earliest execution of u is less that $\bar{\rho}_k + \bar{\rho}_\ell$ time before the execution of v. Intuitively, $z_{u,v,k}$ indicates whether there must be a copy of u executed on the same machine that first

executes v. For each job v and group $\langle k \rangle$, $y_{v,k}$ indicates whether $x_{v,k} = 1$ or $z_{u,v,k} = 1$ for some u; that is, whether or not some copy of v is placed on group $\langle k \rangle$. Constraints (7 - 11) guarantee that all variables are non-negative.

Makespan (2, 1). Constraint 1 states that the makespan is at least the maximum completion time of any job. Constraint 2 states that the makespan is at least the load on any single group.

Delays (3, 5). Constraint 3 states that the earliest completion time of $v \in [\![\ell]\!]$ must be at least $\bar{\rho}_k + \bar{\rho}_\ell$ after the earliest completion time of any predecessor u if v is first executed on a machine in group $\langle k \rangle$ and no copy of u is duplicated on the same machine as v. Constraint 5 limits the amount of duplication that can be done to improve the completion time of any job: if $v \in [\![\ell]\!]$ first executes on a machine in group $\langle k \rangle$ at time t, then the number of predecessors that may be executed in the $\bar{\rho}_k + \bar{\rho}_\ell$ steps preceding t is at most $\bar{\rho}_k$.

The remaining constraints enforce standard scheduling conditions. Constraint 4 states that the completion time of v is at least the completion time of any of its predecessors, and constraint 6 ensures that every job is executed on some group. Constraints 6 and 8 guarantee that $z_{u,v,k} \leq 1$ for all u, v, k. This is an important feature of the LP, since a large z-value could be used to disproportionately reduce the delay between two jobs in constraint 3.

▶ **Lemma 3** (LP_1 is a valid relaxation). *The minimum of C_1^* is at most* OPT.

Proof. Consider an arbitrary schedule σ with makespan C_σ, i.e. $C_\sigma = \max_{v,i,t}\{t : (i,t) \in \sigma(v)\}$.

LP solution. Set $C_1^* = C_\sigma$. For each job v, set C_v to be the earliest completion time of v in σ, i.e. $C_v = \min_{i,t}\{t : (i,t) \in \sigma(v)\}$. Set $x_{v,k} = 1$ if $\langle k \rangle$ is the group that contains the machine on which v first completes (choosing arbitrarily if there is more than one) and 0 otherwise. For u, v, k, set $z_{u,v,k} = 1$ if $u \prec v$, $x_{v,k} = 1$, $v \in [\![\ell]\!]$, and $C_v - C_u < \bar{\rho}_k + \bar{\rho}_\ell$ (0 otherwise). Set $y_{u,k} = \max\{x_{u,k}, \max_v\{z_{u,v,k}\}\}$.

Feasibility. We now establish that the solution defined is feasible. Constraints (1, 7–11) are easy to verify. We now establish constraints (2–5). Consider constraint 2 for fixed group $\langle k \rangle$. $\sum_v y_{v,k}$ is upper bound by the total load Λ on $\langle k \rangle$. The constraint follows from $C_\alpha^* \geq C_\sigma \geq \Lambda/|\langle k \rangle|$.

Consider constraint 3 for fixed u, v, k where $u \prec v$. Let $X = x_{v,k}$ and let $Z = z_{u,v,k}$. If $(X, Z) = (0,0), (0,1)$, or $(1,1)$ then the constraint follows from constraint 4. If $(X, Z) = (1,0)$, then by the assignment of $z_{u,v,k}$ we can infer that $C_v - C_u \geq \bar{\rho}_k + \bar{\rho}_\ell$, which shows the constraint is satisfied.

Consider constraint 5 for fixed v, k. If $x_{v,k} = 0$ then the result follows from the fact that $z_{u,v,k} = 0$ for all u. If $x_{v,k} = 1$, then we can infer that $v \in [\![\ell]\!]$. So, at most $\bar{\rho}_k + \bar{\rho}_\ell$ predecessors of v that can be scheduled in the $\bar{\rho}_k + \bar{\rho}_\ell$ time before C_v, ensuring that the constraint is satisfied. ◀

2.3 Deriving a rounded solution to the linear program

▶ **Definition 4.** (C, x, y, z) *is a* rounded solution *to LP_α if all values of x, y, z are either 0 or 1.*

Let LP_1 be defined over machine groups $\langle 1\rangle, \langle 2\rangle, \ldots, \langle K\rangle$ and job groups $[\![1]\!], [\![2]\!], \ldots, [\![L]\!]$. Given a solution $(\hat{C}, \hat{x}, \hat{y}, \hat{z})$ to LP_1, we construct an integer solution (C, x, y, z) to LP_{2K} as follows. For each v, k, set $x_{v,k} = 1$ if $k = \max_{k'}\{\hat{x}_{v,k'}\}$ (if there is more than one maximizing k, arbitrarily select one); set to 0 otherwise. Set $z_{u,v,k} = 1$ if $x_{v,k} = 1$ and $\hat{z}_{u,v,k} \geq 1/(2K)$; set to 0 otherwise. For all u, k, $y_{u,k} = \max\{x_{u,k}, \max_v\{z_{u,v,k}\}\}$. Set $C_v = 2K \cdot \hat{C}_v$. Set $C^*_{2K} = 2K \cdot \hat{C}^*_1$.

▶ **Lemma 5.** *If $(\hat{C}, \hat{x}, \hat{y}, \hat{z})$ is a valid solution to LP_1, then (C, x, y, z) is a valid solution to LP_{2K}.*

Proof. By constraint (6), $\sum_k \hat{x}_{v,k}$ is at least 1, so $\max_k\{\hat{x}_{v,k}\}$ is at least $1/K$. Therefore, $x_{v,k} \leq K\hat{x}_{v,k}$ for all v and k. Also, $z_{u,v,k} \leq 2K\hat{z}_{u,v,k}$ for any u, v, k by definition. By the setting of C_v for all v, $y_{v,k}$ for all v, k, and C^*_{2K}, it follows that constraints (1, 4-11) of LP_1 imply the respective constraints of LP_{2K}. We first establish constraint (2). For any fixed group $\langle k\rangle$,

$$\begin{aligned} 2K\hat{C}_1 \cdot |\langle k\rangle| &\geq 2K \sum_v \hat{y}_{v,k} = 2K \sum_v \max\{\hat{x}_{v,k}, \max_u\{\hat{z}_{v,u,k}\}\} && \text{by constraints 2, 11 of } \text{LP}_1 \\ &\geq 2K \sum_v \frac{x_{v,k} + \max_u\{z_{v,u,k}\}}{2K} \geq \sum_v y_{v,k} && \text{by definition of } y_{v,k} \end{aligned}$$

which entails constraint (2) by $C^*_{2K} = 2K\hat{C}^*_1$. It remains to establish constraint (3) for fixed u, v, k. We consider two cases. If $x_{v,k} - z_{u,v,k} \leq 0$, then the constraint is trivially satisfied in LP_{2K}. If $x_{v,k} - z_{u,v,k} = 1$, then, by definition of x and z, $\hat{x}_{v,k} - \hat{z}_{u,v,k}$ is at least $1/(2K)$. This entails that $\hat{C}_v \geq \hat{C}_u + ((\bar{\rho}_k + \bar{\rho}_\ell)/2K)$ which establishes constraint (3) of LP_{2K} by definition of C_v and C_u. ◀

▶ **Lemma 6.** $C_{2K} \leq 4K \cdot OPT$.

Proof. Lemma 2 shows that our grouping of machines does not increase the value of the LP by more than a factor of 2. Therefore, by Lemmas 3 and 5, $C_{2K} = 2K \cdot \hat{C}_1 \leq 4K \cdot \text{OPT}$. ◀

2.4 Computing a schedule given an integer solution to the LP

Suppose we are given a partition of M into K groups such that group $\langle k\rangle$ is composed of identical machines (i.e. for all $i, j \in \langle k\rangle$, $\rho_i = \rho_j$). Also, suppose we are given a partition of V into L groups such that group $[\![\ell]\!]$ is composed of jobs with identical in-delay. Finally, we are given a rounded solution (C, x, y, z) to LP_α defined over machine groups $\langle 1\rangle, \ldots, \langle K\rangle$ and job groups $[\![1]\!], \ldots [\![L]\!]$. In this section, we show that we can construct a schedule that achieves an approximation for machine delays in terms of α, K, and L. The combinatorial subroutine that constructs the schedule is defined in Algorithm 1. In the algorithm, we use a subroutine UDPS-Solver for Uniform Delay Precedence-Constrained Scheduling. An $O(\log \rho / \log\log \rho)$-asympototic approximation is given in [26]. For completeness, we use the UDPS-Solver presented and analyzed in [42], which generalizes the algorithm of [26] to incorporate non-uniform machine sizes.

We now describe Algorithm 1 informally. The subroutine takes as input the rounded LP_α solution (C, x, y, z) and initializes an empty schedule σ and global parameters T, θ to 0. For a fixed value of T, we iterate through all machine groups $\langle k\rangle$ and job groups $[\![\ell]\!]$, with decreasing ℓ. For a fixed value of T, k, ℓ, we check if there is some integer d such that $T = d(\bar{\rho}_k + \bar{\rho}_\ell)$. If so, we define $V_{k,\ell,d}$ and $U_{k,\ell,d}$ as in lines 4 and 5. $V_{k,\ell,d}$ represents the set of jobs in $[\![\ell]\!]$ assigned by the LP to machine group $\langle k\rangle$ in a single phase of length $\bar{\rho}_k + \bar{\rho}_\ell$.

Algorithm 1 Machine Delay Scheduling with Duplication.

Init: $\forall v,\ \sigma(v) \leftarrow \varnothing;\ T \leftarrow 0;\ \theta \leftarrow 0$
1 **while** $T \leq C^*_\alpha$ **do**
2 **forall** *machine groups* $\langle k \rangle$ **do**
3 **for** *job group* $[\![\ell]\!] = [\![L]\!]$ *to* $[\![1]\!]$*:* $\exists$ *integer* $d,\ T = d(\bar{\rho}_k + \bar{\rho}_\ell)$ **do**
4 $V_{k,\ell,d} \leftarrow \{v \in [\![\ell]\!] : x_{v,k} = 1 \text{ and } T \leq C_v < T + \bar{\rho}_k + \bar{\rho}_\ell\}$
5 $U_{k,\ell,d} \leftarrow \{u : \exists v \in V_{k,\ell,d},\ u \prec v \text{ and } T \leq C_u < T + \bar{\rho}_k + \bar{\rho}_\ell\}$
6 $\sigma' \leftarrow$ UDPS-Solver on $(V_{k,\ell,d} \cup U_{k,\ell,d}, \langle k \rangle, \bar{\rho}_k + \bar{\rho}_\ell)$
7 $\forall v, i, t,$ if $(i,t) \in \sigma'(v)$ then $\sigma(v) \leftarrow \sigma(v) \cup \{(i, \theta + \bar{\rho}_k + \bar{\rho}_\ell + t)\}$
8 $\theta \leftarrow \theta + 2(\bar{\rho}_k + \bar{\rho}_\ell)$
9 $T \leftarrow T + 1$

$U_{k,\ell,d}$ represents predecessors of $V_{k,\ell,d}$ whose LP completion times are within $\bar{\rho}_k + \bar{\rho}_\ell$ of their successor in $V_{k,\ell,d}$. We then call UDPS-Solver to construct a UDPS schedule σ' on jobs $V_{k,\ell,d} \cup U_{k,\ell,d}$, machines in $\langle k \rangle$, and delay $\bar{\rho}_k + \bar{\rho}_\ell$. We then append σ' to σ. Once all values of k, ℓ have been checked, we increment T and repeat until all jobs are scheduled. The structure of the schedule produced by Algorithm 1 is depicted in Figure 4. Lemma 7 (entailed by Lemma 45 of [42]) provides guarantees for the UDPS-Solver subroutine.

▶ **Lemma 7.** *Let U be a set of η jobs such that for any $v \in U$, $|\{u \in U : u \prec v\}| \leq \alpha\delta$. Given input U, a set of μ identical machines, and delay δ, UDPS-Solver produces, in polynomial time, a valid UDPS schedule with makespan at most $3\alpha\delta \log(\alpha\delta) + (2\eta/\mu)$.*

▶ **Lemma 8.** *Algorithm 1 outputs a valid schedule in polynomial time.*

Proof. It is easy to see that the algorithm runs in polynomial time, and Lemma 7 entails that precedence constraints are obeyed on each machine. Consider a fixed v, k, d such that $v \in V_{k,\ell,d}$. By line 7, we insert a communication phase of length $\bar{\rho}_k + \bar{\rho}_\ell$ before appending the schedule of any set of jobs $V_{k,\ell,d} \cup U_{k,\ell,d}$ on any machine group $\langle k \rangle$. So, by the time Algorithm 1 executes any job in $V_{k,\ell,d}$, every job u such that $C_u < d(\bar{\rho}_k + \bar{\rho}_\ell)$ is available to all machines, including those in group $\langle k \rangle$. So the only predecessors of v left to execute are those jobs in $U_{k,\ell,d}$. Therefore, all communication constraints are satisfied. ◀

▶ **Lemma 9.** *If (C, x, y, z) is a rounded solution to LP_α then Algorithm 1 outputs a schedule with makespan at most $12\alpha \log(\rho_{\max})(KLC^*_\alpha + \rho_{\max}(K + L))$.*

Proof. Fix any schedule σ. Note that the schedule produced by the algorithm executes a single job group on a single machine group at a time. Our proof establishes a bound for the total time spent executing a single job group on a single machine group, then sums this bound over all K machine groups and L job groups.

▷ Claim 10. For any v, u, k, ℓ, d, if $v \in V_{k,\ell,d}$ and $C_v < C_u + (\bar{\rho}_k + \bar{\rho}_\ell)$ then $z_{u,v,k,\ell} = 1$.

Proof. Fix u, v, k, ℓ, d such that $v \in V_{k,\ell,d}$ and $C_v < C_u + (\bar{\rho}_k + \bar{\rho}_\ell)$. By the definition of $V_{k,\ell,d}$, $x_{v,k}$ is 1. By constraint 3, $C_v \geq C_u + \bar{\rho}_k(1 - z_{u,v,k})$, implying that $z_{u,v,k}$ cannot equal 0. Since $z_{u,v,k}$ is either 0 or 1, we have $z_{u,v,k} = 1$. ◁

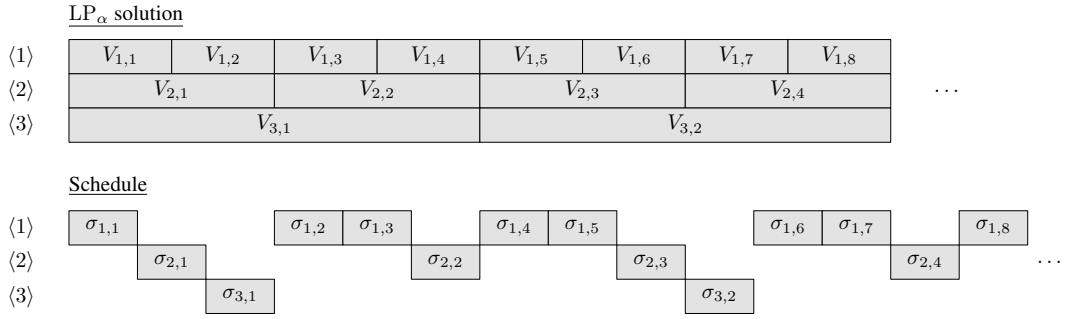

Figure 4 Structure of the schedule produced by Algorithm 1. $\sigma_{k,d}$ denotes a schedule of $V_{k,\ell,d}$ on the machines in group $\langle k \rangle$. The algorithm scans the LP$_\alpha$ solution by increasing time (left to right). At the start of each $V_{k,\ell,d}$, the algorithm constructs a schedule of the set and appends it to the existing schedule.

▷ Claim 11. For any k, ℓ, we show

a $\sum_d |V_{k,\ell,d} \cup U_{k,\ell,d}| \leq C^*_\alpha \cdot |\langle k \rangle|$ and

b for any d and $v \in V_{k,\ell,d}$, the number of v's predecessors in $V_{k,\ell,d} \cup U_{k,\ell,d}$ is at most $\alpha(\bar{\rho}_k + \bar{\rho}_\ell)$.

Proof. Fix k, ℓ. We first prove a. For any v in $V_{k,\ell,d}$ we have $x_{v,k} = 1$ by the definition of $V_{k,\ell,d}$. Consider any u in $U_{k,\ell,d}$. By definition, there exists a $v' \in V_{k,\ell,d}$ such that $x_{v',k} = 1$ and $C_v < C_u + (\bar{\rho}_k + \bar{\rho}_\ell)$; fix such a v'. By claim 10, $z_{u,v',k} = 1$. So, by constraint 10, $y_{v,k} = 1$ for every job $v \in V_{k,\ell,d} \cup U_{k,\ell,d}$. For any $d' \neq d$, $V_{k,\ell,d}$ and $V_{k,\ell,d'}$ are disjoint. So $\sum_d |V_{k,\ell,d} \cup U_{k,\ell,d}|$ is at most the right-hand side of constraint 2, which is at most $C^*_\alpha \cdot |\langle k \rangle|$.

We now prove b. Fix v, d such that $v \in V_{k,\ell,d}$. Consider any u in $V_{k,\ell,d} \cup U_{k,d}$ such that $u \prec v$. By definition of $V_{k,\ell,d}$ and $U_{k,\ell,d}$, $C_v < C_u + (\bar{\rho}_k + \bar{\rho}_\ell)$. By Claim 10, $z_{u,v,k} = 1$. The claim then follows from constraint (5). ◁

By Lemma 7 and Claim 11b, the time spent executing jobs in $[\![\ell]\!]$ on machines in $\langle k \rangle$ is at most

$$\sum_d \left(3\alpha(\bar{\rho}_k + \bar{\rho}_\ell) \log(\alpha(\bar{\rho}_k + \bar{\rho}_\ell)) + \frac{2 \cdot |V_{k,\ell,d} \cup U_{k,\ell,d}|}{|\langle k \rangle|} \right)$$

The summation over the first term is at most $\lceil C^*_\alpha / (\bar{\rho}_k + \bar{\rho}_\ell) \rceil \, 3\alpha(\bar{\rho}_k + \bar{\rho}_\ell) \log(\alpha(\bar{\rho}_k + \bar{\rho}_\ell))$ which is at most $3C^*_\alpha \alpha \log(\alpha(\bar{\rho}_k + \bar{\rho}_\ell)) + 3\alpha(\bar{\rho}_k + \bar{\rho}_\ell) \log(\alpha(\bar{\rho}_k + \bar{\rho}_\ell))$. The summation over the second term is at most $2C^*_\alpha$ by claim 11a. Summing over all K machine groups and L job groups, and considering $K, L \leq \log \rho_{\max}$, the total length of the schedule is at most $12\alpha \log(\rho_{\max})(KLC^*_\alpha + \rho_{\max}(K + L))$. ◀

▶ **Theorem 1** (Job Delays and Machine Delays). *There exists a polynomial time algorithm to compute a valid machine delays and job precedence delays schedule with makespan* $O((\log n)^9(\mathrm{OPT} + \rho_{\max}))$.

Proof. Lemma 5 entails that (C, x, y, z) is a valid solution to LP$_{2K}$. Lemma 6 entails that $C^*_{2K} \leq 4K \cdot \mathrm{OPT}$. With $\alpha = 2K$, Lemma 9 entails that the makespan of our schedule is at most $12\alpha \log(\rho_{\max})(KLC^*_\alpha + \rho_{\max}(K+L)) = 48(\log \rho_{\max})^5 \mathrm{OPT} + 24(\log \rho_{\max})^3 \rho_{\max}$ for the case with no out-delays. By Lemma 37 of [42], the length of our schedule is $O((\log \rho_{\max})^9(\mathrm{OPT} + \rho_{\max})$ The theorem is entailed by $\rho_{\max} \leq n$. This proves the theorem. ◀

▶ **Corollary 12** (Machine Delays). *There exists a polynomial time algorithm to compute a valid machine delays schedule with makespan* $O((\log n)^5 \cdot (OPT + \rho))$.

Proof. Lemma 5 entails that (C, x, y, z) is a valid solution to LP_{2K}. Lemma 6 entails that $C^*_{2K} \leq 4K \cdot \text{OPT}$. With $\alpha = 2K$, Lemma 9 entails that the makespan of our schedule is at most $12\alpha \log(\rho_{\max})(KLC^*_\alpha + \rho_{\max}(K + L)) = 48(\log \rho_{\max})^5 \text{OPT} + 24(\log \rho_{\max})^3 \rho_{\max}$ for the case with no out-delays. By Lemma 41 of [42], the length of our schedule is $O((\log \rho_{\max})^5(\text{OPT} + \rho_{\max})$ The theorem is entailed by $\rho_{\max} \leq n$. ◀

2.5 Combinatorial Algorithm for Uniform Machine Delays

The only noncombinatorial subroutine of our algorithm is solving the linear program. In this section, we describe how to combinatorially construct a rounded solution to LP_1 when machine delays are uniform (i.e. for all i, j, $\rho^{\text{in}}_i = \rho^{\text{out}}_i = \rho^{\text{in}}_j = \rho^{\text{out}}_j$), machine speeds are unit, and machine capacities are unit. We let δ represent the uniform machine delay. By Lemma 37 of [42], we focus on the case where all job out-delays are 0. We let $\rho_v = \delta + \rho^{\text{in}}_v$ for any job v.

Since delays, speeds, and capacities are uniform, there is only one machine group: $\langle 1 \rangle$. Set $x_{v,1} = y_{v,1} = 1$ for all v. For each job v, we define C_v as follows. If v has no predecessors, we set $C_v = 0$. Otherwise, we order v's predecessors such that $C_{u_i} \geq C_{u_{i+1}}$. We define $C_v = \max_{1 \leq i \leq \rho_v}\{C_{u_i} + i\}$. We set $C^* = \max\{n/m, \max_v\{C_v\}\}$. We set $z_{u,v,1} = 1$ if $u \prec v$ and $C_v - C_u < \rho_v$; and set to 0 otherwise.

▶ **Lemma 13.** $C^* \leq OPT$.

Proof. Consider an arbitrary schedule in which t_v is the earliest completion time of any job v. We show that, for any v, $t_v \geq C_v$, which is sufficient to prove the lemma.

We prove the claim by induction on the number of predecessors of v. The claim is trivial if v has no predecessors. Suppose that the claim holds for all of v's predecessors and let $y = \arg\max_{1 \leq i \leq \rho_v}\{C_{u_i} + i\}$. Then $C_v = C_{u_y} + y \leq t_{u_y} + y$ (by IH) $= t_y + |\{u_x : 0 \leq x \leq y\}| \leq t_y + \rho_v$. This entails that all jobs $u_1, \ldots u_y$ must be executed on the same machine as v. Now suppose, for the sake of contradiction, that $t_v < C_v$. Then all jobs $u \in \{u_x : 0 \leq x < y\}|$ must be executed serially in the time $t_v - t_{u_y} < C_v - t_{u_y} = |\{u_x : 0 \leq x \leq y\}|$ which gives us our contradiction. ◀

▶ **Lemma 14.** (C, x, y, z) *is a rounded solution to* LP_1.

Proof. It is easy to see that constraints (1, 2, 3, 4, 6, 7, 8, 9, 10 11) are satisfied by the assignment. So we must only show that constraint (5) is satisfied for fixed v. We can see from the definition of C_v, that maximum number of predecessors u such that $C_v - C_u < \rho_v + \rho$ is at most $\rho_v + \rho$. This proves the lemma. ◀

▶ **Lemma 15** (Combinatorial Algorithm for Job Delays). *There exists a purely combinatorial, polynomial time algorithm to compute a schedule for Job Delays with makespan* $O((\log n)^6(OPT + \max_v\{\rho_v\}))$.

Proof. Lemma 9 entails that the length of the schedule is at most $12(\log \rho_{\max})^2(\text{OPT} + \rho_{\max})$ for the problem with job in-delays. By Lemma 37 of [42] we achieve a makespan of $O((\log \rho_{\max})^6(\text{OPT} + \rho_{\max}))$ for job in- and out-delays. ◀

Zero-Rate Thresholds and New Capacity Bounds for List-Decoding and List-Recovery

Abstract

In this work we consider the list-decodability and list-recoverability of arbitrary q-ary codes, for all integer values of $q \geqslant 2$. A code is called $(p, L)_q$-list-decodable if every radius pn Hamming ball contains less than L codewords; $(p, \ell, L)_q$-list-recoverability is a generalization where we place radius pn Hamming balls on every point of a combinatorial rectangle with side length ℓ and again stipulate that there be less than L codewords.

Our main contribution is to precisely calculate the maximum value of p for which there exist infinite families of positive rate $(p, \ell, L)_q$-list-recoverable codes, the quantity we call the *zero-rate threshold*. Denoting this value by p_*, we in fact show that codes correcting a $p_* + \varepsilon$ fraction of errors must have size $O_\varepsilon(1)$, i.e., independent of n. Such a result is typically referred to as a "Plotkin bound." To complement this, a standard random code with expurgation construction shows that there exist positive rate codes correcting a $p_* - \varepsilon$ fraction of errors. We also follow a classical proof template (typically attributed to Elias and Bassalygo) to derive from the zero-rate threshold other tradeoffs between rate and decoding radius for list-decoding and list-recovery.

Technically, proving the Plotkin bound boils down to demonstrating the Schur convexity of a certain function defined on the q-simplex as well as the convexity of a univariate function derived from it. We remark that an earlier argument claimed similar results for q-ary list-decoding; however, we point out that this earlier proof is flawed.

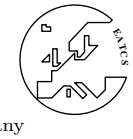
1 Introduction

Given a code $\mathcal{C} \subset [q]^n$, a fundamental problem of coding-theory is to determine how "well-spread" $\mathcal{C}$ can be if we also insist that $\mathcal{C}$ have large rate $R = \frac{\log_q |\mathcal{C}|}{n}$. The most basic way of quantifying "well-spread" is by insisting that all pairs of codewords are far apart. That is,



we hope that the minimum distance $d := \min\{d_{\mathrm{H}}(\boldsymbol{c}, \boldsymbol{c}') : \boldsymbol{c} \neq \boldsymbol{c}' \in \mathcal{C}\}$ is large, where $d_{\mathrm{H}}(\cdot, \cdot)$ denotes Hamming distance, i.e., the number of coordinates on which the two strings differ. Equivalently, given any word $\boldsymbol{y} \in [q]^n$, we have that $|\mathcal{B}_{\mathrm{H}}(\boldsymbol{y}, r) \cap \mathcal{C}| \leqslant 1$, where $r = \lfloor d/2 \rfloor$ and $\mathcal{B}_{\mathrm{H}}(\boldsymbol{y}, r) = \{\boldsymbol{x} \in [q]^n : d_{\mathrm{H}}(\boldsymbol{x}, \boldsymbol{y}) \leqslant r\}$ denotes the Hamming ball of radius r centered at $\boldsymbol{y}$.

One can naturally relax this requirement to the notion of list-decodability: instead of upper-bounding $|\mathcal{B}_{\mathrm{H}}(\boldsymbol{y}, r) \cap \mathcal{C}|$ by 1, we upper bound it by a larger integer $L - 1$.[1] Equivalently, if we place Hamming balls of radius r on each codeword of $\mathcal{C}$, no vector in $[q]^n$ is covered by L or more balls. If $\mathcal{C}$ satisfies this property we call it $(p, L)_q$-list-decodable. Initially introduced by Elias and Wozencraft in the 1950's [16, 50, 17], this relaxed notion of decoding has been intensively studied in recent years, in part motivated by purely coding-theoretic concerns, but also due to its connections with theoretical computer science more broadly [20, 3, 38, 37, 33, 47].

A further generalization of list-decoding is provided by *list-recoverability*. In this case, one considers tuples of input lists $\boldsymbol{\mathcal{Y}} = (\mathcal{Y}_1, \ldots, \mathcal{Y}_n)$ where each $\mathcal{Y}_i \subset [q]$ is of size at most ℓ, and the requirement is that the number of codewords $\boldsymbol{c}$ satisfying $|\{i \in [n] : c_i \notin \mathcal{Y}_i\}| \leqslant pn$ is at most $L - 1$. Such a code is deemed $(p, \ell, L)_q$-list-recoverable. Note that $(p, 1, L)_q$-list-recoverability is the same as $(p, L)_q$-list-decoding, demonstrating that list-recoverability is a more general notion. While it was originally defined as an abstraction required for the task of uniquely-/list-decoding concatenated codes [21, 22, 23, 24], it has since found myriad further applications in computer science more broadly, e.g., in cryptography [30, 31], randomness extraction [29], hardness amplification [14], group testing [32, 41], streaming algorithms [15], and beyond.

When it comes to list-decoding and list-recovery, the optimal tradeoff between decoding-radius p and rate R is well-understood if one is satisfied with list-sizes $L = O(1)$.[2] That is, there exist $(p, \ell, O(\ell/\varepsilon))_q$-list-recoverable codes of rate $1 - H_{q,\ell}(p) - \varepsilon$ where[3]

$$H_{q,\ell}(p) \coloneqq p \log_q \left(\frac{q - \ell}{p} \right) + (1 - p) \log_q \left(\frac{\ell}{1 - p} \right);$$

conversely, if the rate is at least $1 - H_{q,\ell}(p) + \varepsilon$ then it will not be list-recoverable for any $L = o\left(q^{\varepsilon n}\right)$ [44, Theorem 2.4.12]. (Note that setting $\ell = 1$ recovers the more well-known list-decoding capacity theorem.) While this already provides some "coarse-grained" information concerning the list-decodability/-recoverability of codes, it leaves many questions unanswered.

For example, one can ask about the maximum rate of a $(p, 3)_q$-list-decodable code. That is, what is the maximum rate of a code that never contains more than 2 points from a Hamming ball of radius pn? However, this question as stated appears be quite difficult to solve: any improvement for the special case of $L = 2$ and $q = 2$ would require improving either on the Gilbert-Varshamov bound [19, 48] (on the "possibility" side) or the linear programming bounds [49, 39, 13] (on the "impossibility" side). Unfortunately, despite decades of interest in this basic question hardly any asymptotic improvements on these bounds have been provided in the past fifty years.

Zero-rate thresholds for list-decoding and -recovery. We therefore begin by targeting a more modest question: what is the maximum $p_* = p_*(q, \ell, L)$ such that for any $p < p_*$ there exist infinite families of q-ary $(p, \ell, L)_q$-list-recoverable codes of positive rate? That is,

[1] We find it most convenient to let L denote 1 more than the list-size, which is admittedly nonstandard, but will make our computations much cleaner.

[2] Or indeed, if we insist on L just being subexponential.

[3] For $\ell = 1$, $H_{q,1}$ reduces to the q-ary entropy function denoted by H_q.

imagining the curve describing the achievable tradeoffs with the rate R on the y-axis and decoding radius p on the x-axis, instead of asking to describe this entire curve, we simply seek to determine the point where this curve crosses the x-axis (clearly, this curve is monotonically decreasing).

Over the binary alphabet, setting $\ell = 1$ and $L = 2$ in this question we recover a famous result of Plotkin [42]: the maximum fraction of errors that can be uniquely-decoded by an infinite family of positive rate binary codes is $1/4$. Over general q-ary alphabets, this value is similarly known to be $\frac{q-1}{2q}$ (folklore; see, e.g., [28, Theorem 4.4.1]). The value of $p_*(2, 1, L)$ has been computed by Blinovsky [5] for all L, and is known to be

$$p_*(2, 1, L) = \frac{1}{2} - \frac{\binom{2k}{k}}{2^{2k+1}} \text{ if } L = 2k \text{ or } L = 2k + 1.$$

While this expression is quite impenetrable at first glance, here is a natural probabilistic interpretation: given $x_1, \ldots, x_L \in \{0, 1\}$, let $\mathsf{pl}(x_1, \ldots, x_L)$ denote the number of times the more popular bit appears.[4] We then have

$$p_*(2, 1, L) = 1 - \frac{1}{L} \mathop{\mathbb{E}}_{(X_1,\cdots,X_L)\sim \mathrm{Bern}(1/2)^{\otimes L}} [\mathsf{pl}(X_1, \cdots, X_L)],$$

where the notation $(X_1, \cdots, X_L) \sim \mathrm{Bern}(1/2)^{\otimes L}$ denotes that L independent unbiased bits are sampled.

It is then not difficult to conjecture the value for $p_*(q, \ell, L)$: if $\mathsf{pl}_\ell(x_1, \ldots, x_L)$ denotes the top-ℓ-plurality value of $x_1, \ldots, x_L \in [q]$, i.e., $\mathsf{pl}_\ell(x_1, \ldots, x_L) = \max_{\Sigma\subseteq[q]:|\Sigma|=\ell} |\{i \in [L] : x_i \in \Sigma\}|$, then it should be that

$$p_*(q, \ell, L) = 1 - \frac{1}{L} \mathop{\mathbb{E}}_{(X_1,\cdots,X_L)\sim \mathrm{Unif}([q])^{\otimes L}} [\mathsf{pl}_\ell(X_1, \cdots, X_L)]. \tag{1}$$

This quantity is fairly natural: one can interpret it as the minimum radius of a list-recovery ball (i.e., a set of the form $\{\boldsymbol{v} \in [q]^n : v_i \in \mathcal{Y}_i \text{ for at least } (1-p)n \ i \in [n]\}$) that will contain L codewords in the "typical" case. For the case of $\ell = 1$, i.e., q-ary list-decoding, a proof is claimed in [6, 7]; however, as we outline in Section 3 this proof is flawed. In this work we provide a rigorous derivation of Equation (1) for all values of ℓ, L and q with $1 \leqslant \ell \leqslant q$.

More precisely, we obtain the following results:

- A proof that $(p, \ell, L)_q$-list-recoverable q-ary codes with $p > p_*(q, \ell, L)$ have *constant-size*, i.e., independent of n. This should be interpreted as a generalization of the Plotkin bound [42], which states that binary codes uniquely-decodable from a $1/4 + \varepsilon$ fraction of errors have size at most $O(1/\varepsilon)$. For this reason we call our result a "Plotkin bound for list-recovery."
- Adapting the Elias-Bassalygo argument [4], we subsequently derive upper bounds on the rate of $(p, \ell, L)_q$-list-recoverable q-ary codes when $p < p_*(q, \ell, L)$.
- To complement this, we show that there exist infinite families of positive rate q-ary codes that are $(p, \ell, L)_q$-list-recoverable whenever $p < p_*(q, \ell, L)$. We are therefore justified in calling $p_*(q, \ell, L)$ the zero-rate threshold for list-recovery.

We now describe our techniques in more detail.

[4] We use pl to stand for "plurality". However, we caution that this function does not output a most popular symbol (as is perhaps more in line with the standard meaning of plurality), but the number of $i \in [L]$ for which x_i equals a most popular symbol.

1.1 Our techniques

Schur convexity of the function $f_{q,L,\ell}$. Following prior work [6],[5] our task requires us to answer the following question. Consider the function on distributions P over the alphabet $[q]$ defined as

$$f_{q,L,\ell}(P) \coloneqq \mathop{\mathbb{E}}_{(X_1,\cdots,X_L)\sim P^{\otimes L}} \left[\mathsf{pl}_\ell(X_1,\cdots,X_L)\right].$$

Analogously to before, the notation $(X_1,\cdots,X_L)\sim P^{\otimes L}$ means that L independent samples are taken from the distribution P. A crucial ingredient for deriving the Plotkin bound is a demonstration that this function is minimized by the uniform distribution.

There is a well-studied class of functions on finite distributions with the property that they are minimized by the uniform distribution: *Schur convex* functions. These are the functions that are monotonically-increasing with respect to the *majorization*-ordering, which compares vectors of real numbers by first sorting the vectors in descending order and then checking to see if all the prefix sums of one vector is greater than or equal to the prefix sums of the other. The important detail for us is that the uniform vector $(1/q,\ldots,1/q)\in\mathbb{R}^q$, corresponding to the uniform distribution, is majorized by *every* other vector corresponding to a distribution over $[q]$.

To demonstrate the Schur convexity of this function, we use the Schur-Ostrowski criterion, which states that Schur-convexity is equivalent to the non-negativity of a certain expression involving partial derivatives. Showing that this expression is non-negative boils down to a combinatorial accounting game, where we can show that the positive contributions arising from certain terms exceed the negative contributions arising from others.

Convexity of the univariate function $g_{q,L,\ell}$. Another important technical ingredient that we need for the proof of the Plotkin bound is the convexity of the univariate function

$$g_{q,L,\ell}(w) \coloneqq f_{q,L,\ell}(P_{q,\ell,w}),$$

where the distribution $P_{q,\ell,w}=(p_1,\ldots,p_q)$ is defined as

$$p_i = \begin{cases} \frac{w}{q-\ell} & \text{if } i \leqslant q-\ell \\ \frac{1-w}{\ell} & \text{if } i \geqslant q-\ell+1 \end{cases}.$$

In order to show the function is convex, we prove the second derivative is non-negative. In differentiating, we use the expression for $g_{q,L,\ell}$ in terms of $f_{q,L,\ell}$ and apply the chain rule. Showing the resulting expression is positive is again a sort of combinatorial accounting game: we can show the positive terms contribute more than the negative terms.

Quite interestingly, for $\ell=1$ (i.e., the case relevant for list-decoding) we only prove the convexity of the function $f_{q,1,L}$ on the interval $[0,(q-1)/q]$. Fortunately, as we can also easily show that $g_{q,1,L}$ decreases on the interval $[0,(q-1)/q]$ and then increases on the interval $[(q-1)/q,1]$,[6] convexity of $f_{q,1,L}$ on $[0,(q-1)/q]$ suffices for our purposes. And indeed, this is not an artifact of the proof: Blinovsky had already observed that convexity of $f_{q,1,L}$ does not hold on the entire interval $[0,1]$ [6, 7]. However, for $\ell\geqslant 2$ we obtain that convexity of $f_{q,\ell,L}$ does indeed hold on the entire interval $[0,1]$. We note that the second derivative does behave qualitatively differently, so this is perhaps not too surprising in hindsight; we comment on this further in [46, Remark 5].

---

[5] In fact, [6] only considers list-decoding, so a slight adaptation of this argument is required for list-recovery.
[6] This is in fact an easy corollary of the Schur convexity of $f_{q,1,L}$.

Plotkin bound. Armed with these (Schur-)convexity results, we aim to prove a Plotkin bound for list-decoding/-recovery. That is, if a q-ary code is $(p, \ell, L)_q$-list-recoverable with $p \geqslant p_*(q, \ell, L) + \varepsilon$, how large can the code be? Following the template of the standard argument (although certain subtleties arise when generalizing to list-recovery), we can show that such a code must be of constant size, i.e., independent of n.

Informally, the argument begins with a "preprocessing step" that prunes away some (but, crucially, not too many) codewords and yields a more structured subcode that we can subsequently analyze. The codewords of this subcode are very "balanced" in the sense that all patterns of symbols appear with roughly the same frequency. In particular, every pattern of length t should appear roughly a $1/q^t$ fraction of the time (or the code is very "biased," in which case a separate argument bounds its size).

To analyze this subcode $\mathcal{C}'$ we apply a double-counting argument to the average radius (see [46, Definition 10]) to cover L-subsets (where for list-recoverability, this radius is measured via the distance to a tuple of input lists). The lower bound on this quantity follows quite naturally from the list-decodability/-recoverability of the code, together with the "balancedness" of the subcode. For the upper bound, we compute the radius of an L-subset in terms of the empirical distribution of a coordinate $k \in [n]$, i.e., each $x \in [q]$ is assigned probability mass $P_k(x) = \frac{1}{M} \sum_{\boldsymbol{x} \in \mathcal{C}'} \mathbb{1}\{x_k = x\}$. By the Schur convexity of the function $f_{q,L,\ell}$ and the convexity of the univariate function $g_{q,L,\ell}$, we can bound this in terms of a distribution placing total mass $w \leqslant \frac{q-\ell}{q}$ on the last ℓ elements of $[q]$ and mass $\frac{1-w}{q-\ell}$ on each of the others. The result then follows.

We remark that, due to our use of Ramsey-theoretic arguments, the precise bound we obtain on the code size is quite poor. We have made no effort to optimize this constant. However, we do believe it would be interesting to improve this bound; we discuss this further in Section 4.

Elias-Bassalygo-style bound. After deriving this Plotkin bound, a well-known argument template (typically attributed to Elias and Bassalygo [4]) allows one to derive more general tradeoffs between the rate R and the noise-resilience parameters $(p, \ell, L)_q$. Informally, this proceeds by covering the space $[q]^n$ by a bounded number of list-recovery balls. The radius of these balls is carefully chosen to allow one to apply the Plotkin bound to the subcodes obtained by taking the intersection of the code with these balls. On the other hand, the number of list-recovery balls needed to cover $[q]^n$, known as the covering number, can be sharply estimated. From the above two bounds (the Plotkin bound and the covering number), a bound on the size of the whole code can be derived.

Possibility result: random code with expurgation. To complement the Plotkin bound, we show that if the decoding radius p is less than $p_*(q, \ell, L)$ then there exist infinite families of $(p, \ell, L)_q$-list-recoverable q-ary codes. This justifies our "zero-rate threshold" terminology for $p_*(q, \ell, L)$. The argument is completely standard, obtained by sampling a random code and subsequently expurgating codewords to destroy all size-L lists that can fit into Hamming balls of radius np. In fact, the lower bound on achievable rate is derived from the exact large deviation exponent of a certain quantity known as the average radius (cf. [46, Definition 12]) of a tuple of random vectors. Therefore the bound holds under a stronger notion called average-radius list-recovery: namely, for any subset of L codewords $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_j$ and any tuple of input lists $(\mathcal{Y}_1, \ldots, \mathcal{Y}_n)$, we have

$$\sum_{j=1}^{L} |\{i \in [n] : x_{j,i} \notin \mathcal{Y}_i\}| > Lpn \ .$$

1.2 Discussion on related work

Lower bounds for small q and/or L. For the case of $(p,3)_2$-list-decoding, it was shown in [26, Theorem 6.1] that the *threshold rate*[7] of random binary *linear* codes equals

$$\frac{1}{2}(2 - H_2(3p) - 3p\log_2(3)). \tag{2}$$

The term *threshold* refers to the critical rate below which a random binary linear code is $(p,3)_2$-list-decodable with high probability and above which it is not with high probability. This result was recently extended to the following two cases [45]. For $(p,4)_2$-list-decoding, the threshold rate of random binary linear code is lower bounded by [45, Theorem 1.3]

$$\frac{1}{3}\min_{\substack{x_1,x_2\geqslant 0\\ x_1+2x_2\leqslant 4p\\ x_1+x_2\leqslant 1}} 3 - \eta_2(x_1,x_2) - 2x_1 - x_2\log_2(3). \tag{3}$$

Here we use the notation

$$\eta_q(x_1,\ldots,x_t) \coloneqq \sum_{i=1}^{t} x_i \log_q \frac{1}{x_i} + \left(1 - \sum_{i=1}^{t} x_i\right)\log_q \frac{1}{1-\sum_{i=1}^{t} x_i}$$

for a partial probability vector $(x_1,\ldots,x_t) \in \mathbb{R}^t_{\geqslant 0}$ satisfying $t \leqslant q$ and $x_1 + \cdots + x_t \leqslant 1$. Note that $\eta_2(x) = H_2(x)$, however, this is no longer the case for $q > 2$. Moreover, for $(p,3)_q$-list-decoding, [45, Theorem 1.5] showed that the threshold rate of random linear code is at least

$$\frac{1}{2}\min_{\substack{x_1,x_2\geqslant 0\\ x_1+2x_2\leqslant 3p\\ x_1+x_2\leqslant 1}} 2 - \eta_q(x_1,x_2) - x_1\log_q(3(q-1)) - x_2\log_q(q-1)(q-2). \tag{4}$$

Our general lower bound (cf. Theorem 14) for list-recovery (numerically) matches Equations (2)–(4) upon particularizing the parameters q,ℓ,L suitably. See Figures 1a–1c. It is possible to analytically prove this observation, though we do not pursue it in the current paper. The rationale underlying this phenomenon is that the threshold rate of random linear codes for list-recovery is expected to match the rate achieved by random codes with expurgation (with the notable exception of zero-error list-recovery [25]). This conjecture, in its full generality, remains unproved, although it is partially justified in several recent works [40, 25, 26, 45].

Hash codes. One may note that for $\ell \geqslant 2$, our upper and lower bounds typically exhibit a large gap even at $p = 0$. See Figures 1e–1h. We provide evidence below indicating that closing this gap is in general a rather challenging task and necessarily requires significantly new ideas. Let us focus on the vertical axis $p = 0$, known as *zero-error list-recovery*. We observe that some configurations of q,ℓ,L in this regime encode several longstanding open questions in combinatorics. Indeed, consider $\ell = q-1, L = q$. The $(0,q-1,q)_q$-list recoverability condition can then be written as: for any $\mathcal{Y}_1,\cdots,\mathcal{Y}_n \in \binom{[q]}{q-1}$,

$$|\{\boldsymbol{x} \in \mathcal{C} : |\{j \in [n] : x_j \notin \mathcal{Y}_j\}| = 0\}| \leqslant L-1,$$

[7] We warn the reader not not to confuse this concept with that of the zero-rate threshold.

i.e.,

$$|\{\boldsymbol{x} \in \mathcal{C} : \forall j \in [n],\, x_j \in \mathcal{Y}_j\}| \leqslant L - 1.$$

Taking the contrapositive, we note that this condition is further equivalent to: for any $\{\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L\} \in \binom{\mathcal{C}}{L}$, there exists $j \in [n]$ such that $|\{x_{1,j}, \cdots, x_{L,j}\}| = q$. In words, for any q-tuple of codewords in a $(0, q-1, q)_q$-list-recoverable code, there must exist one coordinate such that the corresponding q-ary symbols in the tuple are all distinct. Such a code is also known as a *q-hashing* in combinatorics. It is well-known [18, 35] that a probabilistic construction yields such codes of rate[8] at least

$$C_{(0,q-1,q)_q} \geqslant \frac{1}{q-1} \log_q \frac{1}{1 - \frac{q!}{q^q}}. \tag{5}$$

In the same paper [18] also proved an upper bound

$$C_{(0,q-1,q)_q} \leqslant \frac{q!}{q^{q-1}} \log_q(2). \tag{6}$$

Another upper bound

$$C_{(0,q-1,q)_q} \leqslant \log_q \frac{q}{q-1} \tag{7}$$

can be proved using either a double-counting argument (a.k.a. first moment method), or (hyper)graph entropy [35, 36, 34]. Equation (6) is much better than Equation (7) for $q \geqslant 4$. However, the latter bound $\log_3 \frac{3}{2}$ remains the best known for $q = 3$ (called the *trifference problem* by Körner). For larger q, both lower [51] and upper bounds [2, 11, 27, 10, 12] can be improved. However, improving the bound for $q = 3$ is recognized as a formidable challenge. We will show in [46, Remark 9] that our lower bound for list-recovery (cf. Theorem 14) recovers Equation (5) for q-hashing upon setting $\ell = q - 1, L = q$. Furthermore, our upper bound Theorem 16 recovers Equation (7) for q-hashing (cf. [46, Remark 7]).

A generalization of q-hashing known as *(q, L)-hashing* ($q \geqslant L$) can also be cast as zero-error list-recoverable codes with more general values of ℓ, L. Indeed, taking $L = \ell + 1$ and $\ell \leqslant q - 1$, we can write $(0, \ell, \ell + 1)_q$-list-recoverability alternatively as: for any $\{\boldsymbol{x}_1, \cdots, \boldsymbol{x}_{\ell+1}\} \in \binom{\mathcal{C}}{\ell+1}$, there exists $j \in [n]$ such that $|\{x_{1,j}, \cdots, x_{\ell+1,j}\}| = \ell + 1$. This is in turn the precise definition of $(q, \ell + 1)$-hashing. It can be immediately seen that (q, q)-hashing is nothing but q-hashing. The upper and lower bounds in [18] also extend to $(q, \ell + 1)$-hashing and read as follows:

$$\frac{1}{\ell} \log_q \frac{1}{1 - \frac{\binom{q}{\ell+1}(\ell+1)!}{q^{\ell+1}}} \leqslant C_{(0,\ell,\ell+1)_q} \leqslant \frac{\binom{q}{\ell}\ell!}{q^\ell} \log_q(q - \ell + 1). \tag{8}$$

Our lower bound for list-recovery in Theorem 14 also recovers the above lower bound for $(q, \ell + 1)$-hashing by [18] upon setting $L = \ell + 1$ (see [46, Remark 8]). The upper bound was later improved in [36] for $q > L$ using the notion of hypergraph entropy:

$$C_{(0,\ell,\ell+1)_q} \leqslant \min_{0 \leqslant j \leqslant \ell-1} \frac{\binom{q}{j+1}(j+1)!}{q^{j+1}} \log_q \frac{q-j}{\ell-j}, \tag{9}$$

though it coincides with Equation (6) when $\ell = q - 1$. Some improved upper bounds in [27, 12] apply to $(q, \ell + 1)$-hashing as well. To the best of our knowledge, no improvement on lower bounds is known for $\ell < q - 1$.

[8] The bounds in [36, 18] are slightly adjusted so that they are consistent with our definition of code rate which adopts a $\log_q$ normalization (cf. [46, Definition 6]).

Zero-rate thresholds for general adversarial channels. The problem of locating the zero-rate threshold has been addressed in a much more general context [52]. The results in [52] on *general adversarial channel* model can be specialized to the list-recovery setting and read as follows. Given q, p, ℓ, L, define the *confusability set* $\mathcal{K}_{(p,\ell,L)_q}$ as the set of types[9] (cf. [46, Definition 15]) of all "confusable" L-tuple of codewords in the sense that they can fit into a certain list-recovery ball (cf. [46, Definition 3]) of radius np. Specifically,

$$\mathcal{K}_{(p,\ell,L)_q} \coloneqq \left\{ \sum_{\mathcal{Y}\in\binom{[q]}{\ell}} P_{X_1,\cdots,X_L,Y=\mathcal{Y}} \in \Delta\left([q]^L\right) : \begin{array}{c} P_{X_1,\cdots,X_L,Y} \in \Delta\left([q]^L \times \binom{[q]}{\ell}\right) \\ \forall i \in [L], \quad \sum_{\substack{(x,\mathcal{Y})\in[q]\times\binom{[q]}{\ell} \\ x\notin\mathcal{Y}}} P_{X_i,Y}(x,\mathcal{Y}) \leqslant p \end{array} \right\}.$$

In the above definition, we use the notation $\sum_b P_{A,B=b}$ to denote the marginalization of $P_{A,B}$ onto the first variable A, and use $P_{X_i,Y}$ to denote the marginal of $P_{X_1,\cdots,X_i,Y}$ on (X_i, Y). It is not hard to verify that the confusability set is (i) "increasing" in p in the sense that $\mathcal{K}_{(p,\ell,L)_q} \subset \mathcal{K}_{(p',\ell,L)_q}$ if $p \leqslant p'$, and (ii) convex. Define also the convex cone of *completely positive (CP) tensors* of order L, i.e., tensors that can be written as a sum of *element-wise non-negative* rank-one tensors:

$$\mathsf{CP}_q^{\otimes L} \coloneqq \left\{ \sum_{i=1}^{k} \boldsymbol{p}_i^{\otimes L} \in (\mathbb{R}_{\geqslant 0}^q)^{\otimes L} : k \in \mathbb{Z}_{\geqslant 1}, (\boldsymbol{p}_1, \cdots, \boldsymbol{p}_k) \in (\mathbb{R}_{\geqslant 0}^q)^k \right\}.$$

It is proved in [52] that the zero-rate threshold $p_*(q, \ell, L)$ can be expressed as the smallest p such that all completely positive distributions are confusable:

$$p_*(q, \ell, L) = \inf\left\{ p \in [0,1] : \mathsf{CP}_q^{\otimes L} \cap \Delta([q]^L) \subset \mathcal{K}_{(p,\ell,L)_q} \right\}. \tag{10}$$

The above characterization is *single-letter* in the sense that it is independent of the blocklength n. For q, ℓ, L independent of n (which is assumed to be the case in the current paper), the optimization problem on the RHS of Equation (10) can be solved in constant time. However, it does not immediately provide an explicit formula of $p_*(q, \ell, L)$ and analytically solving the optimization problem does not appear easy to the authors. On the other hand, the characterization $p_*(q, \ell, L) = 1 - \frac{1}{L}\mathbb{E}\left[\mathsf{pl}_\ell(X_1, \cdots, X_L)\right]$ (where the expectation is over $(X_1, \cdots, X_L) \sim \mathrm{Unif}([q])^{\otimes L}$, cf. Equation (1)) in this paper can be seen as the explicit solution to the optimization problem, though the way it is obtained is *not* by solving the latter problem per se. Instead, we prove the characterization from the first principle by leveraging specific structures of list-recovery. We hope that our characterization can shed light on the geometry of the high-dimensional polytopes – the confusability set and the set of CP distributions – involved in the characterization in Equation (10).

1.3 Organization

We state our main results in Section 2. We discuss the flaw in Blinovsky's proof in Section 3. We summarize our results and state open problems in Section 4. Additional notation, definitions, preliminary results and missing proofs can be found in [46].

[9] More precisely, the confusability set is the *closure* of the set of types of all confusable codeword tuples, since types are dense in distributions.

2 Main results

2.1 q-ary list-decoding

Define $f_{q,L}\colon \Delta([q]) \to \mathbb{R}_{\geqslant 0}$ as

$$f_{q,L}(P) := \mathop{\mathbb{E}}_{(X_1,\ldots,X_L)\sim P^{\otimes L}} [\mathsf{pl}(X_1,\ldots,X_L)] \tag{11}$$

for $P \in \Delta([q])$.

For $w \in [0,1]$, let $P_{q,w} \in \Delta([q])$ denote the following probability vector:

$$P_{q,w} := \left(\frac{w}{q-1},\ldots,\frac{w}{q-1},1-w\right). \tag{12}$$

Define $g_{q,L}\colon [0,1] \to \mathbb{R}_{\geqslant 0}$ as

$$g_{q,L}(w) := f_{q,L}(P_{q,w}). \tag{13}$$

▶ **Definition 1** (Majorization). *Let $\boldsymbol{a},\boldsymbol{b} \in \mathbb{R}^d$. Let $\boldsymbol{a}^{\downarrow},\boldsymbol{b}^{\downarrow} \in \mathbb{R}^d$ denote the vectors obtained by sorting the elements in $\boldsymbol{a}$ and $\boldsymbol{b}$ in descending order, respectively. We say that $\boldsymbol{a}$* majorizes *$\boldsymbol{b}$, written as $\boldsymbol{a} \succeq \boldsymbol{b}$, if*

$$\sum_{i=1}^{k} a_i^{\downarrow} \geqslant \sum_{i=1}^{k} b_i^{\downarrow}$$

for every $k \in [d]$, and

$$\sum_{i=1}^{d} a_i = \sum_{i=1}^{d} b_i.$$

▶ **Definition 2** (Schur convexity). *A function $f\colon \mathbb{R}^d \to \mathbb{R}$ is called* Schur-convex *if $f(\boldsymbol{x}) \geqslant f(\boldsymbol{y})$ for every $\boldsymbol{x},\boldsymbol{y} \in \mathbb{R}^d$ such that $\boldsymbol{x} \succeq \boldsymbol{y}$ (in the sense of Definition 1).*

▶ **Theorem 3** (Schur convexity of $f_{q,L}$). *For any $q \in \mathbb{Z}_{\geqslant 2}$ and $L \in \mathbb{Z}_{\geqslant 2}$, the function $f_{q,L}\colon \Delta([q]) \to \mathbb{R}_{\geqslant 0}$ defined in Equation (11) is Schur convex.*

Proof. See [46, Sec. 4]. ◀

▶ **Theorem 4** (Convexity of $g_{q,L}$). *For any $q \in \mathbb{Z}_{\geqslant 2}$ and $L \in \mathbb{Z}_{\geqslant 2}$, the function $g_{q,L}\colon [0,1] \to \mathbb{R}_{\geqslant 0}$ defined in Equation (13) is convex in the interval $[0,(q-1)/q]$.*

Proof. See [46, Sec. 5]. ◀

▶ Remark 5. In the binary case (i.e., $q = 2$), understanding the functions $f_{2,L}$ and $g_{2,L}$ is an easier task. In fact, $f_{2,L}$ collapses to a univariate function and coincides with $g_{2,L}$. It can be computed [8, Eqn. (2.15) and (2.16)] that for $L = 2k, 2k+1$,

$$p_*(2,L;w) := 1 - \frac{1}{L} g_{2,L}(w) = \sum_{i=1}^{k} \frac{\binom{2i-2}{i-1}}{i} (w(1-w))^i,$$

and

$$\frac{\partial^2}{\partial w^2} p_*(2,L;w) = -k\binom{2k}{k}(w(1-w))^{k-1}.$$

The concavity (see also [43, Lemma 8]) and monotonicity of $p_*(2,L;w)$ immediately follow. Such explicit computation cannot be performed in the $q > 2$ case (and for list-recovery) and we have to work with summations like in [46, Lemma 14]. Other approaches to arguing monotonicity such as induction [1, Lemma 8(d)] do not seem to work well either for larger q.

As convexity only holds in the interval $[0,(q-1)/q]$, we will also require the following monotonicity properties, which follow easily from the Schur convexity of $f_{q,L}$.

▶ **Lemma 6.** *For any $q \in \mathbb{Z}_{\geqslant 2}$ and $L \in \mathbb{Z}_{\geqslant 2}$, the function $g_{q,L}\colon [0,1] \to \mathbb{R}_{\geqslant 0}$ defined in Equation (13) is non-increasing on $[0,(q-1)/q]$ and non-decreasing on $[(q-1)/q,1]$.*

Proof. See [46, Appendix B]. ◀

Define

$$p_*(q,L;w) \coloneqq 1 - \frac{1}{L} g_{q,L}(w). \tag{14}$$

▶ **Theorem 7** (Plotkin bound for q-ary list-decoding)**.** *Fix any $q \in \mathbb{Z}_{\geqslant 2}$ and $L \in \mathbb{Z}_{\geqslant 2}$. Let $\mathcal{C} \subset [q]^n$ be an arbitrary $(p,L)_q$-list-decodable code with $p = p_*\left(q,L;\frac{q-1}{q}\right) + \tau$ for any constant $\tau \in (0,1)$. Then there exists a constant $M_* = M_*(q,L,\tau)$ independent of n such that $|\mathcal{C}| \leqslant M_*$. As a consequence, in particular, we have*

$$p_*(q,L) \leqslant p_*\left(q,L;\frac{q-1}{q}\right) = 1 - \frac{1}{L} g_{q,L}\left(\frac{q-1}{q}\right).$$

Proof. The proof of this theorem can be found in [46, Sec. 6]. Specifically, a theorem (cf. [46, Theorem 16]) of the above kind will be first proved for *approximately constant-weight* codes in which all codewords have approximately the same Hamming weight. This theorem can then be used to prove Theorem 7 above (see [46, Corollary 18] for a more quantitative version) by partitioning a general (weight-unconstrained) code into a constant number of almost constant-weight subcodes. ◀

The upper bound on the zero-rate threshold in Theorem 7 is in fact sharp. It turns out that positive rate $(p,L)_q$-list-decodable codes exist for any p strictly smaller than the bound $1 - \frac{1}{L} g_{q,L}\left(\frac{q-1}{q}\right)$ in Theorem 7. Indeed, Blinovsky [6] proved the following lower bound on the $(p,L)_q$-list-decoding capacity which remains the best known to date. It can also be implied by our lower bound (Theorem 14 below) for list-recovery upon setting $\ell = 1$.

▶ **Theorem 8** ([6, Sec. 2])**.** *For any $q \in \mathbb{Z}_{\geqslant 2}$, $L \in \mathbb{Z}_{\geqslant 2}$ and $0 \leqslant p < p_*\left(q,L;\frac{q-1}{q}\right)$, the following lower bound on the $(p,L)_q$-list-decoding capacity holds:*

$$C_{(p,L)_q} \geqslant \frac{L}{L-1} - \frac{1}{L-1}\left\{\lambda_* p + \log_q\left[\sum_{\boldsymbol{a} \in \mathcal{A}_{q,L}} \binom{L}{\boldsymbol{a}} \exp_q\left(-\lambda_*\left(1 - \frac{1}{L}\max\{\boldsymbol{a}\}\right)\right)\right]\right\},$$

where $\lambda_* = \lambda_*(q,L,p)$ is the solution to the following equation

$$p = \frac{\sum_{\boldsymbol{a} \in \mathcal{A}_{q,L}} \binom{L}{\boldsymbol{a}} \exp_q\left(-\lambda_*\left(1 - \frac{1}{L}\max\{\boldsymbol{a}\}\right)\right)\left(1 - \frac{1}{L}\max\{\boldsymbol{a}\}\right)}{\sum_{\boldsymbol{a} \in \mathcal{A}_{q,L}} \binom{L}{\boldsymbol{a}} \exp_q\left(-\lambda_*\left(1 - \frac{1}{L}\max\{\boldsymbol{a}\}\right)\right)}.$$

Blinovsky's lower bound is plotted in Figure 1d. It is not hard to verify that the lower bound above vanishes at

$$p = q^{-L} \sum_{\boldsymbol{a} \in \mathcal{A}_{q,L}} \binom{L}{\boldsymbol{a}} \left(1 - \frac{1}{L}\max\{\boldsymbol{a}\}\right),$$

and the corresponding λ_* equals 0.

Theorems 7 and 8 together pin down the exact value of $p_*(q,L)$ shown in the following corollary.

▶ **Corollary 9.** *For any $q \in \mathbb{Z}_{\geqslant 2}$ and $L \in \mathbb{Z}_{\geqslant 2}$, the zero-rate threshold $p_*(q, L)$ for $(p, L)_q$-list-decoding is given by*

$$p_*(q, L) = p_*\left(q, L; \frac{q-1}{q}\right) = 1 - \frac{1}{L} g_{q,L}\left(\frac{q-1}{q}\right) = q^{-L} \sum_{\boldsymbol{a} \in \mathcal{A}_{q,L}} \binom{L}{\boldsymbol{a}} \left(1 - \frac{1}{L}\max\{\boldsymbol{a}\}\right). \tag{15}$$

From now on, we will use $p_*(q, L)$ to denote the RHS of Equation (15).

▶ **Theorem 10** (Elias–Bassalygo bound for q-ary list-decoding)**.** *Fix any $q \in \mathbb{Z}_{\geqslant 2}$, $L \in \mathbb{Z}_{\geqslant 2}$ and $0 \leqslant p < p_*(q, L)$. Then the $(p, L)_q$-list-decoding capacity can be upper bounded as $C_{(p,L)_q} \leqslant 1 - H_q(w_{q,L})$ where $w_{q,L}$ is the solution to the equation $p_*(q, L; w) = p$ in $w \in [0, (q-1)/q]$.*

Proof. The above theorem is implied by [46, Theorem 19] proved in [46, Sec. 7]. The latter theorem shows that for any $(p, L)_q$-list-decodable code $\mathcal{C} \subset [q]^n$ with $p < p_*(q, L)$ and any sufficiently small constant $\tau > 0$, $|\mathcal{C}|$ is at most $B \cdot n^{1.5} \cdot q^{n(1-H_q(w_{q,L,\tau}))}$, where $B = B(q, L, \tau)$ is a constant and $w_{q,L,\tau}$ is the solution to $p_*(q, L; w) = p - \tau$. Taking $\tau \to 0$ and neglecting polynomial factors, we obtain the upper bound on the list-decoding capacity. ◀

The above upper bound is plotted in Figure 1d.

2.2 List-recovery

Define $f_{q,L,\ell} \colon \Delta([q]) \to \mathbb{R}_{\geqslant 0}$ as

$$f_{q,L,\ell}(P) \coloneqq \mathop{\mathbb{E}}_{(X_1,\ldots,X_L) \in P^{\otimes L}} [\mathsf{pl}_\ell(X_1, \ldots, X_L)] \tag{16}$$

for $P \in \Delta([q])$. Define $g_{q,L,\ell} \colon [0, 1] \to \mathbb{R}_{\geqslant 0}$ as

$$g_{q,L,\ell}(w) \coloneqq f_{q,L,\ell}(P_{q,\ell,w}), \tag{17}$$

where the distribution $P_{q,\ell,w} \in \Delta([q])$ is defined as

$$P_{q,\ell,w}(i) = \begin{cases} \frac{w}{q-\ell}, & 1 \leqslant i \leqslant q - \ell \\ \frac{1-w}{\ell}, & q - \ell + 1 \leqslant i \leqslant q \end{cases}. \tag{18}$$

▶ **Theorem 11** (Schur convexity of $f_{q,L,\ell}$)**.** *For any $q \in \mathbb{Z}_{\geqslant 2}$, $L \in \mathbb{Z}_{\geqslant 2}$ and integer $1 \leqslant \ell \leqslant q-1$, the function $f_{q,L,\ell} \colon \Delta([q]) \to \mathbb{R}_{\geqslant 0}$ defined in Equation (16) is Schur convex.*

Proof. See [46, Sec. 8]. ◀

▶ **Theorem 12** (Convexity of $g_{q,L,\ell}$)**.** *For any $q \in \mathbb{Z}_{\geqslant 2}$, $L \in \mathbb{Z}_{\geqslant 2}$ and integer $2 \leqslant \ell \leqslant q-1$, the function $g_{q,L,\ell} \colon \Delta([q]) \to \mathbb{R}_{\geqslant 0}$ defined in Equation (17) is convex in the interval $w \in [0, 1]$.*

Proof. See [46, Sec. 9]. ◀

Define

$$p_*(q, \ell, L; w) \coloneqq 1 - \frac{1}{L} g_{q,L,\ell}(w). \tag{19}$$

▶ **Theorem 13** (Plotkin bound for list-recovery)**.** *Fix any $q \in \mathbb{Z}_{\geqslant 2}$, $L \in \mathbb{Z}_{\geqslant 2}$ and integer $2 \leqslant \ell \leqslant q-1$. Let $\mathcal{C} \subset [q]^n$ be an arbitrary $(p, \ell, L)_q$-list-recoverable code with $p = p_* \left(q, \ell, L; \frac{q-\ell}{q}\right) + \tau$ for any constant $\tau \in (0,1)$. Then there exists a constant $M_* = M_*(q, \ell, \tau)$ independent of n such that $|\mathcal{C}| \leqslant M_*$. This implies, in particular,*

$$p_*(q, \ell, L) \leqslant p_* \left(q, \ell, L; \frac{q-\ell}{q}\right) = 1 - \frac{1}{L} g_{q,L,\ell} \left(\frac{q-\ell}{q}\right).$$

Proof. The proof structure is similar to that of Theorem 7. We first prove the analogous the statement for almost constant-weight codes (in which all codewords have approximately the same list-recovery weight) in [46, Theorem 20] and then pass to general codes by weight partitioning (cf. [46, Corollary 21]). Since the technical proofs bear many similarities to those in the list-decoding case, we only present proof sketches in [46, Sec. 10]. ◀

To complement Theorem 13, we prove in [46, Sec. 12] the following lower bound on the $(p, \ell, L)_q$-list-recovery capacity. To the best of our knowledge, this is the first bound for list-recovery with q, ℓ, L all being *constants* (independent of p and n). We believe that improving it likely requires novel techniques beyond expurgation.

▶ **Theorem 14.** *For any $q \in \mathbb{Z}_{\geqslant 2}$, $L \in \mathbb{Z}_{\geqslant 2}$, integer $2 \leqslant \ell \leqslant q-1$ and $0 \leqslant p < p_* \left(q, \ell, L; \frac{q-\ell}{q}\right)$, the following lower bound on the $(p, \ell, L)_q$-list-recovery capacity holds:*

$$C_{(p,\ell,L)_q} \geqslant \frac{L}{L-1} - \frac{1}{L-1} \left\{ \lambda_* p + \log_q \left[\sum_{\boldsymbol{a} \in \mathcal{A}_{q,L}} \binom{L}{\boldsymbol{a}} \exp_q \left(-\lambda_* \left(1 - \frac{1}{L} \max_\ell \{\boldsymbol{a}\} \right) \right) \right] \right\},$$

where $\lambda_* = \lambda_*(q, \ell, L, p)$ is the solution to the following equation

$$p = \frac{\sum_{\boldsymbol{a} \in \mathcal{A}_{q,L}} \binom{L}{\boldsymbol{a}} \exp_q \left(-\lambda_* \left(1 - \frac{1}{L} \max_\ell \{\boldsymbol{a}\} \right) \right) \left(1 - \frac{1}{L} \max_\ell \{\boldsymbol{a}\} \right)}{\sum_{\boldsymbol{a} \in \mathcal{A}_{q,L}} \binom{L}{\boldsymbol{a}} \exp_q \left(-\lambda_* \left(1 - \frac{1}{L} \max_\ell \{\boldsymbol{a}\} \right) \right)}.$$

Similar to the list-decoding case (Theorem 8), the above lower bound vanishes at

$$p = q^{-L} \sum_{\boldsymbol{a} \in \mathcal{A}_{q,L}} \binom{L}{\boldsymbol{a}} \left(1 - \frac{1}{L} \max_\ell \{\boldsymbol{a}\} \right),$$

and the corresponding λ_* equals 0.

Theorems 13 and 14 jointly determine the value of $p_*(q, \ell, L)$ shown in the corollary below.

▶ **Corollary 15.** *For any $q \in \mathbb{Z}_{\geqslant 2}$, $L \in \mathbb{Z}_{\geqslant 2}$ and integer $2 \leqslant \ell \leqslant q-1$, the zero-rate threshold $p_*(q, \ell, L)$ for $(p, \ell, L)_q$-list-recovery is given by*

$$\begin{aligned} p_*(q, \ell, L) &= p_* \left(q, \ell, L; \frac{q-\ell}{q}\right) = 1 - \frac{1}{L} g_{q,L,\ell} \left(\frac{q-\ell}{q}\right) \\ &= q^{-L} \sum_{\boldsymbol{a} \in \mathcal{A}_{q,L}} \binom{L}{\boldsymbol{a}} \left(1 - \frac{1}{L} \max_\ell \{\boldsymbol{a}\} \right). \end{aligned} \tag{20}$$

From now on, we use $p_*(q, \ell, L)$ to refer to the same quantity as the RHS of Equation (20).

▶ **Theorem 16** (Elias–Bassalygo bound for list-recovery)**.** *Fix any $q \in \mathbb{Z}_{\geqslant 2}$, $L \in \mathbb{Z}_{\geqslant 2}$, integer $2 \leqslant \ell \leqslant q-1$ and $0 \leqslant p < p_*(q, \ell, L)$. Then the $(p, \ell, L)_q$-list-recovery capacity can be upper bounded as $C_{(p,\ell,L)_q} \leqslant 1 - H_{q,\ell}(w_{q,\ell,L})$ where $w_{q,\ell,L}$ is the solution to the equation $p_*(q, \ell, L; w) = p$ in $w \in [0, (q-\ell)/q]$.*

Proof. Parallel to Theorem 10, the above theorem is immediately implied by a finite-blocklength version [46, Theorem 22] (analogous to [46, Theorem 19]) whose full proof is presented in [46, Sec. 11]. ◀

3 Discussion of Blinovsky's results [6, 7]

As mentioned in Section 1, part of the motivation of this work is to fill in the gaps in the proofs in [6, 7] for q-ary list-decoding. We discuss in detail below the issues therein. The main result in [6] is a Plotkin bound (as our Theorem 7) for an arbitrary q-ary list-decodable code $\mathcal{C} \subset [q]^n$. For the sake of brevity, we assume in the proceeding discussion that $\mathcal{C}$ is w-constant weight. Additional bookkeeping is needed to handle small deviations in the weight, as we did in the proof of [46, Theorem 16]. The skeleton of the proof in [6] follows Blinovsky's proof in the *binary* case [5] which we adopt here as well: (i) pass to an (approximately) equi-coupled subcode $\mathcal{C}' = \{\boldsymbol{x}_1, \cdots, \boldsymbol{x}_M\} \subset \mathcal{C}$ using a Ramsey reduction; (ii) handle asymmetric coupling using Komlós's argument (and its order-L generalization [9]); (iii) prove an upper bound on the size M of the subcode $\mathcal{C}'$ using a double-counting argument. In completing the double-counting argument, one is required to upper bound the average radius (averaged over all L-lists in the subcode) by the zero-rate threshold $p_*(q, L; w) = 1 - \frac{1}{L} g_{q,L}(w)$:

$$\frac{1}{M^L} \sum_{(i_1,\cdots,i_L)\in[M]^L} \overline{\mathrm{rad}}(\boldsymbol{x}_{i_1}, \cdots, \boldsymbol{x}_{i_L}) = \sum_{k=1}^{n} \left(1 - \frac{1}{L} f_{q,L}(P_k)\right) \leqslant n \left(1 - \frac{1}{L} g_{q,L}(w)\right), \quad (21)$$

where $\overline{\mathrm{rad}}$ is defined in [46, Definition 10] and $P_k \in \Delta([q])$ is the empirical distribution of the k-th column of $\mathcal{C}' \in [q]^{M\times n}$. The equality in Equation (21) is by elementary algebraic manipulations (see [46, Eqn. (58)] for details). To show the inequality in Equation (21), we need the following properties of the functions $f_{q,L}$ and $g_{q,L}$:

1. For any $P = (p_1, \cdots, p_q) \in \Delta([q])$, we have $f_{q,L}(P) \geqslant g_{q,L}(1-p_q)$. In words, uniformizing P except one entry will only make $f_{g,L}$ no larger.
2. $g_{q,L}$ is convex as a univariate real-valued function on $[0, (q-1)/q]$.

If these properties hold, one can deduce [46, Eqn. (59) and (61)] from which Equation (21) follows. However, we observe that the proofs in [6, 7] for both properties above are problematic.

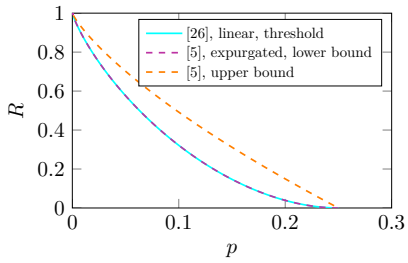
To show Item 1 above, the idea in [6] is to show instead monotonicity of $f_{q,L}$ under the so-called *Robin Hood operation* which averages two distinct entries of P. Specifically, [6] attempts to show

$$f_{q,L}(p_1, \cdots, p_i, \cdots, p_j, \cdots, p_q) \geqslant f_{q,L}\left(p_1, \cdots, \frac{p_i + p_j}{2}, \cdots, \frac{p_i + p_j}{2}, \cdots, p_q\right), \quad (22)$$

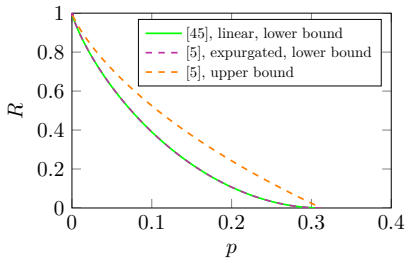
for any $1 \leqslant i < j \leqslant q$. This suffices since a sequence of Robin Hood operations can turn P into $P_{q,1-p_q}$ (defined in Equation (12)). [6] then proceeds to show Equation (22) by checking the derivative of a certain function related to the Robin Hood operation. Specifically, fix $(p_k)_{k\in[q]\setminus\{i,j\}}$ and assume $p_i + p_j = c$ (or equivalently $\sum_{k\in[q]\setminus\{i,j\}} p_i = 1 - c$) for some constant $0 \leqslant c \leqslant 1$. Consider the function $F_{q,L} \colon [0, c] \to \mathbb{R}$ defined as:

$$F_{q,L}(p) = f_{q,L}(p_1, \cdots, p, \cdots, c - p, \cdots, p_q),$$

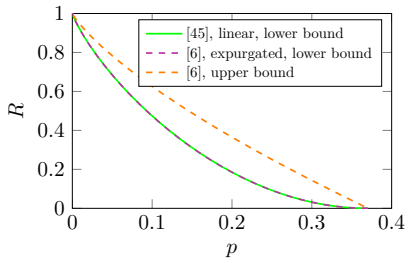
i.e., $f_{q,L}$ evaluated at P with $p_i = p, p_j = c - p$. The proof of Equation (22) is reduced to proving $F'_{q,L}(p) \leqslant 0$ for $p \in [0, c/2]$ and $F'_{q,L}(p) \geqslant 0$ for $p \in [c/2, c]$. If true, it implies that $f_{q,L}(P)$ is minimized at $p_i = p_j = c/2$ with fixed $(p_k)_{k\in[q]\setminus\{i,j\}}$. However, we note that the



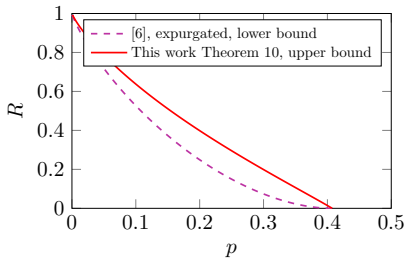
(a) $q = 2, \ell = 1, L = 3$ (list-decoding).



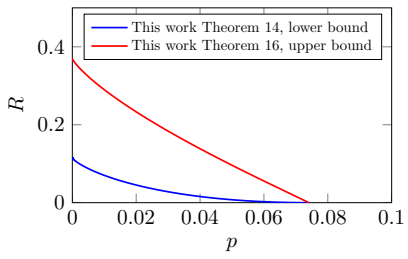
(b) $q = 2, \ell = 1, L = 4$ (list-decoding).



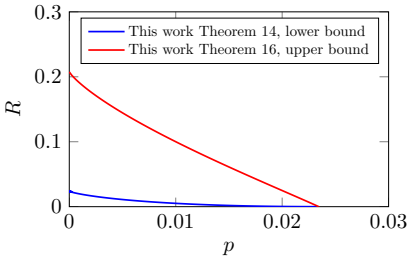
(c) $q = 3, \ell = 1, L = 3$ (list-decoding).



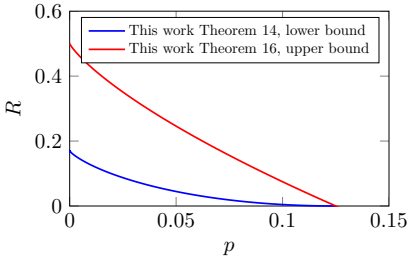
(d) $q = 3, \ell = 1, L = 4$ (list-decoding).



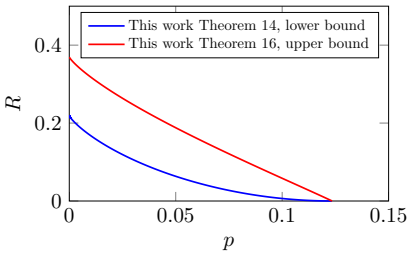
(e) $q = 3, \ell = 2, L = 3$ (list-recovery, 3-hashing).



(f) $q = 4, \ell = 3, L = 4$ (list-recovery, 4-hashing).



(g) $q = 4, \ell = 2, L = 3$ (list-recovery, $(4, 3)$-hashing).



(h) $q = 3, \ell = 2, L = 5$ (list-recovery).

Figure 1 Plots of upper and lower bounds in [5, 6, 26, 45] and this work for various values of $q \geqslant 2, 1 \leqslant \ell \leqslant q - 1, L \geqslant 2$.

expression of $F'_{q,L}(p)$ (see the second displayed equation on page 27 of [6]) is incorrect. Upon correcting it, we do not see an easy way to argue its non-positivity/-negativity. In particular, the claim in [6] that $F'_{q,L}(p)$, as a sum of multiple terms, is *term-wise* non-positive/-negative can be in general falsified by counterexamples.

The proof (attempt) of Item 2 is deferred to a subsequent paper [7]. The methodology thereof is similar to ours, i.e., verifying $g''_{q,L} \geqslant 0$. However, the expression of $g''_{q,L}$ in [7] is not exactly correct (see the first displayed equation on page 36 of [7] and compare it with ours in [46, Eqn. (34)][10]) and we have trouble verifying the case analysis of the values of $G(\cdot)$ (see [46, Eqn. (35)] in our notation, denoted by $\gamma(\cdot)$ in [7]) following that expression.

In contrast to Blinovsky's approach [6, 7], we deduce the monotonicity property of $f_{q,L}$ (cf. Item 1 above) from a stronger property: Schur convexity (cf. Theorem 3). Also, we believe that our proof of the convexity of $g_{q,L}$ (cf. Item 2 above) is cleaner, more transparent and easier to verify. Both results can be extended to list-recovery setting. Another advantage is that the monotonicity property of $g_{q,L}$ (specifically, $g_{q,L}$ is non-increasing in $[0, (q-1)/q]$ and non-decreasing in $[(q-1)/q, 1]$) which is needed in the proof of the Plotkin bound appears to be a simple consequence of the Schur convexity of $f_{q,L}$ (see Lemma 6). In [7], this is proved by checking the first derivative of $g_{q,L}$ which involves somewhat cumbersome calculations and case analysis.

4 Conclusion

In this work, we addressed the basic question of determining the maximum achievable decoding radius for positive rate list-recoverable codes, i.e., we pinned down the list-recovery zero-rate threshold. We then adapted known techniques to show that codes correcting more errors must in fact have *constant* size. Subsequently, we transferred this bound to give upper bounds on the rate of list-recoverable codes for all values of decoding radius.

As we apply general Ramsey-theoretic tools in bounding the size of list-recoverable codes in the zero-rate regime, our dependence on the corresponding parameters is quite poor, and indeed, we made no efforts to optimize these constants. However, for list-decodable binary codes in the zero-rate, a recent work of Alon, Bukh and Polyanskiy [1] derived new (and, in some cases, tight) upper bounds on their size. Obtaining similarly improved size upper bounds for q-ary list-decodable/-recoverable codes in the zero-rate regime therefore appears to be a natural next step.

Abstract

Consider words of length n. The set of all periods of a word of length n is a subset of $\{0, 1, 2, \ldots, n-1\}$. However, any subset of $\{0, 1, 2, \ldots, n-1\}$ is not necessarily a valid set of periods. In a seminal paper in 1981, Guibas and Odlyzko proposed to encode the set of periods of a word into an n long binary string, called an autocorrelation, where a one at position i denotes the period i. They considered the question of recognizing a valid period set, and also studied the number of valid period sets for strings of length n, denoted κ_n. They conjectured that $\ln(\kappa_n)$ asymptotically converges to a constant times $\ln^2(n)$. Although improved lower bounds for $\ln(\kappa_n)/\ln^2(n)$ were proposed in 2001, the question of a tight upper bound has remained open since Guibas and Odlyzko's paper. Here, we exhibit an upper bound for this fraction, which implies its convergence and closes this longstanding conjecture. Moreover, we extend our result to find similar bounds for the number of correlations: a generalization of autocorrelations which encodes the overlaps between two strings.

1 Introduction

A linear word can overlap itself if one of its prefixes is equal to one of its suffixes. The corresponding prefix (or suffix) is called a border and the shift needed to match the prefix to the suffix is called a period. The dual notions of period and border are critical concepts in word combinatorics: important definitions such as periodic and primitive words, or the normal form of a word rely on them. These concepts play a role in key results of the field like the Critical Factorization Theorem [14]. In computer science, in the field of string algorithms (a.k.a. stringology), pattern matching algorithms heavily exploit borders/periods to optimize the search of occurrences of a word in a text [21]. For clarity, note that the terms *word* and

string both mean a sequence of letters taken from an alphabet. These notions also play a role in statistics. The set of periods of a word controls how two occurrences of the same word can overlap in a text. Hence, the set of periods (or autocorrelation) is a key variable to study the statistics of word occurrences in random texts (waiting time, distance between successive occurrences, etc.) [19]. The notion of autocorrelation has been extended to describe how two distinct words can have overlapping occurrences in the same text. This has been used for instance to study the number of missing words in random texts [16] or to design procedures for testing pseudo-random number generators [15].

An autocorrelation is a binary vector representing the set of periods of a word. The concept of autocorrelation was introduced by Guibas and Odlyzko in [10]. They gave a characterization of autocorrelations and proved the following bounds on κ_n - the cardinality of the set Γ_n of autocorrelations of words of length n.

$$\frac{1}{2\ln(2)} + o(1) \leq \frac{\ln(\kappa_n)}{\ln^2(n)} \leq \frac{1}{2\ln(3/2)} + o(1)$$

They conjectured that $\ln(\kappa_n)$ is asymptotic to a constant times $\ln^2(n)$. Rivals and Rahmann [18], later on studied the combinatorial structure of the set of autocorrelations Γ_n, and improved the lower bound on κ_n as follows:

$$\frac{\ln(\kappa_n)}{\ln^2(n)} \geq \frac{1}{2\ln(2)}\left(1 - \frac{\ln(\ln(n))}{\ln(n)}\right)^2 + \frac{0.4139}{\ln(n)} - \frac{1.47123\ln(\ln(n))}{\ln^2(n)} + O\left(\frac{1}{\ln^2(n)}\right).$$

However, to date, no one has focused on improving the upper bound on κ_n. In this work, we apply the notion of irreducible period sets introduced by Rivals and Rahmann [17, 18] to prove that

$$\frac{\ln(\kappa_n)}{\ln^2(n)} \leq \frac{1}{2\ln(2)} + \frac{3}{2\ln(n)} \quad \forall n \in \mathbb{N}_{\geq 2}.$$

Together with known asymptotic lower bounds [18], we find that

$$\frac{\ln \kappa_n}{\ln^2(n)} \to \frac{1}{2\ln(2)} \quad \text{as} \quad n \to \infty,$$

thus resolving the conjecture of Guibas and Odlyzko.

In their paper about autocorrelations [10], Guibas and Odlyzko also introduced the notion of correlation between words. For two words u and v, the *correlation* of u over v is a binary vector indicating all overlaps between suffixes of u and prefixes of v. In particular, an autocorrelation is the correlation of a word with itself. We show that the number of correlations between two words of length n, denoted by δ_n, has the same asymptotic convergence behaviour as the number of autocorrelations of words of length n, that is

$$\frac{\ln \delta_n}{\ln^2(n)} \to \frac{1}{2\ln(2)} \quad \text{as} \quad n \to \infty.$$

1.1 Related works

Apart from previously cited articles that deal with the combinatorics of period sets, some related works exist in the literature.

For instance, the question of the average period of a random word has been investigated in [13]. Clearly, the number of periods of a word of length n lies between one and n. A recent work exhibits an upper bound on the number of periods of a word as a function of its *initial*

critical exponent – a characteristic of the word related to its degree of periodicity [9], but this has not been used to bound the number of period sets. Last, the combinatorics of period sets has also been investigated in depth for a generalization of the notion of words, called *partial words* [6]. In partial words, some positions may contain a *don't care* symbol, which removes some constraints of equality between positions. To study the combinatorics of period sets, Blanchet-Sadri *et al.* defined weak and strong periods, and proved several important theorems [4], including lower and upper bounds on the number of binary and ternary autocorrelations [6, 5]. However, the cardinality of the family of period sets differs between normal words and partial words, and a tight upper bound for normal words cannot be deduced from that for partial words. Several works investigate sets of words with constraints (either absence or presence) on their mutual overlaps: mutually bordered (overlapping) pairs of words are studied in [8], while methods for constructing a set of mutually unbordered words (also called cross-bifix-free words) are provided in [3, 1, 2].

2 Preliminaries

A string $u = u[0\,..\,n-1] \in \Sigma^n$ is a sequence of n letters over a finite alphabet Σ. For any $0 \le i \le j \le n-1$, we denote the substring starting at position i and ending at position j with $u[i\,..\,j]$. In particular, $u[0\,..\,j]$ denotes a prefix and $u[i\,..\,n-1]$ a suffix of u. Throughout this paper, all our strings and vectors will be zero-indexed.

2.1 Periodicity

In this subsection, we define the concepts of period, period set, basic period, and autocorrelation, and then review some useful results. For the sake of self-containment, we provide in Appendix A the proofs for all lemmas of this subsection.

▶ **Definition 1** (Period). *String $u = u[0\,..\,n-1]$ has a period $p \in \{1, \ldots, n-1\}$ if and only if for any $0 \le i, j \le n-1$ such that $i \equiv j \mod p$, we have $u[i] = u[j]$. Moreover, we consider that $p = 0$ is a period of any string of length n.*

An equivalent definition is the following.

▶ **Definition 2** (Period). *The string $u = u[0\,..\,n-1]$ has period $p \in \{0, 1, \ldots, n-1\}$ if and only if $u[0\,..\,n-p-1] = u[p\,..\,n-1]$, i.e. for all $0 \le i \le n-p-1$, we have $u[i] = u[i+p]$.*

The smallest non-zero period of u is called its *basic period*. The *period set* of a string u is the set of all its periods and is denoted by $P(u)$. We will now list some useful properties about periods, which we will need later on. Their proofs can be found in [10, 14] and in Appendix A.

▶ **Lemma 3.** *Let p be a period of $u \in \Sigma^n$ and $k \in \mathbb{Z}_{\ge 0}$ such that $kp < n$. Then kp is also a period of u.*

▶ **Lemma 4.** *Let p be a period of $u \in \Sigma^n$ and q a period of the suffix $w = u[p\,..\,n-1]$. Then $(p+q)$ is a period of u. Moreover, $(p+kq)$ is also a period of u for all $k \in \mathbb{Z}_{\ge 0}$ with $p + kq < n$.*

▶ **Lemma 5.** *Let p, q be periods of $u \in \Sigma^n$ with $0 \le q \le p$. Then the prefix and the suffix of length $(n-q)$ have the period $(p-q)$.*

▶ **Lemma 6.** *Suppose p is a period of $u \in \Sigma^n$ and there exists a substring v of u of length at least p and with period r, where $r|p$. Then r is also a period of u.*

Table 1 This table illustrates the set of period and the autocorrelation of the word $u = \texttt{abbaabba}$ of length 8. A first copy of the word u is shown on the second line. Another copy of u is displayed on (each) line $(3 + i)$ shifted by i positions to the right, with i going from 0 to 7. If the suffix of the copy of u matches the prefix of the first copy u on line 2, then i is a period, and both the line and the corresponding position/shift (on the first line) are colored in blue. The last column contains the autocorrelation of u, with 1 bits corresponding to periods colored in blue.

pos.	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	
u	a	b	b	a	a	b	b	a	-	-	-	-	-	-	-	s
u	a	b	b	a	a	b	b	a	-	-	-	-	-	-	-	1
	-	a	b	b	a	a	b	b	a	-	-	-	-	-	-	0
	-	-	a	b	b	a	a	b	b	a	-	-	-	-	-	0
	-	-	-	a	b	b	a	a	b	b	a	-	-	-	-	0
	-	-	-	-	a	b	b	a	a	b	b	a	-	-	-	1
	-	-	-	-	-	a	b	b	a	a	b	b	a	-	-	0
	-	-	-	-	-	-	a	b	b	a	a	b	b	a	-	0
	-	-	-	-	-	-	-	a	b	b	a	a	b	b	a	1

We will also use the famous Fine and Wilf theorem [7], a.k.a. the periodicity lemma, for which a short proof was provided by Halava and colleagues [12].

▶ **Theorem 7** (Fine and Wilf). *Let p, q be periods of $u \in \Sigma^n$. If $n \geq p + q - \gcd(p, q)$, then $\gcd(p, q)$ is a period of u.*

2.2 Autocorrelation

We now give a formal definition of an autocorrelation.

▶ **Definition 8** (Autocorrelation). *For every string $u \in \Sigma^n$, its autocorrelation is the string $s \in \{0, 1\}^n$ such that*

$$s[i] = \begin{cases} 1 & \text{if } i \text{ is a period of } u \\ 0 & \text{otherwise} \end{cases} \qquad \forall i \in \{0, \ldots, n-1\}.$$

To illustrate this concept, consider the following example (detailed in Table 1).

▶ **Example 9.** We consider the word $u = \texttt{abbaabba}$ of length 8. Its period set is $P(u) = \{0, 4, 7\}$, its basic period is 4 and its autocorrelation is $s = 10001001$. See Table 1.

Guibas and Odlyzko [10] show that *any alphabet of size at least two will give rise to the same set of correlations* (Corollary 5.1). Autocorrelations have many other useful properties [10, 18]. The most significant one for our work is the following.

▶ **Lemma 10** (Lemma 3.1 [10] and Theorem 1.3 [18]). *If $s \in \{0, 1\}^n$ is an autocorrelation and $s[i] = 1$, then $s[i \,..\, n-1]$ is the autocorrelation of $u[i \,..\, n-1]$*

Proof. Note that $s[i] = 1$ means: i is a period of u. Suppose $s[i + j] = 1$. Then $i + j$ is a period of u. Thus $u[i \,..\, n-1]$ has period $(i + j) - i = j$ by Lemma 5. Conversely, suppose $u[i \,..\, n-1]$ has period $(i + j) - i = j$. Then $i + j$ is a period of u by Lemma 4. Thus $s[i + j] = 1$. Combining these results, we find that $s[i + j] = 1$ if and only of j is a period of $u[i \,..\, n-1]$, and equivalently $s[i \,..\, n-1]$ is the autocorrelation of $u[i \,..\, n-1]$. ◀

2.3 Irreducible Period Set

To prove the upper bound on the number of autocorrelations, we use the notion of irreducible period sets as introduced by Rivals and Rahmann [18]. An irreducible period set is the minimum subset of a period set that determines the period set using the Forward Propagation Rule. Before formally introducing the irreducible period set, we will first explain what forward propagation is.

▶ **Lemma 11** (Forward Propagation Rule). *Let $p \leq q$ be periods of a string u of length n and let $k \in \mathbb{Z}_{\geq 0}$ such that $p + k(q-p) < n$. Then $p + k(q-p)$ is a period of $u[0\,..\,n-1]$.*

Proof. It follows from Lemma 5 that $u[p\,..\,n-1]$ has period $(q-p)$. Applying Lemma 4 we find that $u[0\,..\,n-1]$ has period $p + k(q-p)$ for all $k \in \mathbb{Z}_{\geq 0}$. ◀

The forward closure $FC_n(S)$ of a set $S \subseteq \{0, \ldots, n-1\}$ (not necessarily a period set, typically a subset of one) is the closure of S under the forward propagation rule.

▶ **Definition 12** (Forward Closure). *Let $S \subseteq \{0, \ldots, n-1\}$. Its forward closure $FC_n(S)$ is the minimum superset of S such that for any $p, q \in FC_n(S)$ and $k \geq 0$ with $p \leq q$ and $p + k(q-p) < n$, we have*

$$p + k(q-p) \in FC_n(S).$$

We can now define the irreducible period set.

▶ **Definition 13** (Irreducible Period Set). *Let P be the period set of a string $u \in \Sigma^n$. An irreducible period set of P is a minimal subset $R(P) \subseteq P$ with forward closure P.*

Observe that there exists an irreducible period set for any period set P, because $FC_n(P) = P$ by the forward propagation rule. We will now give a useful characterization of an irreducible period set as the set of periods which are not in the forward closure of the set of all smaller periods. Consequently, every period set has exactly one irreducible period set, whose elements we will call irreducible periods.

Recall that for a given length n, we denote the set of all period sets by Γ_n. Formally stated Γ_n is defined as:

$$\Gamma_n = \{S \subseteq \{0, 1, \ldots, n-1\} : \exists u \in \Sigma^n \text{ such that } P(u) = S\}.$$

As in [18], for a given length n, we denote the set of all irreducible period sets by Λ_n:

$$\Lambda_n = \{T \subseteq \{0, 1, \ldots, n-1\} : \exists u \in \Sigma^n \text{ such that } R(P(u)) = T\}.$$

The bijective relation between period sets and irreducible period sets implies that $|\Gamma_n| = |\Lambda_n|$.

▶ **Lemma 14.** *Let P be the period set of a string $u \in \Sigma^n$ and $R(P)$ an irreducible period set of P. Then*

$$R(P) = \{q \in P \mid q \notin FC_n(P \cap [0, q-1])\}.$$

Proof. Let $p \in P$. We will prove the two alternative cases separately:
(a) $p \notin \{q \in P \mid q \notin FC_n(P \cap [0, q-1])\} \implies p \notin R(P)$ and
(b) $p \in \{q \in P \mid q \notin FC_n(P \cap [0, q-1])\} \implies p \in R(P)$.

(a) Suppose $p \notin \{q \in P \mid q \notin FC_n(P \cap [0, q-1])\}$, or equivalently $p \in FC_n(P \cap [0, p-1])$. Then

$$\begin{aligned} p \in FC_n(P \cap [0,p-1]) &= FC_n(FC_n(R(P)) \cap [0,p-1]) \\ &\subseteq FC_n(FC_n(R(P) \cap [0,p-1])) \\ &= FC_n(R(P) \cap [0,p-1]) \\ &\subseteq FC_n(R(P) \setminus \{p\}). \end{aligned}$$

It follows that $FC_n(R(P) \setminus \{p\}) = FC_n(R(P))$. By minimality of irreducible period sets, we have $p \notin R(P)$.

(b) Suppose on the other hand that $p \notin FC_n(P \cap [0, p-1])$. Then $p \notin FC_n(P \setminus \{p\})$ either. As

$$FC_n(P \setminus \{p\}) \supseteq FC_n(R(P) \setminus \{p\}),$$

then $p \notin FC_n(R(P) \setminus \{p\})$. However, as $p \in P$ and $P = FC_n(R(P))$, it follows that $p \in R(P)$. ◀

3 Asymptotic convergence of κ_n

In this section, we present a new upper bound on κ_n, the number of distinct autocorrelations of strings of length n. Moreover, we shall prove that $\ln(\kappa_n)$ asymptotically converges to $c \cdot \ln^2(n)$, where $c = \frac{1}{2\ln(2)}$.

▶ **Theorem 15** (Upper bound on κ_n)**.** *For all $n \in \mathbb{N}_{\geq 2}$ we have*

$$\frac{\ln(\kappa_n)}{\ln^2(n)} \leq \frac{1}{2\ln(2)} + \frac{3}{2\ln(n)}.$$

Proof. To prove this theorem, we need several lemmas.

▶ **Lemma 16.** *Let $u \in \Sigma^n$ with autocorrelation s, period set P, and irreducible period set $R(P) = \{0 = a_0 < \ldots < a_i < \ldots < a_k < n\}$. Then for all $0 \leq i \leq k$, there exists $q_i \in \{1, \ldots, n - a_i\}$ such that*

1. *$q_i \leq n/2^i$, and*
2. *$a_i + q_i = n$ or $a_i + q_i$ is in the forward closure of $\{a_0, \ldots, a_i\}$.*

Proof. We will prove this by induction.

Basis. By picking $q_0 = n \in \{1, \ldots, n - a_0\}$, we satisfy both $q_0 \leq n/2^0$ and $a_0 + q_0 = n$.

Hypothesis. For some $0 \leq i < k$, there exists a $q_i \in \{1, \ldots, n - a_i\}$ such that

1. $q_i \leq n/2^i$, and
2. $a_i + q_i = n$ or $a_i + q_i$ is in the forward closure of $\{a_0, \ldots, a_i\}$.

Step. We first note that if $n - a_{i+1} \leq n/2^{i+1}$, then we can pick $q_{i+1} = n - a_{i+1}$. Suppose on the other hand that $n - a_{i+1} > n/2^{i+1}$. We distinguish two cases.

- If $a_i + q_i = n$, then

$$\begin{aligned} a_{i+1} - a_i &= (n - a_i) - (n - a_{i+1}) \\ &< n/2^i - n/2^{i+1} \\ &= n/2^{i+1} \\ &< n - a_{i+1}. \end{aligned}$$

Thus, we can pick $q_{i+1} = a_{i+1} - a_i \in \{1, \ldots, n - a_{i+1}\}$, since

1. it satisfies $q_{i+1} \leq n/2^{i+1}$ and
2. $a_{i+1} + q_{i+1} = a_i + 2(a_{i+1} - a_i)$ is in the forward closure of $\{a_0, \ldots, a_{i+1}\}$.

- If $a_i + q_i$ is in the forward closure of $\{a_0, \ldots, a_i\}$, then

$$a_i + \lambda q_i = a_i + \lambda(a_i + q_i - a_i)$$

is in the forward closure of $\{a_0, \ldots, a_i\}$ for all integers $0 \leq \lambda \leq (n-1-a_i)/q_i$. Since a_{i+1} is an irreducible period, there must exist an integer $\lambda_0 \in [0, (n-1-a_i)/q_i]$ such that

$$a_i + \lambda_0 q_i < a_{i+1} < a_i + (\lambda_0 + 1)q_i.$$

In other words, a_{i+1} is comprised between two successive, non-irreducible periods generated from a_i and q_i using the FPR (or $n \leq a_i + (\lambda_0 + 1)q_i$). We pick

$$q_{i+1} = \min(a_{i+1} - (a_i + \lambda_0 q_i), (a_i + (\lambda_0 + 1)q_i) - a_{i+1}, n - a_{i+1})$$

and note that

$$\begin{aligned} q_{i+1} &\leq \frac{a_{i+1} - (a_i + \lambda_0 q_i) + (a_i + (\lambda_0 + 1)q_i) - a_{i+1}}{2} \\ &= q_i/2 \\ &\leq n/2^{i+1}. \end{aligned}$$

It follows that $a_{i+1} + q_{i+1} < n$. Consequently, either $a_{i+1} + q_{i+1} = (a_i + \lambda_0 q_i) + 2(a_{i+1} - (a_i + \lambda_0 q_i))$ or $a_{i+1} + q_{i+1} = a_i + (\lambda_0 + 1)(a_i + q_i - a_i)$. Hence, $a_{i+1} + q_{i+1}$ is in the forward closure of $\{a_0, \ldots, a_{i+1}\}$. Therefore q_{i+1} has all desired properties.

Conclusion. For all $0 \leq i \leq k$, there exists $q_i \in \{1, \ldots, n - a_i\}$ such that

1. $q_i \leq n/2^i$, and
2. $a_i + q_i = n$ or $a_i + q_i$ is in the forward closure of $\{a_0, \ldots, a_i\}$. ◀

▶ **Lemma 17.** *Let $R(P) = \{0 = a_0 < a_1 < \ldots < a_k\}$ be the irreducible period set of a string of length n. Then $k \leq \log_2(n)$.*

Proof. It follows from the Lemma 16 that there exists an integer $q_k \in \{1, \ldots, n - a_k\}$ such that $n/2^k \geq q_k$. Hence $k \leq \log_2(n)$. ◀

To count the number of irreducible period sets, we count the number of possibilities for each a_i with $1 \leq i \leq k$. We know that $a_0 = 0$ is fixed. The other a_i take values in the set $\{1, \ldots, n-1\}$.

▶ **Lemma 18.** *Let $0 \leq i \leq k-1$. Then a_{i+1} can take at most $2^{1-i}n - 1$ possible values given $a_0, \ldots, a_i$.*

Proof. Let q_i be defined as in Lemma 16. We distinguish 3 cases:

1. If $a_{i+1} \leq a_i + q_i$, there are at most $q_i - 1 \leq n/2^i - 1$ possible values for a_{i+1} (note that $a_{i+1} \neq a_i + q_i$, because a_{i+1} cannot be in the forward closure of $\{a_0, \ldots, a_i\}$, nor can it be equal to n).
2. If $a_{i+1} \geq n - q_i$, there are at most $q_i \leq n/2^i$ possible values for a_{i+1}.
3. In the remaining case, $a_{i+1} \in [a_i + q_i + 1, n - q_i - 1]$.

Let us first show that case 3 is impossible. For the sake of contradiction, assume we are in case 3. Since $a_i + q_i < n$, we know that $a_i + q_i$ is in the forward closure of $\{a_0, \ldots, a_i\}$ (by property 2 from Lemma 16). Hence q_i is a period of $u[a_i \,..\, n-1]$. Moreover $a_{i+1} - a_i$ is also a period of $u[a_i \,..\, n-1]$. By the Fine and Wilf theorem, it follows that

(a) either $n - a_i < q_i + (a_{i+1} - a_i) - \gcd(q_i, a_{i+1} - a_i)$

(b) or $\gcd(q_i, a_{i+1} - a_i)$ is a period of $u[a_i \,..\, n-1]$.

We are not in subcase (a) since by hypothesis $a_{i+1} \leq n - q_i - 1$. Suppose we are in subcase (b). Note that $a_i + \gcd(q_i, a_{i+1} - a_i) \leq a_i + q_i < a_{i+1}$ and that a_{i+1} is in the forward propagation of $\{a_0, \ldots, a_i, a_i + \gcd(q_i, a_{i+1} - a_i)\}$. It follows that a_{i+1} is not an irreducible period, which is a contradiction. Therefore both subcases (a) and (b) are impossible.

Summing over cases 1 and 2 (since case 3 is impossible), we conclude that, given $a_0, \ldots, a_i$, there are at most

$$(n/2^i - 1) + n/2^i + 0 = 2^{1-i}n - 1$$

possibilities for a_{i+1}. ◀

Note that the bound of Lemma 18 is not tight: indeed, there are $n-1$ possible values for a_1, while the lemma gives an upper bound of $2n-1$. However, this bound suffices to prove our asymptotic result. Since an autocorrelation is uniquely defined by its irreducible period set, it suffices to count the possible such sets $\{a_0, \ldots, a_k\}$ for all possible values of k. Recall that a_0 is fixed at 0 and that $k \leq \log_2(n)$ by Lemma 17. We thus derive a bound on the total number of autocorrelations by taking the product of all possibilities for a_{i+1} with i going from 0 to $k-1$ and sum this over all integers k from 1 to $\lfloor \log_2(n) \rfloor$, as follows:

$$\begin{aligned}
\kappa_n = |\Gamma_n| = |\Lambda_n| &\leq \sum_{k=1}^{\lfloor \log_2(n) \rfloor} \prod_{i=0}^{k-1} \left(2^{1-i}n - 1\right) \\
&\leq \sum_{k=1}^{\lfloor \log_2(n) \rfloor} \left(\left(2^{2-k}n - 1\right) \prod_{i=0}^{k-2} 2^{1-i}n \right).
\end{aligned}$$

Writing $2^{2-k}n \prod_{i=0}^{k-2} 2^{1-i}n$ and $\prod_{i=0}^{k-2} 2^{1-i}n$ in exponential form, we get

$$\begin{aligned}
\kappa_n \leq \sum_{k=1}^{\lfloor \log_2(n) \rfloor} \Bigg(&\exp\left(\frac{-k(k-3)\ln(2)}{2} + k\ln(n)\right) \\
&- \exp\left(\frac{-(k-1)(k-4)\ln(2)}{2} + (k-1)\ln(n)\right) \Bigg).
\end{aligned}$$

Observe that this is a telescoping sum, so all but two terms cancel out.

$$\kappa_n \leq \exp\left(\frac{-\lfloor \log_2(n) \rfloor (\lfloor \log_2(n) \rfloor - 3)\ln(2)}{2} + \lfloor \log_2(n) \rfloor \ln(n)\right) - 1$$

Since $\frac{d}{dk}\left(\frac{-k(k-3)\ln(2)}{2} + k\ln(n)\right) = \frac{(-2k+3)\ln(2)}{2} + \ln(n)$ is positive for all $k \leq \log_2(n)$, we have

$$\begin{aligned}
\kappa_n &< \exp\left(\frac{\ln(n)(3\ln(2) - \ln(n))}{2\ln(2)} + \frac{\ln^2(n)}{\ln(2)}\right) \\
&= \exp\left(\frac{3\ln(n)}{2} + \frac{\ln^2(n)}{2\ln(2)}\right).
\end{aligned}$$

Taking the natural logarithm of both sides and dividing by $\ln^2(n)$, we get that

$$\frac{\ln(\kappa_n)}{\ln^2(n)} \leq \frac{1}{2\ln(2)} + \frac{3}{2\ln(n)},$$

thereby proving Theorem 15. ◀

▶ **Corollary 19** (Asymptotic Convergence of κ_n). *Let κ_n be the number of autocorrelations of length n. Then*

$$\frac{\ln \kappa_n}{\ln^2(n)} \to \frac{1}{2\ln(2)} \quad \textit{as} \quad n \to \infty.$$

Proof. It follows from Theorem 15 that for $n \in \mathbb{N}_{\geq 2}$

$$\frac{\ln(\kappa_n)}{\ln^2(n)} \leq \frac{1}{2\ln(2)} + \frac{3}{2\ln(n)} = \frac{1}{2\ln(2)} + o(1).$$

The lower bound for κ_n from Theorem 5.1 in [18] indicates that asymptotically

$$\begin{aligned}\frac{\ln(\kappa_n)}{\ln^2(n)} &\geq \frac{1}{2\ln(2)}\left(1 - \frac{\ln(\ln(n))}{\ln(n)}\right)^2 + \frac{0.4139}{\ln(n)} - \frac{1.47123\ln(\ln(n))}{\ln^2(n)} + O\left(\frac{1}{\ln^2(n)}\right) \\ &= \frac{1}{2\ln(2)} - O\left(\frac{\ln(\ln(n))}{\ln(n)}\right).\end{aligned}$$

Combining this lower bound with our upper bound, we obtain

$$\frac{1}{2\ln(2)} - O\left(\frac{\ln\ln n}{\ln n}\right) \quad \leq \quad \frac{\ln \kappa_n}{\ln^2(n)} \quad \leq \quad \frac{1}{2\ln(2)} + o(1).$$

Using the classic *sandwich theorem*, we conclude that

$$\frac{\ln \kappa_n}{\ln^2(n)} \to \frac{1}{2\ln(2)} \quad \text{as} \quad n \to \infty$$

thereby proving the conjecture by Guibas and Odlyzko. ◀

The known values of κ_n are recorded in entry A005434 (see `https://oeis.org/A005434`) of the On-Line Encyclopedia of Integer Sequences [20]. Because the enumeration of Γ_n takes exponential time, the list of κ_n values is limited to a few hundred. In Figure 1, we compare the values of κ_n with the so-called Fröberg lower bound from [18], the upper bound of Guibas and Odlyzko [10], and our new upper bound. The figure illustrates the improvement brought by the new upper bound compared to that given by Guibas and Odlyzko [10]. At $n = 500$, the lower bound, our new upper bound and the values of κ_n clearly differ, meaning the sequences are far from convergence at $n = 500$.

4 Correlation

In this section, we show that the number of correlations between two strings of length n has the same asymptotic convergence behaviour as the number of autocorrelations of strings of length n.

In [11], Guibas and Odlyzko introduced the notion of *correlation* of two strings: it encodes the offset of possible overlaps between these two strings. In [10], the same authors investigate the self-overlaps of a string, which is then encoded in an *autocorrelation*. Before we start, let us define precisely the notion of correlation (which is illustrated in Table 2).

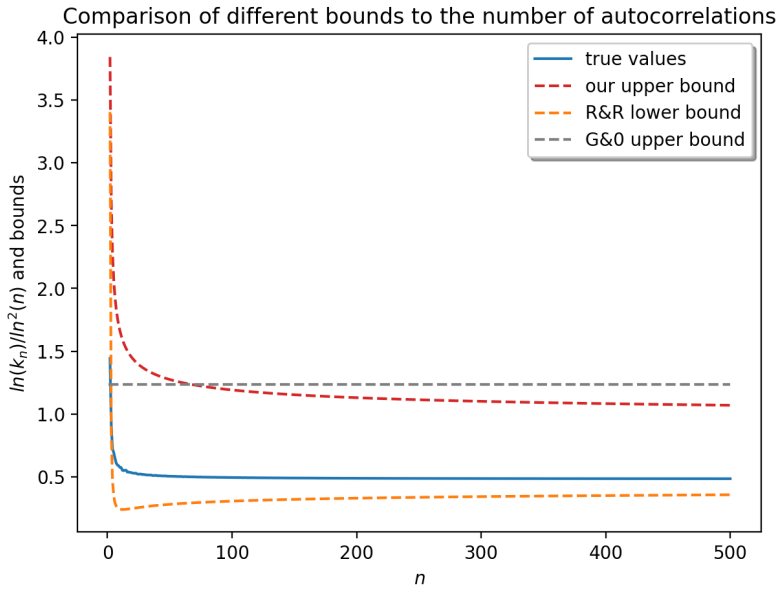

Figure 1 The true values of $\ln k_n / \ln^2(n)$ for $n \leq 500$ are compared to: the upper bound of Guibas & Odlyzko (G&O upper bound) [10], the Fröberg lower bound (R&R lower bound) [18], and our upper bound. Our upper bound seems not so tight: the reason is that n is small, as $\ln 500 \approx 6.2$.

Table 2 The correlation of word $u =$ `aabbaa` over word $v =$ `baabaa` (both of length 6) is $t = 000100$. This table is organized as Table 1 – see the corresponding caption for details.

pos.	0	1	2	3	4	5	6	7	8	9	10	
u	a	a	b	b	a	a	-	-	-	-	-	t
v	b	a	a	b	a	a	-	-	-	-		0
	-	b	a	a	b	a	a	-	-	-	-	0
	-	-	b	a	a	b	a	a	-	-	-	0
	-	-	-	b	a	a	b	a	a	-	-	1
	-	-	-	-	b	a	a	b	a	a	-	0
	-	-	-	-	-	b	a	a	b	a	a	0

▶ **Definition 20** (Correlation). *For every pair of strings $(u, v) \in \Sigma^n \times \Sigma^m$, the correlation of u over v is the vector $t \in \{0,1\}^n$ such that for all $k \in \{0, \ldots, n-1\}$*

$$t[k] = \begin{cases} 1 & \text{if } u[i] = v[j] \text{ for all } i \in \{0,\ldots,n-1\}, j \in \{0,\ldots,m-1\} \\ & \text{with } i = j + k, \\ 0 & \text{otherwise.} \end{cases}$$

Intuitively, we can find correlations as follows. For each index $i \in \{0, \ldots, n-1\}$ we write v below u starting under the ith character of u. Then the ith element of the correlation is 1, if all pairs of characters that are directly above each other match, and 0 otherwise. See Table 2 for an example.

Observe, that if $v \in \Sigma^m$ is longer than $u \in \Sigma^n$, then the correlation of u over v equals the correlation of u over $v[0\,..\,n-1]$. Conversely, any binary vector $t \in \{0,1\}^n$ is the correlation of $u = t \in \{0,1\}^n$ over $v = 1 \in \{0,1\}^1$. Therefore we will restrict ourselves to the interesting case where both strings have the same length.

Let Δ_n be the set of all correlations between two strings of the same length n and let δ_n be the cardinality of Δ_n. We can characterize Δ_n as follows.

▶ **Lemma 21.** *The set of correlations of length n is of the form*

$$\Delta_n = \left\{ 0^{(n-j)} s_j \;\mid\; s_j \in \Gamma_j,\ j \in [0, n] \right\},$$

where Γ_j is the set of autocorrelations of length j.

Proof. Let $t = 0^{(n-j)} s_j$ with s_j the autocorrelation of some string w of length j with $0 \leq j \leq n$. Without loss of generality, w does not start with the letter $\mathtt{a}$. Let $u = \mathtt{a}^{(n-j)} w$ and $v = w\mathtt{b}^{(n-j)}$. Observe that the correlation of u over v is precisely $0^{(n-j)} s_j = t$. Therefore

$$\left\{ 0^{(n-j)} s_j \;\mid\; s_j \in \Gamma_j,\ j \in [0, n] \right\} \subseteq \Delta_n.$$

Conversely, let $u, v \in \Sigma^n$ and let t' be the correlation of u over v. We can write t' in the form $0^{(n-j)} s_j$, where s_j is a binary string starting with 1 (or is empty). If s_j is the empty string, then it is the only autocorrelation of length 0. Otherwise, there is a 1 at position $n - j$, which indicates that $u[n - j \,..\, n - 1] = v[0 \,..\, j - 1]$. Moreover, s_j is the correlation of $u[n - j \,..\, n - 1]$ over v. It follows that s_j is exactly the autocorrelation of $u[n - j \,..\, n - 1] = v[0 \,..\, j - 1]$. Therefore

$$\Delta_n \subseteq \left\{ 0^{(n-j)} s_j \;\mid\; s_j \in \Gamma_j,\ j \in [0, n] \right\}. \qquad \blacktriangleleft$$

In the above characterization, we consider strings over a finite alphabet and found that a correlation depends on some autocorrelation. As it is known that Γ_n is independent of the alphabet size (provided $|\Sigma| > 1$), the reader may wonder whether the number of correlations depends on it. In Appendix B, we show that the set of correlations for equally long strings is independent of the alphabet size, provided that Σ is not unary.

Now we have characterized Δ_n, we can easily deduce its cardinality.

▶ **Lemma 22.** *Let κ_n be the number of autocorrelations of length n and δ_n the number of correlations between two strings of length n. Then*

$$\delta_n = \sum_{j=0}^{n} \kappa_j.$$

Proof. Since autocorrelations do not start with a zero, no two strings of the form $0^{(n-j)} s_j$ with $s_j \in \Gamma_j$ and $j \in [0, n]$ are the same. Therefore

$$\delta_n = |\Delta_n| = \left| \left\{ 0^{(n-j)} s_j \;\mid\; s_j \in \Gamma_j,\ j \in [0, n] \right\} \right| = \sum_{j=0}^{n} |\Gamma_j| = \sum_{j=0}^{n} \kappa_j. \qquad \blacktriangleleft$$

▶ **Theorem 23** (Asymptotic Convergence of δ_n)**.** *Let δ_n be the number of correlations between two strings of length n. Then*

$$\frac{\ln \delta_n}{\ln^2(n)} \to \frac{1}{2\ln(2)} \quad \textit{as} \quad n \to \infty.$$

Proof. From Lemma 18 we know that for all $n \in \mathbb{N}_{\geq 2}$

$$\ln(\kappa_n) \leq \frac{\ln^2(n)}{2\ln(2)} + \frac{3\ln(n)}{2}.$$

It follows that for all $n \in \mathbb{N}_{\geq 2}$ we have

$$\begin{aligned}\frac{\ln(\delta_n)}{\ln^2(n)} &= \ln\left(\sum_{i=0}^{n} \kappa_n\right) / \ln^2(n) \\ &\leq \ln\left(2 + (n-1)\exp\left(\frac{\ln^2(n)}{2\ln(2)} + \frac{3\ln(n)}{2}\right)\right) / \ln^2(n) \\ &\leq \left(\frac{\ln^2(n)}{2\ln(2)} + \frac{3\ln(n)}{2} + \ln(n)\right) / \ln^2(n) \\ &= \frac{1}{2\ln(2)} + o(1) \quad \text{as} \quad n \to \infty.\end{aligned}$$

Conversely, using the fact that $\delta_n \geq \kappa_n$, we find

$$\frac{\ln \delta_n}{\ln^2(n)} \geq \frac{\ln \kappa_n}{\ln^2(n)} = \frac{1}{2\ln(2)} + o(1) \quad \text{as} \quad n \to \infty.$$

Again, by the sandwich theorem we conclude

$$\frac{\ln \delta_n}{\ln^2(n)} \to \frac{1}{2\ln(2)} \quad \text{as} \quad n \to \infty. \qquad \blacktriangleleft$$

A Omitted proofs

▶ **Lemma 3.** *Let p be a period of $u \in \Sigma^n$ and $k \in \mathbb{Z}_{\geq 0}$ such that $kp < n$. Then kp is also a period of u.*

Proof. If $p = 0$ or $k = 0$, the statement trivially holds. Suppose $p \in \{1, \ldots, n-1\}$ and $k > 0$. If $i, j \in \{0, \ldots, n-1\}$ such that $i \equiv j \mod kp$, then we also have $i \equiv j \mod p$, and hence $u[i] = u[j]$ by Definition 1. This shows kp is a period of u by Definition 1. ◀

▶ **Lemma 4.** *Let p be a period of $u \in \Sigma^n$ and q a period of the suffix $w = u[p\,..\,n-1]$. Then $p+q$ is a period of u. Moreover, $p+kq$ is also a period of u for all $k \in \mathbb{Z}_{\geq 0}$ with $p+kq < n$.*

Proof. By Definition 2 of period, the fact that p is a period of u implies $u[0\,..\,n-p-1] = u[p\,..\,n-1]$, while q is a period of w implies $w[0\,..\,n-p-q-1] = w[q\,..\,n-p-1]$. As w is the suffix of u starting at position p, we can combine the above results to find that

$$\begin{aligned} u[0\,..\,n-p-q-1] &= u[p\,..\,n-q-1] = w[0\,..\,n-p-q-1] \\ &= w[q\,..\,n-p-1] = u[p+q\,..\,n-1], \end{aligned}$$

which indicates that $p+q$ is a period of u. Moreover, if $p+iq$ is a period of u for some $i \in \mathbb{N}$, then we can similarly show that $p+(i+1)q$ is also a period of u if $p+(i+1)q < n$. It follows by induction that $p+kq$ is a period of u for all $k \in \mathbb{N}$ with $p+kq < n$. The case $k = 0$ is trivial. ◀

▶ **Lemma 5.** *Let p, q be periods of $u \in \Sigma^n$ with $0 \leq q \leq p$. Then the prefix and the suffix of length $n - q$ have the period $p - q$.*

Proof. Since p, q be periods of $u \in \Sigma^n$ with $0 \leq q \leq p$, we have

$$\begin{aligned} u[0\,..\,n-p-1] &= u[p\,..\,n-1] && \text{(by periodicity } p\text{)} \\ &= u[p-q\,..\,n-q-1] && \text{(by periodicity } q\text{)}. \end{aligned}$$

It follows that $u[0\,..\,n-q-1]$ has period $p-q$. Similarly the suffix of u of length $(n-q)$ also has period $p-q$. ◀

▶ **Lemma 6.** *Suppose p is a period of $u \in \Sigma^n$ and there exists a substring v of u of length at least p and with period r, where $r|p$. Then r is also a period of u.*

Proof. If $p = 0$, then $r = 0$ and the lemma trivially holds.

Otherwise p is non-zero. Let $i, j \in [0, n-1]$ with $i \equiv j \mod r$. We can write $v = u[h\,..\,k]$ with $0 \leq h < k \leq n-1$. Since v has length at least p, there exist $i', j' \in [h, k]$ such that $i \equiv i' \mod p$ and $j \equiv j' \mod p$. By Definition 1 of period, we have $u[i] = u[i']$ and $u[j] = u[j']$. Note that $i' \equiv i \equiv j \equiv j' \mod r$, because $r \mid p$. Applying Definition 1 again, we obtain $u[i'] = u[j']$. It follows that $u[i] = u[i'] = u[j'] = u[j]$. Therefore r is a period of u. ◀

B Independence of alphabet

Guibas and Odlyzko showed that for every autocorrelation, there exists a string over a binary alphabet with that autocorrelation [10]. A nice alternative constructive proof appears in [12]. We will now show that the same holds for arbitrary correlations of equally long strings.

▶ **Corollary 24.** *For any $t \in \Delta_n$, there exist $u, v \in \{\mathtt{a}, \mathtt{b}\}^n$ such that the correlation of u over v is t.*

Proof. Let t be the correlation of u' over v' with $u', v' \in \Sigma^n$. By Lemma 21, we can write $t = 0^{(n-j)}s_j$, where $s_j \in \{0,1\}^j$ is the autocorrelation of $u'[n-j\,..\,n-1] = v'[0\,..\,j-1]$. By the result of Guibas and Odlyzko, we know that there also exists some binary string $w \in \{\mathtt{a}, \mathtt{b}\}^j$ with the same autocorrelation. Without loss of generality, we can assume that w starts with $\mathtt{b}$. It follows that the constructed strings $u = \mathtt{a}^{(n-j)}w$ and $v = w\mathtt{b}^{(n-j)}$, which have a correlation of t by the proof of Lemma 21, use the same binary alphabet. ◀

We conclude that the number of correlations between strings of equal length is alphabet-independent (i.e. every alphabet of size at least 2 gives rise to the same set of correlations).

▶ Remark 25. Such a binary string w can be constructed from $u'[n-j\,..\,n-1]$ in linear time using the algorithm of Halava, Harju and Ilie [12]. Therefore u and v can also be constructed in linear time given u' and v'.

Lasserre Hierarchy for Graph Isomorphism and Homomorphism Indistinguishability

Abstract

We show that feasibility of the t^{th} level of the Lasserre semidefinite programming hierarchy for graph isomorphism can be expressed as a homomorphism indistinguishability relation. In other words, we define a class $\mathcal{L}_t$ of graphs such that graphs G and H are not distinguished by the t^{th} level of the Lasserre hierarchy if and only if they admit the same number of homomorphisms from any graph in $\mathcal{L}_t$. By analysing the treewidth of graphs in $\mathcal{L}_t$ we prove that the $3t^{\text{th}}$ level of Sherali–Adams linear programming hierarchy is as strong as the t^{th} level of Lasserre. Moreover, we show that this is best possible in the sense that $3t$ cannot be lowered to $3t-1$ for any t. The same result holds for the Lasserre hierarchy with non-negativity constraints, which we similarly characterise in terms of homomorphism indistinguishability over a family $\mathcal{L}_t^+$ of graphs. Additionally, we give characterisations of level-t Lasserre with non-negativity constraints in terms of logical equivalence and via a graph colouring algorithm akin to the Weisfeiler–Leman algorithm. This provides a polynomial time algorithm for determining if two given graphs are distinguished by the t^{th} level of the Lasserre hierarchy with non-negativity constraints.

1 Introduction

The aim of this paper is to relate two rich sets of tools used to distinguish non-isomorphic graphs: the Lasserre semidefinite programming hierarchy and homomorphism indistinguishability.

Distinguishing non-isomorphic graphs is a ubiquitous problem in the theoretical and practical study of graphs. The ability of certain graph invariants to distinguish graphs has long been a rich area of study, leading to fundamental questions such as the longstanding open problem of whether almost all graphs are determined by their spectrum [35]. In practice, deploying e.g. machine learning architectures powerful enough to distinguish graphs with different features is of great importance [12]. This motivates an in-depth study of the power of various graph invariants and tools used to distinguish graphs.

Among such techniques is the Lasserre semidefinite programming hierarchy [17] which can be used to relax the integer program for graph isomorphism $\mathrm{ISO}(G, H)$, cf. Section 2.4. This yields a sequence of semidefinite programs, i.e. the level-t Lasserre relaxation of $\mathrm{ISO}(G, H)$ for $t \geq 1$, which are infeasible for more and more non-isomorphic graphs as t grows. In [33, 25, 5], it was shown that in general only the level-$\Omega(n)$ Lasserre system of equations can distinguish all non-isomorphic n-vertex graphs. In [4], the Lasserre hierarchy was compared with the Sherali–Adams[1] linear programming hierarchy [32], which is closely related to the Weisfeiler–Leman algorithm [36, 3, 13], the arguably most relevant combinatorial method for distinguishing graphs. It was shown in [4] that there exists a constant c such that, for all graphs G and H, if the level-ct Sherali–Adams relaxation of $\mathrm{ISO}(G, H)$ is feasible then so is the level-t Lasserre relaxation, which in turn implies that the level-t Sherali–Adams relaxation is feasible, cf. [18].

Another set of expressive equivalence relations comparing graphs is given by homomorphism indistinguishability, a notion originating from the study of graph substructure counts. Two graphs G and H are *homomorphism indistinguishable* over a family of graphs $\mathcal{F}$, in symbols $G \equiv_{\mathcal{F}} H$, if the number of homomorphisms from F to G is equal to the number of homomorphisms from F to H for every graph $F \in \mathcal{F}$. The study of this notion began in 1967, when Lovász [19] showed that two graphs G and H are isomorphic if and only if they are homomorphism indistinguishable over all graphs. In recent years, many prominent equivalence relations comparing graphs were characterised as homomorphism indistinguishability relations over restricted graph classes [9, 10, 11, 8, 20, 15, 2, 23, 1, 27, 26]. For example, a folklore result asserts that two graphs have cospectral adjacency matrices iff they are homomorphism indistinguishable over all cycle graphs, cf. [15]. Two graphs are quantum isomorphic iff they are homomorphism indistinguishable over all planar graphs [20]. Furthermore, feasibility of the level-t Sherali–Adams relaxation of $\mathrm{ISO}(G, H)$ has been characterised as homomorphism indistinguishability over all graphs of treewidth at most $t-1$ [3, 13, 10]. In this way, notions from logic [10, 11, 26], category theory [8, 23, 1], algebraic graph theory [9, 15], and quantum groups [20] have been related to homomorphism indistinguishability.

1.1 Contributions

Although feasibility of the level-t Lasserre relaxation of $\mathrm{ISO}(G, H)$ was sandwiched between feasibility of the level-ct and level-t Sherali–Adams relaxation in [4], the constant c remained unknown. In fact, this c is not explicit and depends on the implementation details of an algorithm developed in that paper. Our main result asserts that c can be taken to be three and that this constant is best possible.

▶ **Theorem 1.** *For two graphs G and H and every $t \geq 1$, the following implications hold:*

$$G \simeq_{3t}^{\mathrm{SA}} H \implies G \simeq_{t}^{\mathrm{L}} H \implies G \simeq_{t}^{\mathrm{SA}} H$$

Furthermore, for every $t \geq 1$, there exist graphs G and H such that $G \simeq_{3t-1}^{\mathrm{SA}} H$ and $G \not\simeq_{t}^{\mathrm{L}} H$.

Here, $G \simeq_{t}^{\mathrm{L}} H$ and $G \simeq_{t}^{\mathrm{SA}} H$ denote that the level-t Lasserre relaxation and respectively the level-t Sherali–Adams relaxation of $\mathrm{ISO}(G, H)$ are feasible.

Theorem 1 is proven using the framework of homomorphism indistinguishability. In previous works [9, 22, 15, 26], the feasibility of various systems of equations associated to graphs like the Sherali–Adams relaxation of $\mathrm{ISO}(G, H)$ was characterised in terms of

[1] Following [4], when referring to the Sherali–Adams relaxation of $\mathrm{ISO}(G, H)$ in this article, we do not refer to the original relaxation [32] but to its variant introduced by [3, 13], which corresponds more directly to other graph properties, cf. Theorem 8 and [15].

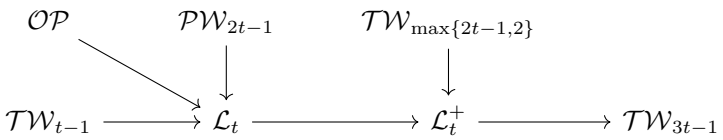

Figure 1 Relationship between $\mathcal{L}_t$, $\mathcal{L}_t^+$, the classes of graphs of bounded treewidth, bounded pathwidth, and the class of outerplanar graphs. An arrow $\mathcal{A} \to \mathcal{B}$ indicates that $\mathcal{A} \subseteq \mathcal{B}$ and thus that $G \equiv_{\mathcal{B}} H$ implies $G \equiv_{\mathcal{A}} H$ for all graphs G and H. For formal statements, see Sections 4.1 and 4.2.

homomorphism indistinguishability over certain graph classes. We continue this line of research by characterising the feasibility of the level-t Lasserre relaxation of $\mathrm{ISO}(G, H)$ by homomorphism indistinguishability of G and H over the novel class of graphs $\mathcal{L}_t$ introduced in Definition 22.

▶ **Theorem 2.** *For every integer $t \geq 1$, there is a minor-closed graph class $\mathcal{L}_t$ of graphs of treewidth at most $3t-1$ such that for all graphs G and H it holds that $G \simeq_t^{\mathrm{L}} H$ if and only if $G \equiv_{\mathcal{L}_t} H$.*

The bound on the treewidth of graphs in $\mathcal{L}_t$ in Theorem 2 yields the upper bound in Theorem 1 given the result of [3, 13, 4, 10] that two graphs G and H satisfy $G \simeq_t^{\mathrm{SA}} H$ if and only if they are homomorphism indistinguishable over the class $\mathcal{TW}_{t-1}$ of graphs of treewidth at most $t-1$. To our knowledge, Theorem 1 is the first result which tightly relates equivalence relations on graphs by comparing the graph classes which characterise them in terms of homomorphism indistinguishability.

Our techniques extend to a stronger version of the Lasserre hierarchy which imposes non-negativity constraints on all variables. Denoting feasibility of the level-t Lasserre relaxation of $\mathrm{ISO}(G, H)$ with non-negativity constraints by $G \simeq_t^{\mathrm{L}^+} H$, we characterise $\simeq_t^{\mathrm{L}^+}$ in terms of homomorphism indistinguishability over the graph class $\mathcal{L}_t^+$, defined in Definition 22 as a super class of $\mathcal{L}_t$. This is in line with previous work in [9, 15], where the feasibility of the level-t Sherali–Adams relaxation of $\mathrm{ISO}(G, H)$ without non-negativity constraints was characterised as homomorphism indistinguishable over the class $\mathcal{PW}_{t-1}$ of graphs of pathwidth at most $t-1$.

▶ **Theorem 3.** *For every integer $t \geq 1$, there is a minor-closed graph class $\mathcal{L}_t^+$ of graphs of treewidth at most $3t-1$ such that for all graphs G and H it holds that $G \simeq_t^{\mathrm{L}^+} H$ if and only if $G \equiv_{\mathcal{L}_t^+} H$.*

Given the aforementioned correspondence between the Sherali–Adams relaxation with and without non-negativity constraints and homomorphism indistinguishability over graphs of bounded treewidth and pathwidth, we conduct a detailed study of the relationship between the class of graphs of bounded treewidth, pathwidth, and the classes $\mathcal{L}_t$ and $\mathcal{L}_t^+$. Their results, depicted in Figure 1, yield independent proofs of the known relations between feasibility of the Lasserre relaxation with and without non-negativity constraints and the Sherali–Adams relaxation with and without non-negativity constraints [5, 4, 15] using the framework of homomorphism indistinguishability.

In the course of proving Theorems 2 and 3, we derive further equivalent characterisations of $\simeq_t^{\mathrm{L}}$ and $\simeq_t^{\mathrm{L}^+}$. These characterisations, which are mostly of a linear algebraic nature, ultimately yield a characterisation of $\simeq_t^{\mathrm{L}^+}$ in terms of a fragment of first-order logic with counting quantifiers and indistinguishability under a polynomial time algorithm akin to

the Weisfeiler–Leman algorithm. In this way, we obtain the following algorithmic result. It implies that *exact* feasibility of the Lasserre semidefinite program with non-negativity constraints can be tested in polynomial time. In general, only the *approximate* feasibility of semidefinite programs can be decided efficiently, e.g. using the ellipsoid method [16, 4].

▶ **Theorem 4.** *Let $t \geq 1$. Given graphs G and H, it can be decided in polynomial time whether $G \simeq_t^{\mathrm{L}^+} H$.*

Finally, for $t = 1$, we show that $\mathcal{L}_1$ and $\mathcal{L}_1^+$ are respectively equal to the class $\mathcal{OP}$ of outerplanar graphs and to the class of graphs of treewidth at most 2. The following Theorem 5 parallels a result of [20] asserting that two graphs G and H are indistinguishable under the 2-WL algorithm iff $G \simeq_1^{\mathrm{L}^+} H$.

▶ **Theorem 5.** *Two graphs G and H satisfy $G \simeq_1^{\mathrm{L}} H$ iff $G \equiv_{\mathcal{OP}} H$.*

1.2 Techniques

In the first part of the paper (Section 3), linear algebraic tools developed in [21, 20] are generalised to yield reformulations of the entire Lasserre hierarchy with and without non-negativity results. Section 4 is concerned with the graph theoretic properties of the graph classes $\mathcal{L}_t$ and $\mathcal{L}_t^+$. For understanding the homomorphism indistinguishability relations over these graph classes, the framework of bilabelled graphs and their homomorphism tensors developed in [22, 15] is used. Despite this, our approach is different from [15, 26] in the sense that here the graph classes $\mathcal{L}_t$ and $\mathcal{L}_t^+$ are inferred from given systems of equations, namely the Lasserre relaxation, rather than that a system of equations is built for a given graph class.

2 Preliminaries

2.1 Linear Algebra

Let $\mathcal{S}_+$ denote the family of real *positive semidefinite matrices*, i.e. of matrices M of the form $M_{ij} = v_i^T v_j$ for vectors $v_1, \dots, v_n$, the *Gram vectors* of M. Write $M \succeq 0$ iff $M \in \mathcal{S}_+$. Let $\mathcal{DNN}$ denote the family of *doubly non-negative matrices*, i.e. of entry-wise non-negative positive semidefinite matrices.

A linear map $\Phi\colon \mathbb{C}^{m\times m} \to \mathbb{C}^{n\times n}$ is *trace-preserving* if $\operatorname{tr}\Phi(X) = \operatorname{tr} X$ for all $X \in \mathbb{C}^{m\times m}$, *unital* if $\Phi(\mathrm{id}_m) = \mathrm{id}_n$, *$\mathcal{K}$-preserving* for a family of matrices $\mathcal{K}$ if $\Phi(K) \in \mathcal{K}$ for all $K \in \mathcal{K}$, *positive* if it is $\mathcal{S}_+$-preserving, i.e. if $\Phi(X)$ is positive semidefinite for all positive semidefinite X, *completely positive* if $\mathrm{id}_r \otimes \Phi$ is positive for all $r \in \mathbb{N}$. The *Choi matrix* of Φ is $C_\Phi = \sum_{i,j=1}^m E_{ij} \otimes \Phi(E_{ij}) \in \mathbb{C}^{mn\times mn}$.

A *tensor* is an element $A \in \mathbb{C}^{n^t \times n^t}$ for some $n, t \in \mathbb{N}$. The symmetric group $\mathfrak{S}_{2t}$ acts on $\mathbb{C}^{n^t\times n^t}$ by permuting the coordinates, i.e. for all $\boldsymbol{u}, \boldsymbol{v} \in [n]^t$, $A^\sigma(\boldsymbol{u}, \boldsymbol{v}) \coloneqq A(\boldsymbol{x}, \boldsymbol{y})$ where $\boldsymbol{x}_i \coloneqq (\boldsymbol{u}\boldsymbol{v})_{\sigma^{-1}(i)}$ and $\boldsymbol{y}_{j-t} \coloneqq (\boldsymbol{u}\boldsymbol{v})_{\sigma^{-1}(j)}$ for all $1 \leq i \leq t < j \leq 2t$.

For two vectors $v, w \in \mathbb{C}^n$, write $v \odot w$ for their *Schur product*, i.e. $(v \odot w)(i) \coloneqq v(i)w(i)$ for all $i \in [n]$.

2.2 Bilabelled Graphs and Homomorphism Tensors

All graphs in this article are undirected, finite, and without multiple edges. A graph is *simple* if it does not contain any loops. A *homomorphism* $h\colon F \to G$ from a graph F to a graph G is a map $V(F) \to V(G)$ such that for all $uv \in E(F)$ it holds that $h(u)h(v) \in E(G)$.

Note that this implies that any vertex in F carrying a loop must be mapped to a vertex carrying a loop in G. Write $\hom(F,G)$ for the number of homomorphisms from F to G. For a family of graphs $\mathcal{F}$ and graphs G and H write $G \equiv_{\mathcal{F}} H$ if G and H are *homomorphism indistinguishable over* $\mathcal{F}$, i.e. $\hom(F,G) = \hom(F,H)$ for all $F \in \mathcal{F}$. Since the graphs G and H into which homomorphisms are counted, are throughout assumed to be simple, looped graphs in $\mathcal{F}$ can generally be disregarded as they do not admit any homomorphisms into simple graphs.

We recall the following definitions from [20, 15]. Let $\ell \geq 1$. An (ℓ,ℓ)*-bilabelled graph* is a tuple $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ where F is a graph and $\boldsymbol{u}, \boldsymbol{v} \in V(F)^\ell$. The $\boldsymbol{u}$ are the *in-labelled vertices* of $\boldsymbol{F}$ while the $\boldsymbol{v}$ are the *out-labelled vertices* of $\boldsymbol{F}$. Given a graph G, the *homomorphism tensor* of $\boldsymbol{F}$ for G is $\boldsymbol{F}_G \in \mathbb{C}^{V(G)^\ell \times V(G)^\ell}$ whose $(\boldsymbol{x},\boldsymbol{y})$-th entry is the number of homomorphisms $h\colon F \to G$ such that $h(\boldsymbol{u}_i) = \boldsymbol{x}_i$ and $h(\boldsymbol{v}_i) = \boldsymbol{y}_i$ for all $i \in [\ell]$.

For an (ℓ,ℓ)-bilabelled graph $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$, write $\operatorname{soe} \boldsymbol{F} \coloneqq F$ for the underlying unlabelled graph of $\boldsymbol{F}$. Write $\operatorname{tr} \boldsymbol{F}$ for the unlabelled graph underlying the graph obtained from $\boldsymbol{F}$ by identifying $\boldsymbol{u}_i$ with $\boldsymbol{v}_i$ for all $i \in [\ell]$. For $\sigma \in \mathfrak{S}_{2t}$, write $\boldsymbol{F}^\sigma \coloneqq (F, \boldsymbol{x}, \boldsymbol{y})$ where $\boldsymbol{x}_i \coloneqq (\boldsymbol{uv})_{\sigma(i)}$ and $\boldsymbol{y}_{j-t} \coloneqq (\boldsymbol{uv})_{\sigma(j)}$ for all $1 \leq i \leq t < j \leq 2t$, i.e. $\boldsymbol{F}^\sigma$ is obtained from $\boldsymbol{F}$ by permuting the labels according to σ. As a special case, define $\boldsymbol{F}^* \coloneqq (F, \boldsymbol{v}, \boldsymbol{u})$ the graph obtained by swapping in- and out-labels.

For two (ℓ,ℓ)-bilabelled graphs $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ and $\boldsymbol{F}' = (F', \boldsymbol{u}', \boldsymbol{v}')$, write $\boldsymbol{F} \cdot \boldsymbol{F}'$ for the graph obtained from them by *series composition*. That is, the underlying unlabelled graph of $\boldsymbol{F} \cdot \boldsymbol{F}'$ is the graph obtained from the disjoint union of F and F' by identifying $\boldsymbol{v}_i$ and $\boldsymbol{u}'_i$ for all $i \in [\ell]$. Multiple edges arising in this process are removed. The in-labels of $\boldsymbol{F} \cdot \boldsymbol{F}'$ lie on $\boldsymbol{u}$, the out-labels on $\boldsymbol{v}'$. Moreover, write $\boldsymbol{F} \odot \boldsymbol{F}'$ for the *parallel composition* of $\boldsymbol{F}$ and $\boldsymbol{F}'$. That is, the underlying unlabelled graph of $\boldsymbol{F} \odot \boldsymbol{F}'$ is the graph obtained from the disjoint union of F and F' by identifying $\boldsymbol{u}_i$ with $\boldsymbol{u}'_i$ and $\boldsymbol{v}_i$ with $\boldsymbol{v}'_i$ for all $i \in [\ell]$. Again, multiple edges are dropped. The in-labels of $\boldsymbol{F} \odot \boldsymbol{F}'$ lie on $\boldsymbol{u}$, the out-labels on $\boldsymbol{v}$.

As observed in [20, 15], the benefit of these combinatorial operations is that they have an algebraic counterpart. Formally, for all graphs G and all (ℓ,ℓ)-bilabelled graphs $\boldsymbol{F}, \boldsymbol{F}'$, it holds that $\operatorname{soe} \boldsymbol{F}_G = \hom(\operatorname{soe} \boldsymbol{F}, G)$, $\operatorname{tr} \boldsymbol{F}_G = \hom(\operatorname{tr} \boldsymbol{F}, G)$, $(\boldsymbol{F}_G)^\sigma = (\boldsymbol{F}^\sigma)_G$, $(\boldsymbol{F} \cdot \boldsymbol{F}')_G = \boldsymbol{F}_G \cdot \boldsymbol{F}'_G$, and $(\boldsymbol{F} \odot \boldsymbol{F}')_G = \boldsymbol{F}_G \odot \boldsymbol{F}'_G$.

Slightly abusing notation, we say that two graphs G and H are homomorphism indistinguishable over a family of bilabelled graphs $\boldsymbol{S}$, in symbols $G \equiv_{\mathcal{S}} H$ if G and H are homomorphism indistinguishable over the family $\{\operatorname{soe} \boldsymbol{S} \mid \boldsymbol{S} \in \mathcal{S}\}$ of the underlying unlabelled graphs of the $\boldsymbol{S} \in \mathcal{S}$.

2.3 Pathwidth and Treewidth

▶ **Definition 6.** *Let F and T be graphs. A* T-decomposition of F *is a map $\beta\colon V(T) \to 2^{V(F)}$ such that*

1. $\bigcup_{t \in V(T)} \beta(t) = V(F)$,
2. *for every $e \in E(F)$, there is $t \in V(T)$ such that $e \subseteq \beta(t)$,*
3. *for every $v \in V(F)$, the set of $t \in V(T)$ such that $v \in \beta(t)$ induces a connected component of T.*

The width *of a T-decomposition β is $\max_{t \in V(T)} |\beta(t)| - 1$. For a graph class $\mathcal{T}$, the* $\mathcal{T}$-width of F *is the minimal width of a T-decomposition of F for $T \in \mathcal{T}$.*

The *treewidth* $\operatorname{tw} F$ of a graph F is the minimal width of a T-decomposition of F where T is a tree. Similarly, the *pathwidth* $\operatorname{pw} F$ is the minimal width of a P-decomposition of F where P is a path. For every $t \geq 0$, write $\mathcal{TW}_t$ and $\mathcal{PW}_t$ for the classes of all graphs of treewidth and respectively pathwidth at most t.

2.4 Systems of Equations for Graph Isomorphism

Two simple graphs G and H are isomorphic if and only if there exists a $\{0,1\}$-solution to the system of equations $\mathrm{ISO}(G,H)$ which comprises variables X_{gh} for $gh \in V(G) \times V(H)$ and equations

$$\sum_{h \in V(H)} X_{gh} - 1 = 0 \qquad \text{for all } g \in V(G), \tag{1}$$

$$\sum_{g \in V(G)} X_{gh} - 1 = 0 \qquad \text{for all } h \in V(H), \tag{2}$$

$$X_{gh} X_{g'h'} = 0 \qquad \text{for all } gh, g'h' \in V(G) \times V(H) \text{ s.t. } \mathrm{rel}_G(g,g') \neq \mathrm{rel}_H(h,h'). \tag{3}$$

Here, $\mathrm{rel}_G(g,g') = \mathrm{rel}_H(h',h')$ if and only if both pairs of vertices are adjacent, non-adjacent, or identical.

The Lasserre relaxation of $\mathrm{ISO}(G,H)$ is defined as follows. An element $\{g_1h_1, \dots g_\ell h_\ell\} \in \binom{V(G)\times V(H)}{\ell}$ is a *partial isomorphism* if $g_i = g_j \Leftrightarrow h_i = h_j$ and $g_ig_j \in E(G) \Leftrightarrow h_ih_j \in E(H)$ for all $i,j \in [\ell]$. See also [28] for a comparison to the version used in [4].

▶ **Definition 7.** *Let $t \geq 1$. The* level-t Lasserre relaxation for graph isomorphism *has variables y_I ranging over $\mathbb{R}$ for $I \in \binom{V(G)\times V(H)}{\leq 2t}$. The constraints are*

$$M_t(y) \coloneqq (y_{I\cup J})_{I,J \in \binom{V(G)\times V(H)}{\leq t}} \succeq 0, \tag{4}$$

$$\sum_{h \in V(H)} y_{I \cup \{gh\}} = y_I \text{ for all } I \text{ s.t. } |I| \leq 2t-2 \text{ and all } g \in V(G), \tag{5}$$

$$\sum_{g \in V(G)} y_{I \cup \{gh\}} = y_I \text{ for all } I \text{ s.t. } |I| \leq 2t-2 \text{ and all } h \in V(H), \tag{6}$$

$$y_I = 0 \text{ if } I \text{ s.t. } |I| \leq 2t \text{ is not partial isomorphism} \tag{7}$$

$$y_\emptyset = 1. \tag{8}$$

If the system is feasible for two graphs G and H, write $G \simeq_t^{\mathrm{L}} H$. If the system together with the constraint $y_I \geq 0$ for all $I \in \binom{V(G)\times V(H}{\leq 2t}$ is feasible, write $G \simeq_t^{\mathrm{L}^+} H$.

For a definition of the Sherali–Adams relaxation of $\mathrm{ISO}(G,H)$ in the version used here following [4], the reader is referred to [14, Appendix D.1]. Instead of feasibility of the level-t Sherali–Adams relaxation, one may think of the following equivalent notions:

▶ **Theorem 8** ([4, 10, 6])**.** *Let $t \geq 1$. For graphs G and H, the following are equivalent:*

1. *the level-t Sherali–Adams relaxation of $\mathrm{ISO}(G,H)$ is feasible, i.e. $G \simeq_t^{\mathrm{SA}} H$,*
2. *G and H satisfy the same sentences of t-variable first order logic with counting quantifiers,*
3. *G and H are homomorphism indistinguishable over the graphs of treewidth at most $t-1$,*
4. *G and H are not distinguished by the $(t-1)$-dimensional Weisfeiler–Leman algorithm,*

3 From Lasserre to Homomorphism Tensors

In this section, the tools are developed which will be used to translate a solution to the level-t Lasserre relaxation into a statement on homomorphism indistinguishability. For this purpose, three equivalent characterisations of $\simeq_t^{\mathrm{L}}$ and $\simeq_t^{\mathrm{L}^+}$ are introduced. Theorems 9 and 10 summarise our results. The notions in items 2–4 and the graph classes $\mathcal{L}_t$ and $\mathcal{L}_t^+$ are defined in Sections 3.1, 3.2, 3.4, and 4, respectively. Most of the proofs are of a linear algebraic nature. Graph theoretical repercussions are discussed in Section 4.

▶ **Theorem 9.** *Let $t \geq 1$. For graphs G and H, the following are equivalent:*
1. *the level-t Lasserre relaxation of* $\mathrm{ISO}(G, H)$ *is feasible,*
2. *G and H are level-t $\mathcal{S}_+$-isomorphic,*
3. *there is a level-t $\mathcal{S}_+$-isomorphism map from G to H,*
4. *G and H are partially t-equivalent,*
5. *G and H are homomorphism indistinguishable over $\mathcal{L}_t$.*

▶ **Theorem 10.** *Let $t \geq 1$. For graphs G and H, the following are equivalent:*
1. *the level-t Lasserre relaxation of* $\mathrm{ISO}(G, H)$ *with non-negativity constraints is feasible,*
2. *G and H are level-t $\mathcal{DNN}$-isomorphic,*
3. *there is a level-t $\mathcal{DNN}$-isomorphism map from G to H,*
4. *G and H are t-equivalent,*
5. *G and H are homomorphism indistinguishable over $\mathcal{L}_t^+$.*

Variants of the notions in items 2–4 have already been defined for the case $t = 1$ in [22]. Our contribution amounts to extending these definitions to the entire Lasserre hierarchy. A recurring theme in this context is accounting for additional symmetries. The variables y_I of the Lasserre system of equations, cf. Definition 7, are indexed by sets of vertex pairs rather than by tuples of such. Hence, when passing from such variables to tuple-indexed matrices, one must impose the additional symmetries arising this way. This is formalised at various points using an action of the symmetric group on the axes of the matrices. In the case $t = 1$, such a set up is not necessary since indices I are of size at most 2 and all occurring matrices can be taken to be invariant under transposition.

In the subsequent sections, Theorems 9 and 10 will be proven in parallel. The equivalence of items 1 and 2, 2 and 3, and 3 and 4 are established in Section 3.3, Section 3.2, and Section 3.4, respectively. The statements on homomorphism indistinguishability are proven in Section 4.

3.1 Isomorphism Relaxations via Matrix Families

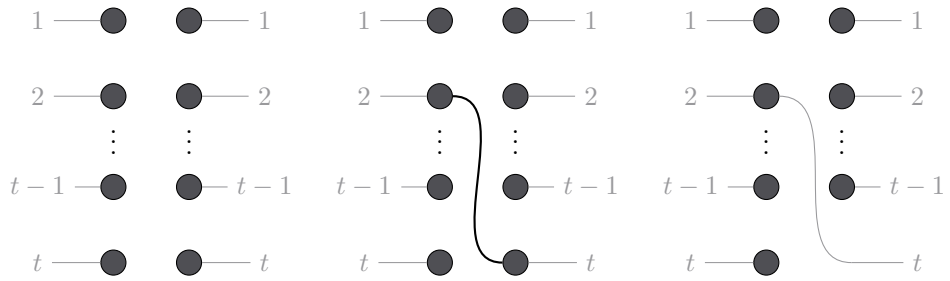
In this section, as a first step towards proving Theorems 9 and 10, the notion of level-t $\mathcal{K}$-isomorphic graphs for arbitrary families of matrices $\mathcal{K}$ is introduced. In [22], level-1 $\mathcal{K}$-isomorphic graphs where studied for various families of matrices $\mathcal{K}$. In this work, the main interest lies on the family of positive semidefinite matrices $\mathcal{S}_+$ and the family of entry-wise non-negative positive semidefinite matrices $\mathcal{DNN}$. Level-t isomorphism for these families is proven to correspond to $\simeq_t^{\mathrm{L}}$ and $\simeq_t^{\mathrm{L}^+}$ respectively, cf. Theorems 16 and 17.

▶ **Definition 11.** *Let $\mathcal{K}$ be a family of matrices. Graphs G and H are said to be* level-t $\mathcal{K}$-isomorphic*, in symbols $G \cong_{\mathcal{K}}^t H$, if there is a matrix $M \in \mathcal{K}$ with rows and columns indexed by $(V(G) \times V(H))^t$ such that for every $g_1h_1 \dots g_th_t, g_{t+1}h_{t+1} \dots g_{2t}h_{2t} \in (V(G) \times V(H))^t$ the following equations hold:*

For every $i \in [2t]$,

$$\sum_{g_i \in V(G)} M_{g_1h_1 \dots g_th_t, g_{t+1}h_{t+1} \dots g_{2t}h_{2t}} = \sum_{h_i \in V(H)} M_{g_1h_1 \dots g_th_t, g_{t+1}h_{t+1} \dots g_{2t}h_{2t}}, \tag{9}$$

$$\sum_{h_1', \dots, h_{2t}' \in V(H)} M_{g_1h_1' \dots g_th_t', g_{t+1}h_{t+1}' \dots g_{2t}h_{2t}'} = 1 = \sum_{g_1', \dots, g_{2t}' \in V(G)} M_{g_1'h_1 \dots g_t'h_t, g_{t+1}'h_{t+1} \dots g_{2t}'h_{2t}}. \tag{10}$$



(a) $\boldsymbol{J}$. (b) $\boldsymbol{A}^{2,2t}$. (c) $\boldsymbol{I}^{2,2t}$.

Figure 2 Examples of the atomic graphs from Definition 13. The gray lines (the *wires* [20]) indicate the in-labels (left) and out-labels (right).

If $\mathrm{rel}_G(g_1,\dots,g_{2t}) \neq \mathrm{rel}_H(h_1,\dots,h_{2t})$ *then*

$$M_{g_1h_1\dots g_th_t,g_{t+1}h_{t+1}\dots g_{2t}h_{2t}} = 0. \tag{11}$$

For all $\sigma \in \mathfrak{S}_{2t}$,

$$M_{g_1h_1\dots g_th_t,g_{t+1}h_{t+1}\dots g_{2t}h_{2t}} = M_{g_{\sigma(1)}h_{\sigma(1)}\cdots g_{\sigma(t)}h_{\sigma(t)},g_{\sigma(t+1)}h_{\sigma(t+1)}\cdots g_{\sigma(2t)}h_{\sigma(2t)}}. \tag{12}$$

Note that for $t = 1$ and any family of matrices $\mathcal{K}$ closed under taking transposes Equation (12) is vacuous.

Systems of equations comparing graphs akin to Equations (9)–(12) were also studied by [15]. Feasibility of such equations is typically invariant under taking the complements of the graphs as remarked below. This semantic property of the relation $\cong^t_{\mathcal{K}}$ is relevant in the context of homomorphism indistinguishability as shown by [30].

▶ Remark 12. For a simple graph G, write $\overline{G}$ for its complement, i.e. $V(\overline{G}) \coloneqq V(G)$ and $E(\overline{G}) \coloneqq \binom{V(G)}{2} \setminus E(G)$. For all graphs G and H and $g_1,\dots,g_{2t} \in V(G)$, $h_1,\dots,h_{2t} \in V(H)$, it holds that

$$\mathrm{rel}_G(g_1,\dots,g_{2t}) = \mathrm{rel}_H(h_1,\dots,h_{2t}) \iff \mathrm{rel}_{\overline{G}}(g_1,\dots,g_{2t}) = \mathrm{rel}_{\overline{H}}(h_1,\dots,h_{2t}).$$

Thus, $G \cong^t_{\mathcal{K}} H$ if and only if $\overline{G} \cong^t_{\mathcal{K}} \overline{H}$ for all families of matrices $\mathcal{K}$ and $t \in \mathbb{N}$.

3.2 Choi Matrices and Isomorphism Maps

In this section, an alternative characterisation for level-t $\mathcal{K}$-isomorphism is given. Intuitively, the indices of the matrix $M \in \mathbb{C}^{(V(G)\times V(H))^t\times(V(G)\times V(H))^t}$ from Definition 11 are regrouped yielding a linear map $\Phi\colon \mathbb{C}^{V(G)^t\times V(G)^t} \to \mathbb{C}^{V(H)^t\times V(H)^t}$. In linear algebraic terms, M is the Choi matrix of Φ. The map Φ will later be interpreted as a function sending homomorphism tensors of (t,t)-bilabelled graphs $\boldsymbol{F}_G \in \mathbb{C}^{V(G)^t\times V(G)^t}$ with respect to G to their counterparts $\boldsymbol{F}_H$ for H.

The most basic bilabelled graphs, so called *atomic* graphs, make their first appearance in Theorem 14. These graphs are used to reformulate Equations (7) and (11). The atomic graphs are also the graphs which the sets $\mathcal{L}_t$ and $\mathcal{L}^+_t$ of Theorems 2 and 3 are generated by, cf. Definition 22. Examples are depicted in Figures 2 and 3.

▶ **Definition 13.** *Let* $t \geq 1$. *A* (t,t)*-bilabelled graph* $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ *is* atomic *if all its vertices are labelled. Write* $\mathcal{A}_t$ *for the set of* (t,t)*-bilabelled atomic graphs. Note that the the set of atomic graphs* $\mathcal{A}_t$ *is generated under parallel composition by the graphs*

- $\boldsymbol{J} \coloneqq (J, (1, \dots, t), (t+1, \dots, 2t))$ *with* $V(J) = [2t]$, $E(J) = \emptyset$,
- $\boldsymbol{A}^{ij} \coloneqq (A^{ij}, (1, \dots, t), (t+1, \dots, 2t))$ *with* $V(A^{ij}) = [2t]$, $E(A^{ij}) = \{ij\}$ *for* $1 \leq i < j \leq 2t$,
- $\boldsymbol{I}^{ij}$ *for* $1 \leq i < j \leq 2t$ *which is obtained from* $\boldsymbol{A}^{ij}$ *by contracting the edge* ij.

The following Theorem 14 relates the properties of Φ and M. In Equation (15), J denotes the all-ones matrix of appropriate dimension. Its proof is deferred to the full version [28].

▶ **Theorem 14.** *Let* $t \geq 1$. *Let* G *and* H *be graphs and* $\mathcal{K} \in \{\mathcal{DNN}, \mathcal{S}_+\}$ *be a family of matrices. Let* $\Phi \colon \mathbb{C}^{V(G)^t \times V(G)^t} \to \mathbb{C}^{V(H)^t \times V(H)^t}$ *be a linear map. Then the following are equivalent.*

1. *The Choi matrix* C_Φ *of* Φ *satisfies Equations* (9)–(12) *and* $C_\Phi \in \mathcal{K}$,
2. Φ *is a* level-t $\mathcal{K}$-isomorphism map from G to H, *i.e. it satisfies*

$$\Phi \text{ is completely } \mathcal{K}\text{-preserving}, \tag{13}$$

$$\Phi(\boldsymbol{A}_G \odot X) = \boldsymbol{A}_H \odot \Phi(X) \text{ for all atomic } \boldsymbol{A} \in \mathcal{A}_t \text{ and all } X \in \mathbb{C}^{V(G)^t \times V(G)^t}, \tag{14}$$

$$\Phi(J) = J = \Phi^*(J), \tag{15}$$

$$\Phi(X^\sigma) = \Phi(X)^\sigma \text{ for all } \sigma \in \mathfrak{S}_{2t} \text{ and all } X \in \mathbb{C}^{V(G)^t \times V(G)^t}. \tag{16}$$

3. Φ^* *is a level-*t $\mathcal{K}$*-isomorphism map from* H *to* G.

We remark that Theorem 14 and in particular its Equation (15) has brought us closer to interpreting the Lasserre system of equation from the perspective of homomorphism indistinguishability. As argued in Remark 15, the map Φ, which will be understood as mapping homomorphism tensors $\boldsymbol{F}_G$ to $\boldsymbol{F}_H$, is sum-preserving. Since the sum of the entries of these tensors equals the number of homomorphisms from their underlying unlabelled graphs to G and H, respectively, for establishing a connection between $\mathcal{K}$-isomorphism maps and homomorphism indistinguishability.

▶ Remark 15. If a linear map $\Phi \colon \mathbb{C}^{n \times n} \to \mathbb{C}^{m \times m}$ is such that $J = \Phi^*(J)$ then it is *sum-preserving*, i.e. $\operatorname{soe} X = \operatorname{soe} \Phi(X)$ for all $X \in \mathbb{C}^{n \times n}$. Indeed, $\operatorname{soe} X = \langle X, J \rangle = \langle X, \Phi^*(J) \rangle = \langle \Phi(X), J \rangle = \operatorname{soe} \Phi(X)$ where $\langle A, B \rangle \coloneqq \operatorname{tr}(AB^*)$. In particular, if there is Φ satisfying Equations (14) and (15) for graphs G and H then $|G| = |H|$.

3.3 Connection to Lasserre

By the following Theorems 16 and 17, the notions introduced in Definition 11 and Theorem 14 are equivalent to the object of our main interest, namely feasibility of the level-t Lasserre relaxation with and without non-negativity constraints. Our results extend those of [22, Lemma 9.1] to the entire Lasserre hierarchy. The proofs are deferred to the full version [28].

▶ **Theorem 16.** *Let* $t \geq 1$. *Two graphs* G *and* H *are level-*t $\mathcal{S}_+$*-isomorphic if and only if the level-*t *system of the Lasserre hierarchy for graph isomorphism, i.e. Equations* (4)–(8), *is feasible.*

▶ **Theorem 17.** *Let* $t \geq 1$. *Two graphs* G *and* H *are level-*t $\mathcal{DNN}$*-isomorphic if and only if the level-*t *system of the Lasserre hierarchy for graph isomorphism Equations* (4)–(8) *with the additional constraint* $y_I \geq 0$ *for all* $I \in \binom{V(G) \times V(H)}{\leq 2t}$ *is feasible.*

(a) J. (b) $A^{1,2}$. (c) $I^{1,2}$.

Figure 3 The three atomic graphs in $\mathcal{A}_1$.

3.4 Isomorphisms between Matrix Algebras

To the two reformulations of $\simeq_t^{\mathrm{L}}$ and $\simeq_t^{\mathrm{L}^+}$ from the previous sections, a third characterisation is added in this section. It is shown that two graphs are level-t $\mathcal{S}_+$-isomorphic ($\mathcal{DNN}$-isomorphic) if and only if certain matrix algebras associated to them are isomorphic. These algebras will be identified as the algebras of homomorphism tensors for graphs from the families $\mathcal{L}_t$ and $\mathcal{L}_t^+$. The so called (partially) coherent algebras considered in this section are natural generalisations of the coherent algebra which are well-studied in the context of the 2-dimensional Weisfeiler–Leman algorithm [7].

3.4.1 Partially Coherent Algebras and $\mathcal{S}_+$-Isomorphism Maps

Let $S \subseteq \mathbb{C}^{n^t \times n^t}$. A matrix algebra $\mathcal{A} \subseteq \mathbb{C}^{n^t \times n^t}$ is *S-partially coherent* if it is unital, self-adjoint, contains the all-ones matrix, and is closed under Schur products with any matrix in S. A matrix algebra $\mathcal{A} \subseteq \mathbb{C}^{n^t \times n^t}$ is *self-symmetrical* if for every $A \in \mathcal{A}$ and $\sigma \in \mathfrak{S}_{2t}$ also $A^\sigma \in \mathcal{A}$. Note that for $t = 1$, an algebra $\mathcal{A}$ is self-symmetrical if for all $A \in \mathcal{A}$ also $A^T \in \mathcal{A}$.

▶ **Definition 18.** *Given a graph G, construct its* t-partially coherent algebra $\widehat{\mathcal{A}}_G^t$ *as the minimal self-symmetrical S-partially coherent algebra where S is the set of homomorphism tensors of (t,t)-bilabelled atomic graphs for G.*

Two n-vertex graphs G and H are partially t-equivalent *if there is a* partial t-equivalence*, i.e. a vector space isomorphism $\varphi\colon \widehat{\mathcal{A}}_G^t \to \widehat{\mathcal{A}}_H^t$ such that*

1. $\varphi(M^*) = \varphi(M)^*$ *for all* $M \in \widehat{\mathcal{A}}_G^t$,
2. $\varphi(MN) = \varphi(M)\varphi(N)$ *for all* $M, N \in \widehat{\mathcal{A}}_G^t$,
3. $\varphi(I) = I$, $\varphi(\boldsymbol{A}_G) = \boldsymbol{A}_H$ *for all* $\boldsymbol{A} \in \mathcal{A}_t$, *and* $\varphi(J) = J$,
4. $\varphi(\boldsymbol{A}_G \odot M) = \boldsymbol{A}_H \odot \varphi(M)$ *for all* $\boldsymbol{A} \in \mathcal{A}_t$ *and any* $M \in \widehat{\mathcal{A}}_G^t$.
5. $\varphi(M^\sigma) = \varphi(M)^\sigma$ *for all* $M \in \widehat{\mathcal{A}}_G^t$ *and all* $\sigma \in \mathfrak{S}_{2t}$.

The following Theorem 19 extends [22, Theorem 5.2]. Its proof is deferred to the full version [28].

▶ **Theorem 19.** *Let $t \geq 1$. Two graphs G and H are partially t-equivalent if and only if there is a level-t $\mathcal{S}_+$-isomorphism map from G to H.*

3.4.2 Coherent Algebras and $\mathcal{DNN}$-Isomorphism Maps

A matrix algebra $\mathcal{A} \subseteq \mathbb{C}^{n \times n}$ is *coherent* if it is unital, self-adjoint, contains the all-ones matrix and is closed under Schur products.

For $t = 1$, the 1-adjacency algebra as defined below is equal to the well-studied *adjacency algebra* of a graph G, cf. [7]. The latter is the smallest coherent algebra containing the adjacency matrix of the graph. The former is generated by the homomorphism tensors of $(1,1)$-bilabelled atomic graphs. These graphs are depicted in Figure 3. Their homomorphism tensors are the all-ones matrix, the adjacency matrix of the graph, and the identity matrix.

▶ **Definition 20.** *Let $t \geq 1$. The* t-adjacency algebra $\mathcal{A}_G^t$ *of a graph G is the self-symmetrical coherent algebra generated by the homomorphism tensors of the atomic graphs $\mathcal{A}_t$.*

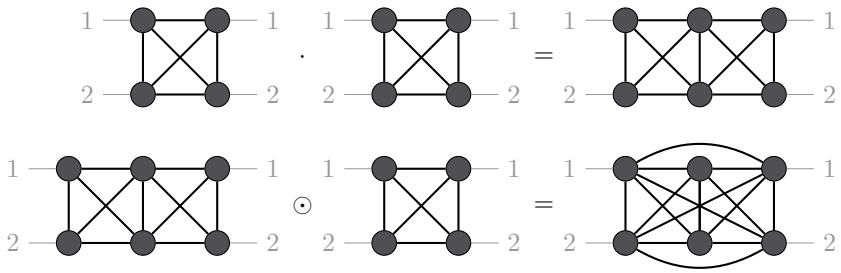


Figure 4 The bilabelled graphs in Observation 23 for $t = 2$.

Two n-vertex graphs G and H are t-equivalent *if there is* t-equivalence*, i.e. a vector space isomorphism $\varphi\colon \mathcal{A}_G^t \to \mathcal{A}_H^t$ such that*

1. $\varphi(M^*) = \varphi(M)^*$ *for all* $M \in \mathcal{A}_G^t$,
2. $\varphi(MN) = \varphi(M)\varphi(N)$ *for all* $M, N \in \mathcal{A}_G^t$,
3. $\varphi(I) = I$, $\varphi(\boldsymbol{A}_G) = \boldsymbol{A}_H$ *for all* $\boldsymbol{A} \in \mathcal{A}_t$, *and* $\varphi(J) = J$,
4. $\varphi(M \odot N) = \varphi(M) \odot \varphi(N)$ *for all* $M, N \in \mathcal{A}_G^t$.
5. $\varphi(M^\sigma) = \varphi(M)^\sigma$ *for all* $M \in \mathcal{A}_G^t$ *and all* $\sigma \in \mathfrak{S}_{2t}$.

The following Theorem 21 extends [22, Theorem 6.3]. Its proof is deferred to the full version [28].

▶ **Theorem 21.** *Let $t \geq 1$. Two graphs G and H are t-equivalent if and only if there is a level-t $\mathcal{DNN}$-isomorphism map from G to H.*

4 Homomorphism Indistinguishability

Using techniques from [15], we finally establish a characterisation of when the level-t Lasserre relaxation of $\mathrm{ISO}(G, H)$ is feasible in terms of homomorphism indistinguishability of G and H. In order to do so, we introduce the graph classes $\mathcal{L}_t$ and $\mathcal{L}_t^+$. In Section 4.1, we relate $\mathcal{L}_t$ and $\mathcal{L}_t^+$ to the classes of graphs of bounded treewidth and pathwidth obtaining the results depicted in Figure 1. In Section 4.2, $\mathcal{L}_1$ and $\mathcal{L}_1^+$ are identified as the classes of outerplanar graphs and graphs of treewidth two, respectively.

▶ **Definition 22.** *Let $t \geq 1$. Write $\mathcal{L}_t^+$ for the class of (t,t)-bilabelled graphs generated by the set of atomic graphs $\mathcal{A}_t$ under parallel composition, series composition, and the action of $\mathfrak{S}_{2t}$ on the labels.*

Write $\mathcal{L}_t \subseteq \mathcal{L}_t^+$ for the class of (t,t)-bilabelled graphs generated by the set of atomic graphs $\mathcal{A}_t$ under parallel composition with graphs from $\mathcal{A}_t$, series composition, and the action of $\mathfrak{S}_{2t}$ on the labels.

Note that the only difference between $\mathcal{L}_t$ and $\mathcal{L}_t^+$ is that $\mathcal{L}_t$ is closed under parallel composition with atomic graphs only. This reflects an observation by [15] relating the closure under arbitrary gluing products to non-negative solutions to systems of equations characterising homomorphism indistinguishability. Intuitively, one may use arbitrary Schur products, the algebraic counterparts of gluing, for a Vandermonde interpolation argument, cf. [14, Appendix B.4].

The following Observation 23 illustrates how the operations in Definition 22 can be used to generate more complicated graphs from the atomic graphs, cf. Figure 4.

▶ **Observation 23.** *Let $t \geq 1$. The class $\mathcal{L}_t$ contains a bilabelled graph whose underlying unlabelled graph is isomorphic to the $3t$-clique K_{3t}.*

Proof. Let $\boldsymbol{E} \coloneqq \bigodot_{1 \leq i < j \leq 2t} \boldsymbol{A}^{ij} \in \mathcal{A}_t$. The graph underlying $\boldsymbol{E} \odot (\boldsymbol{E} \cdot \boldsymbol{E})$ is isomorphic to K_{3t}. ◀

The only missing implications of Theorems 9 and 10 follow from the next two theorems:

▶ **Theorem 24.** *Let $t \geq 1$. Two graphs G and H are homomorphism indistinguishable over $\mathcal{L}_t$ if and only if they are partially t-equivalent.*

▶ **Theorem 25.** *Let $t \geq 1$. Two graphs G and H are homomorphism indistinguishable over $\mathcal{L}_t^+$ if and only if they are t-equivalent.*

For the proofs of Theorems 24 and 25, we extend the framework developed by [15]. In this work, the authors introduced tools for constructing systems of equations characterising homomorphism indistinguishably over classes of labelled graphs. A requirement of these tools is that the graph class in question is *inner-product compatible* [15, Definition 24]. This means that for every two labelled graphs $\boldsymbol{R}$ and $\boldsymbol{S}$ one can write the inner-product of their homomorphism vectors $\boldsymbol{R}_G$ and $\boldsymbol{S}_G$ as the sum-of-entries of some $\boldsymbol{T}_G$ where $\boldsymbol{T}$ is labelled graph from the class. Due to the correspondence between combinatorial operations on labelled graphs and algebraic operations on their homomorphism vectors, cf. Section 2.2, this is equivalent to the graph theoretic assumption that $\operatorname{soe}(\boldsymbol{R} \odot \boldsymbol{S}) = \operatorname{soe}(\boldsymbol{T})$, i.e. the unlabelled graph obtained by unlabelling the gluing product of $\boldsymbol{R}$ and $\boldsymbol{S}$ can be labelled such that the resulting labelled graph is in the class.

We extend this notion to bilabelled graphs. A class of (t,t)-bilabelled graphs $\mathcal{S}$ is said to be *inner-product compatible* if for all $\boldsymbol{R}, \boldsymbol{S} \in \mathcal{S}$ there is a graph $\boldsymbol{T} \in \mathcal{S}$ such that $\operatorname{tr}(\boldsymbol{R} \cdot \boldsymbol{S}^*) = \operatorname{soe}(\boldsymbol{T})$. This definition is inspired by the inner-product on $\mathbb{C}^{n \times n}$ given by $\langle A, B \rangle \coloneqq \operatorname{tr}(AB^*)$.

▶ **Lemma 26.** *Let $t \geq 1$. The classes $\mathcal{L}_t$ and $\mathcal{L}_t^+$ are inner-product compatible.*

Proof. Since $\mathcal{L}_t$ is closed under matrix products and taking transposes, it suffices to show that for every $\boldsymbol{S} \in \mathcal{L}_t$ the graph $\operatorname{tr} \boldsymbol{S}$ is the underlying unlabelled graph of some element of $\mathcal{L}_t$. Indeed, for every (t,t)-bilabelled graphs $\boldsymbol{F}$ it holds that $\operatorname{tr}(\boldsymbol{F}) = \operatorname{soe}(\boldsymbol{I}^{1,t+1} \odot \cdots \odot \boldsymbol{I}^{t,2t} \odot \boldsymbol{F})$ where the $\boldsymbol{I}^{ij}$ are as in Definition 13. Since $\mathcal{L}_t$ is closed under parallel composition with atomic graphs, the claim follows. For $\mathcal{L}_t^+$, an analogous argument yields the claim. ◀

The following Theorem 27, which extends the toolkit for constructing systems of equations characterising homomorphism indistinguishability over families of bilabelled graphs, is the bilabelled analogue of [15, Theorem 13]. Write $\mathbb{C}\mathcal{S}_G \subseteq \mathbb{C}^{V(G)^t \times V(G)^t}$ for the vector space spanned by homomorphism tensors $\boldsymbol{S}_G$ for $\boldsymbol{S} \in \mathcal{S}$.

▶ **Theorem 27.** *Let $t \geq 1$ and $\mathcal{S}$ be an inner-product compatible class of (t,t)-bilabelled graphs containing $\boldsymbol{J}$. For graphs G and H, the following are equivalent:*

1. *G and H are homomorphism indistinguishable over $\mathcal{S}$,*
2. *there exists a sum-preserving vector space isomorphism $\varphi \colon \mathbb{C}\mathcal{S}_G \to \mathbb{C}\mathcal{S}_H$ such that $\varphi(\boldsymbol{S}_G) = \boldsymbol{S}_H$ for all $\boldsymbol{S} \in \mathcal{S}$.*

Theorems 24 and 25 follows from this theorem as described in the full version [28].

4.1 The Classes $\mathcal{L}_t$ and $\mathcal{L}_t^+$ and Graphs of Bounded Treewidth

In this section, the classes $\mathcal{L}_t$ and $\mathcal{L}_t^+$ are compared to the classes of graphs of bounded treewidth and pathwidth. Figure 1 depicts the relationships between these classes. The first result, Lemma 28, gives an upper bound on the treewidth of graphs in $\mathcal{L}_t^+$.

▶ **Lemma 28.** *Let $t \geq 1$. The treewidth of an unlabelled graph F underlying some $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v}) \in \mathcal{L}_t^+$ is at most $3t-1$.*

Proof. By structural induction, it is shown that every $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v}) \in \mathcal{L}_t^+$ admits a tree decomposition $\beta\colon V(T) \to 2^{V(F)}$ of width at most $3t-1$ such that the labelled vertices $\boldsymbol{u}$ and $\boldsymbol{v}$ lie together in one bag, i.e. there exists $x \in V(T)$ such that $\{\boldsymbol{u}_1, \dots, \boldsymbol{u}_t, \boldsymbol{v}_1, \dots, \boldsymbol{v}_t\} \subseteq \beta(x)$.

This is clearly the case for all $\boldsymbol{F} \in \mathcal{A}_t$. Let $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ and $\boldsymbol{F}' = (F', \boldsymbol{u}', \boldsymbol{v}')$ from $\mathcal{L}_t^+$ be given. Suppose there are tree decompositions $\beta\colon V(T) \to 2^{V(F)}$ and $\beta'\colon V(T') \to 2^{V(F')}$ as in the inductive hypothesis. Let $x \in V(T)$ and $x' \in V(T')$ be such that the labelled vertices of $\boldsymbol{F}$ and $\boldsymbol{F}'$ lie in $\beta(x)$ and $\beta'(x')$ respectively. Let S be the tree obtained by taking the disjoint union of T, T', and a fresh vertex y, and connecting x and x' to y.

For the graph $\boldsymbol{F} \cdot \boldsymbol{F}'$, an S-decomposition is given by the function

$$\gamma\colon z \mapsto \begin{cases} \beta(z), & \text{if } z \in V(T), \\ \beta'(z), & \text{if } z \in V(T'), \\ \{\boldsymbol{u}_1, \dots, \boldsymbol{u}_t, \boldsymbol{v}'_1, \dots, \boldsymbol{v}'_t, \boldsymbol{v}_1, \dots, \boldsymbol{v}_t\}, & \text{if } z = y. \end{cases}$$

where one may note that $\boldsymbol{v}_i = \boldsymbol{u}'_i$ for every $i \in [t]$ in $\boldsymbol{F} \cdot \boldsymbol{F}'$. It is easy to check that Definition 6 is satisfied. The decomposition is of width $3t-1$.

For the graph $\boldsymbol{F} \odot \boldsymbol{F}'$, an S-decomposition is given by the function

$$\gamma\colon z \mapsto \begin{cases} \beta(z), & \text{if } z \in V(T), \\ \beta'(z), & \text{if } z \in V(T'), \\ \{\boldsymbol{u}_1, \dots, \boldsymbol{u}_t, \boldsymbol{v}_1, \dots, \boldsymbol{v}_t\}, & \text{if } z = y. \end{cases}$$

where one may note that $\boldsymbol{u}_i = \boldsymbol{u}'_i$ and $\boldsymbol{v}_i = \boldsymbol{v}'_i$ for every $i \in [t]$ in $\boldsymbol{F} \odot \boldsymbol{F}'$. Again, it is easy to check that Definition 6 is satisfied. The decomposition is of width at most $3t-1$. ◀

Lemma 28 in conjunction with Theorems 9 and 10 implies Theorems 2 and 3. As a corollary, this yields the upper bound in Theorem 1. Indeed, by Theorem 8, $G \simeq_t^{\mathrm{SA}} H$ if and only if G and H are homomorphism indistinguishable over the class of graphs of treewidth at most $t-1$. Hence, if $G \simeq_{3t}^{\mathrm{SA}} H$ then $G \simeq_t^{\mathrm{L}^+} H$ and in particular $G \simeq_t^{\mathrm{L}} H$.

It remains to show the lower bound asserted by Theorem 1, i.e. that $3t$ cannot be replaced by $3t-1$ for no $t \geq 1$. To that end, first observe that Observation 23 implies that the bound in Lemma 28 is tight. However, this syntactic property of the graph class $\mathcal{L}_t$ does not suffice to derive the aforementioned semantic property of $\simeq_t^{\mathrm{SA}}$ and $\simeq_t^{\mathrm{L}}$. In fact, it could well be that for all graphs G and H if G and H are homomorphism indistinguishable over the graphs of treewidth at most $3t-2$ also $\hom(K_{3t}, G) = \hom(K_{3t}, H)$ despite that $\operatorname{tw} K_{3t} > 3t-2$. That this does not hold is implied by a conjecture of the first author [27] which asserts that every minor-closed graph class $\mathcal{F}$ which is closed under taking disjoint unions (*union-closed*) is *homomorphism distinguishing closed*, i.e. for all $F \notin \mathcal{F}$ there exist graphs G and H such that $G \equiv_{\mathcal{F}} H$ but $\hom(F, G) \neq \hom(F, H)$. Although being generally open, this conjecture was proven by Neuen [24] for the class of graphs of treewidth at most t for every t. Theorem 29 implies the last assertion of Theorem 1.

▶ **Theorem 29.** *For every $t \geq 1$, there exist graphs G and H such that $G \simeq^{\mathrm{SA}}_{3t-1} H$ and $G \not\simeq^{\mathrm{L}}_{t} H$.*

Proof. Towards a contraction, suppose that $G \simeq^{\mathrm{SA}}_{3t-1} H \implies G \simeq^{\mathrm{L}}_{t} H$ for all graphs G and H. By Theorem 8, $G \simeq^{\mathrm{SA}}_{3t-1} H$ if and only if G and H are homomorphism indistinguishable over the class $\mathcal{TW}_{3t-2}$ of graphs of treewidth at most $3t-2$. By Observation 23 and Theorem 9, if $G \equiv_{\mathcal{TW}_{3t-2}} H$ then $G \equiv_{\mathcal{L}_t} H$ and in particular $\hom(K_{3t}, G) = \hom(K_{3t}, H)$. As shown in [24], the class $\mathcal{TW}_{3t-2}$ is homomorphism distinguishing closed. As $\operatorname{tw} K_{3t} = 3t-1$, it follows that there exist graphs G and H with $G \simeq^{\mathrm{SA}}_{3t-1} H$ and $\hom(K_{3t}, G) \neq \hom(K_{3t}, H)$. In particular, $G \not\simeq^{\mathrm{L}}_{t} H$ by Theorem 9. ◀

It is worth noting that the classes of unlabelled graphs underlying the elements of $\mathcal{L}_t$ and $\mathcal{L}_t^+$ are themselves minor-closed and union-closed. Hence, they are subject to the aforementioned conjecture. Furthermore, by the Robertson–Seymour Theorem and [29], membership in $\mathcal{L}_t$ and $\mathcal{L}_t^+$ can be tested in polynomial time for every fixed $t \geq 1$. The proof of Lemma 30 is deferred to the full version [28].

▶ **Lemma 30.** *Let $t \geq 1$. The class of graphs underlying the elements of $\mathcal{L}_t$ and the class of graphs underlying the elements of $\mathcal{L}_t^+$ are minor-closed and union-closed.*

The remainder of this section is dedicated to some further relations between the classes of graphs of bounded treewidth or pathwidth, $\mathcal{L}_t$, and $\mathcal{L}_t^+$. Note that these facts give independent proofs for the correspondence between the feasibility of the level-t Sherali–Adams relaxation (without non-negativity constraints), which corresponds to homomorphism indistinguishability over graphs of treewidth (pathwidth) at most $t-1$, as proven by [9, 15], and the feasibility of the level-t Lasserre relaxation with and without non-negativity constraints.

First of all, it is easy to see that dropping the semidefiniteness constraint Equation (4) of the level-t Lasserre system of equations turns this system essentially into the level-$2t$ Sherali–Adams system of equations without non-negativity constraints, e.g. as defined in [14, Appendix D.1]. This is paralleled by Lemma 31.

▶ **Lemma 31.** *Let $t \geq 1$. For every graph F with $\operatorname{pw} F \leq 2t-1$, there is a graph $\boldsymbol{F} \in \mathcal{L}_t$ whose underlying unlabelled graph is isomorphic to F.*

Furthermore, one may drop Equation (4) from the level-t Lasserre system of equations with non-negativity constraints to obtain the level-$2t$ Sherali–Adams system of equations in its original form, i.e. with non-negativity constraints. This is paralleled by Lemma 32.

▶ **Lemma 32.** *Let $t \geq 1$. For every graph F with $\operatorname{tw} F \leq 2t-1$, there is a graph $\boldsymbol{F} \in \mathcal{L}_t^+$ whose underlying unlabelled graph is isomorphic to F.*

Since the diagonal entries of a positive semidefinite matrix are necessarily non-negative, Equation (4) implies that any solution (y_I) to the level-t Lasserre system of equations is such that $y_I \geq 0$ for all $I \in \binom{V(G)\times V(H)}{\leq t}$. Hence, such a solution is a solution to the level-t Sherali–Adams system of equations as well. This is paralleled by Lemma 33.

▶ **Lemma 33.** *Let $t \geq 1$. For every graph F with $\operatorname{tw} F \leq t-1$, there is a graph $\boldsymbol{F} \in \mathcal{L}_t$ whose underlying unlabelled graph is isomorphic to F.*

The proofs of Lemmas 31–33 are all by inductively constructing an element of $\mathcal{L}_t^+$ using a tree decomposition of the given graph. They are deferred to the full version [28].

4.2 The Classes $\mathcal{L}_1$ and $\mathcal{L}_1^+$

The classes $\mathcal{L}_1$ and $\mathcal{L}_1^+$ can be identified as the class of outerplanar graphs and as the class of graphs of treewidth at most two, respectively. This yields Theorem 5. Proofs are deferred to the full version [28].

▶ **Proposition 34.** *The class of unlabelled graphs underlying an element of $\mathcal{L}_1^+$ coincides with the class of graphs of treewidth at most two.*

A graph F is *outerplanar* if it does not have K_4 or $K_{2,3}$ as a minor. Equivalent, it is outerplanar if it has a planar drawing such that all its vertices lie on the same face [34].

▶ **Proposition 35.** *The class of unlabelled graphs underlying an element of $\mathcal{L}_1$ coincides with the class of outerplanar graphs.*

As a corollary of Proposition 35, we observe the following:

▶ **Corollary 36.** *If $G \equiv_{\mathcal{L}_1} H$ then G is connected iff H is connected.*

5 Deciding Exact Feasibility of the Lasserre Relaxation with Non-Negativity Constraints in Polynomial Time

This section is dedicated to proving Theorem 4. To that end, it is argued that $\simeq_t^{\mathrm{L}^+}$ has equivalent characterisations in terms of logical equivalence and a colouring algorithm akin to the k-dimensional Weisfeiler–Leman algorithm [36]. This algorithm has polynomial running time. It is defined as follows:

▶ **Definition 37.** *Let $t \geq 1$, define for a graph G, $i \geq 1$, and $\boldsymbol{r}, \boldsymbol{s} \in V(G)^t$*

$$\begin{aligned}
\mathsf{mwl}_G^0(\boldsymbol{rs}) &\coloneqq \mathrm{rel}_G(\boldsymbol{rs}),\\
\mathsf{mwl}_G^{i-1/2}(\boldsymbol{rs}) &\coloneqq \left(\mathsf{mwl}_G^{i-1}(\sigma(\boldsymbol{rs})) \;\middle|\; \sigma \in \mathfrak{S}_{2t}\right),\\
\mathsf{mwl}_G^{i}(\boldsymbol{rs}) &\coloneqq \left(\mathsf{mwl}_G^{i-1/2}(\boldsymbol{rs}), \left\{\!\!\left\{ \left(\mathsf{mwl}_G^{i-1/2}(\boldsymbol{rt}), \mathsf{mwl}_G^{i-1/2}(\boldsymbol{ts})\right) \;\middle|\; \boldsymbol{t} \in V(G)^t \right\}\!\!\right\}\right).
\end{aligned}$$

The mwl_G^i for $i \in \mathbb{N}$ define increasingly fine colourings of $V(G)^{2t}$. Let mwl_G^∞ denote the finest such colouring. Two graphs G and H are not distinguished by the t-dimensional mwl algorithm *if the multisets*

$$\left\{\!\!\left\{ \mathsf{mwl}_G^\infty(\boldsymbol{rs}) \;\middle|\; \boldsymbol{r}, \boldsymbol{s} \in V(G)^t \right\}\!\!\right\} \quad \text{and} \quad \left\{\!\!\left\{ \mathsf{mwl}_H^\infty(\boldsymbol{uv}) \;\middle|\; \boldsymbol{u}, \boldsymbol{v} \in V(H)^t \right\}\!\!\right\}$$

are the same.

Since the finest colouring mwl_G^∞ is reached in $\leq n^{2t} - 1$ iterations for graphs on n vertices, for fixed t, it can be tested in polynomial time whether two graphs are not distinguished by the t-dimensional mwl algorithm. We are about to show that the latter happens if and only if the level-t Lasserre relaxation with non-negative constraints is feasible. As a by-product, we obtain a logical characterisation for this equivalence relation.

▶ **Definition 38.** *For $t \geq 1$, let M^t denote the fragment of first-order logic with counting quantifiers and at most $3t$ variables comprising the following expressions:*

- *$x_i = x_j$ and Ex_ix_j for all $i, j \in [3t]$,*
- *if $\varphi, \psi \in \mathsf{M}^t$ then $\neg\varphi$, $\varphi \wedge \psi$, and $\varphi \vee \psi$ are in M^t,*
- *if $\varphi, \psi \in \mathsf{M}^t$ and $n \in \mathbb{N}$ then $\exists^{\geq n}\boldsymbol{y}.\ \varphi(\boldsymbol{x}, \boldsymbol{y}) \wedge \psi(\boldsymbol{y}, \boldsymbol{z})$ is in M^t. Here, the bold face letters $\boldsymbol{x}$, $\boldsymbol{y}$, $\boldsymbol{z}$ denote t-tuples of distinct variables.*

The semantic of the quantifier $\exists^{\geq n}\boldsymbol{y}.\ \varphi(\boldsymbol{y})$ is that there exist at least n many t-tuples of vertices from the graph over which the formula is evaluated which satisfy φ. The following Theorem 39 may be thought of as a analogue of Theorem 8 for $\mathcal{L}_t^+$.

▶ **Theorem 39.** *Let $t \geq 1$. For graphs G and H, the following are equivalent:*

1. *G and H are not distinguished by the t-dimensional* mwl *algorithm,*
2. *G and H are homomorphism indistinguishable over $\mathcal{L}_t^+$,*
3. *G and H satisfy the same M^t-sentences.*

The proof of Theorem 39 is deferred to the full version [28]. It is conceptually similar to arguments of [6, 10, 15]. As mentioned above, Theorem 39 implies Theorem 4.

6 Conclusion

We have established a characterisation of the feasibility of the level-t Lasserre relaxation with and without non-negativity constraints of the integer program $\mathrm{ISO}(G, H)$ for graph isomorphism in terms of homomorphism indistinguishability over the graph classes $\mathcal{L}_t$ and $\mathcal{L}_t^+$. By analysing the treewidth of the graphs $\mathcal{L}_t$ and $\mathcal{L}_t^+$ and invoking results from the theory of homomorphism indistinguishability, we have determined the precise number of Sherali–Adams levels necessary such that their feasibility guarantees the feasibility of the level-t Lasserre relaxation. This concludes a line of research brought forward in [4]. For feasibility of the level-t Lasserre relaxation with non-negativity constraints, we have given, besides linear algebraic reformulations generalising the adjacency algebra of a graph, a polynomial time algorithm deciding this property.

Missing in Theorem 1 is a tight lower bound on the number of Lasserre levels necessary to ensure feasibility of a given Sherali–Adams level:

▶ **Question 40.** *Do there exist for every $t \geq 3$ graphs G and H such that $G \simeq_{t-1}^{\mathrm{L}} H$ and $G \not\simeq_t^{\mathrm{SA}} H$?*

Following the path taken in this paper, this question could potentially be resolved in two steps: Firstly, one would need to prove the graph theoretic assertion that the class $\mathcal{L}_t$ does not contain $\mathcal{TW}_t$ for all $t \geq 2$. Secondly, one would need to show that $\mathcal{L}_t$ is homomorphism distinguishing closed or at least that the homomorphism distinguishing closure [27] of $\mathcal{L}_t$ does not contain $\mathcal{TW}_t$ for all $t \geq 2$. Given the means currently available for proving such a statement [27, 24], this would involve giving game characterisations for $\mathcal{L}_t$ (mimicking the robber-cops game for $\mathcal{TW}_t$) and for $\equiv_{\mathcal{L}_t}$ (similar to the bijective $(t+1)$-pebble game for $\mathcal{TW}_t$). For the former, finding analogies to the notions of brambles or heavens seems necessary [31].

Another interesting extension of our work might be an efficient algorithm for computing an explicit partial t-equivalence between two graphs, cf. Definitions 18 and 20, or deciding that no such map exists. This would yield an efficient algorithm for deciding the exact feasibility of the Lasserre semidefinite program without non-negativity constraints, cf. [4].

Average-Case to (Shifted) Worst-Case Reduction for the Trace Reconstruction Problem

Ittai Rubinstein
Qedma Quantum Computing, Tel Aviv, Israel

Abstract

In the *trace reconstruction problem*, one is given many outputs (called *traces*) of a noise channel applied to the same input message $\mathbf{x}$, and is asked to recover the input message. Common noise channels studied in the context of trace reconstruction include the *deletion channel* which deletes each bit w.p. δ, the *insertion channel* which inserts a G_j i.i.d. uniformly distributed bits before each bit of the input message (where G_j is i.i.d. geometrically distributed with parameter σ) and the symmetry channel which flips each bit of the input message i.i.d. w.p. γ.

De et al. and Nazarov and Peres [12, 20] showed that any string $\mathbf{x}$ can be reconstructed from $\exp(O(n^{1/3}))$ traces. Holden et al. [13] adapted the techniques used to prove this upper bound, to construct an algorithm for average-case trace reconstruction from the insertion-deletion channel with a sample complexity of $\exp(O(\log^{1/3} n))$. However, it is not clear how to apply their techniques more generally and in particular for the recent worst-case upper bound of $\exp(\widetilde{O}(n^{1/5}))$ shown by Chase [7] for the deletion channel.

We prove a general reduction from the average-case to smaller instances of a problem similar to worst-case and extend Chase's upper-bound to this problem and to symmetry and insertion channels as well. Using this reduction and generalization of Chase's bound, we introduce an algorithm for the average-case trace reconstruction from the symmetry-insertion-deletion channel with a sample complexity of $\exp(\widetilde{O}(\log^{1/5} n))$.

1 Introduction

The *symmetry-insertion-deletion* (SID) channel with bit-flip probability $\gamma \in [0, 1/2)$, insertion probability $\sigma \in [0, 1)$ and deletion probability $\delta \in [0, 1)$, takes as input a binary string $\mathbf{x} \in \{0,1\}^n$. For each j, the jth bit of $\mathbf{x}$ is flipped w.p. γ (we will sometimes think of this portion of the channel as replacing the jth bit of $\mathbf{x}$ with a random bit w.p. 2γ). Then G_j random uniform and independent bits are inserted before the jth bit of $\mathbf{x}$, where the random variables $G_j \geq 0$ are i.i.d. geometrically distributed with parameter σ. Then, each bit of the message is deleted independently with probability δ. The output string $\widetilde{\mathbf{x}}$ is called a *trace*[1].

[1] The trace reconstruction problem was originally defined with only the deletion channel [2] (i.e. with γ and σ fixed to 0). The more general SID channels were first considered in the "open questions" of [18] and were further researched by Andoni et al. [1] and by De et al. [12].

The *trace reconstruction problem* asks the following question: how many traces are necessary to reconstruct an unknown string $\mathbf{x}$?

The main motivation for studying trace reconstruction comes from computational biology, where one often tries to align several DNA sequences to a common ancestor, and it has been extensively researched since the early 2000's [2].

Perhaps the most natural and well-researched version of the trace reconstruction problem, is the *worst-case*, where the input string $\mathbf{x}$ is adversarially chosen. Holenstein et al. [15] established an upper bound of $\exp(\widetilde{O}(n^{1/2}))$ on its sample complexity. This was improved by Nazarov and Peres [20], and De, O'Donnell and Servedio [12] who simultaneously proved upper and lower bounds of $\exp(O(n^{1/3}))$ on the sample complexity of "mean-based" trace reconstruction techniques. Recently, Chase [7] improved on these methods by proving that a "non-linear" method can be used to solve the worst-case deletion-channel trace reconstruction problem with a far lower sample complexity of $\exp(\widetilde{O}(n^{1/5}))$.

De et al. and Nazarov and Peres's results were highly influential and mean-based separators are used as a central component in the analysis of many other versions of the trace reconstruction problem [5, 8, 10, 13, 16, 21]. However, so far, Chase's techniques have not been extended beyond worst-case trace reconstruction from a deletion channel. In particular, we note the coded [5, 10] and the average-case [13, 21] trace reconstruction problems.

The *average-case* trace reconstruction problem was introduced by Batu et al. [2]. In this problem, the input string $\mathbf{x}$ is chosen uniformly at random from $\{0,1\}^n$, and the reconstruction only needs to succeed w.h.p. over the choice of $\mathbf{x}$. McGregor et al. [17] showed that if $H(n)$ traces are necessary for the worst-case trace reconstruction, then at least $H(\log n)$ are needed for the average-case (and under some conditions $H(\log n)\log n$).

Peres and Zhai [21] adapted mean-based separators to the average-case, constructing an efficient algorithm for the average-case deletion-channel trace reconstruction with $\exp(O(\log^{1/2} n))$ samples and low deletion probability ($\delta \leq 1/2$). This was further improved by Holden et al. [14] who reduced the sample complexity to $\exp(O(\log^{1/3} n))$ and generalized the algorithm to work for all insertion-deletion channels.

Motivated by the question of DNA storage, Cheraghchi et al. [10] introduced the *coded* trace reconstruction problem, where one is asked to construct a code $C \subset \{0,1\}^n$ s.t. any codeword $\mathbf{x} \in C$ can be reconstructed w.h.p. given as few independent traces $\widetilde{\mathbf{x}}$ as possible. Brakensiek et al. [5] proved that this problem is essentially equivalent to the average-case trace reconstruction problem.

1.1 Our Contributions

Let $n \in \mathbb{N}$ be arbitrarily large, and let $\gamma \in [0, 1/2)$, $\sigma \in [0, 1)$ and $\delta \in [0, 1)$ be fixed bit-flip, insertion and deletion probabilities, and let $\mathcal{C}$ be the SID channel with these parameters. Let C be a sufficiently large constant[2].

We introduce a new version of the trace reconstruction problem, called the *shifted* trace reconstruction problem (see Definition 1). In this problem, one is asked to reconstruct the first n bits of a much longer string $\mathbf{x}$ from its traces. Moreover, the error channel is also allowed to "shift" the traces by some unknown distance $s \in \mathbb{N}$ (selected i.i.d. from a known and bounded distribution S for each trace).

The shifted trace reconstruction problem often appears as a component in the analysis of other versions of the trace reconstruction problem [14, 8], but so far it has not been formally defined. Moreover, it could be of interest in its own right. Similar to the approximate trace reconstruction problem introduced by Davies et al. [11] and the average-case approximate

[2] C may depend on γ, σ, δ, but not on n.

trace reconstruction problem by Chase and Peres [8] which model the question of using a smaller number of traces to reconstruct some information about the input string $\mathbf{x}$, the shifted trace reconstruction problem asks a similar question, but with the goal of reconstructing the prefix of a long string.

▶ **Definition 1** (Shifted Trace Reconstruction Problem). *In a* shifted trace reconstruction problem *of size $n \in \mathbb{N}$, with* shift inaccuracy $\Delta_S(n)$*, one must reconstruct the $n+1$th bit of any string $\boldsymbol{x} \in \{0,1\}^{\mathbb{N}}$ of length at most 2^n given the value of its first n bits $\boldsymbol{x}_{:n}$, and $H(n) = \exp(h(n))$ i.i.d. traces $\widetilde{\boldsymbol{x}}$ produced by the following process.*

A random shift s is applied to the input string $\overline{\boldsymbol{x}} \stackrel{\text{def}}{=} \boldsymbol{x}_{s:}$, where $s \leftarrow S$ is drawn from a known shift distribution *S, with bounded support $\mathrm{Supp}(S) \subseteq [a, a+\Delta_S]$ for some $0 \le a \le n - \Delta_S$. Then the noise channel $\mathcal{C}$ is applied to the shifted string $\overline{\boldsymbol{x}}$ to obtain a trace $\widetilde{\boldsymbol{x}}$.*

The shifted trace reconstruction problem is clearly at least as hard as the worst-case trace reconstruction problem, but the differences between the two do not seem to affect the leading reconstruction techniques. In particular, we extend Chase's analysis to SID channels and to the shifted trace reconstruction problem, proving that $\exp(\widetilde{O}(n^{1/5}))$ samples suffice for the (shifted) worst-case trace reconstruction problem from an SID channel (Theorem 2).

▶ **Theorem 2.** *For any SID channel $\mathcal{C}$ as defined above, and for any constant $C > 0$, there exists an algorithm A which solves the shifted trace reconstruction problem of size n with shift inaccuracy $\Delta_S(n) = Ch(n)$ and sample complexity $H(n) = \exp(h(n)) = \exp(O(n^{1/5}\log^7 n))$.*

Furthermore, when the deletion probability is sufficiently low ($\delta < 1/2$), the algorithm A runs in time $\exp(O(n^{4/5}\log n))$ and if $q \ge 1/2$, then A runs in time $\exp(O(n))$.

▶ Remark 3. Note that while De et al.'s reconstruction algorithm has a time complexity polynomial in its sample complexity, Chase only proves an upper bound on the sample complexity. A naïve adaptation of Chase's upper bound to an algorithm would yield a time complexity of $\exp(\Theta(n))$.

Holden et al.'s average-case trace reconstruction algorithm works by partially aligning each trace and then using an oracle that solves a version of the shifted trace reconstruction problem to reconstruct each bit of the input message $\mathbf{x}$. However, much of their analysis is specific to their sample complexity of $\exp(\log^{1/3}(n))$.

We transform Holden et al.'s construction into a general reduction from an average-case trace reconstruction of length n to linearly many instances of shifted trace reconstruction problems of length $O(\log(n))$ (Theorem 4). Moreover, our reduction applies to any SID channel.

▶ **Theorem 4** (Average to Shifted Reduction). *Let A be an oracle that solves the shifted trace reconstruction problem with sample complexity $H(n) = \exp(h(n))$ (for $\log(n) \le h(n) \le \sqrt{n}$), shift inaccuracy $\Delta_S = Ch(n)$, and failure probability $< \exp(-n)$.*

Then there exists an algorithm A' that solves the average-case trace reconstruction problem with success probability $1 - o_n(1)$, sample complexity of $\exp(Ch(C\log n))$, and time complexity $t(n) = n^{1+o(1)}$, given n calls to the oracle A.

▶ Remark 5. Note that the assumption that $\log(n) \le h(n) \le \sqrt{n}$ is not very restrictive, since we show an upper bound of $h(n) \le \widetilde{O}(n^{1/5})$ and the lower bound by Chase [6] implies that

$$h(n) \ge \frac{3}{2}\log n\ .$$

It is interesting to compare Theorem 4 to [17, Lemma 10]. Theorem 4 shows that if $H(n)$ traces suffice for shifted trace reconstruction then $\text{poly}(H(\log n))$ traces suffice for average-case trace reconstruction. Compare this to McGregor et al. [17, Lemma 10] who prove that if $H(n)$ traces are required for worst-case trace reconstruction, then $H(\log n)$ traces are required for average-case trace reconstruction. This means that up to the differences between shifted and worst-case trace reconstruction, Theorem 4 is essentially tight.

We also note Brakensiek et al. [5], who proved reductions between the coded and the average-case trace reconstruction problems. When combined with Theorem 4 and [17, Lemma 10], a computational class of trace reconstruction problems begins to emerge (see Figure 1).

An important question to consider in future trace reconstruction research is whether other versions of the trace reconstruction problem can be reduced to one of these classes. For instance, consider the approximate average-case trace reconstruction problem. The best known approximate average-case trace reconstruction technique at the time of writing this paper is due to Chase and Peres [8], whose approach is based on performing calls to a "shifted" average-case trace reconstruction oracle, making it a good candidate for a more general reduction.

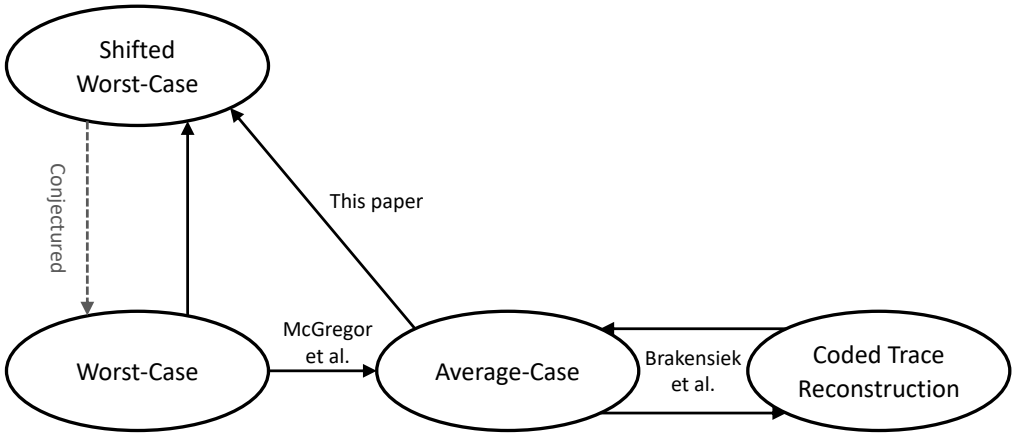

Figure 1 A diagram of several known reductions between trace reconstruction problems. McGregor et al. [17] proved that any solution to the average-case trace reconstruction problem implies a solution to a smaller instance of the worst-case trace reconstruction problem. Brakensiek et al. [5] proved reductions from coded trace reconstruction to average-case trace reconstruction and vice versa. We introduce the shifted trace reconstruction and prove a reduction from the average-case to it. We also show that the current best-known solutions for worst-case trace reconstruction can be extended to shifted trace reconstruction and conjecture that the two are equivalent.

Finally, Theorems 2 and 4 give us an algorithm for the average-case trace reconstruction from SID channels with only $\exp(\widetilde{O}(\log^{1/5} n))$ traces.

▶ **Theorem 6** (Main Result). *For any SID channel $\mathcal{C}$ as defined above, if $\boldsymbol{x} \in \{0,1\}^n$ is a bit-string where the bits are chosen uniformly and independently at random, then we can reconstruct $\boldsymbol{x}$ with probability $1 - o_n(1)$ using $\exp(C \log^{1/5} n \log^7 \log n)$ traces. Moreover, when the deletion probability is sufficiently low ($\delta < 1/2$), this can be done in $n^{1+o(1)}$ time and otherwise, this can be done in polynomial time.*

1.2 An Overview of Previous Constructions

Many trace reconstruction techniques follow a similar high-level pattern [7, 12, 14, 20, 21]. First, a combinatorial analysis allows us to equate some property of the original message $\mathbf{x}$ to a polynomial whose coefficients depend on the traces $\widetilde{\mathbf{x}}$. This polynomial is then analysed on a small sub-arc of the complex disk $\mathbb{D}$ using Borwein and Erdélyi's seminal research on Littlewood polynomials [3] or an extension of it [7], yielding a statistical test on the traces which can be used to reconstruct some property of the original message $\mathbf{x}$.

Our analysis will also follow a similar pattern, and many of its steps will be based on combinations and extensions of components used to prove previous results, so we begin with a short overview of these techniques.

For any $\mathbf{w} \in \{0,1\}^{\mathbb{N}}$, let $I_{\mathbf{w}} : \{0,1\}^{\mathbb{N}} \to \mathbb{R}$ be the function that maps a string $\mathbf{x}$ to 1 if it begins with the prefix $\mathbf{w}$ and otherwise maps it to 0. For any function $f : \{0,1\}^{\mathbb{N}} \to \mathbb{R}$, we define its indicator polynomial on $\mathbf{x}$ to be the polynomial $p_{f,\mathbf{x}}(z) = \sum_j f(\mathbf{x}_{j:})z^j \in \mathbb{R}[z]$.

De et al. and Nazarov and Peres [12, 20] show that the polynomial $p_{\mathbf{x}} \stackrel{\text{def}}{=} p_{I_1,\mathbf{x}}$ whose jth coefficient is the jth bit of the original message $\mathbf{x}_j$ and the polynomial $p_{\widetilde{\mathbf{x}}} \stackrel{\text{def}}{=} \mathbb{E}\left[p_{I_1,\widetilde{\mathbf{x}}}\right]$ whose jth coefficient is the average over the jth bits of the traces $\mathbb{E}\left[\widetilde{\mathbf{x}}_j\right]$ are essentially equivalent up to a parameter change:

$$p_{\widetilde{\mathbf{x}}}(\phi^{-1}(z)) \approx (1-\delta)(1-2\gamma)p_{\mathbf{x}}(z) \tag{1}$$

where $\phi(z) = \frac{(1-\sigma)(\delta+(1-\delta)z)}{1-\sigma z}$ is a Möbius transformation related to the channel parameters[3]. De et al. and Nazarov and Peres then consider points of the form $z = \exp(i\alpha)$ for small $-n^{-1/3} < \alpha < n^{-1/3}$. $p_{\widetilde{\mathbf{x}}}(\phi^{-1}(z))$ can be approximated at such points from a bounded number of traces, because $\left|\phi^{-1}(z)\right| < 1 + O(n^{-2/3})$ and the linear transformation mapping the traces $\widetilde{\mathbf{x}}$ to

$$p_{\widetilde{\mathbf{x}}}(\phi^{-1}(z)) = \sum_{1\le j\le n} \left(\phi^{-1}(z)\right)^j \mathbb{E}\left[\widetilde{\mathbf{x}}_j\right]$$

has bounded coefficients $\left|\phi^{-1}(z)\right|^j \le \exp(O(n^{1/3}))$.

Borwein and Erdélyi [3] showed that for any polynomial $p(z)$ with $\{0, \pm 1\}$ coefficients, there exists some z in this sub-arc $\{\exp(i\alpha) \mid |\alpha| \le n^{-1/3}\}$ for which $|p(z)| \ge \exp(-O(n^{1/3}))$. In the context of trace reconstruction, we take $p(z)$ to be the difference $p_{\mathbf{x}}(z) - p_{\mathbf{y}}(z)$ where $\mathbf{x}$ and $\mathbf{y}$ are two input messages between which we want to differentiate.

This yields a method of differentiating between any two potential input strings $\mathbf{x}, \mathbf{y}$ with $\exp(O(n^{1/3}))$ traces.

Peres and Zhai [21] and Holden et al. [13] use a similar relationship between the original message and the traces, but in their construction the polynomials $p_{\mathbf{x}}$ and $p_{\widetilde{\mathbf{x}}}$ have a much higher degree because they want to reconstruct the first bits of a long string. They overcome this by extending the complex analysis to points of the form $z = \rho\exp(i\alpha)$ for a carefully chosen $\rho = 1 - o(1)$, effectively allowing them to truncate $p_{\mathbf{x}}$ and $p_{\widetilde{\mathbf{x}}}$ to a finite degree.

Holden et al. also use the fact that their input string is random to create partial alignments. The alignments are based on a Boolean test which checks whether or not a substring $\widetilde{\mathbf{w}}$ of a trace $\widetilde{\mathbf{x}}$ was the result of applying the channel to some substring $\mathbf{w}$ of the input message $\mathbf{x}$. This Boolean test is guaranteed to have a low false-positive rate and a non-negligible true-positive rate, when the input string $\mathbf{w}$ is "sufficiently random".

[3] Equation (1) is correct up to minor technical details. Lemma 8 can be used to derive an accurate version of this equation.

Holden et al. use this alignment procedure to reconstruct $\mathbf{x}$ one bit at a time. For each bit, they use this partial alignment to pin the traces to some nearby index and then use a mean-based separator to reconstruct it.

Chen et al. [9] and Narayanan and Ren [19] generalize equation (1) to relate multi-indices where some subsequence $\mathbf{w}$ appears in the input message $\mathbf{x}$ to multi-indices where the same subsequence appears in the traces, but their proof is limited to the deletion channel. As a results, Chase's analysis [7] which relies heavily on this generalized relationship, cannot be directly extended to insertion or symmetry channels.

Chase sets $\mathbf{w}$ to be an "a-periodic" string, in order to ensure that the set of indices where $\mathbf{w}$ appears as a consecutive substring in $\mathbf{x}$ is sparse. Therefore, the polynomial $p_{\mathbf{w},\mathbf{x}}(z) \stackrel{\text{def}}{=} p_{I_{\mathbf{w}},\mathbf{x}}(z)$ has sparse coefficients. Chase uses an extension of Borwein and Erdélyi's methods to prove much stronger bounds on polynomials with sparse coefficients on similar arcs of the unit disk. Balancing out the parameters yields Chase's $\exp(\widetilde{O}(n^{1/5}))$ bound on the worst-case sample complexity.

Much of our paper will be devoted to generalizing and combining the results of Holden et al. [14] and Chase [7]. For the sake of brevity, we will henceforth refer to these papers as the HPPZ and the Chase constructions respectively.

1.3 Sketch of our Proof

We extend these analyses in three key ways.

In the first and most difficult portion of the paper, we extend Chen et al. and Narayanan and Ren's [9, 19] generalization of equation (1) to SID channels. This is non-trivial, as the common method of dealing with insertions and bit-flips is to take a statistic where the unbiased insertions average out to having no effect on the output (this is usually done by looking at the difference between the traces $\widetilde{\mathbf{x}}, \widetilde{\mathbf{y}}$ of two potential input strings $\mathbf{x}, \mathbf{y}$). It is not clear how to perform a similar analysis on a multi-bit property, such as an indicator of some magic string $\mathbf{w}$ which is highly non-linear in its input.

Our main observation in dealing with this problem is that the function $\chi_{(-1,\dots,-1)}(\mathbf{x}) \stackrel{\text{def}}{=} (-1)^{\mathbf{x}_1} \cdots (-1)^{\mathbf{x}_k}$, which we call a "full" character, has the property that if any of its input bits $\mathbf{x}_1, \dots, \mathbf{x}_k$ is an inserted bit or was replaced with a random bit by the symmetry channel, then its output is unbiased and does not affect the average over traces. This allows us to prove a similar relationship between $p_{\chi_{(-1,\dots,-1)},\mathbf{x}}$ and $p_{f,\tilde{\mathbf{x}}}$.

Next, we extend this analysis to all characters $f(\mathbf{x}) = \chi_\omega(\mathbf{x}) \stackrel{\text{def}}{=} \prod_j \omega_j^{\mathbf{x}_j}$ for $\omega \in \{\pm 1\}^k$. This extension is more complex and requires several difficult technical lemmas, but it allows us to reconstruct $p_{f,\mathbf{x}}(z)$ for (almost) any function $f : \{0,1\}^k \to \mathbb{R}$ from the traces. We do this by applying the Fourier transformation on Boolean functions to f, allowing us to write $f(\mathbf{x}) = \sum_\omega \chi_\omega(\mathbf{x}) \widehat{f}(\omega)$ as a linear combination of characters, and by extension

$$p_{f,\mathbf{x}}(z) = p_{\sum_\omega \chi_\omega(\cdot)\widehat{f}(\omega),\mathbf{x}}(z) = \sum_\omega \widehat{f}(\omega) p_{\chi_\omega,\mathbf{x}}(z).$$

In the second portion of our analysis, we extend the Borwein and Erdélyi-type bounds proven by Chase [7] to deal with sparse polynomials when evaluated at points within the unit disk. This step is necessary for our extension of Chase's bounds to the shifted trace reconstruction problem.

In the third and final portion of the paper, we generalize Holden et al.'s [13] construction into a reduction from an average-case trace reconstruction problem of size n to linearly many trace reconstruction problems of size $\Theta(\log(n))$. Moreover, we extend Holden et al.'s proofs originally shown for the insertion-deletion channel to SID channels as well.

1.4 Organization of the Paper

Sections 2 and 3 contain the heart of our analysis, where we convert the shifted trace reconstruction problem into a complex analysis one (2) and use complex analysis techniques to solve it (3). We adapt Holden et al.'s techniques to prove a general reduction in Section 4, proving Theorems 4 and 6. Section 5 is reserved for a discussion of our results.

2 Conversion to Complex Analysis

Let $\mathbf{x} \in \{0,1\}^{\mathbb{N}}$ be some input string and let $\widetilde{\mathbf{x}}$ denote its trace from some shifted trace reconstruction problem. The first step of our analysis will be to relate a property of $\mathbf{x}$ to the expectation of some function applied to its traces $\widetilde{\mathbf{x}}$. By bounding this function of the traces in absolute value, we prove that this function can be approximated from a bounded number of traces. Then, in Section 3, we will show that approximating this property of the input string $\mathbf{x}$ allows us to reconstruct $\mathbf{x}$ one bit at a time.

This approach to trace reconstruction is common in recent literature. De et al., Holden et al. and Nazarov and Peres [12, 14, 20] show how "single bit statistics" of the input string $\mathbf{x}$ can be related to its traces through SID channels and shifts. Chase [7], building off of the works of Chen et al. [9] and Narayanan and Ren [19], extended this relationship to multi-bit statistics, in order to prove a stronger bound on the sample complexity of trace reconstruction.

However, Chase's analysis is limited to deletion channels and the main known tools for dealing with insertions and bit-flips are inherently limited to single-bit statistics. Our goal in this section will be to combine these approaches, allowing us to estimate multi-bit properties of the input string $\mathbf{x}$ from traces through an SID channel.

Let $1 \leq \ell \leq 2n^{1/5} + 1$ be some integer. For any function $f : \{0,1\}^{\ell} \to \mathbb{D}$ from the hypercube to the unit disk $\mathbb{D}$ (for our use-case, we will want $f = I_{\mathbf{w}}$ to be the indicator of some marker $\mathbf{w} \in \{0,1\}^{\mathbb{N}}$), we define $q_{f,\mathbf{x}}(z_0, \ldots, z_\ell)$ to be

$$q_{f,\mathbf{x}}(z_0, \ldots, z_\ell) \stackrel{\text{def}}{=} \sum_{k_0 < k_1 < \cdots < k_\ell} (-1)^{\mathbf{x}_0} z_0^{k_0} f(\mathbf{x}_{k_1}, \ldots, \mathbf{x}_{k_\ell}) \prod_{1 \leq j \leq \ell} z_j^{k_j - k_{j-1} - 1}.$$

In essence, $q_{f,\mathbf{x}}(z_0, \ldots, z_\ell)$ is a multivariate polynomial whose coefficients encode the value of f when applied to subsequences of the input string $\mathbf{x}$. Our goal will be to show that the value of this polynomial can be estimated at certain points from a bounded number of traces (see Theorem 7).

▶ **Theorem 7.** *Let z_0 be a point on the arc $\left\{(1 - n^{-4/5}\log^6 n)\exp(i\alpha) \mid \alpha \in [-n^{-2/5}, n^{-2/5}]\right\}$. If $\delta < 1/2$, let $z_1, \ldots, z_\ell = 0$. Otherwise, let $z_1 = \cdots = z_\ell$ be any point in the segment $[1 - c_1, 1 - c_2]$ for sufficiently small constants $c_1 > c_2 > 0$.*

Given $H(n) = \exp(h(n))$ traces with shift inaccuracy $\eta = O(h(n))$, we can estimate $q_{f,\boldsymbol{x}}$ at the point $(z_0, \ldots, z_\ell)$ to within an additive error of order $\pm\exp(-\Omega(h(n)))$ and with success probability $1 - \exp(-\omega(n))$, where $h(n) = n^{1/5}\log^7 n$.

We separate the proof of Theorem 7 into three parts. In the first part of the proof (Lemma 8), we will show that the statement holds for the function $f(\mathbf{x}_1, \ldots, \mathbf{x}_\ell) = \prod_{1 \leq j \leq \ell}(-1)^{\mathbf{x}_j}$. We will call this function a "full character".

We will then extend this proof to any character $f(\mathbf{x}_1, \ldots, \mathbf{x}_\ell) = \chi_\omega(\mathbf{x}_1, \ldots, \mathbf{x}_\ell) = \prod_{1 \leq j \leq \ell} \omega_j^{\mathbf{x}_j}$ (with $\omega \in \{\pm 1\}^{\ell}$) of the Fourier transformation on Boolean functions. Finally, to complete the proof, we will use the fact that any function $f : \{0,1\}^{\ell} \to \mathbb{D}$ can be written as a linear combination of characters $f = \sum_\omega \hat{f}(\omega)\chi_\omega$ (where $\hat{f}$ is the Fourier transformation of f).

▶ **Lemma 8.** *Let S be a shift distribution with bounded support (*$\mathrm{Supp}\,(S) \subseteq \{0,1,\ldots,d\}$*). Let $\boldsymbol{x} \in \{0,1\}^{\mathbb{N}}$ be an input string, and let $\widetilde{\boldsymbol{x}}$ be the trace of $\boldsymbol{x}$, sampled by applying the SID channel with deletion probability δ, insertion probability σ and bit-flip rate γ applied to the randomly shifted string $\boldsymbol{x}_s$: (where $s \leftarrow S$).*

Define $\phi_1(z) \stackrel{\text{def}}{=} (1-\delta)z+\delta$, $\phi_2(z) \stackrel{\text{def}}{=} \frac{(1-\sigma)z}{1-\sigma z}$, $\phi \stackrel{\text{def}}{=} \phi_2 \circ \phi_1$. For all j, we set $\zeta_j = \phi^{-1}(z_j)$. Define $P(z) \stackrel{\text{def}}{=} \sum_{s=0}^{d} \Pr[S=s] z^s$. Then:

$$\begin{aligned} P(z_0^{-1}) &\sum_{k_0<k_1<\cdots<k_\ell} (-1)^{\boldsymbol{x}_0} z_0^{k_0} \prod_{1\le j\le \ell} z_j^{k_j-k_{j-1}-1}(-1)^{\boldsymbol{x}_j-\boldsymbol{x}_{j-1}-1} = \\ &= \left(\prod_{0\le j\le \ell} \frac{\phi_1(\zeta_j)}{(1-\delta)(1-2\gamma)\zeta_j}\right) \mathop{\mathbb{E}}_{\widetilde{\boldsymbol{x}}} \left[\sum_{r_0<\cdots<r_\ell} \zeta_0^{r_0}(-1)^{\widetilde{\boldsymbol{x}}_{r_0}} \left(\prod_{j=1}^{\ell}(-1)^{\widetilde{\boldsymbol{x}}_{r_j}} \zeta_j^{r_j-r_{j-1}-1}\right)\right] \end{aligned} \tag{2}$$

Lemma 8 moves us closer to the goal of proving Theorem 7, because the left-hand-side of equation (2) is essentially equivalent to $q_{f,\mathbf{x}}(z_0,\ldots,z_\ell)$ for the function $f(\mathbf{x}_1,\ldots,\mathbf{x}_\ell) = \prod_{1\le j\le \ell}(-1)^{\mathbf{x}_j}$, while the right-hand-side depends only on the traces.

2.1 Proof of Lemma 8

We begin by proving Lemma 8 for the simpler case, where the shift s and the bit-flip probability are both fixed to 0.

Let D_k denote the event that the kth bit of the input string $\mathbf{x}$ was *not* deleted by the channel. Conditioned on D_k, let R_k be the distribution of the index r_k within the trace $\widetilde{\mathbf{x}}$ to which this bit was mapped. For any distribution V, let $G_V(\zeta) \stackrel{\text{def}}{=} \sum_v \Pr[V=v]\zeta^v$ denote its generating function.

Consider the generating function $G_{R_k}(\zeta)$ of R_k. Each of the first k bits of the input message $\mathbf{x}$ was expanded to an i.i.d. geometrically distributed number of bits, and then each of those was either retained or deleted, resulting in a Bernoulli distribution of bits (except for the last bit which was not deleted, because we conditioned on D_k). Using common identities on products and compositions of generating functions, we derive equation (3).

$$G_{R_k}(\zeta) = \left(G_{\mathrm{Geom}(\sigma)}\left(G_{\mathrm{Bern}(\delta)}(\zeta)\right)\right)^{k-1} G_{\mathrm{Geom}(\sigma)-1}\left(G_{\mathrm{Bern}(\delta)}(\zeta)\right)\zeta = \frac{\zeta}{\phi_1(\zeta)}\phi(\zeta)^k \tag{3}$$

Denote by I_r the event that the rth bit of the trace was an insertion. Conditioned on I_r, the rth bit of $\widetilde{\mathbf{x}}$ is a Bernoulli$\left(\frac{1}{2}\right)$ random variable independent of the rest of the problem. Consider the expectation of $f(\widetilde{\mathbf{x}}_{r_0},\ldots,\widetilde{\mathbf{x}}_{r_\ell}) = \prod_{1\le j\le l}(-1)^{\widetilde{\mathbf{x}}_{r_j}}$ over the traces. Due to our choice of f, if even one of its inputs is an insertion, then its expectation is $\mathbb{E}_{\widetilde{\mathbf{x}}}\left[\prod_{0\le j\le l}(-1)^{\widetilde{\mathbf{x}}_{r_j}} \,\middle|\, I_{r_j}\right] = 0$.

The event that the rth bit of the trace $\widetilde{\mathbf{x}}_r$ was not due to an insertion is exactly equal to the event that some bit $\mathbf{x}_k$ in the input message was not deleted (D_k) and that it was transmitted as the rth bit of the trace ($R_k = r$). Therefore, the expectation of f on the multi-index $r_0,\ldots,r_\ell$ of the trace is equal to

$$\begin{aligned} \mathop{\mathbb{E}}_{\widetilde{\mathbf{x}}}\left[\prod_{0\le j\le l}(-1)^{\widetilde{\mathbf{x}}_{r_j}}\right] &= \sum_{k_0<\cdots<k_\ell}(-1)^{\mathbf{x}_{k_j}} \Pr\left[\bigwedge_{0\le j\le \ell}\left(D_{k_j}\wedge\left(R_{k_j}=r_j\right)\right)\right] \\ &= (1-\delta)^\ell \sum_{k_0<\cdots<k_\ell}(-1)^{\mathbf{x}_{k_j}} \Pr\left[\bigwedge_{0\le j\le \ell}\left(R_{k_j}=r_j\right) \,\middle|\, \bigwedge_{0\le j\le \ell} D_{k_j}\right] \end{aligned} \tag{4}$$

Finally, note that given D_{k_j} and the value of $r_j = R_{k_j}$, the effect of the channel on the next bits is independent of r_j. Therefore, conditioned on D_k and D_{k+1}, we have

$$\Pr_{\tilde{\mathbf{x}}}\left[R_{k_j} = r_j \,\middle|\, R_{k_{j-1}} = r_{j-1}\right] = \Pr_{\tilde{\mathbf{x}}}\left[R_{k_j - k_{j-1}-1} = r_j - r_{j-1} - 1\right]. \tag{5}$$

Combining equations (3), (4) and (5), we see that

$$\begin{aligned}
&(1-\delta)^{-\ell}\mathop{\mathbb{E}}_{\tilde{\mathbf{x}}}\left[\sum_{r_0<\cdots<r_\ell}(-1)^{\tilde{\mathbf{x}}_{r_0}}\zeta_0^{r_0}\prod_{1\le j\le l}(-1)^{\tilde{\mathbf{x}}_{r_j}}\zeta_j^{r_j-r_{j-1}-1}\right] = \\
&\quad = \sum_{r_0<\cdots<r_\ell}\sum_{k_0<\cdots<k_\ell}\Pr\left[\bigwedge_{0\le j\le \ell}(R_{k_j}=r_j)\,\middle|\,\bigwedge_{0\le j\le \ell}D_{k_j}\right] \\
&\qquad\qquad (-1)^{\mathbf{x}_{k_0}}\zeta_0^{r_0}\prod_{1\le j\le l}\zeta_j^{r_j-r_{j-1}-1}(-1)^{\mathbf{x}_{k_j}} = \\
&\quad = \sum_{k_0<\cdots<k_\ell}\frac{\zeta_0}{\phi_1(\zeta_0)}\phi(\zeta_0)^{k_0}(-1)^{\mathbf{x}_{k_0}}\prod_{1\le j\le l}\frac{\zeta_j}{\phi_1(\zeta_j)}\phi(\zeta_j)^{k_j-k_{j-1}-1}(-1)^{\mathbf{x}_{k_j}}
\end{aligned} \tag{6}$$

Some minor manipulations to equation (6), yields equation (2) for the case when s and γ are fixed to 0. Finally, we extend the proof to shifts and bit-flips. Let $\overline{\mathbf{x}}$ denote the output of the shift and symmetry portions of the channel. It is easy to show that

$$\begin{aligned}
&\mathop{\mathbb{E}}_{\overline{\mathbf{x}}}\left[\sum_{k_0<\cdots<k_\ell}z_0^{k_0}(-1)^{\overline{\mathbf{x}}_{k_0}}\prod_{1\le j\le l}z_j^{k_j-k_{j-1}-1}(-1)^{\overline{\mathbf{x}}_{k_j}}\right] = \\
&\quad = (1-2\gamma)^\ell\mathop{\mathbb{E}}_{s\leftarrow S}\left[\sum_{k_0<\cdots<k_\ell}z_0^{k_0}(-1)^{\mathbf{x}_{k_0+s}}\prod_{1\le j\le l}z_j^{k_j-k_{j-1}-1}(-1)^{\mathbf{x}_{k_j+s}}\right] = \\
&\quad = (1-2\gamma)^\ell P\left(\frac{1}{z_0}\right)\sum_{k_0<\cdots<k_\ell}z_0^{k_0}(-1)^{\mathbf{x}_{k_0}}\prod_{1\le j\le l}z_j^{k_j-k_{j-1}-1}(-1)^{\mathbf{x}_{k_j}}
\end{aligned} \tag{7}$$

Combining equations (6) and (7) yields Lemma 8.

2.2 Sketch of the Proof of Theorem 7

Due to space limitations, we reserve the rest of the proof of Theorem 7 to the full version of the paper which can be found on arxiv [23], where we show that Lemma 8 implies Theorem 7. The rest of this section is devoted to giving the high-level idea of this proof.

The first step of the proof is an analysis of the Möbius transformations in Lemma 8. In particular, we show that for the points $z_0, \ldots, z_\ell$ chosen as in Theorem 7, the absolute values of $\zeta_0, \ldots, \zeta_\ell$ are bounded below 1.

This allows us to truncate the RHS of equation (2) to only its low degree terms with a negligible effect on the output. This truncation enables us to evaluate this polynomial at the required points, proving Theorem 7 for the full character $f(\mathbf{x}_1, \ldots, \mathbf{x}_\ell) = \prod_j (-1)^{\mathbf{x}_j}$.

In fact, this allows us to estimate $q_{f,\mathbf{x}}(z_0, \ldots, z_\ell)$ for any choice of $z_1, \ldots, z_\ell$ sufficiently close to those defined Theorem 7 when f is the full character. We use this fact to prove Theorem 7 for general characters. In essence, we show that $q_{\chi_\omega,\mathbf{x}}(z_0, \ldots, z_\ell)$ can be written as a high-order derivative of $q_{f',\mathbf{x}}$ for a full character f' on fewer bits $\ell' < \ell$ and that this derivative can be approximated from a limited number of samples using Lemma 9.

▶ **Lemma 9.** *Let $c, \delta > 0$ be some real parameters and let P be an oracle that computes for a given point $z_1, \ldots, z_l \in [-c, c]^l$ the value of some polynomial p of degree at most n at the given point, up to some additive error $\delta > 0$. Let $\boldsymbol{j} = (j_1, \ldots, j_l)$ be some vector of integers (all smaller than n), define $m_{\boldsymbol{j}} = z_1^{j_1} \cdots z_l^{j_l}$ be the $\boldsymbol{j}$th monomial and $j_{\text{tot}} = \sum_i j_i$.*

Given $\text{poly}(n, 1/c)^{O(l+j_{\text{tot}})}$ queries to P, we can compute the coefficient of $m_{\boldsymbol{j}}$ to within an additive error of $\text{poly}(n, 1/c)^{O(l+j_{\text{tot}})}\delta$ in time $\text{poly}(n, 1/c)^{O(l+j_{\text{tot}})}$.

Finally, we use the fact that $q_{f,\mathbf{x}}$ is linear in our choice of f (i.e. for any f_1, f_2, $q_{f_1+f_2,\mathbf{x}} = q_{f_1,\mathbf{x}} + q_{f_2,\mathbf{x}}$), and the fact that any function f can be written as a linear combination of character functions $f = \sum_{\omega \in \{\pm 1\}^\ell} \hat{f}(\omega)\chi_\omega$ via a Fourier transformation. Combining these observations, we see that

$$q_{f,\mathbf{x}} = \sum_{\omega \in \{\pm 1\}^\ell} \hat{f}(\omega) q_{\chi_\omega,\mathbf{x}}.$$

The RHS of this equation can be estimated from the traces (one element at a time) and the LHS was our original goal, thus proving Theorem 7.

3 Proof of Theorem 2

In Section 2, we showed that for any function f from $\{0,1\}^\ell$ to the unit disk $\mathbb{D}$, we can map it into a polynomial related to the input message which can be approximated to a high degree of accuracy from the traces. In this section, we will construct a function f for which our approximation of $q_{f,\mathbf{x}}$ as promised by Theorem 7 will suffice to reconstruct the $n+1$th bit of the input string $\mathbf{x}$, proving Theorem 2.

A central component of our analysis will be Theorem 10, which is a slight generalisation of [7, Theorem 5]. In this theorem we show that members of a certain class of polynomials have some non-negligible values on a sufficiently small sub-arc of the unit disk $\mathbb{D}$.

The polynomial $p(z)$ in Theorem 10 should be thought of as the difference between two polynomials $q_{f,\mathbf{x}}(z, 0, \ldots, 0) - q_{f,\mathbf{y}}(z, 0, \ldots, 0)$ for two hypotheses $\mathbf{x}$ and $\mathbf{y}$ for the input string. By proving that these polynomials differ at a point where they can be estimated from the traces, we show that this estimation can be used to differentiate between the hypotheses.

▶ **Theorem 10** (Extension of [7, Theorem 5])**.** *Let $\mathcal{P}_n^\mu$ denote the set of polynomials of the form $p(z) = \xi - \eta z^d + \sum_{n^\mu \le j \le n} a_j z^j$ where $\eta \in \{0,1\}$, $\xi \in \partial\mathbb{D}$ and $|a_j| \le 2$.*

For any $\mu \in (0,1)$, there exists some constant $C > 0$, such that for all sufficiently large n, any $p \in \mathcal{P}_n^\mu$, it holds that for every $\rho \in [0,1]$:

$$\max_{|\alpha| \le n^{-2\mu}} \left|p(\rho e^{i\alpha})\right| \ge \exp\left(-Cn^\mu \log^5 n\right)$$

Our proof of Theorem 10 is similar to Chase's proof of [7, Theorem 5], and due to space limitations, we reserve it for the full version of this paper [23]. Throughout the rest of this section, we will prove that Theorem 2 follows from Theorem 10.

In Section 3.1, we will extend Theorem 10 to a wider class of polynomials, proving that the estimation method described in Theorem 7 can be used to distinguish between the traces of any two potential input strings $\mathbf{x}, \mathbf{y}$. In Section 3.2, we will show how this distinguishing oracle can be used to reconstruct a string $\mathbf{x}$ from the shifted trace reconstruction problem, proving Theorem 2.

3.1 Corollaries of Theorem 10

In this section, we will extend Theorem 10 to prove that for any strings $\mathbf{x}, \mathbf{y}$ which agree on their first n bits, the estimation oracle described in Theorem 7 can be used to distinguish between their traces. This proof will follow from two main components.

First, we will show that for any two such strings $\mathbf{x}, \mathbf{y}$, there exists some choice of indicator function $f = I_{\mathbf{w}}$, such that for $p_{f,\mathbf{x}}(z) = q_{f,\mathbf{x}}(z, 0, \ldots, 0)$, the polynomial $p_{\text{diff}}(z) = p_{f,\mathbf{x}}(z) - p_{f,\mathbf{y}}(z)$ (almost) fits the requirements of Theorem 10. Therefore, if $\delta < 1/2$, then there exists some point $(z, 0, \ldots, 0)$ such that we can estimate the evaluation of $q_{f,\mathbf{x}}$ from the traces and that $q_{f,\mathbf{x}}$ and $q_{f,\mathbf{y}}$ differ significantly at this same point. This yields a method of distinguishing between their traces (see Corollary 11).

Then, in Corollary 12, we will extend this analysis to higher deletion probabilities, by showing that a similar distinguishing method can also be used at points of the form $(z, 1-c, \ldots, 1-c)$. For the rest of this section, let $\mu = 1/5$, $\rho = 1 - n^{-4/5} \log^6 n$, $\ell = 2n^{1/5} + 1$, and $\mathcal{A} = \{\rho e^{i\alpha} \mid |\alpha| \leq n^{2/5}\}$.

The following is a corollary of Theorem 10:

▶ **Corollary 11** (Adaptation of Proposition 6.3 from [7]). *Let $\boldsymbol{x}, \boldsymbol{y} \in \{0,1\}^{\mathbb{N}}$ be binary strings that agree on their first n bits ($\boldsymbol{x}_{:n} = \boldsymbol{y}_{:n}$) and disagree on their $(n+1)$th bit ($\boldsymbol{x}_{n+1} \neq \boldsymbol{y}_{n+1}$). Then there exist some $\boldsymbol{w} \in \{0,1\}^{\ell}$ and $z_0 \in \mathcal{A}$ such that*

$$|q_{I_w,\boldsymbol{x}}(z_0, 0, \ldots, 0) - q_{I_w,\boldsymbol{x}}(z_0, 0, \ldots, 0)| \geq \exp\left(-n^{1/5} \log^6 n\right) \exp\left(-Cn^{1/5} \log^5 n\right)$$

Proof of Corollary 11. Let $\mathbf{x}$ and $\mathbf{y}$ be two hypotheses for the input string to a shifted trace reconstruction problem (that agree on their first n bits and not on their $n+1$th bit).

Let $\mathbf{w}' = \mathbf{x}(n - \ell + 1 : n)$. Lemmas 1 and 2 of [22] imply that at least one of $\mathbf{w}'0$ or $\mathbf{w}'1$ has no period of length $\leq n^{1/5}$ and that for this choice of $\mathbf{w} \in \{\mathbf{w}'0, \mathbf{w}'1\}$, the indices k for which $\mathbf{x}_{k:k+\ell} = \mathbf{w}$ are $n^{1/5}$ separated.

Consider the polynomial

$$\begin{aligned} p_{\mathbf{w}}(z) &\stackrel{\text{def}}{=} z^{\ell-n-1} \left[q_{I_{\mathbf{w}},\mathbf{x}}(z, 0, \ldots, 0) - q_{I_{\mathbf{w}},\mathbf{y}}(z, 0, \ldots, 0)\right] \\ &= \sum_k \left[(-1)^{\mathbf{x}_k} 1_{\mathbf{x}(k+1:k+\ell)=\mathbf{w}} - (-1)^{\mathbf{y}_k} 1_{\mathbf{y}_{k+1:k+\ell}=\mathbf{w}}\right] z^{k+\ell-n-1} \end{aligned}$$

Because $\mathbf{x}$ and $\mathbf{y}$ agree on their first n bits, $p_{\mathbf{w}}(z)$ has no negative powers. By our definition of $\mathbf{w}$ to be either $\mathbf{x}_{n-\ell+1:n+1}$ or $\mathbf{y}_{n-\ell+1:n+1}$, the 0th power of $p_{\mathbf{w}}(z)$ is ± 1. Moreover, all of $p_{\mathbf{w}}(z)$'s coefficients are bounded by 2 in absolute value and its non-zero powers maintain the sparsity condition of Theorem 10.

The only problem with applying Theorem 10 to $p_{\mathbf{w}}(z)$ is that its degree is not bounded by n. We overcome this issue by defining $\widetilde{p_{\mathbf{w}}}(z)$ to be the truncation of $p_{\mathbf{w}}(z)$ to its nth power. Applying Theorem 10 to the polynomial $\widetilde{p_{\mathbf{w}}}$, we see that there exists a point $z_0 \in \mathcal{A}$ for which $|\widetilde{p_{\mathbf{w}}}(z_0)| \geq \exp\left(-C_1 n^{\mu} \log^5 n\right)$

Because we want to evaluate $\widetilde{p_{\mathbf{w}}}(z)$ at points z with absolute value $|z| = \rho$ strictly below 1, we can also bound the effect of this truncation by

$$|\widetilde{p_{\mathbf{w}}}(z) - p_{\mathbf{w}}(z)| \leq \frac{\rho^n}{1-\rho} = \text{poly}(n) \exp(-n^{\mu} \log^6 n) = o\left(|\widetilde{p_{\mathbf{w}}}|\right)$$

From here we apply the triangle inequality to show that $|p_{\mathbf{w}}(z)| \geq \exp\left(-C_2 n^{\mu} \log^5 n\right)$.

Finally, note that $|q_{I_{\mathbf{w}},\mathbf{x}}(z, 0, \ldots, 0) - q_{I_{\mathbf{w}},\mathbf{y}}(z, 0, \ldots, 0)| = |p_{\mathbf{w}}(z)||z|^{n-\ell+1}$, completing the proof of Corollary 11. ◀

Corollary 11 allowed us to use Theorem 7 to distinguish between the traces of any two string $\mathbf{x}$ and $\mathbf{y}$ when the deletion probability of the channel is low ($\delta < 1/2$).

However, this proof relied on our ability to estimate the value of $q_{I_{\mathbf{w}},\mathbf{x}}$ at points where $z_1 = \cdots = z_\ell = 0$, and when the deletion probability is high ($\delta \geq 1/2$), Theorem 7 only allows us to evaluate $q_{I_{\mathbf{w}},\mathbf{x}}$ at points of the form $z_1 = \cdots = z_\ell \in [1-c_1, 1-c_2]$. In order to distinguish between the traces of $\mathbf{x}$ and $\mathbf{y}$ from high deletion probability channels, we extend Theorem 7 to multivariate polynomials sampled at such points. We do this in Corollary 12.

▶ **Corollary 12** (Adaptation of Corollary 6.1 from [7]). *Let $c_1 > c_2 > 0$ be sufficiently small positive constants, and let $\boldsymbol{x}, \boldsymbol{y} \in \{0,1\}^{\mathbb{N}}$ be as in Corollary 11. There exist some $\boldsymbol{w} \in \{0,1\}^l$, $z_0 \in \mathcal{A}$ and $z_1 = \cdots = z_\ell \in [1-c_1, 1-c_2]$, such that*

$$|q_{I_w,\boldsymbol{x}}(z_0, z_1, \ldots, z_1) - q_{I_w,\boldsymbol{x}}(z_0, z_1, \ldots, z_1)| \geq \exp\left(-n^{1/5}\log^6 n\right)\exp\left(-Cn^{1/5}\log^5 n\right)$$

Proof of Corollary 12. Fix $\mathbf{w}$ and z_0 to be the same as in the proof of Corollary 11. We define Q to be the following polynomial in z_1, for $z_1 \in [0, 1-c_2]$.

$$Q(z_1) \stackrel{\text{def}}{=} (1-\rho)\binom{n}{\ell}^{-1}\left[q_{I_{\mathbf{w}},\mathbf{x}}(z_0, z_1, \ldots, z_1) - q_{I_{\mathbf{w}},\mathbf{y}}(z_0, z_1, \ldots, z_1)\right]$$

Consider the coefficient of the jth power of z_1 in Q. If $j \leq n$, then this coefficient is bounded by 1 in absolute value. This is because our summation over the powers of z_0 can contribute a factor of at most $1/(1-\rho)$, and the number of terms in $q_{I_{\mathbf{w}},\mathbf{x}}$ with total degree j is at most $\binom{n}{\ell}$.

If $j > n$, then the number of monomials of $q_{I_{\mathbf{w}},\mathbf{x}}$ with total degree j is at most $\exp(O(\ell\log(j)))$, but the value of the monomial z_1^j is at most $(1-c_2)^j = \exp(-\Omega(j))$.

Therefore, truncating these higher powers of Q would have a negligible effect on its value. Let $\widetilde{Q}(z_1)$ be the truncation of Q to monomials of degree $\leq n$. $\widetilde{Q}$ is a univariate polynomial in z_1, with coefficients bounded from above by 1, and for any $z_1 \in [0, 1-c_2]$, we have

$$\left|Q(z_1) - \widetilde{Q}(z_1)\right| \leq \exp(-\Omega(n)) \tag{8}$$

In Corollary 11, we showed that $|Q(0)|$ is bounded from below, and this lower bound can be naturally extended to $\left|\widetilde{Q}(0)\right|$. Therefore, $\widetilde{Q}(z_1)$ fits the requirements of Theorem 5.1 of [4], which can be used to show that

$$\max_{z_1 \in [1-c_1, 1-c_2]} \widetilde{Q}(z_1) \geq \exp\left(Cn^\mu \log^6 n\right) \tag{9}$$

Combining equations (8) and (9) yields our claim. ◀

3.2 Completing the Proof

In Section 3.1, we proved that the estimation method promised in Theorem 7 can be used to differentiate between any two potential input strings $\mathbf{x}$ and $\mathbf{y}$ from their traces. In this section, we will show how this distinguishing oracle can be transformed into a reconstruction algorithm, completing the proof of Theorem 2.

The basic idea of this transformation is relatively simple. We enumerate over potential pairs of input strings $\mathbf{y}^0, \mathbf{y}^1$, and use the distinguishing oracle to decide for each pair which is a better candidate for being the input string $\mathbf{x}$.

The main technical difficult we need to overcome is due to the fact that the input string $\mathbf{x}$ may be arbitrarily long, so enumerating over all possible input strings can take an arbitrarily long amount of time. We overcome this, by showing that it suffices to enumerate over the

first $O(n)$ bits of the input string. Moreover, when the deletion probability is below $1/2$, we show that it suffices to enumerate over only a small fraction of the entropy of these $O(n)$ bits, yielding a fast reconstruction algorithm.

Let $\mathbf{x}$ be the input string to the shifted trace reconstruction problem. By our definition of the shifted trace reconstruction problem, the first n bits of $\mathbf{x}$ are known, and our goal is to reconstruct the $n+1$th bit of the input string $\mathbf{x}$.

Let $C > 0$ be a sufficiently large constant. Let $\mathbf{o}^0, \mathbf{o}^1 \in \{0,1\}^{Cn-n-1}$ be two hypotheses for the value of $\mathbf{x}_{n+1:Cn}$. In other words, $\mathbf{y}^0 = \mathbf{x}_{1:n}0\mathbf{o}^0, \mathbf{y}^1 = \mathbf{x}_{1:n}1\mathbf{o}^1$ are our hypotheses for the first Cn bits of $\mathbf{x}$.

If $\delta < 1/2$, let z_0 and $\mathbf{w}$ be as defined in Corollary 11, and let $z_1 = 0$. If $\delta \geq 1/2$, let z_0, z_1 and $\mathbf{w}$ be as defined in Corollary 12.

We use the traces to estimate $p_{I_{\mathbf{w}},\mathbf{x}}(z_0, z_1, \ldots, z_1)$ using the method promised by Theorem 7. This method may have a small failure probability (which would result in a bad estimate), but for the moment we assume that it succeeds. We then compute $p_{I_{\mathbf{w}},\mathbf{y}}(z_0, z_1, \ldots, z_1)$ directly for $\mathbf{y} \in \{\mathbf{y}^0, \mathbf{y}^1\}$.

Consider the case where $\mathbf{y}^b = \mathbf{x}_{:Cn}$ for some $b \in \{0,1\}$. Because we are evaluating $p_{I_{\mathbf{w}},\mathbf{y}}$ at points with coordinates strictly below 1 in absolute value and this polynomial's coefficients are bounded by 1, the contribution of monomials with total degree above Cn is can be bounded. In particular,

$$\begin{aligned}\left|p_{I_{\mathbf{w}},\mathbf{y}^b}(z_0, z_1, \ldots, z_1) - p_{I_{\mathbf{w}},\mathbf{x}}(z_0, z_1, \ldots, z_1)\right| < \exp(-\Omega(Cn^{1/5}\log^6 n)) \ll \\ \ll \left|p_{I_{\mathbf{w}},\mathbf{y}^b}(z_0, z_1, \ldots, z_1) - p_{I_{\mathbf{w}},\mathbf{y}^{1-b}}(z_0, z_1, \ldots, z_1)\right|\end{aligned} \tag{10}$$

Therefore, in this case, our estimate of $p_{I_{\mathbf{w}},\mathbf{x}}(z_0, z_1, \ldots, z_1)$ from the traces will be closer to $p_{I_{\mathbf{w}},\mathbf{y}^b}(z_0, z_1, \ldots, z_1)$ than to $p_{I_{\mathbf{w}},\mathbf{y}^{1-b}}(z_0, z_1, \ldots, z_1)$.

We repeat this process for any such pair $\mathbf{o}^0, \mathbf{o}^1 \in \{0,1\}^{Cn-n-1}$, and for each such pair, we output the value b for which our estimate of $p_{I_{\mathbf{w}},\mathbf{x}}(z_0, z_1, \ldots, z_1)$ from the traces is closest to $p_{I_{\mathbf{w}},\mathbf{y}^b}(z_0, z_1, \ldots, z_1)$.

If $b = \mathbf{x}_{n+1}$, then there exists at least one such $\mathbf{o}^b$ for which the process above always selects b for any $\mathbf{o}^{1-b}$. By enumerating over all pairs, we can find the value of $b = \mathbf{x}_{n+1}$ for which such a string $\mathbf{o}^b$ exists.

This leaves only a few minor technical details in order to prove Theorem 2.

First, we note that the estimation oracle promised in Theorem 7 has a small failure probability. We use the union bound to show that the probability that it will fail even once in the process described above is negligible.

Next we consider the time complexity of our reconstruction. For the high deletion probability regime ($\delta \geq 1/2$), this process can clearly be completed in time $\exp(O(n))$.

For lower deletion probabilities $\delta < 1/2$, we note that $p_{I_{\mathbf{w}},\mathbf{y}}(z_0, 0, \ldots, 0)$ depends only on the indices within $\mathbf{y}$ where the string $\mathbf{w}$ appears as a consecutive substring. By our definition of $\mathbf{w}$ (see the proof of Corollary 11), this set of indices is sparse. By enumerating only over the set of indices where $\mathbf{w}$ appears in $\mathbf{y}$ (and not over the entire Cn bits), we can reduce the time complexity of this reconstruction algorithm to $\exp(o(n))$, thus completing our proof of Theorem 2.

4 Proof of Theorem 4

In Sections 2 and 3, we showed that Chase's worst-case trace reconstruction method can be naturally extended to the shift trace reconstruction problem and to SID channels. In this section, we will construct a general reduction from the average-case trace reconstruction problem to the shifted trace reconstruction problem, proving Theorems 4 and 6.

Our proof will be based based on an adaptation of the HPPZ's methods, and our main contribution is to show that it can be used as a general reduction as well as to extend it to symmetry channels. Due to space limitations, in this version of the paper we will give only a sketch of the proof (for more details, see the full version of this paper [23])

Our reduction will consist of three main ingredients:

- A Boolean test $T(\mathbf{w}, \widetilde{\mathbf{w}})$ on pairs of bit-strings $(\mathbf{w}, \widetilde{\mathbf{w}})$ that returns 1 if $\widetilde{\mathbf{w}}$ is a plausible match for the output of applying the channel $\mathcal{C}$ to $\mathbf{w}$.
- A two-step alignment procedure comprised of a coarse and a fine alignment each of which uses the test T to obtain an estimate τ^k for the positions within some of the traces corresponding to the kth bit of the original message $\mathbf{x}$.
- The reduction target – a bit recovery procedure based on the target of our reduction to produce an estimate of any bit of $\mathbf{x}$ from these aligned traces.

Finally, similar to HPPZ, throughout this section we will perform our analysis when $\delta = \sigma$, but all of these results can be similarly generalized for any values of $\delta, \sigma \in [0, 1)$.

4.1 The Boolean Test

The first component of our reduction is a Boolean test T designed to answer whether a string $\widetilde{\mathbf{w}}$ is likely to have originated from a trace of some string $\mathbf{w}$ or not.

Let $\ell, \lambda < \sqrt{\ell}$ and $c \in (0, 1)$ be parameters of the test. The test $T^c_{\ell,\lambda}$ (when c, ℓ, λ are clear from the context we may omit them) is defined as follows. First, each of the strings $\mathbf{w}$ and $\widetilde{\mathbf{w}}$ is split into $\approx \ell/\lambda$ segments of length λ each. Each segment of each string is assigned a sign $+1$ if most of the bits in this segment are 0s or -1 otherwise. In other words

$$s_i = \operatorname{sign}\left\{ \sum_{i\lambda < j \le (i+1)\lambda} (\mathbf{w}_j - 1/2) \right\} \in \{\pm 1\}.$$

Then, the signs of the segments are compared, and we compute the number of segment pairs whose signs agree. If $\mathbf{w}$ and $\widetilde{\mathbf{w}}$ were two independently distributed random strings, then the number of such pairs would be distributed according to the $\mathrm{Bin}(1/2, \ell/\lambda)$ distribution. If $\mathbf{w}$ and $\widetilde{\mathbf{w}}$ are similar, then we expect these signs to be roughly correlated to one another.

Therefore, we define the test to pass if at least $(1 + c)/2$ fraction of the signs agree.

$$T^c_{\ell,\lambda} = \begin{cases} 1 & \sum_{1 \le i \le \ell/\lambda} s_i \widetilde{s}_i > c \\ 0 & \text{otherwise} \end{cases}$$

We consider this test with two sets of parameters for "coarse" and "fine" alignment procedures. Let $H(n) = \exp(h(n))$ be the sample complexity of the shifted trace reconstruction problem. Then for the coarse and fine alignments we set respectively

$$\ell_c = \Theta\left(\frac{\log^2(n)}{h(\Theta(\log(n)))}\right); \qquad \lambda_c = \Theta\left(\frac{\log(n)}{h(\Theta(\log(n)))}\right)$$
$$\ell_f = \Theta\left(h(\log(n))\right); \qquad \lambda_f = \Theta(1).$$

Ideally, we want this Boolean test to maintain two behaviours:

- If $\widetilde{\mathbf{w}}$ is not a trace of $\mathbf{w}$, the probability that T will return 1 (called a *spurious match*) should be at most $\exp(-\Omega(\ell/\lambda))$.
- If $\widetilde{\mathbf{w}}$ is a trace of $\mathbf{w}$, the probability that T will pass (called a *true match*) will be at least $\exp(-O(\ell/\lambda^2))$.

If these conditions hold, then the probability of a true match may be very small, but when λ is sufficiently large, it will be much higher than the probability of a spurious match. Therefore, when conditioning on a match, it will most likely be a true match. Over the next few paragraphs, we will give a sketch of the proof that these conditions hold for substrings of a random string $\mathbf{x}$.

4.1.1 Spurious Matches are Rare

If $\mathbf{w}$ and $\widetilde{\mathbf{w}}$ are two independently distributed strings chosen uniformly at random, then the signs of their segments s_i as defined above will also be independent and uniformly distributed vectors $s, \widetilde{s} \in \{\pm 1\}^{\ell/\lambda}$. In this case, it can be easily shown from the Chernoff bound that the probability that more than $(1+c)/2$ fraction of their entries agree decays exponentially in their dimension ℓ/λ.

The main difficulty is analysing how this relates to the traces of a random string. Let $\mathbf{w}^0 = \mathbf{x}_{a_0:b_0}$ and $\mathbf{w}^1 = \mathbf{x}_{a_1:b_1}$ be two substrings of the random input string $\mathbf{x}$. If the segments $[a_0, b_0]$ and $[a_1, b_1]$ do not overlap, then (averaging over the random options for the input string $\mathbf{x}$) they are two independent random strings.

Let $\widetilde{\mathbf{w}}^i$ be the trace of $\mathbf{w}^i$. Clearly, when applying the channel $\mathcal{C}$ (which only deletes bits, inserts i.i.d. uniformly distributed bits and replaces some of the bits of $\mathbf{x}$ with i.i.d. uniformly distributed bits) to a random string of length ℓ, the output will also be a random string of length roughly $\frac{1-\delta}{1-\sigma}\ell = \ell$. Therefore, if $\mathbf{w}^0, \mathbf{w}^1$ are non-overlapping substrings of $\mathbf{x}$ as defined above, then $\mathbf{w}^0$ and $\widetilde{\mathbf{w}}^1$ are two independent random strings.

Let us denote by ω the randomness of the channel $\mathcal{C}$. Averaging over both the randomness of the channel and over our selection of the input string $\mathbf{x}$, we have

$$\begin{aligned} \mathop{\mathbb{E}}_{\mathbf{x}}\left[\Pr_{\omega}\left[T(\mathbf{w}^0, \widetilde{\mathbf{w}}^1) = 1\right]\right] &= \Pr_{\omega,\mathbf{x}}\left[T(\mathbf{w}^0, \widetilde{\mathbf{w}}^1) = 1\right] \\ &= \Pr_{\mathbf{w}^0,\mathbf{w}^1 \leftarrow \{0,1\}^\ell}\left[T(\mathbf{w}^0, \mathbf{w}^1)\right] = \exp\left(-\Omega(\ell/\lambda)\right) \end{aligned} \tag{11}$$

We will use equation (11) in the two settings of the alignment procedure. In the coarse alignment, we set $\ell_c/\lambda_c = C\log(n) = \Theta(\log(n))$. Setting C to be sufficiently large, we can ensure that $\Pr_{\omega,\mathbf{x}}\left[T(\mathbf{w}^0, \widetilde{\mathbf{w}}^1) = 1\right] = \exp(-\Omega(C\log(n))) < n^{-10}$ is sufficiently small that a simple union bound on the quasi-linear number of coarse alignment procedures we run will never result in a spurious match.

For the fine alignment procedure, we will have a segment $I = [a, a + C\log(n)]$ of length $\Theta(\log n)$ of the input string $\mathbf{x}$ in which our goal will be to find a subsegment $S = [b, b + \ell_f]$ of length $\ell_f = o(\log(n))$ such that for any non-overlapping subsegment $S' \subset I$ of length ℓ_f, the probability of a spurious match between $\mathbf{w}^0 = \mathbf{x}_S$ and a trace of $\mathbf{w}^1 = \mathbf{x}_{S'}$ is

$$\Pr_{\omega}\left[T(\mathbf{w}^0, \widetilde{\mathbf{w}}^1) = 1\right] = \exp(-\Omega(\ell_f/\lambda_f)).$$

It can be shown from a simple combination of a Markov inequality (used to show that the probability of any such subsegment S to work is $1 - \exp(-\Omega(\ell_f))$) and an enumeration over sufficiently many independent options for S, that at least 1 such subsegment exists w.p. $1 - \exp(-\Omega(C\log(n))) = 1 - n^{-10}$. From here, we can simply apply the union bound over the quasi-linear number of fine alignment procedures in the reduction.

4.1.2 True Matches are Frequent

The next step of our proof will be to show that a string $\mathbf{w}$ and its trace $\widetilde{\mathbf{w}}$ will pass the test $T_{\ell,\lambda}$ with probability at least $\exp\left(-O(\ell/\lambda^2)\right)$. Due to space limitations, we give only a very rough sketch of this proof (for a more detailed proof, see the full version of this paper [23]).

Consider a substring $\mathbf{u} = \mathbf{w}_{i\lambda:(i+1)\lambda}$ of the string $\mathbf{w}$ the matching substring $\widetilde{\mathbf{w}}_{i\lambda:(i+1)\lambda}$ of its trace. The total of the bits in $\mathbf{u}$ is binomially distributed, so there is a non-negligible probability that $\approx 1/2 + \sqrt{1/\lambda}$ fraction of them will be 0 (in which case, its sign will be -1). If this is the case, then with fairly high probability, for any substring $\mathbf{u}' = \mathbf{w}_{i\lambda+d_i,(i+1)\lambda d_{i+1}}$ where $|d_i| < \lambda/100$, at least $\approx 1/2 + \sqrt{1/2\lambda}$ fraction of its bits will be 0.

For now, assume that $\widetilde{\mathbf{w}}_{i\lambda:(i+1)\lambda} = \widetilde{\mathbf{u}'}$ originated from the application of the channel $\mathcal{C}$ to $\mathbf{u}'$. The channel replaced a constant fraction of the bits of $\mathbf{u}'$ with random bits (through the symmetry portion of the channel or the insertion and deletion portions). However, a constant fraction of these bits were retained, so there is some correlation between their total and that of the string $\mathbf{u}'$. It can be shown that this correlation suffices to ensure a probability of at least $1/2 + \Omega(1)$ that the sign of this segment $\widetilde{s}_i$ of the trace will be equal to the sign of the appropriate segment s_i of the input string $\mathbf{w}$.

These correlations suffice to ensure that on average $1/2 + \Omega(1)$ of the segments of the trace $\widetilde{\mathbf{w}}$ of an input string $\mathbf{w}$ will have the same sign as the appropriate segments of the input string $\mathbf{w}$, conditioned on each of the *mismatches* d_i being at most $|d_i| < \lambda/100$ (with probability $1 - \exp(-\Omega(\ell))$ over the choice of $\mathbf{w}$). Therefore, if we properly set the constant c parameter of the test T, under these conditions the probability of a true match will be at least $\Omega(1)$.

The next step of our analysis is to show that the mismatches d_i are sufficiently small with probability at least $\exp(-O(\ell/\lambda^2))$. A formal version of this analysis can be found in the full version of our paper [23].

4.2 Coarse and Fine Alignments

Next, we define our coarse and fine alignment procedures. Let be C a sufficiently large constant. We define the parameters for the test used in our coarse and fine alignment procedures to be:

$$\ell_c = C\frac{\log^2 n}{h(C\log n)}; \qquad \lambda_c = C^{1/2}\frac{\log n}{h(C\log n)}$$
$$\ell_f = C^{2/3}h(C\log n); \qquad \lambda_f = C^{1/12}$$

In the full version of this paper [23], we define a precise condition on the input string $\mathbf{x}$ being "well-behaved" (denoted by $\mathbf{x} \in \Xi_{\text{good}}$), and show that a string $\mathbf{x} \in \{0,1\}^n$ selected uniformly at random is well-behaved with probability $1 - n^{-2}$. We define our alignment procedure for well-behaved strings $\mathbf{x}$.

Let $\mathbf{x} \in \Xi_{\text{good}}$ be a well-behaved string. For any integer $k \in [\ell_c + C\log n, n]$, we set the index $a_1 = k - \ell_c - C\log n$ and select $a_2 \in [k - 2/3C\log n, k - 1/3C]$ through a process defined in the full version of this paper [23].

For any trace $\widetilde{\mathbf{x}}$, we set our *coarse alignment* τ_1^k to be the first integer b for which

$$T_{\ell_c,\lambda_c}(\mathbf{x}([a_1, a_1 + \ell_c]), \widetilde{\mathbf{x}}([b, b + \ell_c])) = 1$$

or ∞ if no such b exists. For any trace $\widetilde{\mathbf{x}}$ with $\tau_1^k < \infty$, we define its *fine alignment* τ_2^k to be the first index $b \in [\tau_1^k - \ell_c, \tau_1^k + 2\ell_c + C\log n]$ such that

$$T_{\ell_f,\lambda_f}(\mathbf{x}([a_2, a_2 + \ell_f]), \widetilde{\mathbf{x}}([b, b + \ell_f])) = 1.$$

We define the *mismatch* $d(k, \tau_i^k)$ of any finite alignment $\tau_i^k < \infty$ as the distance between τ_i^k and the index of the first bit of the trace originating from the kth bit of the input message onwards $\mathbf{x}_{k:}$. The following lemma (which we prove in the full version of this paper [23]) promises that $\tau_i^k < \infty$ with sufficiently high probability and that there is a negligible probability that the mismatch of τ_i^k is large.

▶ **Lemma 13.** *Let $\boldsymbol{x} \in \Xi_{good}$ be a well-behaved string and let $k \in \{\ell_c + C \log n, \ldots, n\}$ be an integer. Then for $a_1, a_2, \tau_1^k, \tau_2^k$ as defined above, the following properties hold:*

- $\Pr\left[\tau_1^k < \infty\right] > \exp(-c_1 C^{1/2} h(C \log n))$
- $\Pr\left[\tau_1^k < \infty \wedge d(k, \tau_1^k) > \ell_c\right] < n^{-2}$
- $\Pr\left[\tau_2^k < \infty \mid \tau_1^k < \infty\right] \geq \exp(-c_2 C^{1/2} h(C \log n))$
- $\Pr\left[\tau_2^k < \infty \wedge d(k, \tau_2^k) > \ell_f \mid \tau_1^k < \infty\right] < \exp(-c_3 C^{7/12} h(C \log n))$

Where the probabilities are taken over the randomness of the channel and $c_1, c_2, c_3, c_4 > 0$ are positive constants that may depend on δ, σ, γ but not on C or n and originate from the $\Omega(\cdot)$s and $O(\cdot)$s of the previous sections.

Moreover, as we prove in the full version of this paper, this alignment can be performed efficiently.

▶ **Lemma 14** (τ_1^k, τ_2^k can be computed efficiently)**.** *There is an algorithm A_{align} such that, for any $\boldsymbol{x} \in \Xi_{good}, k \in \{\ell_c + C \log n, \ldots, n\}$ and any trace $\widetilde{\boldsymbol{x}}$ of $\boldsymbol{x}$ through the channel, given*

$$k, \boldsymbol{x}_{:k}, (\tau_1^1, \ldots, \tau_1^{k-1}), (\tau_2^1, \ldots, \tau_2^k)$$

A_{align} computes τ_1^k, τ_2^k, a_2 in time $n^{o(1)}$, with probability $\geq 1 - n^{-2}$.

4.3 Using the Oracle

In Section 4.1, we introduced the Boolean test which can be used to test whether a substring of a trace $\widetilde{\mathbf{x}}$ originated from a specific substring of the input string $\mathbf{x}$. Then, in Section 4.2, we showed that this test can be used as a central component of an alignment procedure which maps indices of the input string $\mathbf{x}$ to their positions in the traces $\widetilde{\mathbf{x}}$ with high probability. In this section, we will complete the proof of our reduction from the average-case trace reconstruction problem to the shifted trace reconstruction problem.

Proof of Theorem 4. Let $\mathcal{C}$ be an SID channel with parameters γ, σ, δ, and let C to be a sufficiently large constant.

We will prove that given the first $k \geq \ell_c + C \log n$ bits of $\mathbf{x}$, we can reconstruct the rest of its bits one at a time. We can work under this assumption, by adding $\ell_c + C \log n$ virtual 0 bits to the start of $\mathbf{x}$ and adding a trace of 0^k to the beginning of each of the traces $\widetilde{\mathbf{x}}$ before the reconstruction.

Given the first k bits of $\mathbf{x}$, we will show that we can reconstruct the $k+1$th bit of $\mathbf{x}$ and from there, we can continue this process iteratively. Using the alignment algorithm from Lemma 14, we compute τ_1^k and τ_2^k of each of the traces $\widetilde{\mathbf{x}}$.

Given a_2, τ_2^k, we run the shifted trace reconstruction algorithm A with parameters $n', n'-1$, where $n' = k - a_2 \in [1/3C \log n, 2/3C \log n]$, on the set:

$$\mathcal{X} = \left\{ \widetilde{\mathbf{x}}(\tau_2^k :) \middle| \begin{smallmatrix} \widetilde{\mathbf{x}} \text{ is a sample} \\ \tau_2^k(\widetilde{\mathbf{x}}) < \infty \end{smallmatrix} \right\}$$

The first and third claims of Lemma 13, mean that for each of our $N = \exp(Ch(C \log n))$ traces, it will have a finite τ_2^k, with probability at least

$$\exp(-C^{1/2}(c_1 + c_2) h(C \log n)) \geq \exp(-1/3Ch(C \log n)).$$

Therefore, by Hoeffding's inequality, the probability that we will have at least

$$1/2 \exp(2/3Ch(C \log n)) > \exp(1/2Ch(2/3C \log n)) \geq \exp(h(k - a_2)) \log^2(n)$$

traces for which $\tau_2^k < \infty$ is at least

$$1 - \exp(-\Omega(Ch(C \log n))) = 1 - n^{-\omega(1)}$$

Lemma 13 gives us that the probability that any sample for which $\tau_2^k < \infty$ is the result of a spurious match is at most

$$\varepsilon(n) \leq \exp(-(C^{7/12}c_3 - C^{1/2}(c_1 + c_2))h(C \log n)) \leq \exp(-10h(k - a_2))$$

Splitting our samples into $\log^2(n)$ batches of size $\exp(h(k - a_2))$ each, we ensure that

1. From the union bound, for each batch, the probability that even a single sample is due to a spurious match is at most $\exp(-9h(k - a_2)) = o(1)$.
2. For each batch, if this batch contained no spurious matches, then applying the shifted trace reconstruction oracle on this batch separately will yield the correct value of the bit $\mathbf{x}_k$ with probability $1 - o(1)$.
3. The batches are independent of one another.

From here we can use to Chernoff bound to show that the probability that more than $1/3$ of these batches either has at least one spurious match or yielded the wrong output from the shifted trace reconstruction oracle is $\exp(-\Omega(\log^2(n))) = n^{-\omega(1)}$, so taking a majority vote on the applications of the shifted trace reconstruction oracle will yield the correct value of $\mathbf{x}$ with probability $1 - n^{-\omega(1)}$, completing our proof. ◀

5 Conclusions

In this paper we presented two main results. First, we proved a general reduction from the average-case trace reconstruction problem to the shifted trace reconstruction problem, which is similar to the worst-case trace reconstruction problem. Second, we generalised the leading algorithm for the worst-case trace reconstruction problem from deletion channels by Chase [7] to the shifted trace reconstruction problem and to the more general class of symmetry-insertion-deletion channels.

Our reduction is based on the work of Holden et al. [14] who used a similar technique to convert the specific methods of De et al. and Nazarov and Peres [12, 20] from worst-case trace reconstruction to the average-case. Continuing the line of work of Brakensiek et al. [5] who reduced the coded trace reconstruction problem to the average-case trace reconstruction problem, we convert the specific construction of Holden et al. to a reduction. Altogether a computational class of trace reconstruction problems begins to emerge.

Moreover, we note McGregor et al. [17] whose results prove that up to the differences between shifted and worst-case trace reconstruction, our reduction is essentially tight. This leads us to several interesting possibilities for future research on trace reconstruction.

First, many other versions of the trace reconstruction have been introduced over the last few years and analysed with an extension of the methods of De et al. and Nazarov and Peres [12, 20] for worst-case trace. If more of these analyses can be converted to reductions to the worst-case or average-case trace reconstruction problems, this would help to simplify the analysis of the many open questions in this field.

Secondly, it seems that the best known techniques for the worst-case trace reconstruction problem translate nicely to the shifted trace reconstruction problem, leading to the conjecture that the two are equivalent. A reduction between the two would help focus further research on this problem.

Finally, we note our extension of Chase's analysis to symmetry-insertion-deletion channels. This portion of our proof is complicated and would be difficult to extend to other settings. An important question for future research is whether there exists a simpler and more elegant analysis for these channels.

The Support of Open Versus Closed Random Walks

Thomas Sauerwald

University of Edinburgh, UK

Abstract

A *closed* random walk of length ℓ on an undirected and connected graph $G = (V, E)$ is a random walk that returns to the start vertex at step ℓ, and its properties have been recently related to problems in different mathematical fields, e.g., geometry and combinatorics (Jiang et al., Annals of Mathematics '21) and spectral graph theory (McKenzie et al., STOC '21). For instance, in the context of analyzing the eigenvalue multiplicity of graph matrices, McKenzie et al. show that, with high probability, the support of a closed random walk of length $\ell \geqslant 1$ is $\Omega(\ell^{1/5})$ on any bounded-degree graph, and leaves as an open problem whether a stronger bound of $\Omega(\ell^{1/2})$ holds for any regular graph.

First, we show that the support of a closed random walk of length ℓ is at least $\Omega(\ell^{1/2}/\sqrt{\log n})$ for any regular or bounded-degree graph on n vertices. Secondly, we prove for every $\ell \geqslant 1$ the existence of a family of bounded-degree graphs, together with a start vertex such that the support is bounded by $O(\ell^{1/2}/\sqrt{\log n})$. Besides addressing the open problem of McKenzie et al., these two results also establish a subtle separation between *closed* random walks and *open* random walks, for which the support on any regular (or bounded-degree) graph is well-known to be $\Omega(\ell^{1/2})$ for all $\ell \geqslant 1$. For irregular graphs, we prove that even if the start vertex is chosen uniformly, the support of a closed random walk may still be $O(\log \ell)$. This rules out a general polynomial lower bound in ℓ for all graphs. Finally, we apply our results on random walks to obtain new bounds on the multiplicity of the second largest eigenvalue of the adjacency matrices of graphs.

1 Introduction

A random walk on a graph is a Markov chain in which, starting from some vertex of an undirected graph $G = (V, E)$, the walk moves to one of the neighbors of the current vertex according to the transition matrix of G. As a fundamental stochastic process, random walks have been employed to model numerous mathematical and physical processes. In computer science, random walks have been widely applied in designing randomized and distributed algorithms. Classical examples range from algorithms for satisfiability, deciding connectivity to approximating the volume of convex bodies. The vast majority of research on random walks focuses on "open" random walks, as opposed to *closed* random walks, which are random walks of fixed length ℓ conditioned on being at the start vertex at step ℓ.

Following up on an earlier work by Jiang, Tidor, Yao, Zhang and Zhao [11], McKenzie, Rasmussen and Srivastava [16] develop a more systematic study of closed random walks on finite graphs. In particular, they study the support of closed random walks, which is the number of distinct vertices visited by a closed random walk of some length ℓ. As in [11], they then leverage their proven lower bounds on the support of closed random walks to upper bound the eigenvalue multiplicities via the trace method of graph matrices. One of the main ingredients in [16] are general lower bounds on the support of a random walk for any connected graph. For instance, for any bounded-degree graph, a closed random walk is shown to have support at least $\Omega(\ell^{1/5})$. In the same work, they also ask for sharper bounds:

> **Open Question 3 ([16]):** Let $d > 1$ be a fixed integer. Does there exist an $\alpha > 1/5$ such that for every connected d-regular graph G on n vertices and every vertex u of G, a closed random walk[1] of length $2\ell < n$ rooted at u has support $\Omega(\ell^{\alpha})$ in expectation? Is $\alpha = 1/2$ true? Does such a bound hold for simple random walks in general?

Note that the constant $\alpha = 1/2$ is a natural target, since any open random walk on a regular graph has support $\Omega(\ell^{1/2})$ (cf. [3, 7]), and this is matched by the n-cycle. Furthermore, also for closed random walks on n-cycles as well as the continuous analogue called Brownian bridges, the support can be shown to be $\Theta(\ell^{1/2})$. In fact, McKenzie et al. [16] states that "*we know of no example where the answer is* $o(\ell^{1/2})$".

In this paper, we address the Open Question 3 of McKenzie et al. [16]. Our first result proves a lower bound of almost $\Omega(\ell^{1/2})$, provided the random walk is sufficiently long. Here we use X^t to denote the vertex that a (lazy) random walk visits in time t, $\mathsf{supp}_{\mathbf{P}}(\ell)$ to denote the number of distinct vertices that a lazy random walk of length ℓ visits, and $\mathbf{P}$ to denote the associated transition matrix (see Section 2 for more on notation).

▶ **Theorem 1.1** (informal version of Theorem 3.1)**.** *Consider any connected, n-vertex graph $G = (V, E)$ with minimum degree δ and maximum degree Δ. Then, for a lazy random walk of length $\ell = O((\Delta/\delta) \cdot n^2 \log n)$ and any vertex $u \in V$, it holds that*

$$\mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \;\middle|\; X^{\ell} = X^0 = u\right] = \Omega\left(\frac{\ell^{1/2}}{\sqrt{(\Delta/\delta) \cdot \log n}}\right).$$

This theorem shows that, for any regular or bounded-degree graph, the support of a closed random walk of length ℓ is at least $\Omega\left(\ell^{1/2}/\sqrt{\log n}\right)$; this result improves the lower bound of $\Omega\left(\ell^{1/5}\right)$ from [16, Theorem 1.3] whenever $\ell \geqslant (\log n)^{5/3}$. Apart from the $\ell^{1/2}$-term in our lower bound, one may wonder about the $\sqrt{\log n}$-term, which intuitively does not seem tight. However, we can construct a family of graphs to demonstrate that this $\sqrt{\log n}$-term is needed, establishing that our lower bound is tight up to constant factors. Our upper bound result is summarized as follows:

▶ **Theorem 1.2** (informal version of Theorem 4.1)**.** *The following statements hold:*

- *For any $\ell = \Omega((\log n)^{7/2})$, there exists a family of bounded-degree n-vertex graph $G = (V, E)$ such that a lazy random walk of length ℓ starting at some vertex r satisfies*

$$\mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \;\middle|\; X^{\ell} = X^0 = r\right] = O\left(\frac{\ell^{1/2}}{\sqrt{\log n}}\right).$$

[1] The original formulation in [16] is stated for a randomly chosen closed walk, which has the same distribution as a closed random walk since G is regular.

Table 1 Overview of the lower and upper bounds on the support of closed and open random walk. Results highlighted in green are from this work. The lower bound of $\Omega(\ell^{1/5})$ holds for bounded-degree graphs. Note that, while our lower bounds hold for all such graphs and all ℓ, the upper bounds only hold for a specific graph (family) which depends on ℓ and ℓ may be additionally restricted.

Graph	Closed Random Walk		Open Random Walk	
	Lower Bound	Upper Bound	Lower B.	Upper B.
reg./bound. deg.	$\Omega(\ell^{1/5})$ [16]	$O(\ell^{5/14}), \ell \leqslant (\log n)^{7/2}$	$\Omega(\ell^{1/2})$ [7]	$O(\ell^{1/2})$
	$\Omega(\ell^{1/2}/\sqrt{\log n})$	$O(\ell^{1/2}/\sqrt{\log n}), \ell \geqslant (\log n)^{7/2}$		
arbitrary	–	$O(\log \ell), \ell = \Theta(\log n)$	$\Omega(\ell^{1/3})$ [7]	–

- *For any $\ell = O((\log n)^{7/2})$, there exists a family of bounded-degree n-vertex graph $G = (V, E)$ such that a lazy random walk of length ℓ starting at some vertex r satisfies*

$$\mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \;\middle|\; X^{\ell} = X^{0} = r\right] = O\left(\ell^{5/14}\right).$$

This result shows that the potential lower bound of $\Omega(\ell^{1/2})$ mentioned in [16] (Open Question 3) does not hold in general. In fact, on certain graphs the support of a closed lazy random walk can be as small as $O(\ell^{5/14})$; therefore the "right" exponent must be between $1/5$ and $5/14$, which is a strong separation from the exponent $1/2$ for open random walks. In contrast, when assuming a suitable lower bound on ℓ, the support of closed random walks is $\Theta(\ell^{1/2}/\sqrt{\log n})$, which is nearly the $\Theta(\ell^{1/2})$ bound for open random walks. Table 1 lists the known upper and lower bounds for closed and open random walks; the interplay of these bounds for regular and bounded-degree graphs is further illustrated in Figure 1.

We now proceed to study closed random walks, with a focus on (highly) irregular graphs. McKenzie et al. [16] proves that the support of a randomly chosen closed walk can be as small as $O(\log \ell)$, if starting from a specific vertex (note that a *randomly chosen closed walk* will have a different distribution to a *closed random walk*, unless the graph is regular). Here we provide a similar upper bound for the support of a closed random walk on a family of irregular graphs. Interestingly, this upper bound even holds if we assume that the start vertex is chosen uniformly at random. This lower bound also establishes an "exponential discrepancy" on the support of closed random walks versus open random walks on irregular graphs: while the support of open random walks is known to be at least $\ell^{1/3}$ (cf. [3]) for any graph and any start vertex, one can construct graphs for which the support is only $O(\log \ell)$ for closed random walks.

▶ **Theorem 1.3** (informal version of Theorem 4.5). *There exists a family of connected, n-vertex graphs $G = (V, E)$ such that a lazy random walk of some length $\ell = \Theta(\log n)$ that starts from a vertex chosen uniformly at random satisfies*

$$\mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^{\ell} = X^{0}\right] = O(\log \ell).$$

Consequently, there is a vertex $r \in V$ such that

$$\mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^{\ell} = X^{0} = r\right] = O(\log \ell).$$

As side results, we apply our lower bounds on the support of closed random walks to obtain new eigenvalue multiplicity bounds for certain classes of graphs. We state one result below, and an additional result is presented in Section 5.

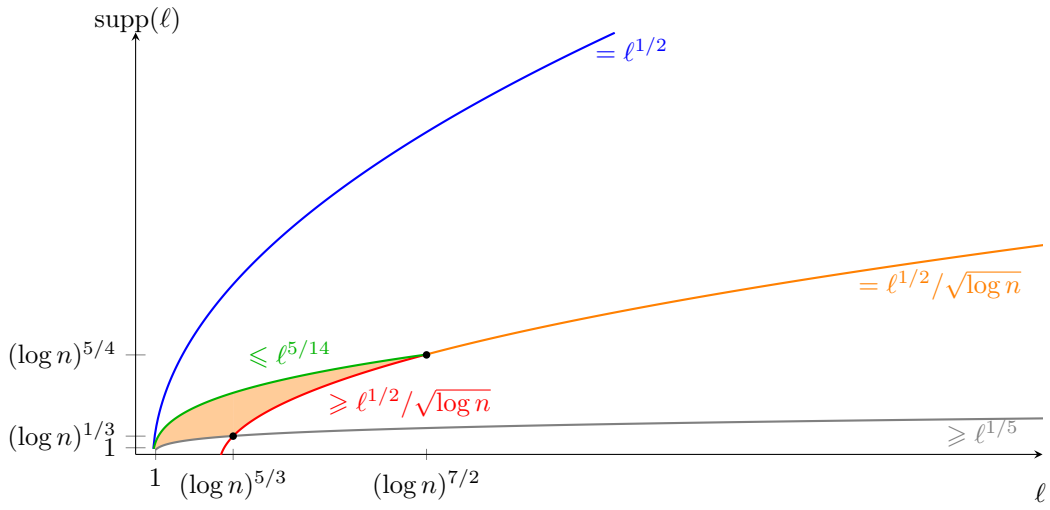

Figure 1 Comparison of the (worst case) support of open random walks to that of closed random walks for bounded-degree graphs. We prove for any $\ell = \Omega((\log n)^{7/2})$ (and $\ell \leqslant n^{1/5}$) that the asymptotic worst case bound for closed random walks equals $\ell^{1/2}/\sqrt{\log n}$, while for $\ell = O((\log n)^{7/2})$ the correct asymptotic bound is confined in the orange area. Since the lower bound $\ell^{1/2}/\sqrt{\log n}$ is tight for any $\ell \geqslant (\log n)^{7/2}$ but becomes trivial for $\ell \leqslant \log n$, we can infer that there must be a phase transition in the interval $[(\log n)^{5/3}, (\log n)^{7/2}]$.

▶ **Theorem 1.4** (informal version of Theorem 5.1). *Consider any connected, n-vertex graph $G = (V, E)$ with minimum degree δ and maximum degree Δ, such that its second largest eigenvalue λ of $\mathbf{P}$ satisfies $|1 - \lambda| = O(\frac{\delta}{\Delta} \cdot \frac{1}{\log^4 n})$. Then, the number of eigenvalues of $\mathbf{P}$ in the range $\left[\left(1 - \frac{\delta}{32c\Delta \cdot \log^5 n}\right) \cdot \lambda, \lambda\right]$ is at most $O(\frac{n}{\log n})$.*

Our eigenvalue multiplicity results are in general incomparable with the ones in [16], and have their own features. For instance, our eigenvalue multiplicity bound above is based on the spectral gap condition of $\mathbf{P}$; as such, this result brings a new connection between the eigenvalue multiplicity and the eigenvalue distribution, the relationship of which is informally established in spectral graph theory through the high-order Cheeger inequalities [12].

1.1 Further Related Work

There is a plethora of works on random walks on graphs, which often revolves around quantities such as mixing times, hitting times and cover times [14]. In particular, properties of short random walks such as their support or return probabilities have found numerous applications in the analysis of randomness amplification [10], space-efficient graph exploration with random walks [2, 7] and the voter model [17]. These concepts have been also successfully applied to algorithmic tasks such as estimating network sizes and densities [4], load balancing [19], information spreading [8], property testing [6] and clustering [20]. In addition to these applications, many of the random walk quantities have close connections to other mathematical areas, such as geometry, group theory, electrical networks and spectral graph theory (see [13, 14] for more details).

More closely related to this work, Benjamini, Izkovsky and Kesten [5] analyze the support of closed random walks on various finite and infinite graphs, with a focus on vertex-transitive and Cayley graphs. In particular, for high-girth expander graphs, they prove that the support

of closed random walks is linear in their length. While there are some studies of closed random walks on finite or infinite graphs with special geometry or symmetries as well as studies of Brownian bridges in continuous space, much less is known about the support of closed random walks on finite graphs (without additional assumptions on their symmetry or geometry).

One specific motivation for studying closed random walks is the relation to the second eigenvalue multiplicity of the normalized adjacency matrix of graphs, as established recently in [11, 15, 16]. By examining the support of closed random walks of short length, it is shown that, for any connected graph G of maximum degree Δ, the second eigenvalue multiplicity of G's normalized adjacency matrix is $\widetilde{O}\left(n \cdot \Delta^{7/5}/\log^{1/5} n\right)$, where the notation $\widetilde{O}(\cdot)$ suppresses $\operatorname{poly}\log\log(n)$ terms. Haiman, Schildkraut, Zhang and Zhao [9] show the existence of infinitely many connected 18-regular graphs G on n vertices with the second largest eigenvalue multiplicity at least $n^{2/5}-1$, and the existence of infinitely many connected n-vertex graphs with maximum degree 4 and second eigenvalue multiplicity at least $\sqrt{n/\log_2 n}$.

1.2 Organization

The remaining part of the paper is organized as follows. Section 2 introduces our notation and provides some basic lemmas used in this work. We derive our lower bound on the support of closed random walks in Section 3, and the proofs of our two upper bound results are presented in Section 4. Finally, we employ our random walk results to analyze the eigenvalue multiplicity problem in Section 5. We summarize our results and point to some open questions in Section 6.

2 Definitions and Preliminaries

All graphs in this paper will be undirected. For any vertex $u \in V$ of a graph $G=(V,E)$, the degree of u is denoted by $\deg(u)$; the maximum and minimum degrees of G are denoted by Δ and δ, respectively. For any $u \in V$ and $\ell \in \mathbb{N}$, let $B_{\leqslant \ell/2}(u) \triangleq \{v \in V\colon \operatorname{dist}(u,v) \leqslant \ell/2\}$. For any integer k, let $[k] \triangleq \{1,\ldots,k\}$.

We use $\mathbf{Q}$ to represent the transition matrix of a non-lazy random walk in G defined by $\mathbf{Q}_{u,v} = \frac{1}{\deg(u)}$ if $\{u,v\} \in E(G)$ and $\mathbf{Q}_{u,v}=0$ otherwise. We use $\mathbf{P}$ to represent the lazy random walk matrix of G, where $\mathbf{P}_{u,u} = \frac{1}{2}$ for all $u \in V$, $\mathbf{P}_{u,v} = \frac{1}{2\deg(u)}$ if $\{u,v\} \in E(G)$, and $\mathbf{P}_{u,v}=0$ otherwise. We use $\mathbf{A}$ to represent the adjacency matrix of G, and $\mathbf{D}$ to represent the diagonal matrix of degrees of G. For any matrix $\Diamond \in \{\mathbf{P},\mathbf{Q}\}$ of size $n \times n$, the eigenvalues of $\Diamond$ are denoted by $\lambda_1(\Diamond) \geqslant \ldots \geqslant \lambda_n(\Diamond)$. We define $M_\Diamond[x,y]$ to be the number of eigenvalues of the matrix $\Diamond$ in the interval $[x,y]$.

For any (non-)lazy random walk that starts from a vertex (or possibly distribution over vertices) $X^0 \in V$, we use X^t to denote the vertex that the random walk reaches at step t for any $t \geqslant 0$, and define

$$p^t_{u,v} \triangleq \mathbf{Pr}\left[X^t = v \;\middle|\; X^0 = u\right]$$

to be the probability that a random walk that starts from u is located at v after t steps; if the start vertex is deterministic and clear from the context, we sometimes omit the conditioning on $X^0=u$. Further, we write $X^0 \sim \mathcal{U}$ if the start vertex of the random walk is chosen uniformly at random from V. We define the support of a random walk of length ℓ to be

$$\mathsf{supp}_\Diamond(\ell) \triangleq \left|\left\{X^i \mid i \leqslant \ell\right\}\right|,$$

where we use $\Diamond \in \{\mathbf{P}, \mathbf{Q}\}$ to distinguish a lazy random walk from a non-lazy one. It is well-known that, for a lazy random walk with loop probability $1/2$ on a connected graph G, it holds for all $u, v \in V$ that $\lim_{t\to\infty} p^t_{u,v} = \pi(v)$, where $\pi \in \mathbb{R}^n_{\geqslant 0}$ is the stationary distribution defined by $\pi(u) \triangleq \frac{\deg(u)}{2\cdot|E(G)|}$ for any $u \in V$.

We list two lemmas used in our analysis. Our first lemma allows us to translate bounds on the support from lazy random walks to non-lazy ones (and vice versa) at the cost of a small constant factor.

▶ **Lemma 2.1.** *For any graph $G = (V, E)$ and any fixed $\ell \geqslant 0$, it holds that $\mathsf{supp}_{\mathbf{Q}}(\ell)$ is stochastically larger than $\mathsf{supp}_{\mathbf{P}}(\ell)$. Moreover, we have for any $x \geqslant 0$ that*

$$\mathbf{Pr}\left[\,\mathsf{supp}_{\mathbf{P}}(4\cdot\ell) \geqslant x\,\right] \geqslant \frac{1}{2}\cdot\mathbf{Pr}\left[\,\mathsf{supp}_{\mathbf{Q}}(\ell) \geqslant x\,\right],$$

and thus

$$\mathbf{E}\left[\,\mathsf{supp}_{\mathbf{P}}(4\cdot\ell)\,\right] \geqslant \frac{1}{2}\cdot\mathbf{E}\left[\,\mathsf{supp}_{\mathbf{Q}}(\ell)\,\right].$$

The next lemma gives a lower bound on the return probability of a random walk. While there are a number of results upper bounding the return probability of a random walk (e.g., [13, 14, 18]),to the best of our knowledge much less is known in terms of lower bounds.

▶ **Lemma 2.2.** *For any connected, n-vertex graph $G = (V, E)$ and a lazy random walk with transition matrix $\mathbf{P}$, it holds for any vertex $u \in V$ and step $t \geqslant 0$ that*

$$p^t_{u,u} \geqslant \pi(u) = \frac{\deg(u)}{2|E|} \geqslant \frac{1}{n^2}.$$

The same also holds for non-lazy random walks with transition matrix $\mathbf{Q}$, if additionally t is even. Furthermore, if G has minimum degree δ and maximum degree Δ, we also have for any $t \geqslant 2$,

$$p^t_{u,u} \geqslant \frac{\delta^t}{\Delta^{t+1}}\cdot\frac{1}{|B_{\leqslant t/2}(u)|},$$

and the same inequality holds for the transition matrix $\mathbf{Q}$ if $t \geqslant 2$ is even.

3 A Lower Bound on the Support of Closed Random Walks

This section provides lower bounds on the support of closed random walks, in particular, we will prove Theorem 1.1. We first present a more detailed formulation of Theorem 1.1, in which all the hidden constants are stated precisely.

▶ **Theorem 3.1.** *Consider any connected, n-vertex graph $G = (V, E)$ with minimum degree δ and maximum degree Δ. Then there is a constant $c \geqslant 1$ independent of n, such that a random walk of length $\ell \leqslant 512\frac{\Delta}{\delta}cn^2\log n$ satisfies for any $u \in V$ that*

$$\mathbf{E}\left[\,\mathsf{supp}_{\Diamond}(\ell)\;\middle|\;X^\ell = X^0 = u\,\right] \geqslant \frac{1}{2}\cdot\left\lfloor\sqrt{\frac{1}{576c}\cdot\frac{\delta}{\Delta}\cdot\frac{\ell}{\log n}}\right\rfloor,$$

where $\Diamond \in \{\mathbf{P}, \mathbf{Q}\}$ (in the case of $\Diamond = \mathbf{Q}$, the length ℓ needs additionally to be even). Furthermore, for any $\mu \in [1, \ell]$ satisfying $\ell \leqslant 32\frac{\Delta}{\delta}cn^2\mu$, it holds that

$$\mathbf{Pr}\left[\,\mathsf{supp}_{\Diamond}(\ell) \leqslant \left\lfloor\sqrt{\frac{1}{64c}\cdot\frac{\delta}{\Delta}\cdot\frac{\ell}{\mu}}\right\rfloor\;\middle|\;X^\ell = X^0 = u\,\right] \leqslant (5/8)^{\mu/2}\cdot\frac{1}{p^\ell_{u,u}},$$

where ℓ is required to be even if $\Diamond = \mathbf{Q}$.

To examine the significance of this result, notice that it is shown in [16, Theorem 1.3] that

$$\mathbf{Pr}\left[\mathsf{supp}_{\mathbf{Q}}(\ell) \leqslant s \;\middle|\; X^{\ell} = u\right] \leqslant \exp\left(-\frac{\ell}{130\Delta^7 s^4}\right),$$

if $s \leqslant \frac{1}{4}\left(\frac{\ell}{2\Delta^7 \log \Delta}\right)^{1/5}$ and ℓ is even. In comparison to their result, our bound is not affected by the density, but only by the degree ratio Δ/δ. Regarding the expected support, it follows that for bounded-degree graphs, the first statement in Theorem 3.1 improves on [16, Theorem 1.3] for moderately longer walks, i.e., $\ell \geqslant (\log n)^{5/3}$, whereas it is worse for $\ell \leqslant (\log n)^{5/3}$.

Next, we present the lemmas needed to prove Theorem 3.1. The first lemma (Lemma 3.3) lower bounds the support of *open* random walks, and relies on the following result by Feige [7] bounding the expected time until a certain number of distinct vertices are visited; similar results are also shown in [3].

▶ **Lemma 3.2** ([7, Theorem 4]). *Consider any connected, n-vertex graph $G = (V, E)$ with minimum degree δ and maximum degree Δ. For any $s \in [1, n]$, let $T(s)$ be the time until a random walk visits s distinct vertices. Then there is a constant $c \geqslant 1$ (independent of s and n), such that for any lazy random walk and any vertex $u \in V$,*

$$\mathbf{E}\left[T(s) \mid X^0 = u\right] \leqslant c \cdot \left(s + \frac{s^2}{\delta} \cdot \min\{s, \Delta\}\right).$$

▶ **Lemma 3.3.** *Consider any connected, n-vertex graph $G = (V, E)$, and a random walk of length ℓ for some $\ell \triangleq 32 \cdot \lceil c \cdot \frac{\Delta}{\delta} \cdot s^2 \rceil$, where $1 \leqslant s \leqslant n$ is any integer. Then, there is some constant $c \geqslant 1$ (independent of n and ℓ), such that it holds for any start vertex $u \in V$ that*

$$\mathbf{Pr}\left[\mathsf{supp}_{\Diamond}(\ell) \geqslant s \mid X^0 = u\right] \geqslant \frac{3}{8},$$

where $\Diamond \in \{\mathbf{P}, \mathbf{Q}\}$.

Proof. First of all, we note that the constant c involved in this result is the constant from Lemma 3.2. With this, we first prove the result for non-lazy random walks, i.e., for $\Diamond = \mathbf{Q}$. Let

$$\widetilde{\ell} \triangleq 8 \cdot \left\lceil c \cdot \frac{\Delta}{\delta} \cdot s^2 \right\rceil.$$

Recall that $T(s)$ is the stopping time until a walk has visited s different vertices. By Lemma 3.2, we have

$$\mathbf{E}\left[T(s) \;\middle|\; X^0 = u\right] \leqslant c \cdot \left(s + \frac{\Delta}{\delta} s^2\right) \leqslant 2 \cdot \left\lceil c \cdot \frac{\Delta}{\delta} s^2 \right\rceil = \frac{1}{4} \cdot \widetilde{\ell}.$$

By Markov's inequality, it holds that

$$\mathbf{Pr}\left[T(s) \geqslant \widetilde{\ell} \;\middle|\; X^0 = u\right] \leqslant \mathbf{Pr}\left[T(s) \geqslant 4 \cdot \mathbf{E}\left[T(s)\right] \;\middle|\; X^0 = u\right] \leqslant \frac{1}{4}.$$

Note that $T(s) \leqslant \widetilde{\ell}$ is equivalent to $\mathsf{supp}(\widetilde{\ell}) \geqslant s$, and this gives us that

$$\mathbf{Pr}\left[\mathsf{supp}(\widetilde{\ell}) \geqslant s \;\middle|\; X^0 = u\right] \geqslant \frac{3}{4} \geqslant \frac{3}{8}, \tag{1}$$

which completes the proof in case of $\Diamond = \mathbf{Q}$. For $\Diamond = \mathbf{P}$, the statement follows immediately from (1), and the second statement of Lemma 2.1, since $\ell = 4 \cdot \widetilde{\ell}$. ◀

We remark that the bound presented in Lemma 3.3 is essentially tight: if one takes a random walk of length ℓ on a path (or cycle), then by the Central Limit Theorem the probability that the walk visits at least $\varepsilon \cdot \sqrt{\ell}$ vertices can be upper bounded by $1 - \delta$ for some $\delta = \delta(\varepsilon) > 0$; in particular, this probability can be bounded independently of ℓ.

Proof of Theorem 3.1. Fix an arbitrary start vertex $u \in V$ as $X^0 = u$. We split the random walk of length ℓ into consecutive sections of length $\ell' \triangleq \lceil \ell/(9 \log n) \rceil$. Without loss of generality, we assume that $\ell \geqslant 576 \frac{\Delta}{\delta} c \log n$, since otherwise the statement holds trivially. Given $\ell \geqslant 576 \frac{\Delta}{\delta} c \log n$ (and $c \geqslant 1$), we have $\ell' \leqslant \ell/(8 \log n)$. Hence, it would take a random walk (at least) $8 \log n$ sections before reaching step ℓ. Next we define the integer

$$\gamma \triangleq \left\lfloor \sqrt{\frac{1}{64c} \cdot \frac{\delta}{\Delta} \cdot \ell'} \right\rfloor,$$

with c being the constant from Lemma 3.2. We make the following observations about the range of γ:

- Since $\ell' \leqslant \ell/(8 \log n)$ and by the precondition $\ell \leqslant 512 \frac{\Delta}{\delta} c n^2 \log n$, we have

$$\gamma \leqslant \sqrt{\frac{1}{64c} \cdot \frac{\delta}{\Delta} \cdot \frac{\ell}{8 \log n}} \leqslant n.$$

- Similarly, since $\ell' \geqslant \ell/(9 \log n)$ and $\ell \geqslant 576 \frac{\Delta}{\delta} c \log n$, we have

$$\gamma \geqslant \left\lfloor \sqrt{\frac{1}{64c} \cdot \frac{\delta}{\Delta} \cdot \frac{\ell}{9 \log n}} \right\rfloor \geqslant 1.$$

In conclusion, γ is an integer between 1 and n. Notice that the definition of γ implies

$$\gamma \leqslant \sqrt{\frac{1}{64c} \cdot \frac{\delta}{\Delta} \cdot \ell'},$$

and thus $\ell' \geqslant 64c \cdot \frac{\Delta}{\delta} \cdot \gamma^2$. Since $\gamma \geqslant 1$, we have $c \cdot \frac{\Delta}{\delta} \cdot \gamma^2 \geqslant 1$ and

$$c \cdot \frac{\Delta}{\delta} \cdot \gamma^2 \geqslant \frac{1}{2} \left\lceil c \cdot \frac{\Delta}{\delta} \cdot \gamma^2 \right\rceil.$$

This implies that

$$\ell' \geqslant 64c \cdot \frac{\Delta}{\delta} \cdot \gamma^2 \geqslant 32 \cdot \left\lceil c \cdot \frac{\Delta}{\delta} \cdot \gamma^2 \right\rceil.$$

We now apply Lemma 3.3 (with $s = \gamma$) and conclude

$$\mathbf{Pr}\left[\mathsf{supp}_{\Diamond}(\ell') \geqslant \gamma \;\middle|\; X^0 = u \right] \geqslant \mathbf{Pr}\left[\mathsf{supp}_{\Diamond}\left(32 \cdot \left\lceil c \cdot \frac{\Delta}{\delta} \cdot \gamma^2 \right\rceil \right) \geqslant \gamma \;\middle|\; X^0 = u \right] \geqslant \frac{3}{8},$$

which holds for any start vertex $u \in V$. Therefore, by considering the at least $8 \log n$ consecutive sections of length ℓ' each, and using the Markov property we have

$$\begin{aligned} \mathbf{Pr}\left[\mathsf{supp}_{\Diamond}(\ell) < \gamma \;\middle|\; X_0 = u \right] &\leqslant \left(\max_{v \in V} \mathbf{Pr}\left[\mathsf{supp}_{\Diamond}(\ell') < \gamma \;\middle|\; X_0 = v \right] \right)^{8 \log n} \leqslant \left(\frac{5}{8} \right)^{8 \log n} \\ &\leqslant n^{-3}, \end{aligned}$$

since $(5/8)^8 \leqslant \mathrm{e}^{-3}$.

By Lemma 2.2, it holds for a lazy random walk (i.e., $\Diamond = \mathbf{P}$) starting with any $u \in V$ and integer $\ell \geqslant 0$ that

$$\mathbf{Pr}\left[X^\ell = u \;\middle|\; X^0 = u \right] \geqslant \pi(u) \geqslant \frac{\delta}{\Delta \cdot n};$$

we also know that the same statement holds for a non-lazy random walk (i.e., $\Diamond = \mathbf{Q}$) and an even value of ℓ. Hence,

$$\begin{aligned}
\mathbf{Pr}\left[\mathsf{supp}_\Diamond(\ell) < \gamma \;\middle|\; X^0 = X^\ell = u \right] &= \frac{\mathbf{Pr}\left[\mathsf{supp}_\Diamond(\ell) < \gamma \cap X^0 = X^\ell = u \right]}{\mathbf{Pr}\left[X^0 = X^\ell = u \right]} \\
&\leqslant \frac{\mathbf{Pr}\left[\mathsf{supp}_\Diamond(\ell) < \gamma \right]}{\mathbf{Pr}\left[X^\ell = u \;\middle|\; X^0 = u \right]} \\
&\leqslant \frac{n^{-3}}{n^{-2}} = n^{-1}. \qquad (2)
\end{aligned}$$

Consequently,

$$\begin{aligned}
\mathbf{E}\left[\mathsf{supp}_\Diamond(\ell) \;\middle|\; X^0 = X^\ell = u \right] &\geqslant \gamma \cdot \mathbf{Pr}\left[\mathsf{supp}_\Diamond(\ell) \geqslant \gamma \;\middle|\; X^0 = X^\ell = u \right] \\
&\geqslant \gamma \cdot \left(1 - n^{-1}\right) \\
&\geqslant \frac{1}{2} \cdot \left\lfloor \sqrt{\frac{1}{64c} \cdot \frac{\delta}{\Delta} \cdot \frac{\ell}{9 \log n}} \right\rfloor = \frac{1}{2} \cdot \left\lfloor \sqrt{\frac{1}{576c} \cdot \frac{\delta}{\Delta} \cdot \frac{\ell}{\log n}} \right\rfloor,
\end{aligned}$$

which proves the first statement.

We proceed to the proof of the second statement, which essentially uses the same argument as before but with different parameters. First note that we may assume $\ell \geqslant 64c \cdot \frac{\Delta}{\delta} \cdot \mu$, since otherwise the statement holds trivially. In particular, this implies $\ell/\mu \geqslant 1$, so if we split the random walk of length ℓ into consecutive sections of length $\ell' \triangleq \lceil \ell/\mu \rceil$, it holds that $\ell' \leqslant 2\ell/\mu$. Hence there are at least $\mu/2$ consecutive sections before reaching step ℓ. We define

$$\gamma \triangleq \left\lfloor \sqrt{\frac{1}{64c} \cdot \frac{\delta}{\Delta} \cdot \ell'} \right\rfloor,$$

and rearranging this implies

$$\ell' \geqslant 64c \cdot \frac{\Delta}{\delta} \cdot \gamma^2 \geqslant 32 \cdot \left\lceil c \cdot \frac{\Delta}{\delta} \cdot \gamma^2 \right\rceil.$$

Again, we examine the range of γ:

- Since $\ell' \leqslant 2\ell/\mu$ and by the precondition $\ell \leqslant 32 \frac{\Delta}{\delta} c n^2 \mu$, we have $\gamma \leqslant n$.
- Since $\ell' \geqslant \ell/\mu$ and $\ell \geqslant 64c \cdot \frac{\Delta}{\delta} \cdot \mu$, we have $\gamma \geqslant 1$.

In conclusion, γ is an integer between 1 and n. By Lemma 3.3 (with $s = \gamma$), it holds that

$$\mathbf{Pr}\left[\mathsf{supp}_\Diamond(\ell') \geqslant \gamma \;\middle|\; X^0 = u \right] \geqslant \mathbf{Pr}\left[\mathsf{supp}_\Diamond\left(32 \left\lceil c \cdot \frac{\Delta}{\delta} \cdot \gamma^2 \right\rceil \right) \geqslant \gamma \;\middle|\; X^0 = u \right] \geqslant \frac{3}{8},$$

and, as in the proof of the first statement,

$$\mathbf{Pr}\left[\mathsf{supp}_\Diamond(\ell) \leqslant \gamma \;\middle|\; X^0 = u \right] \leqslant (5/8)^{\mu/2}.$$

Finally, we apply the same argument as in (2) to conclude that

$$\mathbf{Pr}\left[\mathsf{supp}_\Diamond(\ell) \leqslant \gamma \;\middle|\; X^0 = X^\ell = u \right] \leqslant (5/8)^{\mu/2} \cdot \frac{1}{p^\ell_{u,u}}.$$

◀

4 Upper Bounds on the Support of Closed Random Walks

This section studies upper bounds on the support of closed random walks, by examining certain "worst-case" graphs. The section is structured as follows: we first study a family of bounded-degree graphs, and give the proof of Theorem 1.2 in Section 4.1. We present a more formal statement of Theorem 1.3, and prove the statement in Section 4.2.

4.1 Proof of Theorem 1.2

We first present a more detailed formulation of Theorem 1.2, in which all the hidden constants are stated precisely.

▶ **Theorem 4.1.** *There is a constant $C \geqslant 1$, such that for any pair of integers β being a power of 2 and ℓ with $C \leqslant \ell \leqslant \beta^{1/5}$ the following holds: there is a connected, n-vertex graph G satisfying $n \in [2\beta + 1, 2\beta + \beta^{1/10} - 1]$, $\Delta = 3$, and some vertex $r \in V(G)$, such that it holds for a random walk of length ℓ that starts at r that*

$$\mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \;\middle|\; X^{\ell} = X^{0} = r\right] \leqslant 3 \cdot \ell^{1/2-\varepsilon},$$

where $\varepsilon \triangleq \min\left(1/2 \cdot \log(1/16 \cdot \log_{12} \beta)/\log \ell, 1/7\right)$.

We first construct the family of graphs G used in the proof. Given two integers $p \geqslant 1$ and $D \geqslant 1$, our constructed graph $G = G[p, D]$ is based on the following two graphs:

- let $G_1 = (V_1, E_1)$ be a path graph of length $p + 1$, where $V_1 = \{v_0, v_1, \ldots, v_p\}$ and $E_1 = \{\{v_i, v_{i+1}\} \mid 0 \leqslant i < p\}$;
- let $G_2 = (V_2, E_2)$ be a complete binary tree over $D \geqslant 1$ levels labelled $0, 1, \ldots, D-1$. Hence, G_2 has $2^{D+1} - 1$ vertices.

We set the root of the binary tree to be vertex $z = v_0$, and let G be the union of the graphs G_1 and G_2; see Figure 2 for an illustration of our considered graph. Notice that G has $n = p + (2^{D+1} - 1)$ vertices, as vertex $z = v_0$ appears in both G_1 and G_2. Since all vertices of graph G have degree one, two or three, we have $\Delta = 3$.

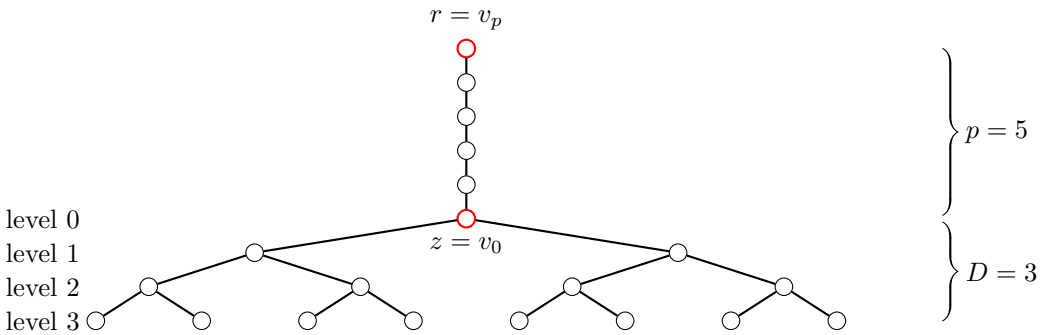

Figure 2 The construction of the graph $G = G[p, D]$ for $p = 5$, $D = 3$. We have $2^4 - 1 = 15$ vertices on the binary tree, and the total number of vertices of G is $n = 5 + 16 - 1 = 20$.

Now we explain the intuition behind our construction. We study a closed random walk from r of length p^{2+c} for some suitably small constant $c > 0$. On one hand, if the closed random walk remains only on the path, then the support of this walk is at most $p \ll (p^{2+c})^{1/2}$. On the other hand, once the random walk leaves the path, the walk is likely to "get lost" in

the binary tree, and the probability for the walk to return to $r = v_p$ is very small. Hence, if we sample from the space of all closed random walks, there is a strong bias towards those walks that never leave the path (and thus have necessarily small support).

Now we turn this intuition into a formal proof. Recall that the *level* of a vertex in the binary tree is the distance to the root vertex z, and recall that the maximum level is equal to the depth D.

▶ **Lemma 4.2.** *Consider a lazy random walk on $G = G[p, D]$ starting at r. For any integer $\ell \geqslant 0$, the following holds with probability at least $1 - \exp(-\ell/288)$: if the random walk makes at least ℓ transitions within the binary tree, it reaches at least once a vertex which is at level $\min(D, \ell/12)$.*

This lemma is quite intuitive, as there is a strong drift on the binary tree to increase the distance to the root, and one can exploit this using Hoeffding's inequality. Next, we present a simple fact of random walks on binary trees.

▶ **Lemma 4.3.** *Consider a lazy random walk in a complete binary tree with levels $0, 1, \ldots, D$ starting at a vertex which has distance $k \in [1, D]$ from the root. Then the probability that the walk reaches the root within ℓ steps is upper bounded by $\ell \cdot 2^{-k}$.*

Lemmas 4.2 and 4.3 together establish the intuitive fact that, once the random walks makes sufficiently many transitions in the binary tree, it is unlikely to return to the root of the tree within a small number of steps.

Next, we consider a lazy random walk on a path with vertices $0, 1, \ldots, p$, starting from p, with the special property that the random walk "gets killed" once it reaches the other endpoint 0. The following lemma lower bounds the probability of the random walk "surviving" after $\gamma \cdot p^2$ steps, i.e., the probability that a random walk does not reach the other endpoint before step $\gamma \cdot p^2$.

▶ **Lemma 4.4.** *Consider a lazy random walk on the integers $\{0, 1, \ldots, p\}$, starting at vertex p, such that the random walk gets killed after reaching vertex 0. More precisely, we define the following $p \times p$ matrix $\mathbf{R}$:* [2]

$$\mathbf{R}_{i,j} = \begin{cases} \frac{1}{2} & \text{if } j = i \in \{1, \ldots, p\}, \\ \frac{1}{2} & \text{if } i = p,\ j = p-1, \\ \frac{1}{4} & \text{if } j = i-1,\ 1 < i < p, \\ \frac{1}{4} & \text{if } j = i+1,\ 1 \leqslant i < p. \end{cases}$$

Let $r^t_{p,\cdot}$ be the probability distribution[3] *of this t-step random walk, when starting at vertex p. Then, it holds for any integer $\gamma \geqslant 1$ that*

$$r^{\gamma \cdot p^2}_{p,p} \geqslant \frac{1}{2p} \cdot 12^{-8 \cdot \gamma}.$$

With the previous lemmas at hand, we are now ready to prove Theorem 4.1.

[2] This matrix is called a "substochastic" matrix [1, Section 3.6.5, page 95]. Note that this is *not* a transition matrix, since from state 1 with probability 1/4 the walk gets killed.

[3] Since the random walk gets killed at vertex 0, $\|r^t_{p,\cdot}\|_1$ may generally not be equal to 1, but it is upper bounded by 1.

Proof of Theorem 4.1. Given the two integers ℓ and β being a power of 2, we will now instantiate a graph $G = G[p, D]$. Firstly, the length of the path is $p \triangleq \ell^\delta$ and $\delta \triangleq 1/2 - \varepsilon$; recall that

$$\varepsilon = \min\left(1/2 \cdot \log(1/16 \cdot \log_{12} \beta)/\log \ell, 1/7\right).$$

Secondly, the depth of the binary tree is $D \triangleq \log_2 \beta$ (so in turn, the binary tree has $2^{\log_2(\beta)+1} - 1$ vertices). Hence, the total number of vertices in G is

$$n = \ell^\delta + 2^{\log_2(\beta)+1} - 1,$$

which is at least $2\beta + 1$ and at most $2\beta + \beta^{1/10}$, as $\ell \leqslant \beta^{1/5}$.

Our objective is to show that the expected support of a closed random walk of length ℓ starting at vertex r is at most $3 \cdot \ell^\delta = 3 \cdot \ell^{1/2-\varepsilon}$. We first upper bound the probability of the event that a random walk (not necessarily closed) visits at least $2\ell^\delta + 1$ vertices in ℓ steps and then returns to r.

In the following, let us define the following events and stopping time:

1. The event $\mathcal{A} := \left\{\mathsf{supp}(\ell) \geqslant 2\ell^\delta + 1\right\}$, meaning the random walk of length ℓ visits at least $2\ell^\delta + 1$ vertices.
2. The event $\mathcal{B} := \left\{X^\ell = r\right\}$, meaning the random walk is at the start vertex at time ℓ.
3. The event $\mathcal{C}$ which occurs if the random walk of length ℓ makes at least ℓ^δ transitions on the binary tree.
4. The stopping time τ, which is the number of transitions on the binary tree until a vertex at level $\min\{D, \ell^\delta/12\}$ is reached for the first time.
5. The event $\mathcal{C}(\tau)$ which occurs if the random walk of length ℓ makes at least τ transitions on the binary tree.

In order to visit at least $2\ell^\delta+1$ vertices, the walk needs to visit at least $2\ell^\delta+1-(\ell^\delta+1) = \ell^\delta$ vertices on the tree (excluding the vertex $z = v_0$), since there are only $\ell^\delta + 1$ vertices on the path. Hence we have

$$\mathcal{A} \subseteq \mathcal{C}. \tag{3}$$

Furthermore, we have by Lemma 4.2 (applied to a random walk on the binary tree with ℓ^δ transitions),

$$\mathbf{Pr}\left[\tau \leqslant \ell^\delta\right] \geqslant 1 - \exp(-\ell^\delta/288). \tag{4}$$

Furthermore, let $T(\tau)$ be the time-step of the random walk on G when the τ-th transition on the binary tree is made; so, $T(\tau) \geqslant \tau$. Then,

$$\mathbf{Pr}\left[X^\ell = r \mid \mathfrak{F}^{T(\tau)}, T(\tau) \leqslant \ell\right] \leqslant \ell \cdot \max\left(2^{-D}, 2^{-\ell^\delta/12}\right), \tag{5}$$

since by Lemma 4.3, the random walk starting from a vertex at level level $\min\{D, \ell^\delta/12\}$ in the binary tree does not even reach $z = v_0$ within ℓ additional steps (and therefore cannot reach the vertex r at step ℓ). By combining the last three inequalities,

$$
\begin{aligned}
&\mathbf{Pr}\left[\mathcal{A} \cap \left\{X^\ell = r\right\}\right] \\
&\leqslant \mathbf{Pr}\left[\mathcal{C} \cap \left\{X^\ell = r\right\}\right] \\
&\leqslant \mathbf{Pr}\left[\mathcal{C} \cap \left\{\tau \leqslant \ell^\delta\right\} \cap \left\{X^\ell = r\right\}\right] + \mathbf{Pr}\left[\tau > \ell^\delta\right] \\
&\leqslant \mathbf{Pr}\left[\mathcal{C}(\tau) \cap \left\{\tau \leqslant \ell^\delta\right\} \cap \left\{X^\ell = r\right\}\right] + \exp\left(-\ell^\delta/288\right) \\
&\leqslant \mathbf{Pr}\left[\tau \leqslant \ell^\delta\right] \cdot \mathbf{Pr}\left[\mathcal{C}(\tau) \mid \tau \leqslant \ell^\delta\right] \cdot \mathbf{Pr}\left[X^\ell = r \mid \mathcal{C}(\tau), \tau \leqslant \ell^\delta\right] + \exp\left(-\ell^\delta\right) \\
&\leqslant \mathbf{Pr}\left[X^\ell = r \mid \mathfrak{F}^{T(\tau)}, T(\tau) \leqslant \ell\right] + \exp\left(-\ell^\delta/288\right) \\
&\leqslant \ell \cdot \max\left(2^{-D}, 2^{-\ell^\delta/12}\right) + \exp\left(-\ell^\delta/288\right) \\
&\leqslant 16\ell \cdot \max\left(\exp(-\ell^\delta/288), 1/\beta\right) =: p_{\mathsf{bad}}.
\end{aligned}
$$

On the other hand, we will now lower bound the probability that a random walk starting at r never leaves the path of length ℓ^δ and is located at vertex r at step ℓ. By Lemma 4.4, we have that this probability is lower bounded by

$$
\mathbf{Pr}\left[\left\{\mathsf{supp}(\ell) \leqslant 2\ell^\delta\right\} \cap \left\{X^\ell = r\right\}\right] \geqslant \frac{1}{2} \cdot \ell^{-1/2+\varepsilon} \cdot 12^{-8\ell^{2\varepsilon}} \geqslant \ell^{-1/2} \cdot 12^{-8\ell^{2\varepsilon}} =: p_{\mathsf{good}}.
$$

Finally, we can now upper bound the expected size of the support of a closed random walk of length ℓ. Using the conditional probabilities and the definitions of p_{bad} and p_{good}, we have that

$$
\begin{aligned}
\frac{\mathbf{Pr}\left[\mathsf{supp}(\ell) \geqslant 2\ell^\delta + 1 \mid X^\ell = r\right]}{\mathbf{Pr}\left[\mathsf{supp}(\ell) \leqslant 2\ell^\delta + 1 \mid X^\ell = r\right]} &= \frac{\mathbf{Pr}\left[\left\{\mathsf{supp}(\ell) \geqslant 2\ell^\delta + 1\right\} \cap \left\{X^\ell = r\right\}\right]}{\mathbf{Pr}\left[\left\{\mathsf{supp}(\ell) \leqslant 2\ell^\delta + 1\right\} \cap \left\{X^\ell = r\right\}\right]} \leqslant \frac{p_{\mathsf{bad}}}{p_{\mathsf{good}}} \\
&\leqslant 16\ell^{1.5} \cdot \max\left(\exp(-\ell^\delta/288), 1/\beta\right) \cdot 12^{8\ell^{2\varepsilon}},
\end{aligned}
$$

which implies that

$$
\mathbf{Pr}\left[\mathsf{supp}(\ell) \geqslant 2\ell^\delta + 1 \mid X^\ell = r\right] \leqslant 16\ell^{1.5} \cdot \max\left(\exp(-\ell^\delta/288), 1/\beta\right) \cdot 12^{8\ell^{2\varepsilon}}.
$$

Therefore, it holds that

$$
\begin{aligned}
&\mathbf{E}\left[\mathsf{supp}(\ell) \mid X^\ell = r\right] \\
&\leqslant \mathbf{Pr}\left[\mathsf{supp}(\ell) < 2\ell^\delta + 1 \mid X^\ell = r\right] \cdot 2\ell^\delta + \mathbf{Pr}\left[\mathsf{supp}(\ell) \geqslant 2\ell^\delta + 1 \mid X^\ell = r\right] \cdot \ell \\
&\leqslant 2\ell^\delta + 1 + 16\ell^{2.5} \cdot \max\left(\exp(-\ell^\delta/288), 1/\beta\right) \cdot 12^{8\ell^{2\varepsilon}}.
\end{aligned}
$$

Since $\varepsilon = \min\left(1/2 \cdot \log(1/16 \cdot \log_{12}\beta)/\log\ell, 1/7\right)$ by definition, we have $\varepsilon \leqslant 1/7$. Together with $\delta = 1/2 - \varepsilon$, this implies $2\varepsilon \leqslant \delta - 1/14$ and therefore

$$
12^{8\ell^{2\varepsilon}} \leqslant 12^{8\ell^{\delta-1/14}} \leqslant \exp\left(\ell^\delta/572\right),
$$

where the last inequality holds if ℓ is lower bounded by a sufficiently large constant $C > 0$. Applying this gives us that

$$
16\ell^{2.5} \cdot \exp(-\ell^\delta/288) \cdot 12^{8\ell^{2\varepsilon}} \leqslant 16\ell^{2.5} \cdot \exp\left(-\ell^\delta/572\right).
$$

Similarly, we have $\varepsilon \leqslant 1/2 \cdot \log(1/16 \cdot \log_{12}\beta)/\log\ell$ by definition, and obtain

$$
16\ell^{2.5} \cdot \frac{1}{\beta} \cdot 12^{8\ell^{2\varepsilon}} \leqslant 16\ell^{2.5} \cdot \frac{1}{\beta} \cdot \sqrt{\beta}.
$$

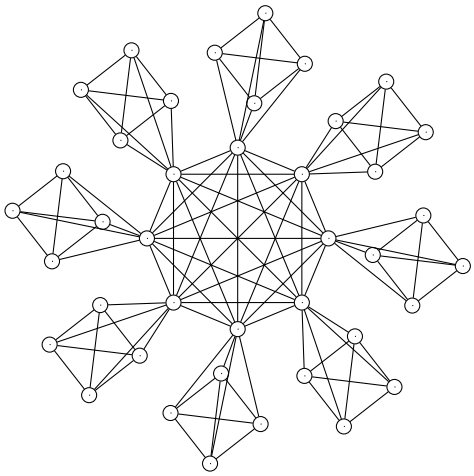

Figure 3 The construction of the graph G, where a large clique of $\beta/\lceil\log\log\beta\rceil$ vertices is connected to $\beta/\lceil\log\log\beta\rceil$ small cliques of size $\lceil\log\log\beta\rceil$ each; recall that our choice of β ensures that $\beta/\lceil\log\log\beta\rceil$ is an integer.

Combining the last two inequalities gives us that

$$\mathbf{E}\left[\,\mathsf{supp}(\ell)\;\middle|\;X^s=r\,\right]\leqslant 2\ell^\delta+1+16\ell^{2.5}\cdot\max\left(\exp\left(-\ell^\delta/572\right),\frac{1}{\sqrt{\beta}}\right)\leqslant 3\ell^\delta,$$

using that $\ell\geqslant C$ for some large constant $C>0$ as well as $\ell\leqslant\beta^{1/5}$. This completes the proof. ◀

4.2 Proof of Theorem 1.3

In this subsection we present a more detailed formulation of Theorem 1.3, and prove the statement afterwards.

▶ **Theorem 4.5** (Formal version of Theorem 1.3). *Let $C\geqslant 1$ be a constant. Then, for every integer $\beta\geqslant C$ such that $\beta/\lceil\log\log\beta\rceil$ is an integer, there is a graph G with $n=\beta+\beta/\lceil\log\log\beta\rceil$ vertices such that a lazy random walk of length $\ell=\lfloor\log\beta\rfloor$ starting from some vertex chosen uniformly at random from $V(G)$ satisfies*

$$\mathbf{E}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell)\;\middle|\;X^\ell=X^0\sim\mathcal{U}\,\right]\leqslant 5\log\ell.$$

In particular, there is a start vertex $r\in V$ such that

$$\mathbf{E}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell)\;\middle|\;X^\ell=X^0=r\,\right]\leqslant 5\log\ell.$$

We first define the graphs used in proving Theorem 4.5. For any given parameter $\beta\in\mathbb{N}$, our graph G is defined as follows:

- Let $G_1=(V_1,E_1)$ consist of $\beta/\lceil\log\log\beta\rceil$ disjoint, "small" cliques of size $\lceil\log\log\beta\rceil$ each.
- Let $G_2=(V_2,E_2)=K_{\beta/\lceil\log\log\beta\rceil}$ be a "big" clique of size $\beta/\lceil\log\log\beta\rceil$.
- Our studied graph G is constructed by taking the union of G_1 and G_2, and additionally connecting each vertex of the smaller cliques to one distinct vertex in the big clique.

See Figure 3 for an illustration of our construction.

Proof of Theorem 4.5. We use the graph G defined above in the proof, and decompose the expected support based on the sampled start vertex according to the uniform distribution over $V(G)$:

$$\begin{aligned}
&\mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 \sim \mathcal{U}\right] \\
&= \sum_{u\in V} \mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 = u\right] \cdot \mathbf{Pr}\left[X^0 = u \mid X^\ell = X^0\right] \\
&= \sum_{u\in V} \mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 = u\right] \cdot \frac{\mathbf{Pr}\left[X^\ell = X^0 = u\right]}{\mathbf{Pr}\left[X^\ell = X^0\right]} \\
&= \sum_{u\in V} \mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 = u\right] \cdot \frac{\mathbf{Pr}\left[X^\ell = u \mid X^0 = u\right] \cdot \frac{1}{n}}{\mathbf{Pr}\left[X^\ell = X^0\right]}
\end{aligned}$$

Splitting the above sum yields

$$\begin{aligned}
&\mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 \sim \mathcal{U}\right] \\
&= \sum_{u\in V(G_1)} \mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 = u\right] \cdot \frac{\mathbf{Pr}\left[X^\ell = u \mid X^0 = u\right] \cdot \frac{1}{n}}{\mathbf{Pr}\left[X^\ell = X^0\right]} \\
&\quad + \sum_{v\in V(G_2)} \mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 = v\right] \cdot \frac{\mathbf{Pr}\left[X^\ell = v \mid X^0 = v\right] \cdot \frac{1}{n}}{\mathbf{Pr}\left[X^\ell = X^0\right]} \\
&= |V(G_1)| \cdot \mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 = u\right] \cdot \frac{\mathbf{Pr}\left[X^\ell = u \mid X^0 = u\right] \cdot \frac{1}{n}}{\mathbf{Pr}\left[X^\ell = X^0\right]} \\
&\quad + |V(G_2)| \cdot \mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 = v\right] \cdot \frac{\mathbf{Pr}\left[X^\ell = v \mid X^0 = v\right] \cdot \frac{1}{n}}{\mathbf{Pr}\left[X^\ell = X^0\right]}, \qquad (6)
\end{aligned}$$

where u is an arbitrary vertex in G_1, v is an arbitrary vertex in G_2, and the last equation holds by symmetry.

Consider now a lazy random walk which starts from some vertex $u \in V_1$ in a small clique. Then the probability that this random walk never leaves the small clique and is at u in step $\ell \triangleq \lfloor \log \beta \rfloor$ is at least

$$\begin{aligned}
&\mathbf{Pr}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \geqslant \lceil \log\log\beta \rceil \cap \{X^\ell = u\} \mid X^0 = u\right] \\
&\geqslant \left(1 - \frac{1}{2\lceil \log\log\beta \rceil}\right)^{\lfloor \log\beta \rfloor - 1} \cdot \min\left(\frac{1}{2}, \frac{1}{2\lceil \log\log\beta \rceil}\right) \\
&\geqslant 8^{-\log\beta/\log\log\beta}. \qquad (7)
\end{aligned}$$

If the random walk leaves a small clique, then the probability of returning to the small clique within ℓ steps is at most $\ell \cdot (\lceil \log\log\beta \rceil)^2/n$; hence, it holds that

$$\begin{aligned}
\mathbf{Pr}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \geqslant \lceil \log\log\beta \rceil \cap \{X^\ell = u\} \mid X^0 = u\right] &\leqslant \ell \cdot \frac{\lceil \log\log\beta \rceil}{\beta/\lceil \log\log\beta \rceil - 1 + \lceil \log\log\beta \rceil} \\
&\leqslant \ell \cdot \frac{(\lceil \log\log\beta \rceil)^2}{\beta}.
\end{aligned}$$

Therefore, as in the proof of Theorem 4.1,

$$\begin{aligned}
&\frac{\mathbf{Pr}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell) \geqslant \lceil \log\log\beta \rceil \;\mid\; X^\ell = X^0 = u\,\right]}{\mathbf{Pr}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell) \leqslant \lceil \log\log\beta \rceil \;\mid\; X^\ell = X^0 = u\,\right]} \\
&= \frac{\mathbf{Pr}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell) \geqslant \lceil \log\log\beta \rceil \cap \left\{X^\ell = u\right\} \;\mid\; X^0 = u\,\right]}{\mathbf{Pr}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell) \leqslant \lceil \log\log\beta \rceil \cap \{X^\ell = u\} \;\mid\; X^0 = u\,\right]} \\
&\leqslant \frac{\ell \cdot \frac{(\lceil \log\log\beta \rceil)^2}{\beta}}{8^{-\log\beta/\log\log\beta}},
\end{aligned}$$

and upper bounding the denominator on the left hand side by 1 yields

$$\mathbf{Pr}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell) \geqslant \lceil \log\log\beta \rceil \;\mid\; X^\ell = u\,\right] \leqslant \frac{\ell \cdot \frac{(\lceil \log\log\beta \rceil)^2}{n}}{8^{-\log\beta/\log\log\beta}}.$$

Therefore, it holds that

$$\begin{aligned}
&\mathbf{E}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell) \;\mid\; X^\ell = X^0 = u\,\right] \\
&\leqslant \mathbf{Pr}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell) \geqslant \lceil \log\log\beta \rceil \;\mid\; X^0 = u\,\right] \cdot \ell \\
&\qquad + \mathbf{Pr}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell) \leqslant \lceil \log\log\beta \rceil \;\mid\; X^0 = u\,\right] \cdot \lceil \log\log\beta \rceil \\
&\leqslant \ell^2 \cdot 8^{\log\beta/\log\log\beta} \cdot \frac{(\lceil \log\log\beta \rceil)^2}{\beta} + 1 \cdot \lceil \log\log\beta \rceil \leqslant 2 \cdot \lceil \log\log\beta \rceil,
\end{aligned}$$

as $\ell = \lfloor \log\beta \rfloor$.

Now we return to (6). By using the three trivial estimates, (i) $|V_1| \leqslant n$, (ii) $|V_2| \leqslant n$ and (iii) $\mathbf{E}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell) \;\mid\; X^\ell = X^0 = v\,\right] \leqslant \ell$, we have

$$\begin{aligned}
&\mathbf{E}\left[\,\mathsf{supp}_{\mathbf{P}}(\ell) \;\mid\; X^\ell = X^0 \sim \mathcal{U}\,\right] \\
&\leqslant n \cdot 2 \cdot \lceil \log\log\beta \rceil \cdot \frac{\mathbf{Pr}\left[\,X^\ell = u \;\mid\; X^0 = u\,\right] \cdot \frac{1}{n}}{\mathbf{Pr}\left[\,X^\ell = X^0\,\right]} + n \cdot \ell \cdot \frac{\mathbf{Pr}\left[\,X^\ell = v \;\mid\; X^0 = v\,\right] \cdot \frac{1}{n}}{\mathbf{Pr}\left[\,X^\ell = X^0\,\right]} \\
&\leqslant 2 \cdot \lceil \log\log\beta \rceil \cdot \frac{\mathbf{Pr}\left[\,X^\ell = u \;\mid\; X^0 = u\,\right]}{\mathbf{Pr}\left[\,X^\ell = X^0\,\right]} + \ell \cdot \frac{\mathbf{Pr}\left[\,X^\ell = v \;\mid\; X^0 = v\,\right]}{\mathbf{Pr}\left[\,X^\ell = X^0\,\right]}. \qquad (8)
\end{aligned}$$

We now proceed to upper bound the expression in Equation (8), by considering the two addends separately. We first upper bound $\frac{\mathbf{Pr}\left[\,X^\ell = u \mid X^0 = u\,\right]}{\mathbf{Pr}\left[\,X^\ell = X^0\,\right]}$. By decomposing and lower bounding the denominator, we have that

$$\begin{aligned}
\mathbf{Pr}\left[\,X^\ell = X^0\,\right] &\geqslant \sum_{u \in V_1} \mathbf{Pr}\left[\,X^0 = u\,\right] \cdot \mathbf{Pr}\left[\,X^\ell = u \;\mid\; X^0 = u\,\right] \\
&\geqslant \frac{1}{2} \cdot \mathbf{Pr}\left[\,X^\ell = u \;\mid\; X^0 = u\,\right] \qquad (9)
\end{aligned}$$

since the probability $\mathbf{Pr}\left[\,X^\ell = X^0 \;\mid\; X^0 = u\,\right]$ is the same for all $u \in V_1$ by symmetry, and by construction of G, at least half of the vertices in G are in V_1. Therefore,

$$\frac{\mathbf{Pr}\left[\,X^\ell = u \;\mid\; X^0 = u\,\right]}{\mathbf{Pr}\left[\,X^\ell = X^0\,\right]} \leqslant 2. \qquad (10)$$

We now turn to the second addend in (8). We first upper bound $\mathbf{Pr}\left[\,X^\ell = v \;\mid\; X^0 = v\,\right] = p^\ell_{v,v}$, where $v \in V_2$. To this end, note that the random walk can only be at v at step ℓ if at least one of the following three cases occurs: (i) the random walk always remains on v by taking ℓ self-loops, (ii) the random walk leaves v, and then returns to v from another vertex

in the big clique, and (iii) the random walk leaves v, and then returns to v from a neighbor in the small clique. Regarding (i), the probability is $2^{-\ell}$. Regarding (ii), the probability of ever using an edge $\{x, v\} \in E$ with $x \in V_2$ during ℓ steps is at most

$$\ell \cdot \frac{1}{2\deg(x)} \leqslant \ell \cdot \frac{1}{2 \cdot \left(\frac{\beta}{\lceil \log\log\beta \rceil} - 1 + \lceil \log\log\beta \rceil \right)} \leqslant \ell \cdot \frac{\lceil \log\log\beta \rceil}{2\beta}.$$

Finally, regarding (iii), the probability that the random walk ever reaches any vertex in V_1 within ℓ steps is upper bounded by

$$\ell \cdot \max_{z \in V_2} \frac{\deg_{V_1}(z)}{2\deg(z)} \leqslant \ell \cdot \frac{\lceil \log\log\beta \rceil}{2 \cdot \left(\frac{\beta}{\lceil \log\log\beta \rceil} - 1 + \lceil \log\log\beta \rceil \right)} \leqslant \ell \cdot \frac{(\lceil \log\log\beta \rceil)^2}{2\beta}.$$

Combining these three cases, we have

$$\mathbf{Pr}\left[X^\ell = v \mid X^0 = v \right] \leqslant 2^{-\ell} + \ell \cdot \frac{(\lceil \log\log\beta \rceil)^2}{\beta}. \tag{11}$$

To lower bound $\mathbf{Pr}\left[X^\ell = X^0 \right]$, we apply (9) and the estimate from (7) to obtain that

$$\mathbf{Pr}\left[X^\ell = X^0 \right] \geqslant \frac{1}{2} \cdot \mathbf{Pr}\left[X^\ell = u \mid X^0 = u \right] \geqslant \frac{1}{2} \cdot 8^{-\log\beta/\log\log\beta}. \tag{12}$$

Finally, combining (10), (11), (12) with (8) gives us that

$$\begin{aligned}
&\mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 \sim \mathcal{U} \right] \\
&\leqslant 4 \cdot \lceil \log\log\beta \rceil + 2 \cdot \ell \cdot 8^{\log\beta/\log\log\beta} \cdot \left(2^{-\ell} + \ell \cdot \frac{(\lceil \log\log\beta \rceil)^2}{\beta} \right) \\
&\leqslant 4 \cdot \lceil \log\log\beta \rceil + 2 \cdot \ell \cdot 8^{\log\beta/\log\log\beta} \cdot \left(2 \cdot \ell \cdot \frac{(\lceil \log\log\beta \rceil)^2}{\beta} \right) \\
&\leqslant 4 \cdot \lceil \log\log\beta \rceil + o(1) \\
&\leqslant 5 \cdot \log\ell,
\end{aligned}$$

where in the second inequality we used the definition $\ell = \lfloor \log\beta \rfloor \geqslant \log\beta - 1$, and similarly the third inequality holds since $\ell = \lfloor \log\beta \rfloor$, and thus the $1/\beta$ term dominates.

For the second statement, note that by conditioning on the vertex sampled for X^0,

$$\begin{aligned}
&\mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 \sim \mathcal{U} \right] \\
&= \sum_{u \in V} \mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 = u \right] \cdot \mathbf{Pr}\left[X^\ell = X^0 = u \mid X^\ell = X^0 \right] \\
&\geqslant \min_{u \in V} \mathbf{E}\left[\mathsf{supp}_{\mathbf{P}}(\ell) \mid X^\ell = X^0 = u \right],
\end{aligned}$$

and thereore the second statement follows immediately from the first statement. ◀

5 Results on Eigenvalue Multiplicity

This section presents some new eigenvalue multiplicity bounds on the transition matrices of random walks. For ease of presentation, we focus on lazy random walks in this section, but our presented method can be employed to analyze non-lazy random walks, too. Our first eigenvalue multiplicity bound is as follows:

▶ **Theorem 5.1** (Formal Statement of Theorem 1.4). *Consider any connected, n-vertex graph $G = (V, E)$ with minimum degree δ and maximum degree Δ. Further assume $\lambda = \lambda_2 \geqslant \gamma$, where $\gamma \triangleq 1 - \frac{\delta}{32c\Delta} \cdot \frac{1}{\log^4 n}$ and $c \geqslant 1$ is the constant from Lemma 3.2. Then, it holds that*

$$M_{\mathbf{P}}\left[\left(1 - \frac{\delta}{32c\Delta \cdot \log^5 n}\right) \cdot \lambda, \lambda\right] = O\left(\frac{n}{\log n}\right). \tag{13}$$

It is shown in [16] that, for the normalized adjacency matrix of any n-vertex graph G with maximum degree Δ, the number of eigenvalues in the range $\left[\left(1 - \frac{\log\log_\Delta}{\log_\Delta n}\right) \cdot \lambda_2, \lambda_2\right]$ is

$$\widetilde{O}\left(n \cdot \frac{\Delta^{7/5}}{\log^{1/5} n}\right). \tag{14}$$

In comparison to their bound, our presented result only holds for graphs with poor expansion. However, Theorem 5.1 does show for such graphs that the number of eigenvalues in our studied range is $O(n/\log n)$, which is significantly smaller than the bound in (14).

The proof of Theorem 5.1 closely follows the approach in [16], by reducing the multiplicity analysis to the support of closed random walks. We consider a lazy random walk of length ℓ on G, and assume that the start vertex X^0 is sampled uniformly at random. We denote by W^ℓ the event $\{X^\ell = X^0\}$ and by $W^{\ell,s}$ the event $\{X^\ell = X^0, \mathsf{supp}(\ell) \leqslant s\}$; that is, the random walk is closed and has support at most s. Abusing notation a bit, let $W^{\ell,\geqslant s}$ be the event where the random walk is closed and has support at least s. We now state the following bound, which is based on the arguments of [16] and the probability bound in Theorem 3.1.

▶ **Lemma 5.2.** *Consider any connected, n-vertex graph, and a lazy random walk of length $\ell \leqslant 32c\mu \cdot \frac{\Delta}{\delta} n^2$ starting from a uniform random vertex. Then with $c > 0$ being the constant from Lemma 3.2, it holds for any $s \leqslant \left\lfloor \sqrt{\frac{1}{64c} \cdot \frac{\delta}{\Delta} \cdot \frac{\ell}{\mu}} \right\rfloor$ that*

$$\mathbf{Pr}\left[W^{\ell,s}\right] \leqslant \frac{\Delta}{\delta} \cdot n \cdot \left(\frac{5}{8}\right)^{\mu/2} \mathbf{Pr}\left[W^\ell\right].$$

Combining Lemma 5.2 with the techniques developed in [16] proves Theorem 5.1.

We further present a different and more elementary approach to bound the multiplicities of the eigenvalue λ_2, and our proof is based on the Random Target Lemma [14, (3.3)].

▶ **Theorem 5.3.** *Consider any connected, n-vertex graph $G = (V, E)$ with average degree d and minimum degree δ. Then there is some constant $C > 0$, such that it holds for any $\varepsilon > 0$ that*

$$M_{\mathbf{P}}[(1-\varepsilon)\lambda_2, \lambda_2] \leqslant C \cdot \frac{d}{\delta} \cdot n \cdot \frac{1 - (1-\varepsilon)\lambda_2}{\sqrt{1-\lambda_2}}.$$

In particular, it holds with $\varepsilon = (1-\lambda_2)/\lambda_2$ that

$$M_{\mathbf{P}}[(1-\varepsilon)\lambda_2, \lambda_2] \leqslant 2C \cdot \frac{d}{\delta} \cdot n \cdot \sqrt{1-\lambda_2}.$$

6 Conclusions

In this work we analyze the support of closed random walks of length ℓ on different graph classes. Contrary to the well-understood worst-case support of *open* random walks, especially on regular and bounded-degree graphs, our results demonstrate that the (worst-case) support

of *closed* random walks is much more complex, and undergoes a delicate phase transition as ℓ varies. While the support is $\Theta(\ell^{1/2}/\sqrt{\log n})$ for $\ell = \Omega((\log n)^{7/2})$, for smaller values of ℓ it is sandwiched between $\Omega(\ell^{1/5})$ and $O(\ell^{5/14})$. This proves a strong separation from the open random walk case, where the support is known to be $\Omega(\ell^{1/2})$ [3, 7], and provides a negative answer to [16, Open Problem 3].

For *(highly) irregular* graphs, we prove that even with a *randomly sampled* start vertex, the support may only be logarithmic in ℓ. This is once more in sharp contrast to open walks, where a lower bound of $\Omega(\ell^{1/3})$ holds for *any* start vertex and any $1 \leqslant \ell \leqslant n^3$ [3].

One interesting open problem is to derive refined bounds on the support of closed random walks. For instance, it is tempting to conjecture that on any bounded-degree expander graph, the lower bound on the support can be improved, possibly even to $\Omega(\ell)$, which would be tight and match the bound for open random walks. To the best of our knowledge, this is only known for the special case where ℓ is upper bounded by the girth of the expander [5].

A Auxiliary Tools

This section lists the auxiliary results used in the paper. Our first lemma is a simple upper bound on the lower tails of a sub-multiplicative random variable. We remark that this is a standard result, however we present the proof here for the sake of completeness.

▶ **Lemma A.1.** *Let X be a non-negative integer random variable such that $\mathbf{E}[X] \geqslant b$, and there exists integer $c \geqslant 1$ such that $\mathbf{Pr}[X > kc] \leqslant \mathbf{Pr}[X > c]^k$ for all integers $k \geqslant 0$. Then, it holds for any $a < c$ that*

$$\mathbf{Pr}[X > a] \geqslant \frac{b-a}{b+2c}.$$

Proof. Let $p \triangleq \mathbf{Pr}[X > a] \geqslant \mathbf{Pr}[X > c]$, since $a < c$ and $\mathbf{Pr}[X > x]$ decreasing in x. Hence, it holds that

$$\begin{aligned}
b &\leqslant \mathbf{E}[X] \\
&= \sum_{i=0}^{\infty} \mathbf{Pr}[X > i] \\
&\leqslant a + \sum_{i=a}^{c-1} \mathbf{Pr}[X > i] + c\sum_{k=1}^{\infty} \mathbf{Pr}[X > kc] \\
&\leqslant a + \sum_{i=a}^{c-1} \mathbf{Pr}[X > i] + c\sum_{k=1}^{\infty} \mathbf{Pr}[X > c]^k \\
&\leqslant a + p(c-a) + cp/(1-p).
\end{aligned}$$

This implies $(1-p)b \leqslant a + 2pc$, rearranging gives the result. ◀

▶ **Theorem A.2** (Cauchy's Interlacing Theorem)**.** *Let $\mathbf{A}$ be a real symmetric $n \times n$ matrix, and $\mathbf{B}$ an $m \times m$ principal submatrix of $\mathbf{A}$ (that is, $\mathbf{B}$ is obtained by deleting both the i^{th} row and column for some values of i). Suppose A has eigenvalues $\lambda_1, \ldots, \lambda_n$, and B has eigenvalues $\beta_1, \ldots, \beta_m$. Then, it holds for $1 \leqslant k \leqslant m$ that $\lambda_k \leqslant \beta_k \leqslant \lambda_{k+n-m}$.*

▶ **Theorem A.3** (Hoeffding's Bound). *Let $Y_1, \ldots, Y_\ell$ be independent bounded random variables with $Y_i \in [a, b]$ for each $i \leqslant \ell$, and define $Y = \sum_{i=1}^{\ell} Y_i$. Then, the following hold for all $\lambda \geqslant 0$:*

$$\mathbf{Pr}\left[\, Y_i - \mathbf{E}\left[\, Y \,\right] \geqslant \lambda \,\right] \leqslant \exp\left(-\frac{2\lambda^2}{\ell(b-a)^2}\right)$$

and

$$\mathbf{Pr}\left[\, Y_i - \mathbf{E}\left[\, Y \,\right] \leqslant -\lambda \,\right] \leqslant \exp\left(-\frac{2\lambda^2}{\ell(b-a)^2}\right).$$

Faster Matroid Partition Algorithms

Tatsuya Terao
Research Institute for Mathematical Sciences, Kyoto University, Japan

Abstract

In the matroid partitioning problem, we are given k matroids $\mathcal{M}_1 = (V, \mathcal{I}_1), \ldots, \mathcal{M}_k = (V, \mathcal{I}_k)$ defined over a common ground set V of n elements, and we need to find a partitionable set $S \subseteq V$ of largest possible cardinality, denoted by p. Here, a set $S \subseteq V$ is called partitionable if there exists a partition $(S_1, \ldots, S_k)$ of S with $S_i \in \mathcal{I}_i$ for $i = 1, \ldots, k$. In 1986, Cunningham [7] presented a matroid partition algorithm that uses $O(np^{3/2} + kn)$ independence oracle queries, which was the previously known best algorithm. This query complexity is $O(n^{5/2})$ when $k \leq n$.

Our main result is to present a matroid partition algorithm that uses $\tilde{O}(k^{1/3}np + kn)$ independence oracle queries, which is $\tilde{O}(n^{7/3})$ when $k \leq n$. This improves upon previous Cunningham's algorithm. To obtain this, we present a new approach *edge recycling augmentation*, which can be attained through new ideas: an efficient utilization of the binary search technique by Nguyễn [25] and Chakrabarty-Lee-Sidford-Singla-Wong [5] and a careful analysis of the number of independence oracle queries. Our analysis differs significantly from the one for matroid intersection algorithms, because of the parameter k. We also present a matroid partition algorithm that uses $\tilde{O}((n + k)\sqrt{p})$ rank oracle queries.

1 Introduction

The *matroid partitioning problem*[1] is one of the most fundamental problem in combinatorial optimization. The problem is sometimes introduced as an important matroid problem along with the *matroid intersection problem*; see [28, Section 41–42] and [21, Section 13.5–6]. In the problem, we are given k matroids $\mathcal{M}_1 = (V, \mathcal{I}_1), \ldots, \mathcal{M}_k = (V, \mathcal{I}_k)$ defined over a common ground set V of n elements, and the objective is to find a partitionable set $S \subseteq V$ of largest possible cardinality, denoted by p. Here, we call a set $S \subseteq V$ partitionable if there exists a partition $(S_1, \ldots, S_k)$ of S with $S_i \in \mathcal{I}_i$ for $i = 1, \ldots, k$. This problem has a number of applications such as matroid base packing, packing and covering of trees and forests, Shannon switching game. There are much more applications; see [28, Section 42].

[1] The *matroid partitioning problem* is sometimes called simply *matroid partition*. Matroid partition is also called *matroid union* or *matroid sum*.

To design an algorithm for arbitrary matroids, it is common to consider an oracle model: an algorithm accesses a matroid through an oracle. The most standard and well-studied oracle is an *independence oracle*, which takes as input a set $S \subseteq V$ and outputs whether $S \in \mathcal{I}$ or not. Some recent studies for fast matroid intersection algorithms also consider a more powerful oracle called *rank oracle*, which takes as input a set $S \subseteq V$ and outputs the size of the maximum cardinality independent subset of S. In the design of efficient algorithms, the goal is to minimize the number of such oracle accesses in a matroid partition algorithm. We consider both independence oracle model and rank oracle model, and present the best query algorithms for both oracle models.

The matroid partitioning problem is closely related to the matroid intersection problem. Actually, the matroid partitioning problem and the matroid intersection problem are polynomially equivalent; see [9, 11].

In the *matroid intersection problem*, we are given two matroids $\mathcal{M}' = (V, \mathcal{I}'), \mathcal{M}'' = (V, \mathcal{I}'')$ defined over a common ground set V of n elements, and the objective is to find a common independent set $S \in \mathcal{I}' \cap \mathcal{I}''$ of largest possible cardinality, denoted by r.

Starting the work of Edmonds [8, 10, 11] in the 1960s, algorithms with polynomial query complexity for the matroid intersection problem have been studied [1–5, 7, 22, 23]. Nguyễn [25] and Chakrabarty-Lee-Sidford-Singla-Wong [5] independently presented a new excellent binary search technique that can find edges in the exchange graph and presented a first combinatorial algorithm that uses $\tilde{O}(nr)$ independence oracle queries[2]. Chakrabarty et al. [5] also presented a $(1-\epsilon)$ approximation matroid intersection algorithm that uses $\tilde{O}(n^{1.5}/\epsilon^{1.5})$ independence oracle queries. Blikstad-van den Brand-Mukhopadhyay-Nanongkai [4] developed a fast algorithm to solve a graph reachability problem, and broke the $\tilde{O}(n^2)$-independence-oracle-query bound by combining this with previous exact and approximation algorithms. Blikstad [2] improved the independence query complexity of the approximation matroid intersection algorithm. This leads to a randomized matroid intersection algorithm that uses $\tilde{O}(nr^{3/4})$ independence oracle queries, which is currently the best algorithm for the matroid intersection problem for the full range of r. This also leads to a deterministic matroid intersection algorithm that uses $\tilde{O}(nr^{5/6})$ independence oracle queries, which is currently the best deterministic algorithm for the matroid intersection problem for the full range of r.

We can solve the matroid partitioning problem by using the reduction to the matroid intersection problem. A well-known reduction reduces the matroid partition to the matroid intersection whose ground set size is kn. Here, one of the input matroids of this matroid intersection is the direct sum of the k matroids. This leads to a matroid partition algorithm using too many independence oracle queries. Even if we use the currently best algorithm for matroid intersection, the naive reduction leads to a matroid partition algorithm that uses $\tilde{O}(k^2np^{3/4})$ independence oracle queries. Since the matroid partition problem itself is an important problem with several applications, it is meaningful to focus on the query-complexity of the matroid partitioning problem.

A direct algorithm for the matroid partitioning problem was first given by Edmonds in 1968 [8]. Algorithms with polynomial query complexity for the matroid partitioning problem have been studied in the literature [3, 7, 12–14, 20, 27].

Cunningham [7] designed a matroid partition algorithm that uses $O(np^{3/2} + kn)$ independence oracle queries. Cunningham uses a *blocking flow* approach, which is similar to Hopcroft-Karp's bipartite matching algorithm or Dinic's maximum flow algorithm. The independence query complexity of Cunningham's algorithm is $O(n^{5/2})$ when $k \leq n$. Note

[2] The $\tilde{O}$ notation omits factors polynomial in $\log n$.

that $p \leq n$ obviously holds. This was the best algorithm for the matroid partitioning problem for nearly four decades. We study faster matroid partition algorithms by using techniques that were recently developed for fast matroid intersection algorithms.

Our first result is the following theorem, which is obtained by combining Cunningham's technique and the binary search technique by Nguyễn [25] and Chakrabarty et al. [5].

▶ **Theorem 1** (Details in Theorem 14). *There is an algorithm that uses $\tilde{O}(kn\sqrt{p})$ independence oracle queries and solves the matroid partitioning problem.*

The independence query complexity of the algorithm given in Theorem 1 improves upon the one of Cunningham's algorithm [7] when k is small. However, when $k = \Theta(n)$, the independence query complexity of the algorithm given in Theorem 1 is $\tilde{O}(n^{5/2})$, and this query complexity is not strictly less than the one in Cunningham's algorithm.

The setting where $k > n$ is unnatural since there must exist a matroid whose independent set is not involved in the optimal partition. Thus, in this paper, we mainly focus on the case where $k \leq n$. Under this assumption, we sometimes bound the number of queries by a function on a single variable n, where we recall that $p \leq n$. This makes it easy to compare the query complexity of different algorithms.

Our second result is to obtain an algorithm that uses $o(kn\sqrt{p})$ independence oracle queries when k is large. It uses $o(n^{5/2})$ independence oracle queries when $k \leq n$.

▶ **Theorem 2** (Details in Theorem 18). *There is an algorithm that uses $\tilde{O}(k^{1/3}np + kn)$ independence oracle queries and solves the matroid partitioning problem.*

This is the main contribution of this paper. The independence query complexity of the algorithm given in Theorem 2 improves the one of the algorithm given in Theorem 1 when $k = \omega(p^{3/4})$. The independence query complexity of the algorithm given in Theorem 2 is $\tilde{O}(n^{7/3})$ when $k \leq n$. This improves the algorithm by Cunningham [7] and our algorithm given in Theorem 1. It should be emphasized here that this is the first improvement since 1986. We note that this algorithm requires $O(k^{2/3}np)$ time complexity other than independence oracle queries.

We also consider the query complexity in the rank oracle model. Note that the rank oracle is at least as powerful as the independence oracle.

▶ **Theorem 3** (Details in the full version of this paper). *There is an algorithm that uses $\tilde{O}((n+k)\sqrt{p})$ rank oracle queries and solves the matroid partitioning problem.*

The rank query complexity of the algorithm given in Theorem 3 is $\tilde{O}(n^{3/2})$ when $k \leq n$.

1.1 Technical Overview

Cunningham's matroid partition algorithm. The auxiliary graph called *exchange graph* plays an important role in almost all combinatorial algorithms for matroid intersection. In matroid intersection algorithms, we begin with an empty set and repeatedly increase the size of the independent set by augmenting along shortest paths in the exchange graph. In the same way, Knuth [20] and Greene-Magnanti [14] give matroid partition algorithms by using the auxiliary graph with $O(np)$ edges, which we call *compressed exchange graph*.

To improve the running time, Cunningham [7] developed *blocking flow* approach for matroid partition and intersection, which is akin to bipartite matching algorithm by Hopcroft-Karp [17]. The blocking flow approach is applied in each phase of the algorithm. In Hopcroft-Karp's bipartite matching algorithm, we find a maximal set of vertex-disjoint shortest paths

and augment along these paths simultaneously. In contrast to this, in a matroid partition algorithm, the augmentations can not be done in parallel, since one augmentation can change the compressed exchange graph. Cunningham showed that we can find multiple augmenting paths of the same length and run all the augmentations in one phase. In Cunningham's matroid partition algorithm, one phase uses only $O(np)$ independence oracle queries (each edge is queried only once in one phase).

Cunningham showed that the number of different lengths of shortest augmenting paths during the algorithm is $O(\sqrt{p})$ and then the number of phases is $O(\sqrt{p})$. Therefore, Cunningham's matroid partition algorithm uses $O(np^{3/2} + kn)$ independence oracle queries in total (enumerating all edges entering sink vertices uses $O(kn)$ independence oracle queries). We note that this query complexity is $O(n^{5/2})$ when $k \leq n$.

Combining blocking flow approach and binary search subroutine. To develop the matroid partition algorithm, given in Theorem 1, that uses $\tilde{O}(kn\sqrt{p})$ independence oracle queries, we combine the blocking flow approach proposed by Cunningham [7] and the binary search procedure proposed by Nguyễn [25] and Chakrabarty et al. [5]. By using the binary search procedure, we obtain an algorithm that uses $\tilde{O}(kn)$ independence oracle queries and performs a breadth first search in the compressed exchange graph. We also obtain an algorithm that uses $\tilde{O}(kn)$ independence oracle queries and runs all the augmentations in a single phase. Since Cunningham showed that the number of phases is $O(\sqrt{p})$, we can easily obtain a matroid partition algorithm that uses $\tilde{O}(kn\sqrt{p})$ independence oracle queries. Our algorithm does not contain technical novelty in a sense that this algorithm is obtained by simply combining Cunningham's technique and the binary search technique by Nguyễn and Chakrabarty et al. Nevertheless, this result is important in a sense that we improve the independence query complexity of a matroid partition algorithm.

Edge Recycling augmentation. In a breadth first search, we need to check, for all vertices v and all indices $i \in [k]$, whether there exists an edge from a vertex v to a vertex $u \in S_i$ in the compressed exchange graph. Then, independence query complexity of a breadth first search of the compressed exchange graph seems to be $\Omega(kn)$, even if we use the binary search procedure. It is not clear whether we can develop a matroid partition algorithm that runs a breadth first search $o(\sqrt{p})$ times, and so, algorithms by the blocking flow approach are now stuck at $\Omega(kn\sqrt{p})$ independence oracle queries. In the setting where $k = \Theta(n)$ and $p = \Theta(n)$, algorithms by the blocking flow approach are stuck at $\Omega(n^{5/2})$ independence oracle queries even if we use the excellent binary search procedure.

In order to break this $O(n^{5/2})$-independence-oracle-query bound, we introduce a new approach *edge recycling augmentation* and develop a matroid partition algorithm whose independence query complexity is sublinear in k. Then we present a matroid partition algorithm that uses $\tilde{O}(n^{7/3})$ independence oracle queries when $k \leq n$.

Our new approach edge recycling augmentation is applied in each phase of the algorithm in the same way as the blocking flow approach. In one phase of edge recycling augmentation, we first compute the edge set E^* in the compressed exchange graph, which uses $O(np)$ independence oracle queries. Then we simply repeat to run a breadth first search and find a shortest path in the compressed exchange graph. This breadth first search is performed by using the information of E^*. The precomputation of E^* may seem too expensive since we have the excellent binary search tool to find edges in the compressed exchange graph. However, we can *recycle* some edges in E^* during the repetition of breadth first searches, which plays an important role in an analysis of our new approach. Note that, edge recycling augmentation runs a breadth first search before every augmentation, while the blocking flow approach runs a breadth first search only once in the beginning of each phase.

Our crucial observation is that all edges entering a vertex in S_i are not changed unless S_i was updated by the augmentation. Then, even after some augmentations, we can use E^* to find edges entering a vertex $u \in S_i$ such that S_i was not updated by the augmentation. This observation is peculiar to the matroid partition. In a breadth first search of the edge recycling augmentation approach, we use the binary search procedure only to find edges entering $u \in S_i$ such that S_i was updated by the augmentation. In one phase, we repeat to run a breadth first search so that the total number of the binary search procedure calls is $O(np)$.

We combine the blocking flow approach algorithm and the edge recycling augmentation approach algorithm. By a careful analysis of independence query complexity, we obtain a matroid partition algorithm that uses $\tilde{O}(k^{1/3}np + kn)$ independence oracle queries.

Note that this edge recycling augmentation approach differs significantly from existing fast matroid intersection algorithms. The key technical contribution of this paper is to introduce this new approach.

1.2 Related Work

Blikstad-Mukhopadhyay-Nanongkai-Tu [3] introduced a new oracle model called dynamic oracle and developed a matroid partitioning algorithm that uses $\tilde{O}((n + r\sqrt{r}) \cdot \mathrm{poly}(k))$ dynamic rank queries, where $r = \max_i \max_{S_i \in \mathcal{I}_i} |S_i|$. Blikstad et al. also obtained an algorithm to solve the k-fold matroid union problem in $\tilde{O}(n\sqrt{r})$ time and dynamic rank queries, which is the special case of the matroid partitioning problem where all matroids $\mathcal{M}_1, \ldots, \mathcal{M}_k$ are identical. Quanrud [27] developed an algorithm that solves the k-fold matroid union problem and uses $\tilde{O}(n^{3/2})$ independence oracle queries for the full range of r and k. Quanrud also considered the k-fold matroid union problem in the more general settings where the elements have integral and real-valued capacities.

For certain special matroids, faster matroid partition algorithms are known. For linear matroids, Cunningham [7] presented an $O(n^3 \log n)$-time algorithm that solves the matroid partitioning problem on $O(n)$ matrices that have n columns and at most n rows. For graphic matroids, the k-forest problem is a special case of the matroid partitioning problem. In the problem, we are given an undirected graph and a positive integer k, and the objective is to find a maximum-size union of k forests. Gabow-Westermann [13] presented an $O(\min\{k^{3/2}\sqrt{nm(m + n\log n)}, k^{1/2}m\sqrt{m + n\log n}, kn^2 \log k, \frac{m^2}{k} \log k\})$-time algorithm to solve the k-forest problem, where n and m denote the number of vertices and edges, respectively. Blikstad et al. [3] and Quanrud [27] independently obtained an $\tilde{O}(m + (kn)^{3/2})$ time algorithm to solve the k-forest problem.

Kawase-Kimura-Makino-Hanna [19] studied matroid partitioning problems for various objective functions.

For the weighted matroid intersection, Huang-Kakimura-Kamiyama [18] developed a technique that transforms any unweighted matroid intersection algorithm into an algorithm that solves the weighted case with an $O(W)$ factor. Huang et al. also presented a $(1 - \epsilon)$ approximation weighted matroid intersection algorithm that uses $\tilde{O}(nr^{3/2}/\epsilon)$ independence oracle queries. Chekuri-Quanrud [6] improved the independence query complexity and presented a $(1 - \epsilon)$ approximation weighted matroid intersection algorithm that uses $O(nr/\epsilon^2)$ independence oracle queries, which can be improved by applying more recent faster approximation unweighted matroid intersection algorithm by Chakrabarty et al. [5] and Blikstad [2]. Tu [29] gave a weighted matroid intersection algorithm that uses $\tilde{O}(nr^{3/4} \log W)$ rank oracle queries, which also uses the binary search procedure proposed by Nguyễn [25] and Chakrabarty et al. [5].

For matroids of rank $n/2$, Harvey [15] showed a lower bound of $(\log_2 3)n - o(n)$ independence oracle queries for matroid intersection. Blikstad-Mukhopadhyay-Nanongkai-Tu [3] showed super-linear $\Omega(n \log n)$ query lower bounds for matroid intersection and partitioning problem in their dynamic-rank-oracle and the independence oracle models.

1.3 Paper Organization

In Section 2, we introduce the notation and the known results for matroid partition and intersection. Next, in Section 3, we present our matroid partition algorithm using blocking flow approach. Then, in Section 4, we present our new approach edge recycling augmentation and our faster matroid partition algorithm for large k. Finally, in Section 5 we conclude by mentioning several open problems relevant to our work.

2 Preliminaries

2.1 Matroids

Notation. For a positive integer a, we denote $[a] = \{1, \ldots, a\}$. For a finite set X, let $\#X$ and $|X|$ denote the cardinality of X, which is also called the *size* of X. We will often write $A+x := A \cup \{x\}$ and $A-x := A \setminus \{x\}$. We will also write $A+B := A \cup B$ and $A-B := A \setminus B$, when no confusion can arise.

Matroid. A pair $\mathcal{M} = (V, \mathcal{I})$ for a finite set V and non-empty $\mathcal{I} \subseteq 2^V$ is called a *matroid* if the following property is satisfied.

(Downward closure) if $S \in \mathcal{I}$ and $S' \subseteq S$, then $S' \in \mathcal{I}$.

(Augmentation property) if $S, S' \in \mathcal{I}$ and $|S'| < |S|$, then there exists $x \in S \setminus S'$ such that $S' + x \in \mathcal{I}$.

A set $S \subseteq V$ is called *independent* if $S \in \mathcal{I}$ and *dependent* otherwise.

Rank. For a matroid $\mathcal{M} = (V, \mathcal{I})$, we define the *rank* of $\mathcal{M}$ as $\mathrm{rank}(\mathcal{M}) = \max\{|S| \mid S \in \mathcal{I}\}$. In addition, for any $S \subseteq V$, we define the *rank* of S as $\mathrm{rank}_{\mathcal{M}}(S) = \max\{|T| \mid T \subseteq S, T \in \mathcal{I}\}$.

Matroid Intersection. Given two matroids $\mathcal{M}' = (V, \mathcal{I}')$, $\mathcal{M}'' = (V, \mathcal{I}'')$, we define their *intersection* by $(V, \mathcal{I}' \cap \mathcal{I}'')$. The *matroid intersection problem* asks us to find the largest common independent set, whose cardinality we denote by r. Note that the intersection of matroids is not a matroid in general and the problem to find a maximum common independent set of more than two matroids is NP-hard.

Matroid Partition (Matroid Union). Given k matroids $\mathcal{M}_1 = (V, \mathcal{I}_1), \ldots, \mathcal{M}_k = (V, \mathcal{I}_k)$, $S \subseteq V$ is called *partitionable* if there exists a partition $(S_1, \ldots, S_k)$ of S such that $S_i \in \mathcal{I}_i$ for $i \in [k]$. The *matroid partitioning problem* asks us to find the largest partitionable set, whose cardinality we denote by p. Let $\tilde{\mathcal{I}}$ be the family of partitionable subset of V. Then, $(V, \tilde{\mathcal{I}})$ is called the *union* or *sum* of k matroids $\mathcal{M}_1 \ldots, \mathcal{M}_k$. Note that Nash-Williams Theorem [24] states that the union $(V, \tilde{\mathcal{I}})$ of the k matroids is also a matroid.

Oracles. Throughout this paper, we assume that we can only access a matroid $\mathcal{M} = (V, \mathcal{I})$ through an oracle. Given a subset $S \subseteq V$, an *independence* oracle outputs whether $S \in \mathcal{I}$ or not. Given a subset $S \subseteq V$, a *rank* oracle outputs $\mathrm{rank}_{\mathcal{M}}(S)$. Since one query of the rank oracle can determine whether a given subset is independent, the rank oracle is more powerful than the independence oracle.

Binary Search Technique. Chakrabarty-Lee-Sidford-Singla-Wong [5] showed that the following procedure can be implemented efficiently by using binary search in the independence oracle model. (This was developed independently by Nguyễn [25].) Given a matroid $\mathcal{M} = (V, \mathcal{I})$, an independent set $S \in \mathcal{I}$, an element $v \in V \setminus S$, and $B \subseteq S$, the objective is to find an element $u \in S$ that is exchangeable with v (that is, $S + v - u \in \mathcal{I}$) or conclude there is no such an element. We skip the proof in this paper; see [5, Section 3] for a proof.

▶ **Lemma 4** (Edge Search via Binary search, Chakrabarty et al. [5], Nguyễn [25]). *There exists an algorithm* `FindOutEdge` *which, given a matroid $\mathcal{M} = (V, \mathcal{I})$, an independent set $S \in \mathcal{I}$, an element $v \in V \setminus S$, and $B \subseteq S$, finds an element $u \in B$ such that $S + v - u \in \mathcal{I}$ or otherwise determine that no such element exists, and uses $O(\log |B|)$ independence queries.*

2.2 Techniques for Matroid Intersection

Here we provide known results about the matroid intersection.

▶ **Definition 5** (Exchange Graph). *Consider a common independent set $S \in \mathcal{I}' \cap \mathcal{I}''$. The* exchange graph *is defined as a directed graph $G(S) = (V \cup \{s, t\}, E)$, with $s, t \notin V$ and $E = E' \cup E'' \cup E_s \cup E_t$, where*

$$\begin{aligned} E' &= \{(u, v) \mid u \in S, v \in V \setminus S, S - u + v \in \mathcal{I}'\}, \\ E'' &= \{(v, u) \mid u \in S, v \in V \setminus S, S - u + v \in \mathcal{I}''\}, \\ E_s &= \{(s, v) \mid v \in V \setminus S, S + v \in \mathcal{I}'\}, \text{ and} \\ E_t &= \{(v, t) \mid v \in V \setminus S, S + v \in \mathcal{I}''\}. \end{aligned}$$

▶ **Lemma 6** (Shortest Augmenting Path). *Let $s, v_1, v_2, \ldots, v_{l-1}, t$ be a shortest (s, t)-path in the exchange graph $G(S)$ relative to a common independent set $S \in \mathcal{I}' \cap \mathcal{I}''$. Then $S' = S + v_1 - v_2 + \cdots - v_{l-2} + v_{l-1} \in \mathcal{I}' \cap \mathcal{I}''$.*

In a matroid intersection algorithm, we begin with an empty set S. Then we repeat to find an augmenting path in the exchange graph $G(S)$ and to update the current set S. If there is no (s, t)-path in the exchange graph $G(S)$, then S is a common independent set of maximum size. If there is an (s, t)-path in the exchange graph $G(S)$, then we pick a shortest path and obtain a common independent set $S' \in \mathcal{I}' \cap \mathcal{I}''$ of $|S| + 1$ elements.

Cunningham's matroid intersection algorithm [7] and recent faster matroid intersection algorithms [2, 4, 5, 25] rely on the following lemma.

▶ **Lemma 7** (Cunningham [7]). *For any two matroids $\mathcal{M}' = (V, \mathcal{I}')$ and $\mathcal{M}'' = (V, \mathcal{I}'')$, if the length of the shortest augmenting path in exchange graph $G(S)$ relative to a common independent set $S \in \mathcal{I}' \cap \mathcal{I}''$ is at least d, then $|S| \geq (1 - \frac{O(1)}{d}) \cdot r$, where r is the size of a largest common independent set.*

Cunningham's [7] matroid intersection algorithm by the blocking flow approach relies on the following monotonicity lemma.

▶ **Lemma 8** (Monotonicity Lemma, [5, 7, 16, 26]). *For any two matroids $\mathcal{M}' = (V, \mathcal{I}')$ and $\mathcal{M}'' = (V, \mathcal{I}'')$, suppose we obtain a common independent set $S' \in \mathcal{I}' \cap \mathcal{I}''$ by augmenting $S \in \mathcal{I}' \cap \mathcal{I}''$ along a shortest augmenting path in $G(S)$. Note that $|S'| > |S|$. Let d denote the distance in $G(S)$ and d' denote the distance in $G(S')$. Then for all $v \in V$,*

- **(i)** *If $d(s, v) < d(s, t)$, then $d'(s, v) \geq d(s, v)$. If $d(v, t) < d(s, t)$, then $d'(v, t) \geq d(v, t)$.*
- **(ii)** *If $d(s, v) \geq d(s, t)$, then $d'(s, v) \geq d(s, t)$. If $d(v, t) \geq d(s, t)$, then $d'(v, t) \geq d(s, t)$.*

2.3 Compressed Exchange Graph for Matroid Partition

The matroid partitioning problem can be solved by a matroid intersection algorithm. Let $\hat{V} = V \times [k]$, and define

$$\hat{\mathcal{I}}' = \{\hat{I} \subseteq \hat{V} \mid \forall v \in V, \#\{i \in [k] \mid (v,i) \in \hat{I}\} \leq 1\},$$
$$\hat{\mathcal{I}}'' = \{\hat{I} \subseteq \hat{V} \mid \forall i \in [k], \{v \in V \mid (v,i) \in \hat{I}\} \in \mathcal{I}_i\}.$$

Then, $\hat{\mathcal{M}}' = (\hat{V}, \hat{\mathcal{I}}')$ is a partition matroid. Since $\hat{\mathcal{M}}'' = (\hat{V}, \hat{\mathcal{I}}'')$ is the direct sum of matroids $(V, \mathcal{I}_i)$ for all $i \in [k]$, it is also a matroid. Then, the family of partitionable subsets of V can be represented as

$$\{S \subseteq V \mid \exists \pi \colon S \to [k], \{(v, \pi(v)) \mid v \in S\} \in \hat{\mathcal{I}}' \cap \hat{\mathcal{I}}''\}.$$

Therefore, we can solve the matroid partitioning problem by computing a common independent set of maximum size in $\mathcal{I}'$ and $\mathcal{I}''$. However, we might use too many independence oracle queries when solving the matroid partitioning problem by using this reduction to the matroid intersection problem. This is due to the following reasons. When solving the matroid intersection problem that was reduced by the matroid partitioning problem, the size of the ground set of that matroid intersection problem is $O(kn)$, and then the number of edges in the exchange graph is $O(knp)$, which depends heavily on k. Furthermore, since we consider the total query complexity of the independence oracle of each matroid $\mathcal{M}_i = (V, \mathcal{I}_i)$ for all $i \in [k]$, the query complexity of the independence query of the matroid $\hat{\mathcal{M}}'' = (\hat{V}, \hat{\mathcal{I}}'')$ also depends heavily on k.

Then, to improve the running time, Knuth [20] and Greene-Magnanti [14] give a matroid partition algorithm that uses the following auxiliary graph with $O(np)$ edges, which we call *compressed exchange graph*.

▶ **Definition 9** (Compressed Exchange Graph [7, 14, 20]). *Consider a partition $(S_1, \ldots, S_k)$ of $S \subseteq V$ such that $S_i \in \mathcal{I}_i$ for all $i \in [k]$. The* compressed exchange graph *is defined as a directed graph $G(S_1, \ldots, S_k) = (V \cup \{s, t_1, \ldots, t_k\}, E)$, with $s, t_1, \ldots, t_k \notin V$ and $E = E' \cup E_s \cup E_t$, where*

$$E' = \{(v,u) \mid \exists i \in [k], u \in S_i, S_i + v \notin \mathcal{I}_i, S_i + v - u \in \mathcal{I}_i\},$$
$$E_s = \{(s,v) \mid v \in V \setminus S\}, \text{ and}$$
$$E_t = \bigcup_{i=1}^{k} \{(v, t_i) \mid v \in V \setminus S_i, S_i + v \in \mathcal{I}_i\}.$$

We set $T = \{t_1, \ldots, t_k\}$.

In the matroid partition algorithm, we begin with an empty set S and initialize $S_i = \emptyset$ for all $i \in [k]$. If there is no vertex in T which is reachable from s in the compressed exchange graph $G(S_1, \ldots, S_k)$, then S is a partitionable set of maximum size. If there is a path from s to T in the compressed exchange graph, then we pick a shortest path $s, v_1, \ldots, v_{l-1}, t_j$. Then we can obtain a partitionable set $S' = S + v_1$ and a partition $(S'_1, \ldots, S'_k)$ of S' such that $S'_i \in \mathcal{I}_i$ for all $i \in [k]$. The validity of the algorithm follows from the following two lemmas, which we use throughout this paper. Cunningham [7] showed these lemmas by using the equivalence of the compressed exchange graph for the matroid partition and the exchange graph for the reduced matroid intersection; see [28, Theorem 42.4] for a direct proof that does not use the reduction to the matroid intersection.

▶ **Lemma 10.** *Given a partition $(S_1, \dots, S_k)$ of S such that $S_i \in \mathcal{I}_i$ for all $i \in [k]$, there exists a partitionable set S' whose size is at least $|S|+1$ if and only if there is a vertex $t_j \in T$ that is reachable from s in the compressed exchange graph $G(S_1, \dots, S_k)$.*

▶ **Lemma 11** (Shortest Augmenting Path)**.** *Let $s, v_1, v_2, \dots, v_{l-1}, t_j$ be a shortest (s,T)-path in the compressed exchange graph $G(S_1, \dots, S_k)$. Then $S' = S + v_1$ is a partitionable set.*

We can construct a partition $(S'_1, \dots, S'_k)$ of S' from a partition $(S_1, \dots, S_k)$ of S and an augmenting path in the compressed exchange graph by using the following procedure `Update` (Algorithm 1).

Algorithm 1 `Update`.

Input: a partition $(S_1, \dots, S_k)$ of S $(\subseteq V)$ such that $S_i \in \mathcal{I}_i$ for all $i \in [k]$. an augmenting path $s, v_1, \dots, v_{l-1}, t_j$.
Output: a partition $(S'_1, \dots, S'_k)$ of S' $(\subseteq V)$ such that $S'_i \in \mathcal{I}_i$ for all $i \in [k]$ and $S' = S + v_1$.

For all $i \in [k]$, set $S'_i \leftarrow S_i$
For all $v \in S$, denote by $\pi(v)$ the index such that $v \in S_{\pi(v)}$
for $i \in [l-2]$ **do**
  $S'_{\pi(v_{i+1})} \leftarrow S'_{\pi(v_{i+1})} + v_i - v_{i+1}$
$S'_j \leftarrow S'_j + v_{l-1}$
return a partition $(S'_1, \dots, S'_k)$ of S'

Cunningham [7] observes that the equivalence between the exchange graph for the matroid intersection of two matroids $\hat{\mathcal{M}}' = (\hat{V}, \hat{\mathcal{I}}')$ and $\hat{\mathcal{M}}'' = (\hat{V}, \hat{\mathcal{I}}'')$ and the compressed exchange graph for the matroid partition of k matroids $(V, \mathcal{I}_1), \dots, (V, \mathcal{I}_k)$ to prove the Lemmas 12 and 13 and to develop an efficient algorithm for matroid partition that employs the blocking flow approach. For a fixed partition $(S_1, \dots, S_k)$ of S and an element $v \in S$, let $\pi(v)$ be the index such that $v \in S_{\pi(v)}$. We also denote by $\hat{S}$ the set $\{(v, \pi(v)) \in \hat{V} \mid v \in S\}$. A path $s, v_1, v_2, \dots, v_{l-1}, t_j$ in the compressed exchange graph for the matroid partition corresponds to a path $s, (v_1, \pi(v_2)), (v_2, \pi(v_2)), (v_2, \pi(v_3)), \dots, (v_{l-1}, \pi(v_{l-1})), (v_{l-1}, j), t$ in the exchange graph for the matroid intersection. Then, for all elements $v \in S$, we have $d_{G(S_1,\dots,S_k)}(s, v) = 1 + \frac{1}{2} d_{G(\hat{S})}(s, (v, \pi(v)))$ and $d_{G(S_1,\dots,S_k)}(v, T) = \frac{1}{2} d_{G(\hat{S})}((v, \pi(v)), t)$. We also have $d_{G(S_1,\dots,S_k)}(s, T) = 1 + \frac{1}{2} d_{G(\hat{S})}(s, t)$.

Cunningham [7] uses the following two lemmas to develop an efficient matroid partition algorithm by using blocking flow approach. These lemmas can be shown from the correspondence between the exchange graph and the compressed exchange graph. We also use these two lemmas in our fast matroid partition algorithms.

▶ **Lemma 12** (Cunningham [7])**.** *Given a partition $(S_1, \dots, S_k)$ of S such that $S_i \in \mathcal{I}_i$ for all $i \in [k]$. If the length of a shortest augmenting path in the compressed exchange graph $G(S_1, \dots, S_k)$ is at least d, then $|S| \geq (1 - \frac{O(1)}{d}) \cdot p$, where p is the size of largest partitionable set.*

▶ **Lemma 13** (Monotonicity Lemma [5, 7, 16, 26])**.** *Suppose we obtain a partition $(S'_1, \dots, S'_k)$ of S' by augmenting a partition $(S_1, \dots, S_k)$ of S along a shortest augmenting path in $G(S_1, \dots, S_k)$. Note that $|S'| > |S|$. let d denote the distance in $G(S_1, \dots, S_k)$ and d' denote the distance in $G(S'_1, \dots, S'_k)$. Then for all $v \in V$,*

(i) *If $d(s,v) < d(s,T)$, then $d'(s,v) \geq d(s,v)$. If $d(v,T) < d(s,T)$, then $d'(v,T) \geq d(v,T)$.*
(ii) *If $d(s,v) \geq d(s,T)$, then $d'(s,v) \geq d(s,T)$. If $d(v,T) \geq d(s,T)$, then $d'(v,T) \geq d(s,T)$.*

As we will see later, we use the binary search technique given in Lemma 4 to find edges in the compressed exchange graph under the independence oracle model. Note that the procedure `FindOutEdge`$(\mathcal{M}_i, S_i, v, B)$ gives us an efficient way to find edges from the vertex v to a vertex $u \in B (\subseteq S_i)$ in the compressed exchange graph.

3 Blocking Flow Algorithm

In this section, we provide our matroid partition algorithms in the independence oracle model, which is obtained by simply combining the *blocking flow* approach proposed by Cunningham [7] and the binary search search procedure proposed by Nguyễn [25] and Chakrabarty-Lee-Sidford-Singla-Wong [5]. In the full version of this paper, we also present a fast matroid partition algorithm using blocking flow approach in the rank oracle model.

3.1 Blocking Flow Algorithm using Independence Oracle

In this subsection we present our matroid partition algorithm using the blocking flow approach in the independence oracle model. We show the following theorem, which implies Theorem 1.

▶ **Theorem 14.** *There is an algorithm that uses $O(kn\sqrt{p}\log p)$ independence oracle queries and solves the matroid partitioning problem.*

This result improves upon the previously known matroid partition algorithm by Cunningham [7] when $k = o(p)$.

For the proof, we first provide the procedure `GetDistanceIndependence` (Algorithm 2) that efficiently finds distances from s to every vertex in the compressed exchange graph. This algorithm simply runs a breadth first search by using the procedure `FindOutEdge`.

Algorithm 2 `GetDistanceIndependence`.

Input: a partition $(S_1, \ldots, S_k)$ of S $(\subseteq V)$ such that $S_i \in \mathcal{I}_i$ for all $i \in [k]$
Output: $d \in \mathbb{R}^{V \cup \{s\} \cup T}$ such that for $v \in V \cup \{s\} \cup T$, d_v is the distance from s to v in $G(S_1, \ldots, S_k)$

$d_s \leftarrow 0$
For all $v \in V \setminus S$ let $d_v \leftarrow 1$
For all $v \in S$ let $d_v \leftarrow \infty$
For all $i \in [k]$ let $d_{t_i} \leftarrow \infty$
$Q \leftarrow \{v \in V \setminus S\}$ // Q : `queue`
For all $i \in [k]$ let $B_i \leftarrow S_i$
while $Q \neq \emptyset$ **do**
  Let v be the element added to Q earliest
  $Q \leftarrow Q - v$
  for $i \in [k]$ *with* $d_{t_i} = \infty$ **do**
    if $v \notin S_i$ *and* $S_i + v \in \mathcal{I}_i$ **then**
      $d_{t_i} \leftarrow d_v + 1$
  for $i \in [k]$ *with* $v \notin S_i$ **do**
    while $u =$ `FindOutEdge`$(\mathcal{M}_i, S_i, v, B_i)$ *satisfies* $u \neq \emptyset$ **do**
      $Q \leftarrow Q + u$
      $d_u \leftarrow d_v + 1$
      $B_i \leftarrow B_i - u$
return d

▶ **Lemma 15** (Breadth First Search using Independence Oracle). *Given a partition $(S_1, \dots, S_k)$ of S $(\subseteq V)$ such that $S_i \in \mathcal{I}_i$ for all $i \in [k]$, the procedure* `GetDistanceIndependence` *(Algorithm 2) outputs $d \in \mathbb{R}^{V \cup \{s\} \cup T}$ such that, for $v \in V \cup \{s\} \cup T$, d_v is the distance from s to v in the compressed exchange graph $G(S_1, \dots, S_k)$. The procedure* `GetDistanceIndependence` *uses $O(kn \log p)$ independence oracle queries.*

Proof. The procedure `GetDistanceIndependence` simply performs a breadth first search in the compressed exchange graph $G(S_1, \dots, S_k)$. Thus, the procedure `GetDistanceIndependence` correctly computes distances from s in $G(S_1, \dots, S_k)$. Note that each vertex $v \in V$ is added to Q at most once and each vertex $v \in S$ is removed from $B_{\pi(v)}$ at most once. Thus, the number of independence oracle queries used in Line 11 is $O(kn)$. The number of `FindOutEdge` calls that do not output $\emptyset$ is $O(p)$, and the number of `FindOutEdge` calls that output $\emptyset$ is $O(kn)$. Hence, by Lemma 4, the number of independence oracle queries used in Line 14 is $O(kn \log p)$, which completes the proof. ◀

Next we provide our augmentation subroutine for our faster matroid partition algorithm. We implement Cunningham's [7] blocking flow approach for matroid partition by using the binary search procedure proposed by Nguyễn [25] and Chakrabarty et al. [5]. This algorithm is similar to Chakrabarty et al.'s matroid intersection algorithm in the rank oracle model [5]. The implementation is described as `BlockFlowIndependence` in the full version of this paper.

In the procedure `BlockFlowIndependence`, given a partition $(S_1, \dots, S_k)$ of S, we first compute the distances from s to every vertex in the compressed exchange graph $G(S_1, \dots, S_k)$ using `GetDistanceIndependence` (Algorithm 2). By using these distances, we divide V into sets $L_1, L_2, \dots$, where each L_i has all vertices v such that the distance from s to v is i in the compressed exchange graph $G(S_1, \dots, S_k)$. Then we search a path $s, a_1, a_2, \dots, a_{d_T-1}, a_{d_T}$ in the compressed exchange graph $G(S_1, \dots, S_k)$, where $a_i \in L_i$ for all $i \in [d_T - 1]$. If we found such a path, we augment a partition $(S_1, \dots, S_k)$ of S and remove a_i from L_i for all $i \in [d_T - 1]$. Then we search a new path again until no (s, T)-path of length d_T can be found. During the search for such a path, if the procedure concludes that some vertex in L_i is not on such a path, then it removes the vertex from L_i. Note that we write $d_T = \min(d_{t_1}, \dots, d_{t_k})$.

▶ **Lemma 16** (Blocking Flow using Independence Oracle). *Given a partition $(S_1, \dots, S_k)$ of S $(\subseteq V)$ such that $S_i \in \mathcal{I}_i$ for all $i \in [k]$, the procedure* `BlockFlowIndependence` *outputs a partition $(S'_1, \dots, S'_k)$ of S' $(\subseteq V)$ such that $S'_i \in \mathcal{I}_i$ for all $i \in [k]$ and $|S'| > |S|$ and $d_{G(S'_1,\dots,S'_k)}(s, T) \geq d_{G(S_1,\dots,S_k)}(s, T) + 1$, or a partition $(S_1, \dots, S_k)$ of S if no such S' exists. The procedure* `BlockFlowIndependence` *uses $O(kn \log p)$ independence oracle queries.*

We provide a proof of Lemma 16 in the full version of this paper.

Now we provide a proof of Theorem 14 by using Lemma 12. In our matroid partition algorithm, we simply apply `BlockFlowIndependence` repeatedly until no (s, T)-path can be found.

Proof of Theorem 14. In our algorithm, we start with $S = \emptyset$ and initialize $S_i = \emptyset$ for all $i \in [k]$. Then we apply `BlockFlowIndependence` repeatedly to augment the current partition $(S_1, \dots, S_k)$ of S until no (s, T)-path can be found in the compressed exchange graph $G(S_1, \dots, S_k)$.

Since each execution of `BlockFlowIndependence` strictly increases $d_{G(S_1,\dots,S_k)}(s, T)$, we have $d_{G(S_1,\dots,S_k)}(s, T) = \Omega(\sqrt{p})$ after $O(\sqrt{p})$ executions of `BlockFlowIndependence`. Lemma 12 implies that, if $d_{G(S_1,\dots,S_k)}(s, T) = \Omega(\sqrt{p})$, then $|S| \geq p - O(\sqrt{p})$. Then the total number of `BlockFlowIndependence` executions is $O(\sqrt{p}) + O(\sqrt{p}) = O(\sqrt{p})$ in the entire matroid partition algorithm. Lemma 16 implies that one execution of `BlockFlowIndependence` uses $O(kn \log p)$ independence oracle queries, which completes the proof. ◀

In the same way as Chakrabarty et al.'s matroid intersection algorithm in the rank oracle model [5], we easily obtain the following theorem.

▶ **Theorem 17.** *For any $\epsilon > 0$, there is an algorithm that uses $O(kn\epsilon^{-1} \log p)$ independence oracle queries and finds a $(1-\epsilon)$ approximation of the largest partitionable set of k matroids.*

Proof. Similar to the proof of Theorem 14, we start with $S = \emptyset$ and initialize $S_i = \emptyset$ for all $i \in [k]$ and apply `BlockFlowIndependence` repeatedly to augment the current partition $(S_1, \ldots, S_k)$ of S. The only difference is that we apply `BlockFlowIndependence` only ϵ^{-1} times, which uses $O(kn\epsilon^{-1} \log p)$ independence oracle queries.

Each execution of `BlockFlowIndependence` strictly increases $d_{G(S_1,\ldots,S_k)}(s,T)$. Thus, after ϵ^{-1} executions of `BlockFlowIndependence`, we have $d_{G(S_1,\ldots,S_k)}(s,T) = \Omega(\epsilon^{-1})$. Lemma 12 implies that, if $d_{G(S_1,\ldots,S_k)}(s,T) = \Omega(\epsilon^{-1})$, then $|S| \geq p - O(p\epsilon)$, which completes the proof. ◀

4 Faster Algorithm for Large k

In this section, we present an algorithm that uses $o(kn\sqrt{p})$ independence oracle queries when k is large. In subsection 3.1, we have presented the algorithm (Algorithm 2), which runs a breadth first search in the compressed exchange graph and uses $O(kn \log p)$ independence oracle queries. In the evaluation of the independence query complexity of the matroid partition algorithm by the *blocking flow* approach given in section 3, a key observation is that the number of different lengths of shortest augmenting paths during the algorithm is $O(\sqrt{p})$. For now, it is not clear whether we can obtain a matroid partition algorithm that runs a breadth first search $o(\sqrt{p})$ times. Then the blocking flow approaches are now stuck at $\Omega(kn\sqrt{p})$ independence oracle queries. To overcome this barrier and improve upon the algorithm that uses $O(kn\sqrt{p} \log p)$ independence oracle queries given in Theorem 14, we introduce a new approach called *edge recycling augmentation*, which can perform breadth first searches with fewer total independence oracle queries. Our new approach can be attained through new ideas: an efficient utilization of the binary search procedure `FindOutEdge` and a careful analysis of the number of independence oracle queries by using Lemma 12. By combining an algorithm by the blocking flow approach and an algorithm by the edge recycling augmentation approach, we obtain the following theorem, which implies Theorem 2.

▶ **Theorem 18.** *There is an algorithm that uses $O(k^{1/3}np \log p + kn)$ independence oracle queries and solves the matroid partitioning problem. When $k \leq n$, the number of queries is $\tilde{O}(n^{7/3})$.*

This theorem implies that we obtain a matroid partition algorithm that uses $o(kn\sqrt{p})$ independence oracle queries when $k = \omega(p^{3/4})$. We note that this algorithm requires $O(k^{2/3}np)$ time complexity other than independence oracle queries.

In Section 4.1, we present our new approach edge recycling augmentation, and in Section 4.2, we present our faster matroid partition algorithm for large k and give a proof of Theorem 18.

4.1 Edge Recycling Augmentation

In order to select appropriate parameters for our algorithm, we have to determine the value of p. However, the size p of a largest partitionable set is unknown before running the algorithm. Instead of using the exact value of p, we use a $\frac{1}{2}$-approximation $\bar{p}$ for p (that is $\bar{p} \leq p \leq 2\bar{p}$), which can be computed using $O(kn)$ independence oracle queries. It is well known that a

$\frac{1}{2}$-approximate solution for the matroid intersection problem can be found by the following simple greedy algorithm; see [21, Proposition 13.26]. We begin with an empty set. For each element in the ground set, we check whether adding it to the set would result in a common independent set. If it does, we add it to the set. Finally, we obtain a maximal common independent set. We convert this algorithm into the following $\frac{1}{2}$-approximation algorithm (Algorithm 3) for the matroid partitioning problem by utilizing the reduction from matroid partition to the intersection of two matroids $\hat{\mathcal{M}}' = (\hat{V}, \hat{\mathcal{I}}')$ and $\hat{\mathcal{M}}'' = (\hat{V}, \hat{\mathcal{I}}'')$ given in subsection 2.3.

Algorithm 3 $\frac{1}{2}$`-ApproximationMatroidPartition`.

```
1 For all i ∈ [k] let S_i ← ∅
2 for i ← 1 to k do
3 |   for v ∈ V \ (⋃_{j=1}^{i-1} S_j) do
4 |   |   if S_i + v ∈ I_i then
5 |   |   |   S_i ← S_i + v
6 return p̄ = |⋃_{i=1}^{k} S_i|
```

Now we present our new approach *Edge Recycling Augmentation*. Our new approach edge recycling augmentation is applied in each phase of the algorithm. One phase of edge recycling augmentation is described as `EdgeRecyclingAugmentation` (Algorithm 5).

In `EdgeRecyclingAugmentation`, we first compute the edges $E^*(\subseteq V \times S)$ in the compressed exchange graph $G(S_1, \ldots, S_k)$, which uses $O(np)$ independence oracle queries. Note that the compressed exchange graph may be changed by augmentations, that is, augmentations may add or delete several edges in the compressed exchange graph, and so, taking one augmenting path may destroy the set E^* of the edges. However, we notice that we can *recycle* some part of the edge set E^* after the augmentations, which is peculiar to the matroid partition.

In `EdgeRecyclingAugmentation`, we simply repeat to run a breadth first search and then to augment the partitionable set. Unlike `GetDistanceIndependence` (Algorithm 2) in Section 3.1, our BFS *recycles* the precomputed edge set E^*. In one phase, we keep a set J of all indices i such that S_i was updated by the augmentations. Our crucial observation is that no edges, in the compressed exchange graph, entering a vertex in S_i are changed by the augmentations unless augmenting paths contain a vertex in $S_i \cup \{t_i\}$. In contrast to `GetDistanceIndependence` that uses the binary search procedure `FindOutEdge` for all indices $i \in [k]$, our new BFS procedure uses `FindOutEdge` only for indices $i \in J$. We can use E^* to search edges entering a vertex in S_i with $i \notin J$. Then, the BFS based on the ideas described above can be implemented as `EdgeRecyclingBFS` (Algorithm 4).

We also provide a new significant analysis of the number of independence oracle queries in entire our matroid partition algorithm. In `EdgeRecyclingAugmentation`, we repeat to run the breadth first search `EdgeRecyclingBFS` so that the total calls of the binary search procedure is $O(np)$. Then, the number of independence oracle queries used by `EdgeRecyclingBFS` in one call of `EdgeRecyclingAugmentation` is almost equal to the one used by the precomputation of E^*. Hence, one call of `EdgeRecyclingAugmentation` uses $\tilde{O}(np)$ independence oracle queries. The number of calls of `EdgeRecyclingBFS` in `EdgeRecyclingAugmentation` depends on how many edges can not be recycled. Thus, to determine the number of calls of `EdgeRecyclingBFS`, we use the value *sum* in the implementation of `EdgeRecyclingAugmentation` (Algorithm 5). In the entire matroid partition

algorithm, we apply `EdgeRecyclingAugmentation` repeatedly. Then, we can obtain a matroid partition algorithm that uses $\tilde{O}(np^{3/2} + kn)$ independence oracle queries. Furthermore, by combining this with the blocking flow approach, the number of total calls of `EdgeRecyclingAugmentation` in the entire matroid partition algorithm can be $O(k^{1/3})$. This leads to obtain a matroid partition algorithm that uses $\tilde{O}(k^{1/3}np + kn)$ independence oracle queries. This analysis differs significantly from that of existing faster matroid intersection algorithms.

For $i \in [k]$, let $F_i (\subseteq V)$ denote the set of vertices adjacent to $t_i \in T$. We first compute the set F_i for all $i \in [k]$ using $O(kn)$ independence oracle queries. Note that, after one augmentation, they can be updated using only $O(n)$ independence oracle queries.

In the following two lemmas, we show the correctness and the independence query complexity of the procedure `EdgeRecyclingAugmentation` (Algorithm 5).

▶ **Lemma 19.** *Given a partition $(S_1, \dots, S_k)$ of $S (\subseteq V)$ such that $S_i \in \mathcal{I}_i$ for all $i \in [k]$, the procedure* `EdgeRecyclingAugmentation` *(Algorithm 5) outputs a partition $(S'_1, \dots, S'_k)$ of $S' (\subseteq V)$ such that $S'_i \in \mathcal{I}_i$ for all $i \in [k]$ and $|S'| \geq |S|$.*

Proof. To prove the correctness of `EdgeRecyclingAugmentation`, we prove the following invariants at the beginning of any iteration of the while loop.

- **(i)** For all $i \in [k] \setminus J$ and all $(v, u) \in V \times S_i$, we have $(v, u) \in E^*$ if and only if $S_i + v - u \in \mathcal{I}_i$ and $S_i + v \notin \mathcal{I}_i$.
- **(ii)** For all $i \in [k]$ and all $v \in V$, we have $v \in F_i$ if and only if $S_i + v \in \mathcal{I}_i$ and $v \notin S_i$.
- **(iii)** For all $i \in [k]$, we have $S_i \in \mathcal{I}_i$.

The invariant is true before the execution of `EdgeRecyclingAugmentation`. Now, assume that the invariants (i)–(iii) hold true at the beginning of an iteration of the while loop. Let a partition $(S_1^{\mathrm{old}}, \dots, S_k^{\mathrm{old}})$ of S^{old} be the partition before the execution of Line 13 and a partition $(S_1^{\mathrm{new}}, \dots, S_k^{\mathrm{new}})$ of S^{new} be the partition after the execution of Line 13. For all $i \in [k] \setminus J$, we have $S_i^{\mathrm{old}} = S_i^{\mathrm{new}}$. Then, invariant (i) remains true. For all $i \in [k] \setminus \{j\}$, we have $|S_i^{\mathrm{old}}| = |S_i^{\mathrm{new}}|$. Hence, for all $i \in [k] \setminus \{j\}$ and all $v \notin S_i^{\mathrm{old}} \cup S_i^{\mathrm{new}}$, we have $S_i^{\mathrm{new}} + v \in \mathcal{I}_i$ if and only if $S_i^{\mathrm{old}} + v \in \mathcal{I}_i$; see [28, Corollary 39.13a] for a proof. Furthermore, for all $i \in [k] \setminus \{j\}$, we have $S_i^{\mathrm{old}} + v \notin \mathcal{I}_i$ for all $v \in S_i^{\mathrm{new}} \setminus S_i^{\mathrm{old}}$ and $S_i^{\mathrm{new}} + v \notin \mathcal{I}_i$ for all $v \in S_i^{\mathrm{old}} \setminus S_i^{\mathrm{new}}$; see [7, Section 5]. Then, invariant (ii) remains true. The procedure `EdgeRecyclingBFS` simply finds a BFS-tree rooted at s by a breadth first search. Thus, if the invariants (i)–(iii) are true, then the procedure `EdgeRecyclingBFS` correctly computes BFS-tree rooted at s. Then, the path P that `EdgeRecyclingBFS` outputs in Line 5 is a shortest augmenting path. Hence, by Lemma 11, invariant (iii) remains true. ◀

▶ **Lemma 20.** *The procedure* `EdgeRecyclingAugmentation` *(Algorithm 5) uses $O(np \log p)$ independence oracle queries.*

Proof of Lemma 20. The number of independence oracle queries used in Line 3 is $O(np)$. Furthermore, the number of independence oracle queries used in Line 14 is $O(np)$, because the number of iterations of the while loop is bounded by p.

Now we show that the number of `FindOutEdge` calls in the entire procedure `EdgeRecyclingAugmentation` is $O(np)$.

In the procedure `EdgeRecyclingBFS`$((S_1, \dots, S_k), E^*, J, \bigcup_{i=1}^k F_i)$, each vertex $v \in V$ is added to Q at most once and each vertex $v \in S$ is removed from $B_{\pi(v)}$ at most once, where $\pi(v)$ is the index such that $v \in S_{\pi(v)}$. This means that the number of `FindOutEdge` calls that do not output $\emptyset$ is bounded by p, and the number of `FindOutEdge` calls that output $\emptyset$ is bounded by $n \cdot |J|$. Then, the number of `FindOutEdge` calls in the procedure `EdgeRecyclingBFS` is $O(p + n \cdot |J|)$.

Algorithm 4 `EdgeRecyclingBFS`.

Input: a partition $(S_1, \ldots, S_k)$ of S $(\subseteq V)$ such that $S_i \in \mathcal{I}_i$ for all $i \in [k]$, a set $E \subseteq V \times S$, a set $J \subseteq [k]$, a set $F = \{v \in V \mid \exists i \in [k], v \notin S_i, S_i + v \in \mathcal{I}_i\}$.
Output: An augmenting (s, T)-path in $G(S_1, \ldots, S_k)$ if one exists.

$Q \leftarrow \{v \in V \setminus S\}$ // Q : `queue`
$B_i \leftarrow S_i$ for all $i \in [k]$
while $Q \neq \emptyset$ **do**
  Let v be the element added to Q earliest
  $Q \leftarrow Q - v$
  if $v \in F$ **then**
    return the shortest augmenting path in the BFS-tree.
  for $i \in J$ **do**
    while $u =$ `FindOutEdge`$(\mathcal{M}_i, S_i, v, B_i)$ *satisfies* $u \neq \emptyset$ **do**
      $Q \leftarrow Q + u$
      $B_i \leftarrow B_i - u$
  for $i \in [k] \setminus J$ **do**
    for $u \in B_i$ *such that* $(v, u) \in E$ **do**
      $Q \leftarrow Q + u$
      $B_i \leftarrow B_i - u$
return NO PATH EXISTS

Algorithm 5 `EdgeRecyclingAugmentation`.

Input: a partition $(S_1, \ldots, S_k)$ of S $(\subseteq V)$ such that $S_i \in \mathcal{I}_i$ for all $i \in [k]$, sets $F_i = \{v \in V \setminus S_i \mid S_i + v \in \mathcal{I}_i\}$ for all $i \in [k]$
Output: a partition $(S'_1, \ldots, S'_k)$ of S' $(\subseteq V)$ such that $S'_i \in \mathcal{I}_i$ for all $i \in [k]$ and $|S'| \geq |S|$.

$sum \leftarrow 0$
$J \leftarrow \emptyset$
$E^* \leftarrow \{(v, u) \in V \times S \mid \exists i \in [k], u \in S_i, S_i + v \notin \mathcal{I}_i, S_i + v - u \in \mathcal{I}_i\}$
while $sum < 2\bar{p}$ **do**
  $P \leftarrow$ `EdgeRecyclingBFS`$((S_1, \ldots, S_k), E^*, J, \bigcup_{i=1}^{k} F_i)$
  if $P =$ NO PATH EXISTS **then**
    break
  For $v \in S$ denote by $\pi(v)$ the index such that $v \in S_{\pi(v)}$
  Denote by $V(P) = \{s, v_1, \ldots, v_{l-1}, t_j\}$ the vertices in the path P
  for $i \leftarrow 2$ **to** $l - 1$ **do**
    $J \leftarrow J + \pi(v_i)$
  $J \leftarrow J + j$
  $(S_1, \ldots, S_k) \leftarrow$ `Update`$((S_1, \ldots, S_k), P)$
  $F_j \leftarrow \{v \in V \mid v \notin S_j$ and $S_j + v \in \mathcal{I}_j\}$
  $sum \leftarrow sum + |J|$
return $(S_1, \ldots, S_k)$

Suppose that the procedure `EdgeRecyclingBFS` is called for $J = J_1, J_2, \ldots, J_c$ in the procedure `EdgeRecyclingAugmentation`. Obivously, $c \leq 2\bar{p} = O(p)$. Furthermore, by the condition of the while loop in `EdgeRecyclingAugmentation`, $\sum_{i=1}^{c} |J_i| = O(p)$. Thus, the number of `FindOutEdge` calls in the entire procedure `EdgeRecyclingAugmentation` is $O\left(\sum_{i=1}^{c}(p + n \cdot |J_i|)\right)$, which is $O(np)$. Hence, by Lemma 4, the number of independence oracle queries by `FindOutEdge` in the entire procedure `EdgeRecyclingAugmentation` is $O(np \log p)$, which completes the proof. ◀

At this point, we can obtain a matroid partition algorithm that uses $O(np^{3/2} \log p + kn)$ independence oracle queries. In the algorithm, we first compute $F_i = \{v \in V \setminus S_i \mid S_i + v \in \mathcal{I}_i\}$ for all $i \in [k]$. Next, we apply `EdgeRecyclingAugmentation` repeatedly to augment the current partition $(S_1, \ldots, S_k)$ of S until no (s, T)-path can be found in the compressed exchange graph $G(S_1, \ldots, S_k)$. As we will show later in Lemma 22, the number of independence oracle queries in this algorithm is $O(np^{3/2} \log p + kn)$. In the next subsection, we improve this by combining the algorithm by the blocking flow approach and the algorithm by the edge recycling augmentation approach.

4.2 Going Faster for Large k by Combining Blocking Flow and Edge Recycling Augmentation

We have already presented two algorithms to solve the matroid partitioning problem in the independence oracle model. We combine the algorithm by the *blocking flow* approach and the one by the *edge recycling augmentation* approach. When the distance from s to T in the compressed exchange graph is small, we use the blocking flow approach. On the other hand, when the distance from s to T in the compressed exchange graph is large, we use the edge recycling augmentation approach. The implementation is described as Algorithm 6. Then we obtain a matroid partitioning algorithm that uses $o(kn\sqrt{p})$ independence oracle queries when $k = \omega(p^{3/4})$. This improves upon the algorithm given in Theorem 14 that uses only the blocking flow approach.

Algorithm 6 Faster Matroid Partition Algorithm for Large k.

1. Compute a $\frac{1}{2}$-approximation $\bar{p}$ for p by running $\frac{1}{2}$-`ApproximationMatroidPartition` (Algorithm 3) and determine the value of d.
2. For all $i \in [k]$ let $S_i \leftarrow \emptyset$
3. Apply `BlockFlowIndependence` repeatedly to augment the current partition $(S_1, \ldots, S_k)$ of S until the distance from s to T in the compressed exchange graph $G(S_1, \ldots, S_k)$ is at least d.
4. For all $i \in [k]$ let $F_i \leftarrow \{v \in V \setminus S_i \mid S_i + v \in \mathcal{I}_i\}$
5. Apply `EdgeRecyclingAugmentation` (Algorithm 5) repeatedly to augment the current partition $(S_1, \ldots, S_k)$ of S and to update F_j with $j \in [k]$ until no (s, T)-path can be found in the compressed exchange graph $G(S_1, \ldots, S_k)$.

The algorithm is parametrized by an integer d which we set in the end. To analyze the independence query complexity of Algorithm 6, we first show that Line 3 uses $\tilde{O}(knd)$ independence oracle queries and Line 5 uses $\tilde{O}\left(\frac{p^{3/2}n}{d^{1/2}}\right)$ independence oracle queries.

▶ **Lemma 21.** *Line 3 of Algorithm 6 uses $O(knd \log p)$ independence oracle queries.*

Proof. Lemma 16 implies that the distance from s to T in the compressed exchange graph increases by at least 1 after the execution of `BlockFlowIndependence`. Consequently, the number of calls of `BlockFlowIndependence` is bounded by d. Furthermore, Lemma 16 implies that the number of independence oracle queries in one call of `BlockFlowIndependence` is $O(kn \log p)$, which completes the proof. ◀

▶ **Lemma 22.** *Line 5 of Algorithm 6 uses* $O\left(\frac{p^{3/2}n}{d^{1/2}} \log p\right)$ *independence oracle queries.*

Proof. Let m denote the number of calls of `EdgeRecyclingAugmentation` in Line 5 of Algorithm 6. By Lemma 20, we only have to show that $m = O\left(\sqrt{\frac{p}{d}}\right)$. For $i \in [m]$, let c_i denote the number of augmenting paths found in the i-th call of `EdgeRecyclingAugmentation`. For $i \in [m-1] \cup \{0\}$, we write $s_i = \sum_{j=i+1}^{m} c_j$.

We first show the following two claims.

▷ Claim 23. There is a positive constant C such that $c_i \geq C\sqrt{s_i}$ for all $i \in [m-1]$.

Proof. Let $i \in [m-1]$. We denote by l_i the length of the augmenting path found in the last `EdgeRecyclingBFS` in the i-th call of `EdgeRecyclingAugmentation`. Lemma 12 implies that $s_i = O\left(\frac{p}{l_i}\right)$. We note that, by Lemma 13, the length of shortest augmenting paths never decreases as the partitionable set size increases.

In the i-th call of `EdgeRecyclingAugmentation`, the sum of the sizes of J is upper bounded by $c_i^2 \cdot l_i$, because the size of J is upper bounded by $c_i \cdot l_i$. Furthermore, by the condition of the while loop in `EdgeRecyclingAugmentation`, the sum of the sizes of J is at least $2\bar{p}(\geq p)$. Thus, we obtain $c_i^2 \cdot l_i \geq p$, and then we have $c_i^2 \geq \frac{p}{l_i}$. Since $s_i = O\left(\frac{p}{l_i}\right)$, we have $\sqrt{s_i} = O(c_i)$, which completes the proof. ◁

▷ Claim 24. For all $i \in [m-1]$, we have $\frac{C}{\sqrt{1+C}} \leq \int_{s_i}^{s_{i-1}} \frac{dx}{\sqrt{x}}$.

Proof. Let $i \in [m-1]$. Since $c_i \geq C\sqrt{s_i}$ by Claim 23, we obtain

$$\begin{aligned}\int_{s_i}^{s_{i-1}} \frac{dx}{\sqrt{x}} = \int_{s_i}^{s_i+c_i} \frac{dx}{\sqrt{x}} &\geq \int_{s_i}^{s_i+C\sqrt{s_i}} \frac{dx}{\sqrt{x}} \geq \int_{s_i}^{s_i+C\sqrt{s_i}} \frac{dx}{\sqrt{s_i+C\sqrt{s_i}}} \\ &= \frac{C\sqrt{s_i}}{\sqrt{s_i+C\sqrt{s_i}}} = \frac{C}{\sqrt{1+C\frac{1}{\sqrt{s_i}}}} \geq \frac{C}{\sqrt{1+C}},\end{aligned}$$

which completes the proof. ◁

By Claim 24, $m-1 = \sum_{i=1}^{m-1} 1 \leq \frac{\sqrt{1+C}}{C} \sum_{i=1}^{m-1} \int_{s_i}^{s_{i-1}} \frac{dx}{\sqrt{x}} = O\left(\int_{s_{m-1}}^{s_0} \frac{dx}{\sqrt{x}}\right) = O\left(\sqrt{s_0}\right)$.

Since Lemma 12 implies that $s_0 = O\left(\frac{p}{d}\right)$, the number of calls of `EdgeRecyclingAugmentation` in Line 5 of Algorithm 6 is $O\left(\sqrt{\frac{p}{d}}\right)$. By Lemma 20, the proof is complete. ◀

In Algorithm 6, we set a parameter d in order to balance the number of independence oracle queries used in Lines 3 and 5. Thus we obtain the following proof.

Proof of Theorem 18. We set $d = \frac{\bar{p}}{k^{2/3}}$ and run Algorithm 6. Then, by Lemmas 21 and 22, the number of independence oracle queries used in Lines 3 and 5 is $O(k^{1/3}np \log p)$. Furthermore, the number of independence oracle queries used in Lines 1 and 4 is $O(kn)$, which completes the proof. ◀

Note that Algorithm 6 requires $O\left(np \cdot \frac{p}{d}\right) = O(k^{2/3}np)$ time complexity other than independence oracle queries. This is because we use the edge set E^* of size np in `EdgeRecyclingBFS` and the number of total `EdgeRecyclingBFS` calls in Algorithm 6 is $O\left(\frac{p}{d}\right)$.

5 Concluding Remarks

By simply combining Cunningham's algorithm [7] and the binary search technique proposed by Nguyễn [25] and Chakrabarty-Lee-Sidford-Singla-Wong [5], we can not break the $O(n^{5/2})$-independence-query bound for the matroid partitioning problem. However, we introduce a new approach *edge recycling augmentation* and break this barrier and obtain an algorithm that $\tilde{O}(n^{7/3})$ independence oracle queries. This result will be a substantial step forward understanding the matroid partitioning problem.

Our key observation is that some edges in the compressed exchange graph will remain the same after an augmentation, and then we need not query again to find them. That is, we can recycle some edges in the compressed exchange graph. This yields a matroid partition algorithm whose independence query complexity is sublinear in k. This idea is quite simple, and we believe that edge recycling augmentation will be useful in the design of algorithms in future.

In a recent breakthrough, Blikstad-van den Brand-Mukhopadhyay-Nanongkai [4] broke the $\tilde{O}(n^2)$-independence-query bound for matroid intersection. Then it is natural to ask whether we can make a similar improvement for the matroid partition algorithm. However, such an improvement is impossible. As one anonymous reviewer pointed out, it is easy to show that the matroid partitioning problem requires $\Omega(kn)$ independence oracle queries, which is $\Omega(n^2)$ when $k = \Theta(n)$.[3] Then, there is a clear difference between these two problems.

We also consider a matroid partition algorithm in the rank oracle model and present a matroid partition algorithm that uses $\tilde{O}(n^{3/2})$ rank oracle queries when $k \leq n$. Blikstad et al. [4] asks whether the tight bounds of the matroid intersection problem are the same under independence oracle model and rank oracle model. The same kind of problem is natural for the matroid partitioning problem. Unlike the matroid intersection problem, we believe there exists a difference between independence oracle and rank oracle in terms of query complexity of the matroid partitioning problem.

[3] Let $M_1, \ldots, M_k$ be matroids of rank 1 defined over a common ground set V of n elements. Now, we construct a bipartite graph $G = (L \cup R, E)$ with $|L| = n$, $|R| = k$ where $(v, i) \in E$ if and only if $\{v\}$ is independent in M_i. Here, the maximum size of a partitionable set is equal to the maximum size of a matching in G. It can be viewed as having edge-query access to this graph G, since it does not make sense to use an independence query to a set of size at least 2. It requires $\Omega(kn)$ edge queries to find the size of a maximum matching; see [30] for details.

Frameworks for Nonclairvoyant Network Design with Deadlines or Delay

Noam Touitou[1]
Amazon, Tel Aviv, Israel

Abstract

Clairvoyant network design with deadlines or delay has been studied extensively, culminating in an $O(\log n)$-competitive general framework, where n is the number of possible request types (Azar and Touitou, FOCS 2020). In the nonclairvoyant setting, the problem becomes much harder, as $\Omega(\sqrt{n})$ lower bounds are known for certain problems (Azar et al., STOC 2017). However, no frameworks are known for the nonclairvoyant setting, and previous work focuses only on specific problems, e.g., multilevel aggregation (Le et al., SODA 2023).

In this paper, we present the first nonclairvoyant frameworks for network design with deadlines or delay. These frameworks are nearly optimal: their competitive ratio is $\tilde{O}(\sqrt{n})$, which matches known lower bounds up to logarithmic factors.

1 Introduction

In network design problems with deadlines, online connectivity requests arrive over time, such that every request must be served by its associated deadline. A solution serves pending requests by transmitting sets of items at various times, thus incurring some cost; the online algorithm constructs the solution by deciding, irrevocably, whether to make a transmission at any given time (and which items to transmit). A concrete example is Steiner tree with deadlines, in which a weighted graph with a designated root node is given offline, and each connectivity request names a terminal node to be connected to the root. Each transmission consists of a set of edges, and serves each pending request if its terminal is connected to the root by the transmitted edges; the cost of the transmission is the total cost of edges. In network design with delay, in lieu of a deadline, every request accumulates delay cost while pending, thus motivating quicker service by the algorithm.

A parameter that influences the difficulty of such problems is called *clairvoyance*. In the clairvoyant model, upon the arrival of a request, the algorithm learns its deadline (in the deadline case) or future delay accumulation (in the delay case). However, in the nonclairvoyant deadline model, the algorithm only learns the deadline of a request upon its expiration (and must then immediately serve the request if pending). Similarly, in the nonclairvoyant delay model, the algorithm is only aware of delay accumulated until the current time.

Various network design problems with deadlines or delay were studied in the clairvoyant setting. This includes problems such as multilevel aggregation [6, 11, 3, 5, 27], facility location [3, 7], TCP Acknowledgement [17, 24, 12] and joint replenishment [13, 10, 8, 16].

[1] This work does not relate to the author's position at Amazon.

For general, clairvoyant network design with deadlines or delay, algorithmic frameworks were presented in [4]. These frameworks yield logarithmic competitiveness with respect to multiple parameters: the number of requests, which we denote m; the number of request *types* (e.g., number of possible terminals for Steiner tree), which we denote n; and the number of items in the item set[2].

The nonclairvoyant setting, however, is less thoroughly studied. Some specific problems of the network design with deadlines/delay class gracefully handle nonclairvoyance; for example, for nonclairvoyant set cover with delay, logarithmic competitiveness is known [1]. Other problems, such as joint replenishment, multilevel aggregation, and facility location with deadlines, have $\Omega(\sqrt{n})$ and $\Omega(\sqrt{m})$ lower bounds on competitiveness in the nonclairvoyant setting, even for randomized algorithms [26][3]. (Note that an earlier, deterministic lower bound along the same lines appears in [2] for the service with delay problem.) Recently, Le et al. [26] presented matching and nearly-matching upper bounds for nonclairvoyant joint replenishment and multilevel aggregation with delay, respectively. However, unlike in the clairvoyant case, a general algorithmic framework for nonclairvoyant network design with deadlines or delay is still not known.

1.1 Our Results

We present the first frameworks for general network design problems with deadlines or delay in the nonclairvoyant setting. Specifically, with n the number of possible request types and m the number of requests, we present:

1. A deterministic, $O\left(\min\left\{\sqrt{n \log n}, \sqrt{m \log m}\right\}\right)$-competitive framework for network design with deadlines.
2. A deterministic, $O\left(\min\left\{\sqrt{n \log n}, \sqrt{m \log m}\right\}\right)$-competitive framework for network design with delay.

The competitiveness of our frameworks is nearly optimal, as implied by the lower bounds of $\Omega(\sqrt{n})$ and $\Omega(\sqrt{m})$ on competitiveness for some network design problems, e.g., multilevel aggregation [26].

While our frameworks provide nearly-optimal upper bounds for nonclairvoyant network design, some components require specific properties to be implemented in polynomial time. In Section 5, we show how to implement the frameworks in polynomial time for a class of network design problems; specifically, those problems that admit *Lagrangian prize-collecting* algorithms. In particular, we obtain the following results:

1. A poly-time, deterministic, $O\left(\min\left\{\sqrt{n \log n}, \sqrt{m \log m}\right\}\right)$-competitive algorithm for Steiner tree with deadlines/delay. Note that for Steiner tree, n equals the number of nodes in the graph.
2. A poly-time, deterministic, $O\left(\sqrt{m \log m}\right)$-competitive algorithm for facility location with deadlines/delay[4].

[2] Note that the bound with respect to the number of request types is implicit in [4].

[3] The lower bound in [26] is stated in terms of joint replenishment; however, joint replenishment can be seen as a special case of multilevel aggregation and facility location, and thus the lower bound applies to those problems as well.

[4] A fine point regarding facility location is that the number of request types n does not yield a meaningful bound, and thus we only state the bound with respect to the number of requests m. This is discussed in more detail in Section 5.

3. A poly-time, deterministic, $O\left(\min\left\{\sqrt{n \log n}, \sqrt{m \log m}\right\}\right)$-competitive algorithm for multicut with deadlines/delay on a tree. Note that for multicut, n equals the number of node pairs in the graph (i.e., quadratic in the number of nodes).

For nonclairvoyant facility location with deadlines/delay, our algorithm is the first algorithm. This is also the case for nonclairvoyant multicut with deadlines or delay. For nonclairvoyant Steiner tree, there existed no *explicit* previous algorithm; however, randomly embedding into an HST [18] then using the multilevel aggregation algorithm of [26] would yield a randomized $O(\sqrt{n} \log n)$-competitive algorithm, with no guarantee in m. Our algorithm for Steiner tree improves the power of the logarithm, is deterministic, and has a guarantee in m.

1.2 Other Related Work

A related problem to network design with deadlines/delay is online service, in which one is given a server (or multiple servers) on a metric space, which must then be moved to locations specified in incoming online requests. In fact, Steiner tree (and multilevel aggregation) with delay can be seen as a special case of this problem, in which the input forces the server to rest at the root node of the given graph (or tree) through an infinite stream of urgent requests at the root. Service with delay was first introduced by Azar et al. [2], and has since seen additional work [9, 3, 20, 25, 21].

The problem of set cover with delay was introduced in [14]; in this problem, the algorithm must transmit sets containing requested elements. While set cover is not usually considered a network design problem, set cover with delay falls within the network design with delay category, and thus the framework of [4] yields a logarithmic-competitive clairvoyant algorithm. As mentioned earlier, this problem also admits a logarithmic-competitive *nonclairvoyant* algorithm, as presented in [1] (and later derandomized in [26]). The best lower bound for this problem, given in [28], is nearly tight given the upper bound for network design implied by the framework in [4].

2 Preliminaries

We now introduce definitions and notation related to network design with deadlines/delay; to make these concrete, we also apply these definitions to the special case of Steiner tree with deadlines/delay.

Offline network design. In offline network design, one is given a set of items $\mathcal{E}$ with associated costs c, and a set of requests H. (In Steiner tree, an input graph is given with a designated root node; the items are the edges of the input graph, and every request demands connecting some terminal to the root.) A request can be served by any chosen subset of items, and we assume that serving requests is *upwards-closed*: that is, if request $h \in H$ is served by a subset of items $E \subseteq \mathcal{E}$, then it is also served by any superset of E. (In Steiner tree, a set of edges satisfies a request if it contains a path connecting the request's terminal to the root; note that satisfaction is indeed upwards-closed.) A solution to the offline problem is a subset of items $E \subseteq \mathcal{E}$ which serves all requests in H; the cost of the solution is the total cost of items in E.

Online network design with deadlines. In online network design with deadlines, one is also given a set of items $\mathcal{E}$ with costs. Now, however, the requests Q arrive over time; we denote by $m := |Q|$ the number of requests in the online input. Each request $q \in Q$ has a *type*, and we

denote the set of all possible request types by $\mathcal{H}$, and define $n := |\mathcal{H}|$; in fact, every request type in the online problem corresponds to a possible request in the offline problem. We denote by r_q the release time of request q, and each request q also has a deadline time d_q by which it must be served. At any point in time, the algorithm may transmit any subset of items $E \subseteq \mathcal{E}$; such a transmission is also called a *service*, and incurs a cost of $c(E) := \sum_{e \in E} c(e)$ for the algorithm. Transmitting E serves all pending requests whose request type is served by E in the offline problem. The goal of the algorithm is to serve every request by its deadline, while minimizing the total cost of services, i.e., $\sum_{\text{service } S} \sum_{e \in E(S)} c(e)$ (where $E(S)$ is the set of items transmitted in S).

For concreteness, consider Steiner tree with deadlines, in which requests for connecting terminals to the root are served by transmitting subsets of edges. As transmissions are momentary, it is meaningful for multiple requests (with different release/deadline times) to request connecting the same terminal v; such requests would belong to the same *request type*, as they would be satisfied by exactly the same subsets of items (i.e., those that contain a path from v to the root). In particular, note that for Steiner tree the number of request types n is equal to the number of nodes in the graph.

Online network design with delay. In the (more general) model with delay, each request q has a nondecreasing, continuous delay function d_q, such that for every $t \geq r_q$ the amount $d_q(t)$ is the total delay cost incurred by q until time t (if it is still pending at that time). The goal of the algorithm in this case is to minimize the total cost of services plus the total delay cost. That is, denoting by C_q the time in which request q is served in the algorithm, the goal is to minimize $\sum_{\text{service } S} \sum_{e \in E(S)} c(e) + \sum_{q \in Q} d_q(C_q)$. For ease of notation, for every set of requests Q' and time t, we define $D(Q', t) := \sum_{q \in Q'} d_q(t)$.

Additional notation. For a request q in online network design with deadlines/delay, we define h_q to be the type of request q. For a set of requests Q', we define $H(Q') \subseteq \mathcal{H}$ to be $\{h_q | q \in Q'\}$. For a set of request types H, we use $\mathrm{ND}(H)$ to denote the minimum cost of serving these request types; slightly abusing notation, for a set of requests Q', we define $\mathrm{ND}(Q') := \mathrm{ND}(H(Q'))$.

For a set of request types H, we define $\ell(H) := \lceil \log \mathrm{ND}(\{H\}) \rceil$. When considering a single request type, we sometimes write $\ell(h)$ instead of $\ell(\{h\})$. Finally, for request q and set of requests Q', we define $\ell(q) := \ell(h_q)$ and $\ell(Q') := \ell(H(Q'))$.

3 Framework for Network Design with Deadlines

In this section, we present a framework for nonclairvoyant network design with deadlines. Analyzing this framework, we obtain the following theorem.

▶ **Theorem 1.** *There exists a deterministic, $O(\min\{\sqrt{n \log n}, \sqrt{m \log m}\})$-competitive algorithm for network design with deadlines.*

Algorithm's description. The algorithm assigns levels to each request according to the logarithm of the cost of serving that request. Upon the deadline of a pending request q, the algorithm starts a service λ that serves the request, thus incurring a cost of at most $2^{\ell(q)}$; the level of the service, denoted ℓ_λ, is defined to be the level of the triggering request q. If a service is *large*, it also serves additional requests; it does so by identifying a set of pending request types which can be served, subject to some specific budget for every request type.

Otherwise, a service is *small*, and does not serve additional requests. Whether a service is large or small is determined by the triggering request q, i.e., the request upon whose deadline the service is started; specifically, the service triggered by the deadline of q will be large if and only if the variable b_q is TRUE at that time.

Specifically, suppose a large service λ takes place. The service will identify the *eligible* requests, i.e., the pending requests whose level is at most ℓ_λ. Denoting by H the set of request types of those eligible requests, the service will give a budget of $\tilde{\Theta}(2^{\ell_\lambda}/\sqrt{|H|})$ to each request type, and will attempt to find a subset of requests that can be served without exceeding the budget for those request types. Thus, the cost of such a large service is at most $\tilde{\Theta}(2^{\ell_\lambda} \cdot \sqrt{|H|})$.

The variable b_q, which controls whether q will trigger a large service, is initially TRUE for every request q. However, if a large service of level at least $\ell(q)$ takes place while q is pending, the variable is set to FALSE. Thus, a request that "experienced" a large service for which it was eligible will never trigger a large service upon its deadline. The formal description of the algorithm is given in Algorithm 1.

Algorithm 1 Nonclairvoyant framework for network design with deadlines.

Event Function UPONREQUEST(q)
  $b_q \leftarrow$ TRUE.
Event Function UPONDEADLINE(q)
  start a new service λ, and set $\ell_\lambda = \ell(q)$.
  define E_λ to be the set of pending requests of level at most ℓ_λ, and define $H \leftarrow H(E_\lambda)$.
  transmit ND($\{h_q\}$), serving all requests of type h_q.
  if b_q **then**
    let $x_\lambda \leftarrow 2^{\ell_\lambda} \cdot \sqrt{\frac{\log(1+|H|)}{|H|}}$.
    let $H' \subseteq H$ be a maximal subset such that ND(H') $\leq x_\lambda \cdot |H'|$.
    transmit ND(H'), serving all requests of types in H'.
    // set $b_{q'}$ for eligible requests q' which are still pending.
    let Q_λ be the subset of requests served by λ.
    foreach $q' \in E_\lambda \setminus Q_\lambda$ **do**
      set $b_{q'} \leftarrow$ FALSE.

3.1 Analysis

We now focus on proving Theorem 1.

▶ **Definition 2.** *We define the following terms:*

1. *We denote by Λ, Λ^* the set of services in the algorithm and in the optimal solution, respectively.*
2. *For a service $\lambda \in \Lambda$, we define Q_λ to be the set of requests served by (the transmissions of) λ. For an optimal service $\lambda^* \in \Lambda^*$, we define Q_{λ^*} in a similar way.*
3. *For a service $\lambda \in \Lambda$, we define $\ell_\lambda, E_\lambda, x_\lambda$ to be the values of the variables of those names in* UPONDEADLINE.
4. *We define $H_\lambda = H(E_\lambda)$. As a shorthand, we define $y_\lambda = |H_\lambda|$.*
5. *We define the* triggering request *of λ, denoted $q^\star_\lambda$, to be the request upon whose deadline λ was initiated.*
6. *We define $c(\lambda)$ to be the total transmission cost incurred in service λ.*

7. *We say that an algorithm service $\lambda \in \Lambda$ is* charged *to an optimal service λ^* if $q^\star_\lambda \in Q_{\lambda^*}$. For every $\lambda^* \in \Lambda^*$, we define $\Lambda_{\lambda^*} \subseteq \Lambda$ to be the set of services charged to λ^*.*
8. *We call a service λ a* large *service if upon the start of λ we have $b_{q^\star_\lambda} =$ True. Otherwise, λ is a* small *service.*
9. *For every service λ in the algorithm or in the optimal solution, denote by t_λ the time in which the service takes place.*

We define k to be the maximum size of $H(E_\lambda)$ over all services λ. In particular, note that $k \leq \min\{n, m\}$, which allows us to prove our competitiveness bounds with respect to k. Fix henceforth any optimal service $\lambda^* \in \Lambda^*$.

▶ **Proposition 3.** *For every $\lambda \in \Lambda_{\lambda^*}$, it holds that $t_\lambda \geq t_{\lambda^*}$.*

Proof. Note that λ is triggered by the deadline of request $q^\star_\lambda$. From the definition of Λ_{λ^*}, we have that $q^\star_\lambda \in Q_{\lambda^*}$; thus, $t_{\lambda^*} \leq d_{q^\star_\lambda} = t_\lambda$. ◀

We partition Λ_{λ^*}, into three parts, the costs of which we bound individually:

- $\Lambda^1_{\lambda^*}$: The large services in Λ_{λ^*}.
- $\Lambda^2_{\lambda^*}$: The small services λ such that $b_{q^\star_\lambda}$ was first set to False at time smaller than t_{λ^*}.
- $\Lambda^3_{\lambda^*}$: The small services λ such that $b_{q^\star_\lambda}$ was first set to False at time at least t_{λ^*}.

▶ **Proposition 4.** *For every level ℓ, there exists at most one level-ℓ service in $\Lambda^1_{\lambda^*}$.*

Proof. Assume otherwise that there exist $\lambda_1, \lambda_2 \in \Lambda_{\lambda^*}$ which are both large, and assume without loss of generality that $t_{\lambda_2} > t_{\lambda_1}$. From the previous claim, we have that $t_{\lambda_1} \geq t_{\lambda^*}$, and thus $q^\star_{\lambda_2}$ is pending at t_{λ_1}. Moreover, as $\ell\left(q^\star_{\lambda_2}\right) = \ell_{\lambda_1} = \ell$, we have that $q^\star_{\lambda_2} \in E_{\lambda_1}$. But Line 13 of λ_1 sets $b_{q^\star_{\lambda_2}}$ to be False, and this value is maintained until λ_2. This is in contradiction to λ_2 being a large service. ◀

▶ **Proposition 5.** *For every ℓ, we have $\sum_{\lambda \in \Lambda^1_{\lambda^*} | \ell_\lambda = \ell} c(\lambda) = O(\sqrt{k \log k}) \cdot 2^\ell$.*

Proof. From Proposition 4, it holds that $\Lambda^1_{\lambda^*}$ contains at most one (large) service of level ℓ, and thus the left-hand side of the equation contains at most one summand. The cost of a large service λ of level ℓ consists of two costs: the first cost is the cost of transmitting $\mathrm{ND}(h_{q^\star_\lambda})$, which is at most 2^ℓ, using the fact that $\ell\left(q^\star_\lambda\right) = \ell$; the second cost is the cost of the transmission in Line 10, which is at most

$$y_\lambda \cdot x_\lambda \leq 2^\ell \cdot \sqrt{y_\lambda \log(1 + y_\lambda)} = O(\sqrt{k \log k}) \cdot 2^\ell$$ ◀

▶ **Proposition 6.** *For every ℓ, we have*

$$\sum_{\lambda \in \Lambda^2_{\lambda^*} | \ell_\lambda = \ell} c(\lambda) = O(\sqrt{k / \log k}) \cdot c(\lambda^*).$$

Proof. Fix any ℓ. We define $\Lambda' := \left\{\lambda \in \Lambda^2_{\lambda^*} | \ell_\lambda = \ell\right\}$ and, as a shorthand, define $z := |\Lambda'|$. We define R to be the set of triggering requests of services in Λ'. First, we claim that the request types of triggering requests of services in Λ' are distinct, i.e., that $|H(R)| = |\Lambda'| = z$. To prove this claim, assume for contradiction that there exist two services in $\lambda_1, \lambda_2 \in \Lambda'$ with triggering requests of the same type, and further assume without loss of generality that $t_{\lambda_1} < t_{\lambda_2}$. Since $q^\star_{\lambda_2} \in Q_{\lambda^*}$, it must be pending at t_{λ^*}; moreover, Proposition 3 implies that $t_{\lambda^*} \leq t_{\lambda_1}$, and thus $q^\star_{\lambda_2}$ is pending at t_{λ_1}. But then λ_1 would serve $q^\star_{\lambda_2}$ in Line 6, in contradiction to $q^\star_{\lambda_2}$ triggering λ_2. Thus, the proof of the claim is complete.

Now, consider the first large service $\lambda \in \Lambda$ after which for every triggering request q of a service in Λ' we have $b_q = \textsc{False}$; it must be that $\ell_\lambda \geq \ell$. From the definition of Λ', it holds that $t_\lambda < t_{\lambda^*}$; combining this with Proposition 3, we have that $t_\lambda < t_{\lambda'}$ for every $\lambda' \in \Lambda'$. In particular, all triggering requests of services from Λ' must be pending at t_λ, and since they are of level ℓ, these requests are also in E_λ. However, they all remain pending after λ, which means that $\mathrm{ND}(H(R)) \geq x_\lambda \cdot |H(R)|$. (Otherwise, we would get a contradiction to the maximality of the set H' defined in Line 9, as $\mathrm{ND}(H(R))$ could be added to the solution without exceeding budget.) We thus have

$$c(\lambda^*) \geq \mathrm{ND}(H(R)) \geq x_\lambda \cdot |H(R)| \geq 2^\ell \cdot \sqrt{\frac{\log(1+k)}{k}} \cdot z \tag{1}$$

where the third inequality uses the fact that $y_\lambda \leq k$. Meanwhile, the total cost of services in Λ' is at most $z \cdot 2^\ell$. Combining with Equation (1) completes the proof. ◀

▶ **Proposition 7.** *For every ℓ, we have $\sum_{\lambda \in \Lambda^3_{\lambda^*} | \ell_\lambda = \ell} c(\lambda) = O(\sqrt{k/\log k}) \cdot c(\lambda^*)$.*

Proof. For ease of notation, define $\Lambda' := \left\{\lambda \in \Lambda^3_{\lambda^*} | \ell_\lambda = \ell\right\}$. We also define R to be the set of triggering requests for requests in Λ'. We define $z := |\Lambda'|$; using an identical argument to that in the proof of Proposition 6, it holds that $|H(R)| = z$. Let λ be the first large service of level at least ℓ such that $t_\lambda \geq t_{\lambda^*}$. Note that the following hold:

1. $t_\lambda < t_{\lambda'}$ for every $\lambda' \in \Lambda'$ (stems from the definition of Λ').
2. R are all pending at t_λ and eligible for λ (as $t_\lambda \geq t_{\lambda^*}$).
3. λ changes b_q from $\textsc{True}$ to $\textsc{False}$ for every $q \in R$.

Since R were all eligible for λ but were not served, it must be the case that $\mathrm{ND}(H(R)) \geq x_\lambda \cdot z \geq 2^\ell \cdot \sqrt{z \log(1+z)}$; since λ^* serves R, it thus holds that $c(\lambda^*) \geq 2^\ell \cdot \sqrt{z \log(1+z)}$. We therefore have $\sum_{\lambda \in \Lambda^3_{\lambda^*} | \ell_\lambda = \ell} c(\lambda) \leq 2^\ell \cdot z \leq \sqrt{z/\log(1+z)} \cdot c(\lambda^*)$. We now note that all requests in R were pending during λ; thus, $z \leq k$, which completes the proof. ◀

Proof of Theorem 1. We first observe that $\mathrm{ALG} = \sum_{\lambda \in \Lambda} c(\lambda) = \sum_{\lambda^* \in \Lambda^*} \sum_{\lambda \in \Lambda_{\lambda^*}} c(\lambda)$. We claim that for every $\lambda^* \in \Lambda^*$, we have $\sum_{\lambda \in \Lambda_{\lambda^*}} c(\lambda) \leq O(\sqrt{k \log k}) \cdot c(\lambda^*)$; since $\mathrm{OPT} = \sum_{\lambda^* \in \Lambda^*} c(\lambda^*)$, proving this claim completes the proof of the theorem.

To prove the claim, fix any optimal service $\lambda^* \in \Lambda^*$, and define $\ell := \lceil \log c(\lambda^*) \rceil$. Note that for every service $\lambda \in \Lambda_{\lambda^*}$ we have $\ell_\lambda \leq \ell$; this is since $q^\star_\lambda$ is served by λ^*, which implies $\mathrm{ND}(q^\star_\lambda) \leq c(\lambda^*)$. We partition Λ_{λ^*} into $\Lambda^1_{\lambda^*}, \Lambda^2_{\lambda^*}, \Lambda^3_{\lambda^*}$ as before, and bound each set separately.

First, we bound the cost of $\Lambda^1_{\lambda^*}$ as follows.

$$\begin{aligned} \sum_{\lambda \in \Lambda^1_{\lambda^*}} c(\lambda) &= \sum_{\ell' \leq \ell} \sum_{\lambda \in \Lambda^1_{\lambda^*} | \ell_\lambda = \ell'} c(\lambda) \leq \sum_{\ell' \leq \ell} O(\sqrt{k \log k}) \cdot 2^{\ell'} \\ &\leq O(\sqrt{k \log k}) \cdot 2^\ell \leq O(\sqrt{k \log k}) \cdot c(\lambda^*) \end{aligned} \tag{2}$$

where the first inequality uses Proposition 5, and the second inequality bounds a geometric series.

Defining $\gamma := \lceil \log k \rceil$, we bound the cost of $\Lambda^2_{\lambda^*}$.

$$\begin{aligned} \sum_{\lambda \in \Lambda^2_{\lambda^*}} c(\lambda) &= \sum_{\lambda \in \Lambda^2_{\lambda^*} | \ell_\lambda \leq \ell - \gamma} c(\lambda) + \sum_{\lambda \in \Lambda^2_{\lambda^*} | \ell - \gamma < \ell_\lambda \leq \ell} c(\lambda) \leq \sum_{\ell' \leq \ell - \gamma} k \cdot 2^{\ell'} + \sum_{\lambda \in \Lambda^2_{\lambda^*} | \ell - \gamma < \ell_\lambda \leq \ell} c(\lambda) \\ &\leq \sum_{\ell' \leq \ell - \gamma} k \cdot 2^{\ell'} + \gamma \cdot O(\sqrt{k/\log k}) \cdot c(\lambda^*) \leq 2 \cdot 2^\ell + \gamma \cdot O(\sqrt{k/\log k}) \cdot c(\lambda^*) \\ &\leq O(\sqrt{k \log k}) \cdot c(\lambda^*) \end{aligned} \tag{3}$$

Here, the first inequality is due to the fact that the total cost of level-ℓ' small services in Λ_{λ^*} cannot exceed $k \cdot 2^{\ell'}$. (As seen in the proof of Proposition 6, the requests of level ℓ' triggering small services are of distinct request types, and are all eligible in a single service λ; thus, their number is at most k.) The second inequality is through using Proposition 6, the third inequality is through the definition of γ and through summing a geometric sequence, and the fourth inequality notes that through the definition of ℓ we have $c(\lambda^*) \geq 2^{\ell-1}$.

Replacing Proposition 6 with Proposition 7, an identical argument to the one used for bounding $\Lambda^2_{\lambda^*}$ can be used for bounding $\Lambda^3_{\lambda^*}$, yielding the following:

$$\sum_{\lambda \in \Lambda^3_{\lambda^*}} c(\lambda) = O(\sqrt{k \log k}) \cdot c(\lambda^*) \tag{4}$$

Combining Equations (2) to (4) yields $\sum_{\lambda \in \Lambda_{\lambda^*}} c(\lambda) \leq O(\sqrt{k \log k}) \cdot c(\lambda^*)$, completing the proof. ◀

4 Framework for Network Design with Delay

In this section, we present a framework for nonclairvoyant network design with delay. Using this framework, we prove the following theorem.

▶ **Theorem 8.** *There exists a deterministic, $O\left(\min\left\{\sqrt{n \log n}, \sqrt{m \log m}\right\}\right)$-competitive algorithm for network design with delay.*

4.1 The Algorithm

We now describe the framework for nonclairvoyant network design with delay. For every time t and set of requests Q' which are pending at t, we say that Q' are *critical* at t if $D(Q', t) \geq \mathrm{ND}(Q')$.

Framework's description. The framework for delay contains many analogues to the deadline framework of Section 3. In the deadline case, a service was triggered upon the deadline of a pending request; in the delay case, the framework initiates a service whenever a set of pending requests becomes "critical", which is when its accumulated delay justifies its service. In the deadline case, whether a service triggered by request q was large is determined by the associated variable b_q. In the delay case, we also maintain the variable b_q for every pending request q.

However, the delay case introduces an additional complication: the triggering set contains multiple requests, and thus multiple values for the variables b_q. Where services for deadlines were either "large" or "small", in the delay case this distinction is no longer binary: services identify a budget for expansive service which depends on the large requests in the triggering set.

The service considers the requests q in its triggering set with $b_q = \textsc{True}$, and finds the largest subset of those requests whose delay is at least a constant fraction of its service cost. This subset is considered "mature" enough to justify expansive service, and its service cost is used as a budget for serving pending requests. Thus, where in deadlines the level of the service was simply the level of the triggering requests, for delay the level depends on the cost of the "mature" subset of large requests.

Algorithm 2 Nonclairvoyant framework for network design with delay.

1 **Event Function** UponRequest(q)
2 $\quad b_q \leftarrow$ True.
3 **Event Function** UponCritical(R) // *called when the delay of some set R exceeds $ND(R)$*
4 $\quad$ Start a new service λ; denote the current time by t.
5 $\quad$ Define $R^\top \leftarrow \{q \in R | b_q = \text{True}\}$.
6 $\quad$ Let $R^\star \subseteq R^\top$ be a maximal subset such that $D(R^\star, t) \geq \frac{\text{ND}(H(R^\star))}{2}$.
7 $\quad$ Define $\ell_\lambda \leftarrow \ell(R^\star)$.
8 $\quad$ Define E to be the set of pending requests of level at most ℓ_λ, and define $H \leftarrow H(E)$.
9 $\quad$ Transmit $\text{ND}(H(R))$, serving all requests of types $H(R)$.
10 $\quad$ Let $x_\lambda \leftarrow 2^{\ell_\lambda} \cdot \sqrt{\frac{\log(1+|H|)}{|H|}}$.
11 $\quad$ Let $H' \subseteq H$ be a maximal subset such that $\text{ND}(H') \leq |H'| \cdot x_\lambda$.
12 $\quad$ Transmit $\text{ND}(H')$, serving all requests of types in H'.
$\quad$ // *set $b_{q'}$ for eligible requests q' which are still pending.*
13 $\quad$ let Q_λ be the subset of pending requests served by λ.
14 $\quad$ **foreach** $q' \in E \setminus Q_\lambda$ **do**
15 $\quad\quad$ set $b_{q'} \leftarrow$ False.

4.2 Analysis

Fix any optimal service $\lambda^* \in \Lambda^*$.

▶ **Definition 9.** *For a service $\lambda \in \Lambda$, define $R_\lambda, R^\top_\lambda, R^\star_\lambda, E_\lambda$ to be the values of the variables $R, R^\top, R^\star, E$ in the call to* UponCritical *which started λ. Moreover, we define $R^\perp_\lambda := R_\lambda \setminus R^\top_\lambda$; these are the requests $q \in R_\lambda$ such that $b_q =$ False at t_λ. In addition, define ℓ_λ, Q_λ as they are defined in the call to* UponCritical.

For a service $\lambda \in \Lambda$ and an optimal service $\lambda^* \in \Lambda^*$, for ease of notation, when referring to a set of jobs related to λ we add λ^* to the subscript to intersect this set with Q_{λ^*}. For example, we define $R_{\lambda,\lambda^*} := R_\lambda \cap Q_{\lambda^*}$, $R^\top_{\lambda,\lambda^*} := R^\top_\lambda \cap Q_{\lambda^*}$, $R^\perp_{\lambda,\lambda^*} := R^\perp_\lambda \cap Q_{\lambda^*}$ and $R^\star_{\lambda,\lambda^*} := R^\star_\lambda \cap Q_{\lambda^*}$. We also define $\ell_{\lambda,\lambda^*} := \ell\left(R^\star_{\lambda,\lambda^*}\right)$.

We define the cost of a service λ, denoted by $c(\lambda)$, to be the total transmission cost in λ, plus the total delay cost of requests served in λ. We define $c(\lambda^*)$ identically for an optimal service $\lambda^* \in \Lambda^*$.

▶ **Proposition 10.** *For a service λ, it holds that*

$$c(\lambda) \leq O(1) \cdot \sum_{\lambda^* \in \Lambda^*} D\left(R^\perp_{\lambda,\lambda^*}, t_\lambda\right) + O(\sqrt{k \log k}) \cdot \sum_{\lambda^* \in \Lambda^*} D\left(R^\star_{\lambda,\lambda^*}, t_\lambda\right)$$

Proof. Since a service is triggered whenever a set of requests becomes critical, the algorithm maintains that for every set Q' of pending requests at any time t we have $D(Q', t) \leq \text{ND}(Q')$. In particular, this holds for the set of requests served by λ with respect to the service time t_λ. Thus, the delay cost of the service can be charged to the transmission costs of the service; we hence focus on bounding the transmission costs of λ.

The service λ performs two transmissions, one at Line 9 and one at Line 12. The first transmission costs $\text{ND}(R_\lambda)$; since R_λ is critical at t_λ, it holds that

$$\text{ND}(R_\lambda) = D(R_\lambda, t_\lambda) = D\left(R^\perp_\lambda, t_\lambda\right) + D\left(R^\top_\lambda \setminus R^\star_\lambda, t_\lambda\right) + D\left(R^\star_\lambda, t_\lambda\right).$$

First, let us bound the delay of requests in $R^\top_\lambda \setminus R^\star_\lambda$. From the choice of $R^\star_\lambda$, it must be the case that $D\big(R^\top_\lambda \setminus R^\star_\lambda, t_\lambda\big) < \frac{\mathrm{ND}(R^\top_\lambda \setminus R^\star_\lambda)}{2}$; assuming otherwise, we would have the following:

$$D\big(R^\top_\lambda, t_\lambda\big) = D\big(R^\star_\lambda, t_\lambda\big) + D\big(R^\top_\lambda \setminus R^\star_\lambda, t_\lambda\big) \geq \frac{\mathrm{ND}(R^\star_\lambda)}{2} + \frac{\mathrm{ND}(R^\top_\lambda \setminus R^\star_\lambda)}{2} \geq \frac{\mathrm{ND}(R^\top_\lambda)}{2},$$

in contradiction to the maximality in the definition of $R^\star_\lambda$; thus, $D\big(R^\top_\lambda \setminus R^\star_\lambda, t_\lambda\big) < \frac{\mathrm{ND}(R^\top_\lambda \setminus R^\star_\lambda)}{2} \leq \frac{\mathrm{ND}(R_\lambda)}{2}$. However, we know that $D(R_\lambda, t_\lambda) = \mathrm{ND}(R_\lambda)$, and therefore conclude that

$$\mathrm{ND}(R_\lambda) \leq 2\big(D\big(R^\perp_\lambda, t_\lambda\big) + D\big(R^\star_\lambda, t_\lambda\big)\big)$$

We have thus bounded the cost of the first transmission.

To bound the cost of the second transmission in λ, let H be the set of pending request types in E_λ. We know that the cost of the second transmission is at most $x_\lambda \cdot |H| = 2^{\ell_\lambda} \cdot \sqrt{|H| \log(1+|H|)}$. Additionally, note that $2^{\ell_\lambda} \leq 2 \cdot \mathrm{ND}(R^\star_\lambda) \leq 4 \cdot D\big(R^\star_\lambda, t_\lambda\big)$, where the second inequality is due to the definition of $R^\star_\lambda$. Overall, the cost of the second transmission is at most $4 \cdot D\big(R^\star_\lambda, t_\lambda\big) \cdot \sqrt{k \log(1+k)}$.

To summarize, we proved that

$$\begin{aligned} c(\lambda) &\leq O(1) \cdot D\big(R^\perp_\lambda, t_\lambda\big) + O(\sqrt{k \log k}) \cdot D\big(R^\star_\lambda, t_\lambda\big) \\ &= O(1) \cdot \sum_{\lambda^* \in \Lambda^*} D\Big(R^\perp_{\lambda,\lambda^*}, t_\lambda\Big) + O(\sqrt{k \log k}) \cdot \sum_{\lambda^* \in \Lambda^*} D\Big(R^\star_{\lambda,\lambda^*}, t_\lambda\Big). \end{aligned}$$ ◀

For every $\lambda \in \Lambda, \lambda^* \in \Lambda^*$ we define the *joint cost* of λ and λ^* as the following.

$$c(\lambda, \lambda^*) := D\Big(R^\perp_{\lambda,\lambda^*}, t_\lambda\Big) + \sqrt{k \log(1+k)} \cdot D\Big(R^\star_{\lambda,\lambda^*}, t_\lambda\Big).$$

Through Proposition 10, we have

$$\mathrm{ALG} \leq O(1) \cdot \sum_{\lambda \in \Lambda} \sum_{\lambda^* \in \Lambda^*} c(\lambda, \lambda^*). \tag{5}$$

We henceforth focus on bounding joint costs.

▶ **Proposition 11.** *For every optimal service $\lambda^* \in \Lambda^*$, it holds that*

$$\sum_{\lambda \in \Lambda | t_\lambda \leq t_{\lambda^*}} c(\lambda, \lambda^*) \leq O(\sqrt{k \log k}) \cdot c(\lambda^*).$$

Proof. For every service $\lambda \in \Lambda$ such that $t_\lambda \leq t_{\lambda^*}$, it holds that

$$c(\lambda, \lambda^*) \leq \sqrt{k \log(1+k)} \cdot D\big(R_{\lambda,\lambda^*}, t_\lambda\big) \leq \sqrt{k \log(1+k)} \cdot D\big(R_{\lambda,\lambda^*}, t_{\lambda^*}\big)$$

Note that every request in Q_{λ^*} is critical in at most one service in the algorithm, as critical requests in a service are always served by that service. Thus, summing over different services, we get the following:

$$\begin{aligned} \sum_{\lambda \in \Lambda | t_\lambda \leq t_{\lambda^*}} c(\lambda, \lambda^*) &\leq \sqrt{k \log(1+k)} \cdot \sum_{\lambda \in \Lambda | t_\lambda \leq t_{\lambda^*}} D\big(R_{\lambda,\lambda^*}, t_{\lambda^*}\big) \\ &\leq \sqrt{k \log(1+k)} \cdot D(Q_{\lambda^*}, t_{\lambda^*}) \leq \sqrt{k \log(1+k)} \cdot c(\lambda^*) \end{aligned}$$ ◀

We thus bounded the joint cost of services prior to λ^*. It remains to bound the joint cost of services at time at least t_{λ^*}.

▶ **Proposition 12.** *For every optimal service λ^*, it holds that*

$$\sum_{\lambda\in\Lambda|t_\lambda>t_{\lambda^*}} D\left(R^\star_{\lambda,\lambda^*},t_\lambda\right) \le O(1)\cdot c(\lambda^*).$$

Proof. Let $\Lambda'\subseteq\Lambda$ be the subset of services that occurred after t_{λ^*}. First, we claim that for every integer ℓ, there exists at most one service in Λ' with $\ell_{\lambda,\lambda^*}=\ell$. To prove the claim, assume for contradiction that there are two services $\lambda_1,\lambda_2\in\Lambda'$ such that $\ell_{\lambda_1,\lambda^*}=\ell_{\lambda_2,\lambda^*}=\ell$, and assume without loss of generality that $t_{\lambda_2}>t_{\lambda_1}>t_{\lambda^*}$. As $t_{\lambda_1}>t_{\lambda^*}$, it must be that all requests in $R^\star_{\lambda_2,\lambda^*}$ were pending before and after t_{λ_1}. Moreover, every request $q\in R^\star_{\lambda_2,\lambda^*}$ must have $\ell(q)\le\ell$, as $\ell=\ell\left(R^\star_{\lambda_2,\lambda^*}\right)\ge\ell(q)$. However, $\ell_{\lambda_1}\ge\ell_{\lambda_1,\lambda^*}=\ell$, and thus $R^\star_{\lambda_2,\lambda^*}\subseteq E_{\lambda_1}$. But, Line 15 in λ_1 sets $b_q=\textsc{False}$ for every $q\in R^\star_{\lambda_2,\lambda^*}$, in contradiction to having $b_q=\textsc{True}$ at t_{λ_2}. We conclude that $R^\star_{\lambda_2,\lambda^*}=\emptyset$; however, this implies that $\ell_{\lambda_2,\lambda^*}=-\infty$, in contradiction to $\ell_{\lambda_2,\lambda^*}=\ell$.

Using this claim, for every level ℓ, there exists at most one service $\lambda\in\Lambda'$ such that $\ell_{\lambda,\lambda^*}=\ell$. For such λ, it holds that $D\left(R^\star_{\lambda,\lambda^*},t_\lambda\right)\le\mathrm{ND}(R^\star_{\lambda,\lambda^*})\le 2^\ell$ (note that delay cannot exceed service cost since critical sets trigger a service). Also note that $\max_{\lambda\in\Lambda'}\ell_{\lambda,\lambda^*}\le\ell(Q_{\lambda^*})$. Summing over the possible levels, we get that

$$\sum_{\lambda\in\Lambda|t_\lambda>t_{\lambda^*}} D\left(R^\star_{\lambda,\lambda^*},t_\lambda\right)\le 2\cdot 2^{\max_{\lambda\in\Lambda'}\ell_{\lambda,\lambda^*}}\le 2\cdot 2^{\ell(Q_{\lambda^*})}\le 4\cdot c(\lambda^*).$$ ◀

At this point, the only missing ingredient for the main theorem is the following lemma.

▶ **Lemma 13.** *For every optimal service $\lambda^*\in\Lambda$, it holds that*

$$\sum_{\lambda\in\Lambda|t_\lambda>t_{\lambda^*}} D\left(R^\perp_{\lambda,\lambda^*},t_\lambda\right)\le O(\sqrt{k\log k})\cdot c(\lambda^*)$$

The proof of Lemma 13 appears in Appendix A; assuming Lemma 13 holds, we proceed to prove Theorem 8.

Proof of Theorem 8. Equation (5) implies that it is enough to bound the sum of joint costs. Fix any optimal service λ^*; we have

$$\begin{aligned}\sum_{\lambda\in\Lambda} c(\lambda,\lambda^*) &= \sum_{\lambda\in\Lambda|t_\lambda<t_{\lambda^*}} c(\lambda,\lambda^*)+\sum_{\lambda\in\Lambda|t_\lambda\ge t_{\lambda^*}} c(\lambda,\lambda^*)\\ &\le O(\sqrt{k\log k})\cdot c(\lambda^*)+\sum_{\lambda\in\Lambda|t_\lambda\ge t_{\lambda^*}}\left(D\left(R^\perp_{\lambda,\lambda^*},t_\lambda\right)+\sqrt{k\log(1+k)}\cdot D\left(R^\star_{\lambda,\lambda^*},t_\lambda\right)\right)\\ &\le O(\sqrt{k\log k})\cdot c(\lambda^*)\end{aligned}$$

where the first inequality uses Proposition 11 and the second inequality uses Proposition 12 and Lemma 13. ◀

5 Polynomial Time through Lagrangian Prize Collecting

While the algorithms in this paper yield proper competitiveness bounds, it is not clear how to implement some of their components in polynomial time. In this section, we focus on a subset of network design problems that admit a *Lagrangian prize-collecting* approximation algorithms, and describe a polynomial-time implementation of the framework. For conciseness, we focus on the delay framework of Section 4; the result for deadlines is a special case of the result for delay.

Considering the framework in Algorithm 2 of Section 4, we note the following components which might take super-polynomial time:

1. The framework for the delay model waits until the delay cost of a subset of pending requests exceeds the cost of serving their request types.
2. The framework solves the offline network design problem optimally, i.e., makes calls to ND (e.g., in Lines 7 and 12).
3. The framework finds a subset of requests whose delay exceeds a constant fraction of their service cost (Line 6).
4. The framework includes a component which, given a penalty x and a set of request types H', finds a maximal subset $H' \subseteq H$ such that $\text{ND}(H') \geq |H'| \cdot x$ (Line 11).

The prize-collecting problem. In the offline network design problems we considered thus far, a valid solution must serve all given requests. However, we now consider a more general model of these problems, which is the *prize-collecting* model. In the (offline) prize-collecting model, in addition to the given connectivity requests H, we are also given a penalty function $\pi : H \to \mathbb{R}^+$; a valid solution in this model can now serve only a subset of the input requests, and pay the penalty for the remaining requests. The total cost of the solution is thus the total service cost plus the total penalty cost; for prize-collecting input (H, π), we use $\text{PCND}(H, \pi)$ to refer to the minimum total cost of a feasible solution to the input. Approximation algorithms are known for many such prize-collecting network design problems; given an approximation algorithm $\widetilde{\text{PCND}}$, we again use $\widetilde{\text{PCND}}(H, \pi)$ to refer to the total cost of $\widetilde{\text{PCND}}$ on the input (H, π). We also use the subscripts b and p to refer to the service and penalty costs of an algorithm, respectively (e.g., $\widetilde{\text{PCND}}_{\text{b}}(H, \pi)$).

To give a polynomial-time implementation to the framework, we require an approximation algorithm for the prize-collecting version of the offline network design problem. In fact, we need a slightly stronger notion of approximation, in which the algorithm's penalty cost is more closely bound to the optimal solution than the service cost; we now define this notion, called *Lagrangian* approximation.

▶ **Definition 14.** *We say that an algorithm for the prize-collecting problem is a Lagrangian γ-approximation if for every prize-collecting input (H, π) it holds that*

$$\widetilde{PCND}_b(H, \pi) + \gamma \cdot \widetilde{PCND}_p(H, \pi) \leq \gamma \cdot PCND(H, \pi).$$

In this section, we present an algorithm which proves the following theorem.

▶ **Theorem 15.** *For an online network design problem with deadlines/delay, whose offline network design prize-collecting problem admits a Lagrangian γ approximation, there exists a poly-time algorithm which achieves the competitiveness of Theorem 8 up to a factor polynomial in γ. Specifically, it achieves a competitive ratio of $O(\gamma^3 \cdot \min\left\{\sqrt{n \log n}, \sqrt{m \log m}\right\})$.*

5.1 Applications

To demonstrate the use of Theorem 15, we apply it to some network design problems for which Lagrangian prize-collecting approximation algorithms are known.

Steiner tree. Goemans and Williamson [19] gave a Lagrangian 2-approximation for the prize-collecting Steiner tree problem. Thus, we obtain the following corollary of Theorem 15.

▶ **Corollary 16.** *There exists an $O(\min\left\{\sqrt{|V| \log |V|}, \sqrt{m \log m}\right\})$-competitive nonclairvoyant algorithm for Steiner tree with deadlines/delay on a graph with vertex set V which runs in polynomial time.*

Facility location. First, we explain the way facility location conforms to the network design setting. The set of items consists of two types: an *opening* item for each location, of the cost of opening a facility at that location; and a *connection* item for each (location, request) pair, of the cost of connecting the request to a facility at the given location. To satisfy a request, there must exist a location for which both the opening item, and the connection item to the request, have been bought; note that the upwards-closed property of network design problems holds. Also note that each request requires a separate connection item; thus, no two requests belong to the same type, and thus $n \geq m$. Hence, we do not state competitiveness in terms of n for this problem.

Charikar et al. [15] gave a Lagrangian 3-approximation for the prize-collecting facility location problem. This implies the following corollary of Theorem 15 for facility location.

▶ **Corollary 17.** *There exists an* $O(\min\left\{\sqrt{m \log m}\right\})$*-competitive algorithm for facility location with deadlines/delay which runs in polynomial time.*

Multicut on a tree. Hou et al. [23] gave a Lagrangian 2-approximation for prize-collecting multicut where the underlying graph is a tree. Note that for multicut on a tree, it holds that n is the number of vertex pairs in the tree, i.e., quadratic in the number of vertices. Thus, we obtain the following corollary of Theorem 15 for multicut on a tree.

▶ **Corollary 18.** *There exists an* $O(\min\left\{|V|\sqrt{\log |V|}, \sqrt{m \log m}\right\})$*-competitive algorithm for multicut with deadlines/delay on a tree with vertices* V *which runs in polynomial time.*

5.2 The Algorithm

Consider a problem which admits a Lagrangian γ-approximation, which we denote by $\widetilde{\text{PCND}}$. As a shorthand, we use $\widetilde{\text{ND}}$ to refer to the offline γ-approximation obtained from using $\widetilde{\text{PCND}}$ with the penalties set to ∞.

The procedure PCSOLVE. The algorithm uses $\widetilde{\text{PCND}}$ in the procedure PCSolve (Algorithm 3), which receives a set of request types $\hat{H}$ and penalties π to those requests, and outputs a subset of request types $H' \subseteq \hat{H}$ and a solution S to H'. We prove the following properties of PCSolve:

1. It holds that the cost of solution S to H' is at most $\gamma\pi(H')$.
2. For every subset $H'' \subseteq \hat{H} \setminus H'$, it holds that $\text{ND}(H'') \geq \pi(H'')$.

These two properties make PCSolve a useful primitive, which is used several times in the algorithm.

Algorithm's Description The algorithm is given in Algorithm 4. The algorithm periodically runs the procedure PCSolve on the set of pending requests, where the penalty of every request type is the total current delay of pending requests of that type. Whenever PCSolve returns a non-empty set of request types H' to serve, the procedure starts the service, and the set of pending requests of types H' is called *critical*. This triggers a call to UponCritical.

Inside UponCritical, as in Algorithm 2, the algorithm chooses the subset of critical requests whose variable b_q is True, and looks for a maximal subset of them whose service cost is at most some factor from their delay cost. However, this factor is now linear in the approximation factor γ rather than a constant. To find this request set $R^\star$, the algorithm makes a call to PCSolve.

Now, the service makes its transmissions. First, it transmits the approximate solution previously calculated for the critical requests, thus serving them. Then, it uses PCSolve to find some subset of the request types of eligible requests to serve in the second transmission; it does so by providing a uniform penalty function to PCSolve. The proof of Theorem 15 using Algorithm 4 appears in Appendix B.

Algorithm 3 Prize-collecting procedure.

Function PCSolve *(H, π)*
  Set $\hat{H} \leftarrow H$.
  Set $S \leftarrow \emptyset$.
  while *True* **do**
    Run PCND($\hat{H}, \pi$) to obtain a solution S' which serves some subset $H' \subseteq \hat{H}$ of request types.
    if $H' = \emptyset$ **then break**
    Set $S \leftarrow S \cup S'$, $\hat{H} \leftarrow \hat{H} \setminus H'$
  return $(S, H \setminus \hat{H})$

Algorithm 4 Polynomial Time Framework for Nonclairvoyant Network Design with Delay.

Event Function UponRequest(q)
  $b_q \leftarrow$ True.
Function TestCritical() *// called continuously*
  Let t be the current time, and let Q' be the set of currently-pending requests.
  Define π which maps from request type $h \in H(Q')$ to $\sum_{q \in Q' | h_q = h} d_q(t)$.
  Call PCSolve(Q', π), and obtain the output (H', S).
  if $H' \neq \emptyset$ **then** define $R \leftarrow \{q \in Q' | h_q \in H'\}$.
  call UponCritical(R, S).
Event Function UponCritical(R, S)
  Start a new service λ; denote the current time by t.
  Define $R^\top \leftarrow \{q \in R | b_q = \text{True}\}$.
  Let π_1 map from request type h to $2\gamma \cdot \sum_{q \in R^\star | h_q = h} d_q(t)$.
  Call PCSolve($H(R^\top), \pi_1$), let $H^\star \subseteq H(R^\top)$ be the request types served by the output, and let S^1 be the returned solution for H'.
  Define $R^\star \leftarrow \{q \in R^\top | h_q \in H^\star\}$
  Define $\hat{\ell}_\lambda \leftarrow \left\lceil \log(c(S^1)) \right\rceil$.
  Define E to be the set of pending requests q such that $\check{\ell}(q) \leq \hat{\ell}_\lambda$, and define $H \leftarrow H(E)$.
  Transmit S, serving all requests of types $H(R)$.
  Let $x_\lambda \leftarrow 2^{\hat{\ell}_\lambda} \cdot \sqrt{\frac{\log(1+|H|)}{|H|}}$.
  Let π_2 map from $h \in H$ to x_λ.
  Call PCSolve(H, π_2); let $H' \subseteq H$ and solution S^2 be the output.
  Transmit S^2, serving all requests of types in H'.
  // Set $b_{q'}$ for eligible requests q' which are still pending.
  Let Q_λ be the subset of pending requests served by λ.
  foreach $q' \in E \setminus Q_\lambda$ **do**
    set $b_{q'} \leftarrow$ False.

6 Conclusions and Future Directions

In this paper, we presented frameworks for obtaining $\tilde{O}(\min\{\sqrt{n}, \sqrt{m}\})$-competitive algorithms for network design with deadlines or delay. For some problems, in particular facility location and multilevel aggregation, lower bounds of $\Omega(\sqrt{k})$ and $\Omega(\sqrt{m})$ exist, making these frameworks optimal up to a logarithmic factor. We then discussed running time, and presented a class of problems (namely those that admit Lagrangian prize-collecting approximations) for which these frameworks can be implemented in polynomial time.

An interesting direction for future work would be to implement this framework in polynomial time for additional problems. This could require a different direction from the one in this paper, as not all network design problems seem amenable to Lagrangian prize-collecting approximations. In particular, for Steiner forest, a Lagrangian prize-collecting approximation implies an approximation of similar ratio for k-Steiner forest; however, no subpolynomial approximation for k-Steiner forest is known (see e.g. [22]).

Additionally, we made little attempt to optimize the dependence of the poly-time framework's competitive ratio on the approximation ratio γ of the Lagrangian approximation algorithm. This is since γ is constant for the problems we consider in this paper. However, improving this dependence could be useful for problems which are harder to approximate; we conjecture that a linear dependence is possible.

A Proof of Lemma 13

Henceforth, fix any optimal service $\lambda^* \in \Lambda^*$. For ease of notation, define $R^\perp := \bigcup_{\lambda \in \Lambda | t_\lambda > t_{\lambda^*}} R^\perp_{\lambda,\lambda^*}$. Also define $\ell^* := c(\lambda^*)$. Note that

$$\sum_{\lambda \in \Lambda | t_\lambda > t_{\lambda^*}} D\left(R^\perp_{\lambda,\lambda^*}, t_\lambda\right) \leq \sum_{\lambda \in \Lambda | t_\lambda > t_{\lambda^*}} \sum_{h \in H(R^\perp_{\lambda,\lambda^*})} \mathrm{ND}(h)$$

We claim that no request type appears twice in the summation on the right-hand side of the above equation. That is, we claim that $\sum_{h \in H(R^\perp)} \mathrm{ND}(h) = \sum_{\lambda \in \Lambda | t_\lambda > t_{\lambda^*}} \sum_{h \in H(R^\perp_{\lambda,\lambda^*})} \mathrm{ND}(h)$. Indeed, note that there cannot be two services $\lambda_1, \lambda_2 \in \Lambda$ such that $t_{\lambda^*} \leq t_{\lambda_1} < t_{\lambda_2}$ and requests $q_1 \in R^\perp_{\lambda_1,\lambda^*}, q_2 \in R^\perp_{\lambda_2,\lambda^*}$ such that $h_{q_1} = h_{q_2}$: otherwise, λ_1 would serve q_2. We conclude that

$$\sum_{\lambda \in \Lambda | t_\lambda > t_{\lambda^*}} D\left(R^\perp_{\lambda,\lambda^*}, t_\lambda\right) \leq \sum_{h \in H(R^\perp)} \mathrm{ND}(h) \tag{6}$$

and it is thus enough to bound $\sum_{h \in H(R^\perp)} \mathrm{ND}(h)$. Note that every request $q \in R^\perp$ has had b_q set to False at some point in the algorithm. Define $R^\perp_1 \subseteq R^\perp$ to be the subset of requests q such that b_q was first set to False prior to t_{λ^*}, and define $R^\perp_2 := R^\perp \setminus R^\perp_1$. For every ℓ, further define $R^\perp_{1,\ell} := \left\{q \in R^\perp_1 \middle| \ell(q) = \ell\right\}$; define $R^\perp_{2,\ell}$ analogously.

▶ **Proposition 19.** *For every optimal service λ^*, and for every ℓ, it holds that*

$$\sum_{h \in H(R^{\perp}_{1,\ell})} ND(h) \leq O\left(\sqrt{k/\log k}\right) \cdot c(\lambda^*).$$

Proof. Observe the first service $\lambda \in \Lambda$ after which $b_q = \text{FALSE}$ for every $q \in R^{\perp}_{1,\ell}$. From the definition of $R^{\perp}_{1,\ell}$, we know that $t_\lambda < t_{\lambda^*}$; as $R^{\perp}_{1,\ell}$ are all served after t_{λ^*}, they are all pending both before and after t_λ. As λ set $b_q \leftarrow \text{FALSE}$ for some $q \in R^{\perp}_{1,\ell}$, we have $\ell_\lambda \geq \ell$. This implies $R^{\perp}_{1,\ell} \subseteq E_\lambda$. Define $z := \left|H(R^{\perp}_{1,\ell})\right|$; since no request from $R^{\perp}_{1,\ell}$ was served in λ, we have

$$c(\lambda^*) \geq \text{ND}(R^{\perp}_{1,\ell}) \geq x_\lambda \cdot z \geq 2^{\ell_\lambda} \cdot \sqrt{\frac{\log(1+k)}{k}} \cdot z \geq 2^{\ell} \cdot \sqrt{\frac{\log(1+k)}{k}} \cdot z$$

Noting that $\sum_{h \in H(R^{\perp}_{1,\ell})} \text{ND}(h) \leq z \cdot 2^{\ell}$, this yields $\sum_{h \in H(R^{\perp}_{1,\ell})} \text{ND}(h) \leq \sqrt{\frac{k}{\log(1+k)}} \cdot c(\lambda^*)$. ◀

▶ **Proposition 20.** *For every optimal service λ^*, and for every ℓ, it holds that*

$$\sum_{h \in H(R^{\perp}_{2,\ell})} ND(h) \leq O\left(\sqrt{\frac{k}{\log k}}\right) \cdot c(\lambda^*).$$

Proof. The proof is similar to that of Proposition 19. Consider the first service $\lambda \in \Lambda$ such that $t_\lambda \geq t_{\lambda^*}$ and $\ell_\lambda \geq \ell$. It must be the case that all requests in $R^{\perp}_{2,\ell}$ are pending before and after λ, and moreover, λ sets $b_q \leftarrow \text{FALSE}$ for every request in $R^{\perp}_{2,\ell}$. Define $z := \left|H(R^{\perp}_{2,\ell})\right|$; since no request from $R^{\perp}_{2,\ell}$ was served in λ, we have

$$c(\lambda^*) \geq \text{ND}(R^{\perp}_{2,\ell}) \geq x_\lambda \cdot z \geq 2^{\ell_\lambda} \cdot \sqrt{\frac{\log(1+k)}{k}} \cdot z \geq 2^{\ell} \cdot \sqrt{\frac{\log(1+k)}{k}} \cdot z$$

Noting that $\sum_{h \in H(R^{\perp}_{2,\ell})} \text{ND}(h) \leq z \cdot 2^{\ell}$, the above yields $\sum_{h \in H(R^{\perp}_{2,\ell})} \text{ND}(h) \leq \sqrt{\frac{k}{\log(1+k)}} \cdot c(\lambda^*)$, which completes the proof. ◀

Proof of Lemma 13. Define $\gamma := \lceil \log k \rceil$. The following holds:

$$\begin{aligned}
&\sum_{\lambda \in \Lambda | t_\lambda > t_{\lambda^*}} D\left(R^{\perp}_{\lambda,\lambda^*}, t_\lambda\right) \leq \sum_{h \in H(R^{\perp})} \text{ND}(h) \leq \sum_{\ell=-\infty}^{\infty} \left(\sum_{h \in H(R^{\perp}_{1,\ell})} \text{ND}(h) + \sum_{h \in H(R^{\perp}_{2,\ell})} \text{ND}(h) \right) \\
&= \sum_{\ell=-\infty}^{\ell^*-\gamma} \left(\sum_{h \in H(R^{\perp}_{1,\ell})} \text{ND}(h) + \sum_{h \in H(R^{\perp}_{2,\ell})} \text{ND}(h) \right) + \sum_{\ell=\ell^*-\gamma+1}^{\ell^*} \left(\sum_{h \in H(R^{\perp}_{1,\ell})} \text{ND}(h) + \sum_{h \in H(R^{\perp}_{2,\ell})} \text{ND}(h) \right)
\end{aligned} \tag{7}$$

where the first inequality uses Equation (6), the second inequality partitions $R^{\perp}$ into $\left\{R^{\perp}_{1,\ell}\right\}_\ell$ and $\left\{R^{\perp}_{2,\ell}\right\}_\ell$, and the equality makes use of the fact that $R^{\perp}$ does not contain requests q such that $\ell(q) > \ell^*$ (since $R^{\perp} \subseteq Q_{\lambda^*}$). From the proof of Proposition 19, we know that for every ℓ the requests $R^{\perp}_{1,\ell}$ were all pending during a single service. Thus, we have $\left|H(R^{\perp}_{1,\ell})\right| \leq k$, and therefore $\sum_{h \in H(R^{\perp}_{1,\ell})} \text{ND}(h) \leq 2^{\ell} \cdot k$. Similarly, using the proof of Proposition 20, we have $\left|H(R^{\perp}_{2,\ell})\right| \leq k$ and thus $\sum_{h \in H(R^{\perp}_{2,\ell})} \text{ND}(h) \leq 2^{\ell} \cdot k$. We can therefore conclude that

$$\sum_{\ell=-\infty}^{\ell^*-\gamma} \left(\sum_{h \in H(R^{\perp}_{1,\ell})} \text{ND}(h) + \sum_{h \in H(R^{\perp}_{2,\ell})} \text{ND}(h) \right) \leq 4 \cdot 2^{\ell^*-\gamma} \cdot k \leq 4 \cdot 2^{\ell^*} \leq 8 \cdot c(\lambda^*). \tag{8}$$

Moreover, using Propositions 19 and 20,

$$\sum_{\ell=\ell^*-\gamma+1}^{\ell^*}\left(\sum_{h\in H(R^{\perp}_{1,\ell})}\mathrm{ND}(h)+\sum_{h\in H(R^{\perp}_{2,\ell})}\mathrm{ND}(h)\right)\leq\gamma\cdot O\left(\sqrt{\frac{k}{\log k}}\right)\cdot c(\lambda^*)=O(\sqrt{k\log k})\cdot c(\lambda^*). \quad (9)$$

Combining Equations (7) to (9) yields $\sum_{\lambda\in\Lambda|t_\lambda>t_{\lambda^*}} D\left(R^{\perp}_{\lambda,\lambda^*},t_\lambda\right)\leq O(\sqrt{k\log k})\cdot c(\lambda^*)$. ◀

B Analysis of Lagrangian Approximation Framework

We focus on proving Theorem 15, following the same lines as the proof of Theorem 8. Following the notation of Section 4, we use the subscript λ to refer to the values of variables in the UponCritical call that started service λ. For example, this includes S^1_λ, S^2_λ.

▶ **Proposition 21** (Properties of PCSolve). *Suppose* PCSolve *is called on request types H and penalties π, and outputs H' and solution S. It holds that:*

1. *The cost of solution S to H' is at most $\gamma\pi(H')$.*
2. *For every subset $H''\subseteq H\backslash H'$, it holds that $ND(H'')\geq\pi(H'')$.*

Proof. Let b be the number of iterations of the main loop in PCSolve. We use subscript i to refer to the value of a variable in the i'th iteration of the loop; note that $c(S)\leq\sum_{i\in[b]}c(S_i)$. For every iteration i, through the Lagrangian approximation guarantee, it holds that $c(S_i)+\gamma\cdot\pi(\hat{H}_i\backslash H'_i)\leq\gamma\cdot\pi(\hat{H}_i)$, implying $c(S_i)\leq\gamma\cdot\pi(H'_i)$; thus, we have $c(S)\leq\sum_i\pi(H'_i)=\gamma\pi(H')$, proving the first claim.

To prove the second claim, observe that in the final iteration no request types from $\hat{H}_b$ were served. Through the Lagrangian guarantee, $\gamma\pi(\hat{H}_b)\leq\gamma\cdot(\mathrm{ND}(H'')+\pi(\hat{H}_b\backslash H''))$ for every subset $H''\subseteq\hat{H}_b$, which implies that $\mathrm{ND}(H'')\geq\pi(H'')$. Observing that $\hat{H}_b=H\backslash H'$ completes the proof of the second claim. ◀

▶ **Proposition 22** (Analogue of Proposition 10). *For a service λ, it holds that*

$$c(\lambda)\leq O(\gamma)\cdot\sum_{\lambda^*\in\Lambda^*}D\left(R^{\perp}_{\lambda,\lambda^*},t_\lambda\right)+O(\gamma^3\sqrt{k\log k})\cdot\sum_{\lambda^*\in\Lambda^*}D\left(R^{\star}_{\lambda,\lambda^*},t_\lambda\right)$$

Proof. According to Proposition 21, the cost of the first transmission of solution S_λ (Line 17) is at most $\gamma\cdot D(R_\lambda,t_\lambda)$. However, Proposition 21 also implies that $2\gamma D\left(R^{\top}_\lambda\backslash R^{\star}_\lambda,t_\lambda\right)\leq\mathrm{ND}(R^{\top}_\lambda\backslash R^{\star}_\lambda)$; together with the fact that S_λ serves $R^{\top}_\lambda\backslash R^{\star}_\lambda$ implies that $\gamma D\left(R^{\top}_\lambda\backslash R^{\star}_\lambda,t_\lambda\right)\leq c(S_\lambda)/2$. Combining, we have the following:

$$c(S_\lambda)\leq\gamma D(R_\lambda,t_\lambda)=\gamma(D\left(R^{\perp}_\lambda,t_\lambda\right)+D\left(R^{\star}_\lambda,t_\lambda\right))+c(S_\lambda)/2$$

Simplifying, $c(S_\lambda)\leq 2\gamma(D\left(R^{\perp}_\lambda,t_\lambda\right)+D\left(R^{\star}_\lambda,t_\lambda\right))$, yielding the bound for the first transmission.

For the second transmission, note that $2^{\hat{\ell}_\lambda}\leq 2\cdot c\left(S^1_\lambda\right)\leq 4\gamma^2 D(R^\star,t_\lambda)$, where the second inequality uses Proposition 21 for PCSolve. Applying Proposition 21 again for Line 20, we obtain the following bound for the cost of the solution S^2_λ used for the second transmission:

$$\begin{aligned}c\left(S^2_\lambda\right)&\leq\gamma\cdot|H_\lambda|\cdot x_\lambda=\gamma\cdot|H_\lambda|\cdot 2^{\hat{\ell}_\lambda}\cdot\sqrt{\log(1+|H_\lambda|)/|H_\lambda|}\leq\gamma\sqrt{k\log(1+k)}\cdot 2^{\hat{\ell}_\lambda}\\&\leq 4\gamma^3\cdot\sqrt{k\log(1+k)}\cdot D\left(R^\star,t_\lambda\right)\end{aligned}$$

Combining this with the previous bound for the first transmission completes the proof. ◀

We henceforth define joint costs $c(\lambda, \lambda^*)$ as in Section 4. Note that Proposition 10 holds for Algorithm 4 without modification.

▶ **Proposition 23** (Analogue of Proposition 12). *For every optimal service λ^*, it holds that*

$$\sum_{\lambda \in \Lambda | t_\lambda > t_{\lambda^*}} D\left(R^\star_{\lambda,\lambda^*}, t_\lambda\right) \leq O(1) \cdot c(\lambda^*).$$

Proof. Let $\Lambda' \subseteq \Lambda$ be the subset of services that occurred after t_{λ^*}. First, we claim that for every integer ℓ, there exists at most one service in Λ' with $\ell_{\lambda,\lambda^*} = \ell$. To prove the claim, assume for contradiction that there are two services $\lambda_1, \lambda_2 \in \Lambda'$ such that $\ell_{\lambda_1,\lambda^*} = \ell_{\lambda_2,\lambda^*} = \ell$, and assume without loss of generality that $t_{\lambda_2} > t_{\lambda_1} > t_{\lambda^*}$. As $t_{\lambda_1} > t_{\lambda^*}$, it must be that all requests in $R^\star_{\lambda_2,\lambda^*}$ were pending before and after t_{λ_1}.

Moreover, every request $q \in R^\star_{\lambda_2,\lambda^*}$ must have $\check{\ell}(q) \leq \ell(q) \leq \ell\left(R^\star_{\lambda_2,\lambda^*}\right) = \ell$. However, $\hat{\ell}_{\lambda_1} \geq \ell_{\lambda_1,\lambda^*} = \ell$, and thus $R^\star_{\lambda_2,\lambda^*} \subseteq E_{\lambda_1}$. But, Line 15 in λ_1 sets $b_q = \textsc{False}$ for every $q \in R^\star_{\lambda_2,\lambda^*}$, in contradiction to having $b_q = \textsc{True}$ at t_{λ_2}. We conclude that $R^\star_{\lambda_2,\lambda^*} = \emptyset$; however, this implies that $\ell_{\lambda_2,\lambda^*} = -\infty$, in contradiction to $\ell_{\lambda_2,\lambda^*} = \ell$.

Using this claim, for every level ℓ, there exists at most one service $\lambda \in \Lambda'$ such that $\ell_{\lambda,\lambda^*} = \ell$. For such λ, it holds that $D\left(R^\star_{\lambda,\lambda^*}, t_\lambda\right) \leq \mathrm{ND}(R^\star_{\lambda,\lambda^*}) \leq 2^\ell$. Also note that $\max_{\lambda \in \Lambda'} \ell_{\lambda,\lambda^*} \leq \ell(Q_{\lambda^*})$. Summing over the possible levels, we get that

$$\sum_{\lambda \in \Lambda | t_\lambda > t_{\lambda^*}} D\left(R^\star_{\lambda,\lambda^*}, t_\lambda\right) \leq 2 \cdot 2^{\max_{\lambda \in \Lambda'} \ell_{\lambda,\lambda^*}} \leq 2 \cdot 2^{\ell(Q_{\lambda^*})} \leq 4 \cdot c(\lambda^*). \qquad \blacktriangleleft$$

▶ **Lemma 24** (Analogue of Lemma 13). *For every optimal service $\lambda^* \in \Lambda$, it holds that $\sum_{\lambda \in \Lambda | t_\lambda > t_{\lambda^*}} D\left(R^\perp_{\lambda,\lambda^*}, t_\lambda\right) \leq O(\log\gamma \cdot \sqrt{k \log k}) \cdot c(\lambda^*)$.*

Proof sketch. The proof follows the same main lines as that of Lemma 13. First, define $R^\perp, R^\perp_1, R^\perp_2$ as in the proof of Lemma 13. Now, define $R^\perp_{1,\ell} = \left\{q \in R^\perp_1 | \hat{\ell}_q = \ell\right\}$; define $R^\perp_{2,\ell}$ analogously. Note that the $\hat{\ell}_q$ is used for these definitions, rather than ℓ_q.

We can prove analogues to Proposition 19 and Proposition 20, using identical proofs. Specifically, for every optimal service λ^*, for every ℓ and for every $b \in \{1, 2\}$, it holds that

$$\sum_{h \in H(R^\perp_{b,\ell})} \mathrm{ND}(h) \leq O\left(\sqrt{k/\log k}\right) \cdot c(\lambda^*) \tag{10}$$

Now, following the proof of Lemma 13, define $\delta := \lceil \log k \rceil + \lceil \log \gamma \rceil$.

$$\begin{aligned}\sum_{\lambda \in \Lambda | t_\lambda > t_{\lambda^*}} D\left(R^\perp_{\lambda,\lambda^*}, t_\lambda\right) &\leq \sum_{h \in H(R^\perp)} \mathrm{ND}(h) \leq \sum_{\ell=-\infty}^{\infty} \left(\sum_{h \in H(R^\perp_{1,\ell})} \mathrm{ND}(h) + \sum_{h \in H(R^\perp_{2,\ell})} \mathrm{ND}(h) \right) \\ &= \sum_{\ell=-\infty}^{\ell^*-\delta} \left(\sum_{h \in H(R^\perp_{1,\ell})} \mathrm{ND}(h) + \sum_{h \in H(R^\perp_{2,\ell})} \mathrm{ND}(h) \right) + \sum_{\ell=\ell^*-\delta+1}^{\ell^*} \left(\sum_{h \in H(R^\perp_{1,\ell})} \mathrm{ND}(h) + \sum_{h \in H(R^\perp_{2,\ell})} \mathrm{ND}(h) \right)\end{aligned} \tag{11}$$

Using a similar argument to that in Lemma 13, we note that $\sum_{h \in H(R^\perp_{1,\ell})} \mathrm{ND}(h) \leq k \cdot \gamma \cdot 2^\ell$; a similar bound applies to $\sum_{h \in H(R^\perp_{2,\ell})} \mathrm{ND}(h)$. Combining with the definition of δ, the first term in the RHS of Equation (11) can be bounded by $O(1) \cdot c(\lambda^*)$. Using Equation (10), the second term can be bounded by $O(\delta) \cdot c(\lambda^*)$, which is $O((\log k + \log \gamma) \cdot \sqrt{k/\log k}) \cdot c(\lambda^*)$; this is at most $O(\log\gamma \cdot \sqrt{k \log k}) \cdot c(\lambda^*)$. This completes the proof. ◀

Proof of Theorem 15. Results from combining Propositions 22 and 23 and Lemma 24. ◀

Tight Bounds for Chordal/Interval Vertex Deletion Parameterized by Treewidth

Michał Włodarczyk
Ben-Gurion University, Beer Sheva, Israel

Abstract

In Chordal/Interval Vertex Deletion we ask how many vertices one needs to remove from a graph to make it chordal (respectively: interval). We study these problems under the parameterization by treewidth **tw** of the input graph G. On the one hand, we present an algorithm for Chordal Vertex Deletion with running time $2^{\mathcal{O}(\mathbf{tw})} \cdot |V(G)|$, improving upon the running time $2^{\mathcal{O}(\mathbf{tw}^2)} \cdot |V(G)|^{\mathcal{O}(1)}$ by Jansen, de Kroon, and Włodarczyk (STOC'21). When a tree decomposition of width **tw** is given, then the base of the exponent equals $2^{\omega-1} \cdot 3 + 1$. Our algorithm is based on a novel link between chordal graphs and graphic matroids, which allows us to employ the framework of representative families. On the other hand, we prove that the known $2^{\mathcal{O}(\mathbf{tw} \log \mathbf{tw})} \cdot |V(G)|$-time algorithm for Interval Vertex Deletion cannot be improved assuming Exponential Time Hypothesis.

1 Introduction

Treewidth [32, §7] is arguably the most extensively studied width measure in the graph theory. Simply speaking, treewidth measures to what extent a graph is similar to a tree, where trees and forests are exactly the graphs of treewidth 1. It plays a crucial role in Robertson and Seymour's Graph Minors series [62]. The usefulness of treewidth stems from the fact that a broad class of problems can be solved in linear time on graphs of bounded treewidth. The celebrated Courcelle's Theorem [30] states that any graph problem expressible in the Counting Monadic Second Order Logic (CMSO) can be solved in time $f(\mathbf{tw}) \cdot |V(G)|$, where **tw** denotes the treewidth of graph G and f is some computable function. In other words, every such problem is fixed-parameter tractable (FPT) when parameterized by treewidth. Furthermore, bounded-treewidth graphs appear in a wide variety of contexts, which makes treewidth-based algorithms a ubiquitous tool in algorithm design [36, 47, 56, 57, 61]. The function f from Courcelle's Theorem may grow very rapidly and a large body of research has been devoted to optimize the dependency on **tw** for particular problems. In the ideal scenario, we would like the function f to be single-exponential, i.e., $f(\mathbf{tw}) = 2^{\mathcal{O}(\mathbf{tw})}$, while possibly allowing a higher (yet constant) exponent at $|V(G)|$. This is often the best we can hope for because sub-exponential running times usually contradict the Exponential Time Hypothesis[1] (ETH) [42].

[1] The Exponential Time Hypothesis states that there exists a constant $\delta > 0$ so that 3-SAT cannot be solved in time $\mathcal{O}(2^{\delta n})$ on n-variable formulas.

While the standard dynamic programming technique yields single-exponential algorithms for problems with "local constraints", such as Vertex Cover, Dominating Set, or Bipartization, it falls short for problems with "connectivity constraints", such as Feedback Vertex Set, Hamiltonian Cycle, or Connected Vertex Cover, leading to parameter dependency $f(\mathbf{tw}) = 2^{\mathcal{O}(\mathbf{tw}\log\mathbf{tw})}$. On the one hand, this issue was dealt with in the landmark work of Cygan et al. [35], who introduced the Cut & Count technique and obtained randomized single-exponential algorithms for the problems above, among others (see also [59]). In following works, Bodlaender et al. [19] and Fomin et al. [38] presented alternative techniques that allow to circumvent randomization: matrix-based approaches and representative families. On the other hand, Lokshtanov et al. [54] provided a framework for proving "slightly super-exponential" lower bounds under ETH, which paved the way for establishing tight lower bounds for problems that require dependency $f(\mathbf{tw}) = 2^{\mathcal{O}(\mathbf{tw}\log\mathbf{tw})}$. In the same work, they obtained such bounds for Disjoint Paths and Chromatic Number. For problems with a single-exponential dependency $f(\mathbf{tw}) = \mathcal{O}(c^{\mathbf{tw}})$, further research has been devoted to establish the optimal base of the exponent c [31, 33, 35, 53, 67].

Vertex-deletion problems. Many optimization graph problems can be phrased in terms of $\mathcal{H}$-Vertex Deletion: remove the smallest number of vertices from a graph so that the resulting graph belongs to the graph class $\mathcal{H}$. For example, Vertex Cover corresponds to the class $\mathcal{H}$ of edge-less graphs. There is a diverse complexity landscape of ETH-tight running times for various vertex-deletion problems under treewidth parameterization. The classes $\mathcal{H}$ for which tight bounds have been established include: edge-less graphs [53], forests [35] (see also [15]), planar graphs [47, 58], classes defined by a connected forbidden minor [9] (see also [10, 11, 12]), bipartite graphs [53], DAGs [22], even-cycle-free graphs [15, 44], and some classes defined by a forbidden (induced) subgraph [34, 65].

We extend this list by studying the vertex-deletion problems into the classes of chordal and interval graphs. A graph is chordal if it does not contain an induced cycle of length at least 4 (a hole) and a graph is interval if it is an intersection graph of intervals on the real line. Any interval graph is chordal and any chordal graph is perfect. Applications of these two graph classes have been long studied in miscellaneous areas of discrete optimization [8, 14, 25, 50, 60, 63]. On the theoretical side, the treewidth (resp. pathwidth) of a graph G equals the minimum clique number of a chordal (resp. interval) supergraph of G [32, 52]. Moreover, some hard problems become tractable on chordal or interval graphs (or even on graphs with small vertex-deletion distance to chordality) [26, 43, 49].

Our results. The state of the art for Chordal Vertex Deletion (ChVD) is the running time $2^{\mathcal{O}(\mathbf{tw}^2)}n^{\mathcal{O}(1)}$, which follows from a more general result for a hybrid graph measure $\mathcal{H}$-treewidth, where $\mathcal{H} = \texttt{chordal}$ [45]. We improve the dependency on treewidth to single-exponential.

▶ **Theorem 1.1.** *Chordal Vertex Deletion can be solved in deterministic time $\mathcal{O}(c^k k^{\omega+1} n)$ on n-vertex node-weighted graphs when a tree decomposition of width k is provided. The constant c equals $2^{\omega-1}\cdot 3 + 1$.*

Here, $\omega < 2.373$ stands for the matrix multiplication exponent [7]. To prove Theorem 1.1 we establish a new link between chordal graphs and graphic matroids, which allows us to exploit the framework of representative families [37, 38]. ChVD is at least as hard as Feedback Vertex Set, what implies barriers for a significant improvement in the constant c (see Lemma 4.1 and the discussion therein). Thanks to a single-exponential constant-factor FPT approximation for treewidth [20], Theorem 1.1 gives running time $2^{\mathcal{O}(\mathbf{tw})}n$ even when no tree decomposition is provided in the input.

The best known running time for Interval Vertex Deletion is $2^{\mathcal{O}(\mathbf{tw}\log \mathbf{tw})}n$ [64]. (While this algorithm has been described for the edge-deletion variant, we briefly explain in the full version of the article how it can be adapted for vertex deletion.) We show that, unlike the chordal case, this running time is optimal under ETH. This gives a sharp separation between the two studied problems.

▶ **Theorem 1.2.** *Under the assumption of ETH, Interval Vertex Deletion cannot be solved in time* $2^{o(\mathbf{tw}\log \mathbf{tw})}n^{\mathcal{O}(1)}$ *on* n*-vertex unweighted graphs of treewidth* $\mathbf{tw}$*.*

In fact, we show a stronger lower bound that rules out the same running time with respect to a different graph parameter, called treedepth, which is never smaller than treewidth. Our lower bound is obtained via a reduction from $k \times k$ Permutation Clique [54], which produces an instance of size $2^{\mathcal{O}(k)}$ and treedepth $\mathcal{O}(k)$.

Related work. The two considered $\mathcal{H}$-Vertex Deletion problems have been studied in several contexts. Both problems are FPT parameterized by the solution size k, with the best-known running times $\mathcal{O}(8^k(n+m))$ for $\mathcal{H} = \texttt{interval}$ [27] and $2^{\mathcal{O}(k\log k)}n^{\mathcal{O}(1)}$ for $\mathcal{H} = \texttt{chordal}$ [28] (but the problem becomes W[2]-hard for $\mathcal{H} = \texttt{perfect}$ [41]). There are polynomial-time approximation algorithms with approximation factor 8 for $\mathcal{H} = \texttt{interval}$ [27] and $k^{\mathcal{O}(1)}$ for $\mathcal{H} = \texttt{chordal}$ [48]. Observe that, in these two regimes, vertex deletion into chordal graphs seems harder than into interval graphs (although no lower bounds are known to justify such a separation formally); this contrasts our results with respect to the treewidth parameterization.

Both studied problems admit exact exponential algorithms with running times of the form $\mathcal{O}((2-\varepsilon)^n)$ [18] as well as polynomial kernelizations [3, 4, 48]. The obstructions to being chordal (resp. interval) enjoy the Erdős-Pósa property: any graph G either contains k vertex-disjoint subgraphs which are not chordal (resp. not interval) or a vertex set X of size $\mathcal{O}(k^2\log k)$ such that $G-X$ is chordal [51] (resp. interval [2]). Vertex deletion into other subclasses of perfect graphs has been studied as well [1, 5, 6, 68]. For other modification variants, where instead of vertex deletions one considers removals, insertions, or contractions of edges, see, e.g., [17, 26, 27, 28, 39, 55, 70].

The concept of representative families, which plays an important role in our algorithm for ChVD, has found applications outside the context of treewidth as well [66, 71]. Our other tool, boundaried graphs, has revealed fruitful insights for various graph classes [9, 21, 45].

Organization of the paper. We begin by describing our technical contributions informally in Section 2. We provide basic preliminaries in Section 3, while the extended preliminaries including tree decompositions and representative families can be found in the full version of the article. Section 4 is devoted to establishing a connection between chordal graphs and graphic matroids. The description of the dynamic programming algorithm over a tree decomposition follows standard conventions and is provided in the full version. In Section 5 we prove our lower bound for Interval Vertex Deletion. We conclude in Section 6. The proofs of statements indicated with ($\star$) are postponed to the full version. The numbering of statements is adjusted to match in both versions.

2 Techniques

Chordal Vertex Deletion. The standard approach to design algorithms over a bounded-width tree decomposition is to assign a data structure to each node t in the decomposition, which stores information about partial solutions for the subgraph associated with the subtree of t. Suppose that $X \subseteq V(G)$ is a bag of t, $A \subseteq V(G)\setminus X$ denote the set of vertices appearing

in the bags of the descendants of t (but not in X), and $B \subseteq V(G)$ is the set of remaining vertices. We say that a subset $S \subseteq V(G)$ is a *solution* if $G[S]$ is chordal; we want to *maximize* the size of S. Next, a pair $(S_A \subseteq A, S_X \subseteq X)$ is a *partial solution* if $G[S_A \cup S_X]$ is chordal. A set $S_B \subseteq B$ is an *extension* of a partial solution (S_A, S_X) if $S_A \cup S_X \cup S_B$ is a solution. Since X separates S_A from S_B, the graph $G[S_A \cup S_X \cup S_B]$ can be regarded as a result of *gluing* $G[S_A \cup S_X]$ with $G[S_B \cup S_X]$ alongside the *boundary* S_X. For a node t and $S_X \subseteq X$, we want to store a family of partial solutions $\mathcal{G}_{t,S_X}$ so that for every possible $S_B \subseteq B$: if S_B is an extension for some partial solution (S_A, S_X), then there exists a partial solution $(S'_A, S_X) \in \mathcal{G}_{t,S_X}$ for which (a) S_B is still a valid extension, and (b) S'_A is at least as large as S_A. We say that such a family satisfies the correctness invariant for (t, S_X).

Jansen et al. [45] showed that any chordal graph H with a boundary of size k can be *condensed* to a graph H' on $\mathcal{O}(k)$ vertices that exhibits the same behavior in terms of gluing. More precisely, the gluing product of H with any graph J is chordal if and only if the gluing product of H' with J is chordal. Since there are $2^{\mathcal{O}(\mathbf{tw}^2)}$ graphs on $\mathcal{O}(\mathbf{tw})$ vertices and $2^{\mathcal{O}(\mathbf{tw})}$ choices for the boundary S_X, it suffices to store only $2^{\mathcal{O}(\mathbf{tw}^2)}$ partial solutions.

We take this idea one step further and show that it is actually sufficient to store only $2^{\mathcal{O}(\mathbf{tw})}$ partial solutions. To this end, we investigate the properties of the class of chordal graphs with respect to the gluing operation and prove a homomorphism theorem relating it to graphic matroids. A *graphic matroid* of a graph J is a set system $\mathcal{I}$ over $E(J)$ where a subset $S \subseteq E(J)$ belongs to $\mathcal{I}$ (and is called *independent*) when S contains no cycles. A *rank* of a matroid is the largest size of an independent set; here this coincides with the size of any spanning forest in J. In the following statement, $\mathcal{G}_{X,B}$ is a family of graphs H that satisfy (a) $V(H) \supseteq X$ and (b) $H[X] = B$. For graphs $H_1, H_2 \in \mathcal{G}_{X,B}$ we assume that $V(H_1) \cap V(H_2) = X$ and define their gluing product as $H_3 = (H_1, X) \oplus (H_2, X)$ where $V(H_3) = V(H_1) \cup V(H_2)$ and $E(H_3) = E(H_1) \cup E(H_2)$.

▶ **Theorem 2.1.** *Consider a family of graphs $\mathcal{G}_{X,B}$ for some pair (X, B). There exists a graphic matroid $M = (E, \mathcal{I})$ of rank at most $|X|-1$ and a polynomial-time computable mapping $\sigma : \mathcal{G}_{X,B} \to 2^E$ such that $(H_1, X) \oplus (H_2, X)$ is chordal if and only if $\sigma(H_1) \cap \sigma(H_2) = \emptyset$ and $\sigma(H_1) \cup \sigma(H_2) \in \mathcal{I}$.*

With this criterion at hand, we can employ the machinery of representative families to truncate the number of partial solutions to be stored for a node of a tree decomposition. Technical details aside, for a family $\mathcal{S}$ of independent sets in a matroid $M = (E, \mathcal{I})$, a subfamily $\widehat{\mathcal{S}} \subseteq \mathcal{S}$ is called *representative* for $\mathcal{S}$ if for every independent set Y in M: if there exists $X \in \mathcal{S}$ so that $X \cap Y = \emptyset$ and $X \cup Y \in \mathcal{I}$, then there exists $\widehat{X} \in \widehat{\mathcal{S}}$ so that $\widehat{X} \cap Y = \emptyset$ and $\widehat{X} \cup Y \in \mathcal{I}$. Fomin et al. [38] showed that for any family $\mathcal{S}$ in a graphic matroid (more generally, in a linear matroid) of rank k there exists a representative family of size at most 2^k and it can be constructed in time $2^{\mathcal{O}(k)}$. We use Theorem 2.1 to translate this result into the language of chordal graphs and gluing. When $\mathcal{G}_{t,S_X}$ is a family of partial solutions that satisfies the correctness invariant for (t, S_X), a representative family for $\sigma(\mathcal{G}_{t,S_X})$ in the related graphic matroid M corresponds to a subfamily $\widehat{\mathcal{G}}_{t,S_X} \subseteq \mathcal{G}_{t,S_X}$ that satisfies condition (a) of the correctness invariant and $|\widehat{\mathcal{G}}_{t,S_X}| \leq 2^{\mathbf{tw}}$. In order to satisfy condition (b), we need to assign weights to the elements of the matroid M, encoding the size of the largest partial solution mapped to each element. We can then utilize the weighted variant of representative families, which preserves the largest-weight elements [38]. By storing only the condensed forms of the partial solutions (having $\mathcal{O}(\mathbf{tw})$ vertices), we also achieve a linear dependency on $|V(G)|$.

In order to prove Theorem 2.1, we give a novel criterion for testing chordality of a gluing product. When G originates from gluing two chordal graphs G_1, G_2 alongside boundary X, then any hole in G must visit both $V(G_1) \setminus X$ and $V(G_2) \setminus X$, so it must traverse X multiple times. We show that if a hole H intersects at least two connected components of

$G[X]$, then it corresponds to a cycle in the graph obtained from G by contracting each of the connected components of $G[X]$, $G_1 - X$, $G_2 - X$ into single vertices. Otherwise, let C be the unique connected component of $G[X]$ that is intersected by the hole. We prove that there exists a vertex set $S \subseteq V(C)$ that is disjoint from $V(H)$ and $C - S$ has two connected components C_1, C_2 satisfying $N_C(C_1) = N_C(C_2) = S$ (below we refer to such components as *relevant*) and having non-empty intersections with $V(H)$. Moreover, every vertex from $V(H) \cap C$ belongs to some relevant component. Consider a graph $\texttt{Aux}(G, X, S)$ obtained from G by (1) removing the connected components of $G[X]$ different than C, (2) contracting relevant components of $C - S$ into single vertices while removing the irrelevant ones, and (3) contracting the components of $G_1 - X$, $G_2 - X$ into single vertices. A detailed construction is given in Definition 4.10; see also Figure 1 on page 9. Then the hole H corresponds to a cycle in $\texttt{Aux}(G, X, S)$. The first scenario can be analyzed with this approach as well, by taking $S = \emptyset$. We prove that considering all minimal vertex separators S in $G[X]$ and checking acyclity of each auxiliary graph $\texttt{Aux}(G, X, S)$ yields a necessary and sufficient condition for G to be chordal.

This criterion allows us to construct a graphic matroid encoding all the information about each of the graphs G_1, G_2 necessary to reconstruct the graphs $\texttt{Aux}(G, X, S)$ and to determine whether G is chordal. In order to bound the rank of this matroid, we investigate the structure of minimal vertex separators in a chordal graph and bound the size of a spanning forest in a certain graph obtained from the union of $\texttt{Aux}(G, X, S)$. A criterion of a similar kind is known for testing planarity of a gluing product of planar graphs when the boundary has a Hamiltonian cycle; then the corresponding auxiliary graph (defined in a different way) should be bipartite [13]. Our criterion can be also compared to the one used by Bonnet et al. [23] for analyzing gluing products with respect to certain subclasses of chordal graphs. We elaborate more on their approach in the full version of the paper.

Interval Vertex Deletion. In order to prove Theorem 1.2 we present a parameterized reduction from $k \times k$ Permutation Clique. Here, the input is a graph G on vertex set $[k] \times [k]$, and we ask whether there exists a permutation $\pi\colon [k] \to [k]$ such that $(1, \pi(1)), (2, \pi(2)), \ldots, (k, \pi(k))$ forms a clique in G. Lokshtanov et al. [54] proved that $k \times k$ Permutation Clique cannot be solved in time $2^{o(k \log k)}$ under ETH. So we seek a reduction from $k \times k$ Permutation Clique to Interval Vertex Deletion that produces a graph of treewidth $\mathcal{O}(k)$.

Imagine an interval model of a complete graph Y on vertex set $[k]$ in which all the right endpoints of the intervals coincide and all the left endpoints are distinct. Choosing the order of the left endpoints encodes some permutation $\pi\colon [k] \to [k]$ (see Figure 2 on page 13). We can extend this interval model by inserting a new vertex v only if $N(v)$ corresponds to a set of intervals intersecting at a single point. This is possible only when $N(v) = \pi([\ell])$ for some $\ell \in [k]$. Furthermore, inserting to Y independent vertices $v_1, v_2, \ldots, v_k$, such that $|N(v_i)| = i$ and $N(v_i) \subset N(v_{i+1})$, enforces the choice of permutation π. We can thus encode a permutation π by an ascending family of sets $N_1 \subset N_2 \subset \cdots \subset N_k = [k]$, satisfying $N_i = \pi([i])$, which correspond to the neighborhoods of $v_1, v_2, \ldots, v_k$ in Y. On the other hand, any ascending family of sets for which the construction above gives an interval graph, must encode some permutation. On an intuitive level, a partial interval model of a size-k separator can encode one of $k!$ permutations.

We need a mechanism to verify that a chosen permutation π encodes a clique, i.e., that it satisfies $\binom{k}{2}$ constraints of the form $(i, \pi(i))(j, \pi(j)) \in E(G)$. To implement a single constraint, we construct a *choice gadget*, inspired by the reduction to Planar Vertex Deletion [58]. Such a gadget $C_{i,j}$ is defined as a path-like structure, divided into blocks, so that each block has some special vertices adjacent to Y (see Figure 3 on page 14). We show that

any minimum-size interval deletion set in $C_{i,j}$ must "choose" one block and leave its special vertices untouched while it can remove the remaining special vertices. We use this gadget to check if a permutation π encoded by an ascending family of sets $N_1 \subset N_2 \subset \cdots \subset N_k$ satisfies the constraint $(i, \pi(i))(j, \pi(j)) \in E(G)$. As $\pi(i)$ is the only element in $N_i \setminus N_{i-1}$, this information can be extracted from the tuple $(N_{i-1}, N_i, N_{j-1}, N_j)$. We create a single block in $C_{i,j}$ for each valid tuple. Since the number of such tuples is $2^{\mathcal{O}(k)}$, we need a choice gadget of exponential length, unlike the mentioned reduction which works in polynomial time. However, producing an instance of size $2^{\mathcal{O}(k)}$ and treewidth $\mathcal{O}(k)$ is still sufficient to achieve the claimed lower bound.

3 Preliminaries

We write $[k] = \{1, 2, \ldots, k\}$ and assume that $[0] = \emptyset$. We abbreviate $X \setminus v = X \setminus \{v\}$. For a function $w\colon X \to \mathbb{N}$ and $S \subseteq X$ we use shorthand $w(S) = \sum_{x \in S} w(x)$. We follow the standard notational conventions for graphs, which are omitted from this extended abstract.

Separators. For vertices $u, v \in V(G)$ a vertex set $S \subseteq V(G) \setminus \{u, v\}$ is called a (u, v)-separator if u, v belong to different connected components of $G - S$. A (u, v)-separator is minimal when no proper subset of it is a (u, v)-separator. A vertex set S is called a minimal vertex separator if S is a minimal (u, v)-separator for some $u, v \in V(G)$.

▶ **Lemma 3.1** (⋆). *Let u, v be vertices in a graph G and S be a (u, v)-separator in G. Denote by C_u, C_v the connected components of $G - S$ that contain respectively u and v. Then S is minimal if and only if $N_G(C_u) = N_G(C_v) = S$.*

A vertex (or a vertex set) is called *simplicial* if its open neighborhood is a clique.

▶ **Lemma 3.2** (⋆). *Let S be a minimal vertex separator in a graph G. Then S does not contain any simplicial vertices.*

Chordal and interval graphs. An interval graph is an intersection graph of intervals on the real line. In an interval model $\mathcal{I}_G = \{I(v) \mid v \in V(G)\}$ of a graph G, each vertex $v \in V(G)$ corresponds to a closed interval $I(v)$; there is an edge between vertices u and v if and only if $I(v) \cap I(u) \neq \emptyset$.

A *hole* in a graph is an induced (i.e., chordless) cycle of length at least four. A graph is chordal when it does not contain any hole. An equivalent definition states that a chordal graph is an intersection graph of a family of subtrees in a tree [40]. This implies that any interval graph is chordal. For more background on these graph classes see surveys [16, 24].

The characterization of the two classes as intersection graphs of intervals/subtrees leads to the following observation.

▶ **Observation 3.3.** *The classes of chordal and interval graphs are closed under vertex deletions and edge contractions.*

An *asteroidal triple* (AT) is a triple of vertices such that for any two of them there exists a path between them avoiding the closed neighborhood of the third. Interval graphs cannot contain ATs, which is a consequence of a linear ordering of any interval model. It turns out that this is the only property that separates the two graph classes.

▶ **Lemma 3.4** ([24]). *A graph is interval if and only if it is chordal and does not contain an AT.*

We collect two more useful facts about chordal graphs.

▶ **Lemma 3.5** ([24]). *Every non-empty chordal graph contains a simplicial vertex.*

When a chordal graph contains a cycle then it also contains a triangle. As a bipartite graph does not have any triangles, we obtain the following.

▶ **Observation 3.6.** *If a graph is chordal and bipartite, then it is a forest.*

A vertex set S in graph G is called a *chordal deletion set* (resp. *interval deletion set*) if $G - S$ is chordal (resp. interval). The Chordal/Interval Vertex Deletion problem is defined as follows. We are given a graph G, a non-negative weight function $w\colon V(G) \to \mathbb{N}$, an integer p, and we ask whether there exists a chordal (resp. interval) deletion set S in G such that $w(S) \leq p$.

Boundaried graphs. For a set X and a graph B on vertex set X, we define a family $\mathcal{G}_{X,B}$ of graphs G that satisfy (a) $V(G) \supseteq X$, (b) $G[X] = B$. For graphs $G_1, G_2 \in \mathcal{G}_{X,B}$ we define their gluing product $(G_1, X) \oplus (G_2, X)$ by taking a disjoint union of G_1 and G_2 and identifying vertices from X. Note that two vertices from X are adjacent in G_1 if and only if they are adjacent in G_2.

For $X \subseteq V(G)$ a pair (G, X) is called a boundaried graph. We say that two boundaried graphs $(G_1, X), (G_2, X)$ are compatible if $G_1, G_2 \in \mathcal{G}_{X,B}$ for some B. We remark that it is common in the literature to define a boundaried graph as a triple (G, X, λ) where $\lambda\colon X \to [|X|]$ is a labeling (cf. [9, 21]). Since we do not need to perform gluing of abstract boundaried graphs, but only ones originating from subgraphs of a fixed graph, this simpler definition is sufficient.

As an example, consider a graph G and $X \subseteq V(G)$. Then for any $A \subseteq V(G) \setminus X$ the graph $G[A \cup X]$ belongs to $\mathcal{G}_{X,G[X]}$. When $A, B \subseteq V(G) \setminus X$ are disjoint and non-adjacent then $G[A \cup B \cup X]$ is isomorphic to $(G[A \cup X], X) \oplus (G[B \cup X], X)$.

4 Chordal Deletion

We begin with a simple treewidth-preserving reduction from Feedback Vertex Set.

▶ **Lemma 4.1** ($\star$)**.** *Let G be a graph and $\ell \in \mathbb{N}$. Let G' be obtained from G by subdividing each edge. Then $\boldsymbol{tw}(G') = \boldsymbol{tw}(G)$ and G has a feedback vertex set (FVS) of size ℓ if and only if G' has a chordal deletion set of size ℓ.*

As a consequence, the base of the exponent c in Theorem 1.1 must be at least 3 under Strong Exponential Time Hypothesis [35] and c must be at least $2^\omega + 1$ if the current-best deterministic algorithm for Feedback Vertex Set parameterized by treewidth is optimal [69]. While we have no evidence that the mentioned algorithm should be optimal for deterministic time, we provide this comparison to indicate that breaching this gap for ChVD would imply the same for a more heavily studied problem.

Minimal vertex separators. We set the stage for the proof of Theorem 2.1. First we need to develop some theory about minimal vertex separators in chordal graphs.

▶ **Definition 4.2.** *Let $\texttt{MinSep}(G)$ denote the set of minimal vertex separators in a graph G. For a graph G and a (possibly empty) set $S \subseteq V(G)$, we define $\texttt{Comp}(G, S)$ to be the set of connected components C_i of $G - S$ for which it holds that $N_G(C_i) = S$.*

Note that whenever G is disconnected then $\emptyset \in \texttt{MinSep}(G)$ and $\texttt{Comp}(G, \emptyset)$ is just the set of connected components of G. According to Lemma 3.1, the set S is a minimal (u, v)-separator if and only if u, v belong to some (distinct) components from $\texttt{Comp}(G, S)$. For later use, we establish a relation between sets $\texttt{MinSep}(G)$, $\texttt{Comp}(G, S)$ in G and a graph obtained by a removal of a simplicial vertex.

▶ **Lemma 4.3** (⋆). *Let v be a simplicial vertex in G and $S \in \mathit{MinSep}(G)$. If $S \neq N_G(v)$ then $S \in \mathit{MinSep}(G - v)$ and $|\mathit{Comp}(G, S)| = |\mathit{Comp}(G - v, S)|$.*

We need a simple technical lemma about minimal vertex separators.

▶ **Lemma 4.4** (⋆). *Let G be a connected graph and $V_1, \ldots, V_k \subseteq V(G)$, $k \geq 2$, be disjoint sets so that $G[V_i]$ is connected, for $i \in [k]$, and $E_G(V_i, V_j) = \emptyset$, for $i \neq j$. Then there exists a minimal vertex separator $S \subseteq V(G) \setminus (V_1 \cup \cdots \cup V_k)$ in G which is a (V_i, V_j)-separator for some $i \neq j$ and each set V_i is contained in some component $C \in \mathit{Comp}(G, S)$.*

We will use the following concept which appears in the current-best algorithm for ChVD by Jansen et al [45]. In the full version, we also provide several properties of this operation, used to process partial solutions in a treewidth DP.

▶ **Definition 4.5** ([46, Def. 5.55]). *For a graph G and a vertex set $X \subseteq V(G)$ let the graph $\mathit{Condense}(G, X)$ be obtained from G by contracting the connected connected components of $G - X$ into single vertices and then removing those of them which are simplicial.*

In this section we will exploit the following property of condensation.

▶ **Lemma 4.9** (⋆). *Consider a graph G with a vertex set X so that $G[X]$ is chordal. Then G is chordal if and only if the following conditions hold:*
1. *for each connected component C of $G - X$ the graph $G[X \cup C]$ is chordal,*
2. *the graph $\mathit{Condense}(G, X)$ is chordal.*

In order to turn Lemma 4.9 into a more convenient criterion, we will compress information about a graph G with a vertex subset X into multiple auxiliary graphs, one for each minimal vertex separator in $G[X]$.

▶ **Definition 4.10.** *Consider a graph G with a vertex set X so that $G[X]$ is chordal. For a set $S \in \mathit{MinSep}(G[X])$ we construct the graph $\mathit{Aux}(G, X, S)$ as follows:*
1. *contract each $C \in \mathit{Comp}(G[X], S)$ into a vertex and remove the remaining vertices of X (including all of S),*
2. *contract each connected component of $G - X$ into a vertex.*

Note that $\mathtt{Aux}(G, X, \emptyset)$ is obtained by just contracting each connected component of $G[X]$ and each connected component of $G - X$. Moreover, observe that $\mathtt{Aux}(G, X, S)$ is always a bipartite graph because there can be no edges between two components from $\mathtt{Comp}(G[X], S)$ nor between two components of $G - X$. See Figure 1 for an example of this construction.

To make a connection between holes in G and cycles in $\mathtt{Aux}(G, X, S)$, we need a criterion to derive existence of a cycle from a closed walk with certain properties. In the following lemma we consider a cyclic order on a sequence of length k. We define the successor operator as $s(i) = i + 1$, for $i \in [k - 1]$, and $s(k) = 1$.

▶ **Lemma 4.11** (⋆). *Let G be a bipartite graph with vertex partition $V(G) = A \cup B$. Suppose there exists a sequence of vertices $(v_1, \ldots, v_k)$ in G such that:*
1. *for $i \in [k]$ it holds $v_i = v_{s(i)}$ or $v_i v_{s(i)} \in E(G)$,*
2. *the multiset $\{v_1, \ldots, v_k\}$ contains at most one occurrence of each vertex from A,*
3. *the set $\{v_1, \ldots, v_k\}$ contains at least two vertices from B.*

Then G contains a cycle.

We are ready to prove a proposition creating a link between chordality and acyclicity.

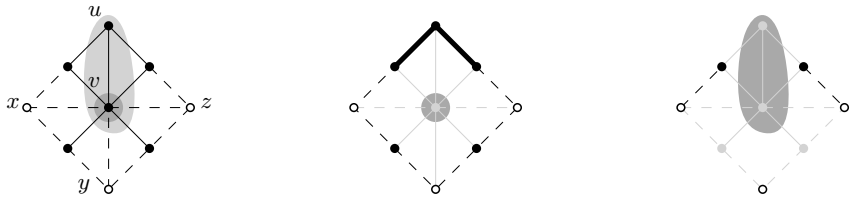

Figure 1 On the left: graph G and set $X \subseteq V(G)$ represented by black disks. The graph $G[X]$ is drawn with solid edges. There are two minimal vertex separators in $G[X]$: $S_1 = \{v\}$ and $S_2 = \{u, v\}$, sketched in gray. In the middle: the graph $\texttt{Aux}(G, X, S_1)$ with thick edges indicating a component that gets contracted into a single vertex; the gray vertices and edges are removed. On the right: the graph $\texttt{Aux}(G, X, S_2)$; note that $|\texttt{Comp}(G[X], S_2)| = 2$ because the lower vertices of X are not adjacent to every vertex in S_2. The graph $\texttt{Aux}(G, X, S_1)$ contains a cycle and this witnesses that G is not chordal. However, removing from G any single vertex among x, y, z results in a chordal graph.

▶ **Proposition 4.12.** *Consider a graph G with a vertex subset $X \subseteq V(G)$ so that for each connected component C of $G - X$ the graph $G[X \cup C]$ is chordal. Then G is chordal if and only if for each $S \in \texttt{MinSep}(G[X])$ the graph $\texttt{Aux}(G, X, S)$ is acyclic.*

Proof. First we argue that if G is chordal then all graphs $\texttt{Aux}(G, X, S)$ are acyclic. Because the class of chordal graphs is closed under vertex deletions and edge contractions, the graphs $\texttt{Aux}(G, X, S)$ are chordal as well. Since each graph $\texttt{Aux}(G, X, S)$ is also bipartite, by Observation 3.6 we obtain that $\texttt{Aux}(G, X, S)$ is acyclic.

Now suppose that G is not chordal. Let $G' = \texttt{Condense}(G, X)$ (recall Definition 4.5). By Lemma 4.9, the graph G' is not chordal as well but for each vertex $v \in V(G') \setminus X$ the graph $G'[X \cup \{v\}]$ is chordal (because contraction preserves chordality). Note that $\texttt{Aux}(G', X, S)$ is an induced subgraph of $\texttt{Aux}(G, X, S)$ for each $S \in \texttt{MinSep}(G[X])$ (they may differ only due to removal of simplicial vertices), so it suffices to show that one of the graphs $\texttt{Aux}(G', X, S)$ has a cycle.

As G' is not chordal, it contains a hole $H = (u_1, \ldots, u_k)$. We consider two cases: either $V(H)$ intersects at least two connected components of $G'[X]$ or only one. In the first case, let $\phi_0 \colon V(G') \to V(\texttt{Aux}(G', X, \emptyset))$ be the mapping given by the contractions from Definition 4.10. Recall that $V(G') \setminus X$ is an independent set in G' so ϕ_0 is an identity on this set. The sequence $(\phi_0(u_1), \ldots, \phi_0(u_k))$ meets the preconditions of Lemma 4.11 for $A = V(G') \setminus X$ and $B = \phi_0(X)$ so $\texttt{Aux}(G', X, \emptyset)$ has a cycle. As $G'[X] = G[X]$ is disconnected, we have $\emptyset \in \texttt{MinSep}(G[X])$.

In the second case, let $Y \subseteq X$ induce the only connected component of $G'[X]$ that intersects $V(H)$. Let $V_1, \ldots, V_\ell \subseteq Y$ be the vertex sets of maximal subpaths of H within Y. By the definition of a hole, we have $E_{G'}(V_i, V_j) = \emptyset$ for distinct $i, j \in [\ell]$. It must be $\ell \geq 2$ because for each $v \in V(G') \setminus X$ the graph $G'[X \cup \{v\}]$ is chordal and the hole H must visit at least two vertices from the independent set $V(G') \setminus X$. By Lemma 4.4, there exists a minimal vertex separator $S \subseteq Y \setminus V(H)$ in $G'[Y]$ such that every set V_i is contained in some component from $\texttt{Comp}(G'[Y], S)$ and at least two components from $\texttt{Comp}(G'[Y], S)$ intersect $V(H)$. Note that $S \in \texttt{MinSep}(G[X])$. Let C_S be the union of the components from $\texttt{Comp}(G'[Y], S)$; note that $V(H) \subseteq V(C_S) \cup (V(G') \setminus X)$.

Let $\phi_S \colon V(C_S) \cup (V(G') \setminus X) \to V(\texttt{Aux}(G', X, S))$ be the mapping given by the contractions from Definition 4.10 which turn each component from $\texttt{Comp}(G'[Y], S)$ into a single vertex. Again, the sequence $(\phi_S(u_1), \ldots, \phi_S(u_k))$ meets the preconditions of Lemma 4.11 for $A = V(G') \setminus X$ and $B = \phi_S(V(C_S))$ so $\texttt{Aux}(G', X, S)$ has a cycle. See Figure 1 for an illustration. ◀

Signatures of boundaried graphs. The next step is to construct a graphic matroid M_B for a chordal graph B so that for any two graphs $G_1, G_2 \in \mathcal{G}_{X,B}$ the information about chordality of $(G_1, X) \oplus (G_2, X)$ could be read from M_B. Proposition 4.12 already relates chordality to acyclicity but the corresponding graphic matroids for G_1, G_2 are disparate. To circumvent this, we will further compress the information about cycles.

▶ **Definition 4.13.** *Consider a graph B. For $S \in \mathit{MinSep}(B)$, let $\mathtt{Base}(B,S)$ be the complete graph on vertex set $\mathtt{Comp}(B,S)$. The graph $\mathtt{Base}(B)$ is a disjoint union of all the graphs $\mathtt{Base}(B,S)$ for $S \in \mathit{MinSep}(B)$.*

That is, we treat the components from $\mathtt{Comp}(B,S)$ as abstract vertices of a new graph which is a union of cliques.

The following transformation is similar to the one used in the algorithm for Steiner Tree based on representative families [38]. For the sake of disambiguation, in the definition below we assume an implicit linear order on the vertices of B; this order may be arbitrary. Since vertices of $\mathtt{Base}(B)$ correspond to distinct subsets of $V(B)$, which can ordered lexicographically, fixing the order on $V(B)$ yields an order on $V(\mathtt{Base}(B))$. We can thus assume that also the vertices of $V(\mathtt{Base}(B))$ are linearly ordered.

▶ **Definition 4.14.** *Consider a chordal graph B and $Y \subseteq V(B)$. We define the* spanning signature *$\mathit{Span}(B,Y) \subseteq E(\mathtt{Base}(B))$ as follows. For each $S \in \mathit{MinSep}(B)$ let $C_{S,Y} \subseteq V(\mathtt{Base}(B,S))$ be given by components from $\mathtt{Comp}(B,S)$ with a non-empty intersection with Y. Let $P_{S,Y} \subseteq E(\mathtt{Base}(B,S))$ be the path connecting the vertices of $C_{S,Y}$ in the increasing order. Then $\mathit{Span}(B,Y) = \bigcup_{S \in \mathit{MinSep}(B)} P_{S,Y}$.*

In other words, $\mathtt{Span}(B,Y)$ is a disjoint union of paths in the graph $\mathtt{Base}(B)$, where each path encodes the relation between Y and a respective minimal vertex separator in B.

The next lemma states that under certain conditions replacing a vertex v with a tree over $N(v)$ (in particular: a path) does not affect acyclicity of the graph. Note that due to the precondition $|N(u) \cap N(v)| \leq 1$ we never attempt to insert an edge that is already present.

▶ **Lemma 4.15 ($\star$).** *Let G be a bipartite graph with a vertex partition $V(G) = A \cup B$ so that for each distinct $u, v \in A$ it holds that $|N_G(u) \cap N_G(v)| \leq 1$. Consider a graph G' obtained from G by replacing each vertex $v \in A$ by an arbitrary tree on vertex set $N_G(v)$. Then G is acyclic if and only if G' is acyclic.*

This allows us to translate the criterion from Proposition 4.12 into a more convenient one, in which the vertex set of the auxiliary graph depends only on $G[X]$ rather than G.

▶ **Lemma 4.16.** *Consider a graph G with a vertex subset $X \subseteq V(G)$. Let $\mathcal{C}$ denote the family of connected components of $G - X$. Suppose that for each $C \in \mathcal{C}$ the graph $G[X \cup C]$ is chordal. Then G is chordal if and only if:*

1. *the sets $\mathit{Span}(G[X], N_G(C))$, for different $C \in \mathcal{C}$, are pairwise disjoint,*
2. *the union of sets $\mathit{Span}(G[X], N_G(C))$, over $C \in \mathcal{C}$, forms an acyclic edge set in $E(\mathtt{Base}(G[X]))$.*

Proof. From Proposition 4.12 we know that G is chordal if and only if for each $S \in \mathtt{MinSep}(G[X])$ the graph $\mathtt{Aux}(G,X,S)$ is acyclic. We consider two cases.

First, suppose that for some $S \in \mathtt{MinSep}(G[X])$ there are two vertices representing distinct components $C_1, C_2 \in \mathcal{C}$ that share two common neighbors x, y in $\mathtt{Aux}(G,X,S)$. In other words, there are two components from $\mathtt{Comp}(G[X],S)$ that intersect both $N_G(C_1)$ and $N_G(C_2)$. Then $\mathtt{Aux}(G,X,S)$ contains a cycle of length 4, so G is not chordal. If $\mathtt{Span}(G[X], N_G(C_1))$

and $\texttt{Span}(G[X], N_G(C_2))$ share an edge, then condition (1) fails, so suppose this is not the case. But then the paths $P_{S,N(C_1)}$ and $P_{S,N(C_2)}$ (recall Definition 4.14) are edge-disjoint and they both visit x and y. As a consequence, x, y lie on a cycle contained in the edge set $\texttt{Span}(G[X], N_G(C_1)) \cup \texttt{Span}(G[X], N_G(C_2))$ so condition (2) fails. In summary, both G is not chordal and one of conditions (1, 2) does not hold.

Next, suppose that for each $S \in \texttt{MinSep}(G[X])$ and any two vertices representing distinct components $C_1, C_2 \in \mathcal{C}$ the intersection of their neighborhoods in $\texttt{Aux}(G, X, S)$ contains at most one element. This implies condition (1). Consider a graph H given by a disjoint union of all graphs $\texttt{Aux}(G, X, S)$ over $S \in \texttt{MinSep}(G[X])$. This graph meets the preconditions of Lemma 4.15. Replacing each $\mathcal{C}$-component-vertex in $\texttt{Aux}(G, X, S)$ by the path $P_{S,N(C)}$ transforms H into a subgraph of $\texttt{Base}(G[X])$ with the edge set $\bigcup_{C \in \mathcal{C}} \texttt{Span}(G[X], N_G(C))$. By Lemma 4.15, this graph is acyclic if and only if the graph H is. By Proposition 4.12, this condition is equivalent to G being chordal. The lemma follows. ◀

We are ready to define the graphic matroid encoding all the necessary information about where a hole can appear after gluing two chordal graphs. Recall that a graphic matroid of a graph G is a set system over $E(G)$ where a subset $S \subseteq E(G)$ is called independent when S contains no cycles. More information about matroids can be found in the preliminaries of the full version of the article.

▶ **Definition 4.17.** *For a graph B on vertex set X we define matroid M_B as the graphic matroid of the graph $\texttt{Base}(B)$. For a graph $G \in \mathcal{G}_{X,B}$ the signature $\texttt{Sign}(G, X) \subseteq E(\texttt{Base}(B))$ is defined as a union of $\texttt{Span}(B, N_G(C))$ over all connected components C of $G - X$.*

It follows from Lemma 4.16 that whenever G is chordal then $\texttt{Sign}(G, X)$ is acyclic and so it forms an independent set in the matroid $M_{G[X]}$. We can now give the existential part of Theorem 2.1. The mapping $\sigma \colon \mathcal{G}_{X,B} \to 2^{E(M_B)}$ therein is given here as $\sigma(G) = \texttt{Sign}(G, X)$.

▶ **Lemma 4.18** ($\star$)**.** *Let (G_1, X) and (G_2, X) be compatible boundaried chordal graphs. Then $G = (G_1, X) \oplus (G_2, X)$ is chordal if and only if the sets $\texttt{Sign}(G_1, X)$, $\texttt{Sign}(G_2, X) \subseteq E(\texttt{Base}(G[X]))$ are disjoint and $\texttt{Sign}(G_1, X) \cup \texttt{Sign}(G_2, X)$ is acyclic.*

Furthermore, $\texttt{Sign}(G, X) = \texttt{Sign}(G_1, X) \cup \texttt{Sign}(G_2, X)$.

The following lemma is the main ingredient in the running time analysis. As the bound on the representative family's size is exponential in the rank of a matroid[2], it is necessary to bound the rank of M_B. It is known that the number of minimal vertex separators in a chordal graph is bounded by the number of vertices but we need a strengthening of this fact.

▶ **Lemma 4.19.** *For a non-empty chordal graph B, the rank of M_B is at most $|V(B)| - 1$.*

Proof. Let $k = |V(B)|$. The rank of M_B equals the size of a spanning forest in $\texttt{Base}(B)$. The vertex sets of connected components of $\texttt{Base}(B)$ are the sets $\texttt{Comp}(B, S)$ for $S \in \texttt{MinSep}(B)$. Therefore it suffices to estimate

$$\sum_{S \in \texttt{MinSep}(B)} (|\texttt{Comp}(B, S)| - 1) \leq k - 1.$$

We first prove the inequality for connected chordal graphs by induction on k. For $k = 1$ the sum is zero. Consider $k > 1$. By Lemma 3.5, B contains a simplicial vertex. Let v be a simplicial vertex in B and suppose that the claim holds for the graph $B - v$ (which is

[2] We remark that Fomin et al. [38] also considered a case when the rank might be large and the exponential term is governed by a different parameter but it is not applicable in our case.

connected). Let S be a minimal vertex separator in B. By Lemma 4.3 when $S \neq N_B(v)$ then $S \in \texttt{MinSep}(B - v)$ and $|\texttt{Comp}(B, S)| = |\texttt{Comp}(B - v, S)|$. In that case the summand coming from S is the same for B and $B - v$.

It remains to handle the case $S = N_B(v)$. Clearly, $\{v\} \in \texttt{Comp}(B, S)$. If $|\texttt{Comp}(B, S)| = 1$ then $S \notin \texttt{MinSep}(B)$ (Lemma 3.1). If $|\texttt{Comp}(B, S)| = 2$ then $S \in \texttt{MinSep}(B) \setminus \texttt{MinSep}(B - v)$ and the sum grows by one. If $|\texttt{Comp}(B, S)| \geq 3$ then $S \in \texttt{MinSep}(B) \cap \texttt{MinSep}(B - v)$ and $|\texttt{Comp}(B, S)| = |\texttt{Comp}(B - v, S)| + 1$ so the sum again grows by one. This concludes the proof of the inequality for connected chordal graphs.

When B is disconnected, let $B_1, B_2, \ldots, B_t$ denote its connected components and let $k_i = |V(B_i)|$. We have $|\texttt{Comp}(B, \emptyset)| - 1 = t - 1$. Together with the sums for $B_1, B_2, \ldots, B_t$ the total sum is at most $\sum_{i=1}^{t} k_i - t + t - 1 = k - 1$. ◀

The last thing to be checked is whether we can compute the signatures efficiently. To this end, we enumerate minimal vertex separators using Lemma 4.3.

▶ **Lemma 4.20** (⋆). *There is a polynomial-time algorithm that, given a graph G with a vertex subset $X \subseteq V(G)$ such that $G[X]$ is chordal, computes $\texttt{Sign}(G, X)$.*

Lemmas 4.18, 4.19, and 4.20 entail Theorem 2.1 but instead of working with that abstract statement we use these three lemmas directly when describing the final algorithm. The results of this section allow us to employ the framework of representative families in order to truncate the number of partial solutions stored at a node of a tree decomposition to $2^{\mathcal{O}(\mathbf{tw})}$. The dynamic programming algorithm follows the lines of proofs in [37] and is described in detail in the full version. The main technical hurdle comes from the necessity to store only the condensed counterparts of the partial solutions. The condensed graphs have only $\mathcal{O}(\mathbf{tw})$ vertices each, what is the key to obtain a linear dependency on $|V(G)|$.

5 Interval Deletion

We switch our attention to Interval Vertex Deletion and show that in this case it is unlikely to achieve any speed-up over the existing $2^{\mathcal{O}(\mathbf{tw} \log \mathbf{tw})} \cdot n$-time algorithm. We prove Theorem 1.2 via a parameterized reduction from $k \times k$ Permutation Clique, which is defined as follows.

$k \times k$ Permutation Clique
Input: Graph G over the vertex set $[k] \times [k]$.
Question: Is there a permutation $\pi\colon [k] \to [k]$ so that $(1, \pi(1)), (2, \pi(2)), \ldots, (k, \pi(k))$ forms a clique in G?

Permutation gadget. We will encode a permutation $\pi\colon [k] \to [k]$ as a family of sets $N_1, N_2, \ldots, N_k$ so that $N_i = \pi([i])$ (i.e., N_i is the set of i numbers appearing first in π). First, we need a gadget to verify that such a family represents some permutation.

▶ **Definition 5.1.** *For an integer k, let Y_k be a graph on a vertex set $\{y_1, y_2, \ldots, y_{k+2}\}$ so that $\{y_1, y_2, \ldots, y_{k+1}\}$ induces a clique and y_{k+2} is adjacent only to y_{k+1}.*

We shall enforce a linear order on $N_1, \ldots, N_k$ by demanding that a particular supergraph of Y_k is interval. The corresponding interval model is depicted on Figure 2.

▶ **Lemma 5.3** (⋆). *Let $N_1, \ldots, N_\ell \subseteq [k]$. Consider a graph G obtained from Y_k by inserting an independent set of vertices $x_1, \ldots, x_\ell$ so that $N_G(x_i) = \{y_j \mid j \in N_i\}$. Then G is interval if and only if there exists a permutation $\pi\colon [k] \to [k]$ so that for each $i \in \ell$ it holds that $N_i = \pi([n_i])$ where $n_i = |N_i|$.*

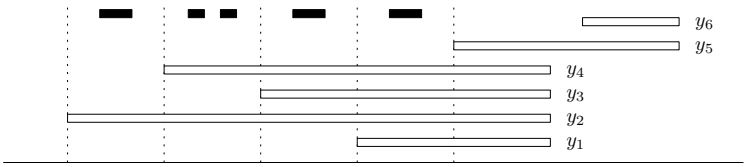

Figure 2 Illustration for Lemma 5.3. The intervals for vertices of Y_4 are blank, ordered from bottom to top. They encode permutation $(2, 4, 3, 1)$. The black intervals represent vertices x_1, x_2, x_3, x_4, x_5 with neighborhoods encoding sets $\{2\}$, $\{2, 4\}$ (twice), $\{2, 4, 3\}$, and $\{2, 4, 3, 1\}$.

Choice gadget. We need to verify that $(i, \pi(i))(j, \pi(j)) \in E(G)$ for each $1 \leq i < j \leq k$. As $\pi(i)$ is the only element in $N_i \setminus N_{i-1}$, the information whether $(i, \pi(i)), (j, \pi(j)) \in E(G)$ can be extracted from the tuple $(N_{i-1}, N_i, N_{j-1}, N_j)$. We construct a gadget that enforces a solution to select one such valid tuple.

We use a following convention to describe the gadgets. When P is a graph with a distinguished vertex named v and a graph H is constructed using explicit vertex-disjoint copies of the graph P, referred to as $P_1, P_2, \ldots, P_\ell$, we refer to the copy of v within the subgraph P_i as $P_i[v]$. We construct the choice gadget as a path-like structure consisting of blocks, each equipped with four special vertices. These are the only vertices that later get connected to the permutation gadget. On the intuitive level, a solution should choose one block, leave its special vertices untouched, and remove the remaining special vertices. See Figure 3 for an illustration.

▶ **Definition 5.4.** *The graph P is obtained from a path $(u_1, u_2, \ldots, u_9)$ by appending to u_2 two subdivided edges, one subdivided edge to u_7, and inserting edge u_4u_8.*

The choice gadget of order s is a graph constructed as follows. We begin with a vertex set $\bigcup_{i=1}^{s}\{v_i^1, v_i^2, v_i^3\} \cup \{v_{left}, v_{right}\}$. For each pair (x, y) of the form $(v_i^1, v_i^2), (v_i^2, v_i^3), (v_i^3, v_i^1), (v_i^3, v_{i+1}^1)$ as well as for (v_{left}, v_1^1), (v_s^3, v_{right}) we create two subdivided edges between x and y. We refer to the subgraph given by the two subdivided edges between x, y as $\langle x, y\rangle$. We refer to the union of $\langle v_i^1, v_i^2\rangle, \langle v_i^2, v_i^3\rangle, \langle v_i^3, v_i^1\rangle$ as Q_i.

Next, for each $i \in [s]$ we create four copies of the graph P, denoted $P_i^1, P_i^2, P_i^3, P_i^4$. We insert edges between v_i^2 and $P_i^1[u_1], P_i^2[u_1], P_i^3[u_1], P_i^4[u_1]$. We refer to vertices $P_i^\alpha[u_8]$, $P_i^\alpha[u_9]$, $\alpha \in [4]$, as respectively h_i^α, g_i^α.

The choice gadget is designed to enforce a special structure of minimum-size interval deletion sets. We exploit the fact that P contains two vertex-disjoint subgraphs with asteroidal triples (see Figure 3) so any interval deletion set in a choice gadget must contain at least two vertices from each copy of P.

We prove several properties of the choice gadget which are analogous to the properties of the gadget used by Pilipczuk in the lower bound for Planar Vertex Deletion [58]. However, in that construction every block has only one special vertex with edges leaving the gadget, while in our case there are four special vertices. We also need to ensure that when the special vertices in some block are not being removed then a solution can remove their neighbors in the gadget. (Inserting a planar graph attached to a single vertex of G does not affect planarity of G but the analogous property does not hold for the class of interval graphs.) The special structure of the graph P allows us to resolve these two issues.

▶ **Lemma 5.6** ($\star$). *Let H_s be the choice gadget of order s.*

1. *The minimal size of an interval deletion set in H_s is $10s$.*
2. *For every $i \in [s]$ there exists a minimum-size interval deletion set X in H_s such that $\{h_i^1, h_i^2, h_i^3, h_i^4\} \subseteq X$ and $\{g_j^1, g_j^2, g_j^3, g_j^4\} \subseteq X$ for each $j \neq i$.*

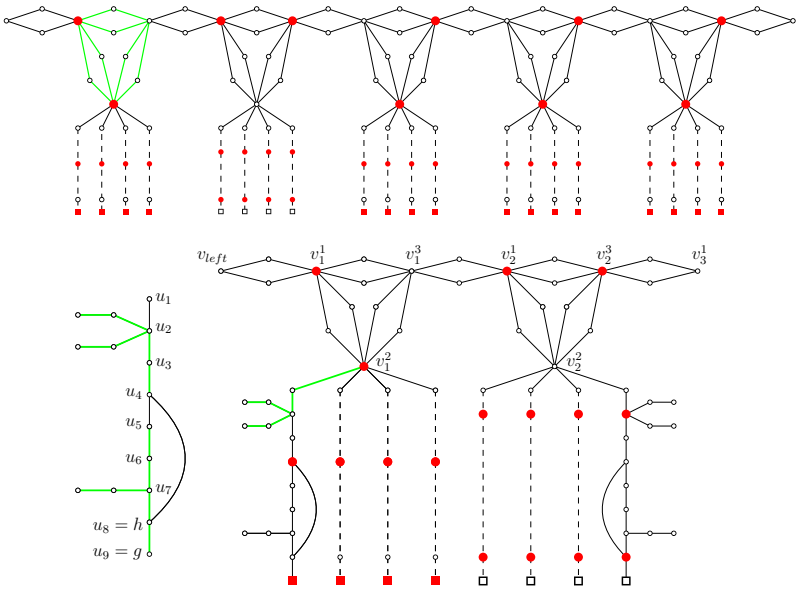

Figure 3 Top: the choice gadget H_5 with the subgraph Q_1 highlighted in green. The copies of P are sketched symbolically with dashed lines and the squares represent vertices g_i^α. The red disks and squares represent a solution constructed in Lemma 5.6(2). This solution "chooses" $i = 2$, leaves untouched the four vertices g_2^α, and removes h_2^α as well as g_i^α for $i \neq 2$. Bottom left: the graph P and vertices named h, g. Two vertex-disjoint non-interval subgraphs of P have green edges. Bottom right: a closer look at the first two blocks of H_5 with two copies of P drawn in detail. The subgraph highlighted in green witnesses that if a minimum-size solution removes g_i^α for at least one $\alpha \in [4]$ then it must also remove v_i^2, what is exploited in Lemma 5.6(3).

3. *For every minimum-size interval deletion set X in H_s there is $i \in [s]$ such that $\{g_i^1, g_i^2, g_i^3, g_i^4\} \cap X = \emptyset$.*
4. *If $s \leq 2^k$ then $\boldsymbol{td}(H_s) \leq \boldsymbol{td}(H_1) + k$, where $\boldsymbol{td}(G)$ stands for the treedepth of G.*

Lokshtanov et al. [54] proved that $k \times k$ Permutation Clique cannot be solved in time $2^{o(k \log k)}$ assuming ETH. According to the reduction below, this also rules out running time of the form $2^{o(\mathbf{td} \log \mathbf{td})} \cdot n^{\mathcal{O}(1)}$ for Interval Vertex Deletion, where $\mathbf{td}$ is the treedepth of the input graph. As $\mathbf{tw}(G) \leq \mathbf{td}(G)$, this entails the same hardness for treewidth, what proves Theorem 1.2.

▶ **Proposition 5.7.** *There is an algorithm that, given an instance (G, k) of $k \times k$ Permutation Clique, runs in time $2^{\mathcal{O}(k)}$ and returns an equivalent unweighted instance (H, p) of Interval Vertex Deletion such that $|V(H)| = 2^{\mathcal{O}(k)}$ and $\boldsymbol{td}(H) = \mathcal{O}(k)$.*

Proof. For $1 \leq i < j \leq k$ and $x \neq y \in [k]$ let $\mathcal{S}_{i,x,j,y}$ be the family of tuples (S_1, S_2, S_3, S_4) of subsets of $[k]$ satisfying:

- $S_1 \subset S_2 \subseteq S_3 \subset S_4$,
- $|S_1| = i - 1$,
- $S_2 \setminus S_1 = \{x\}$,
- $|S_3| = j - 1$,
- $S_4 \setminus S_3 = \{y\}$.

Furthermore, for $1 \leq i < j \leq k$, let $\mathcal{S}_{i,j}$ be the union of $\mathcal{S}_{i,x,j,y}$ over all pairs $x \neq y \in [k]$ such that $(i, x)(j, y) \in E(G)$. Let $s_{i,j} = |\mathcal{S}_{i,j}|$ and $\rho_{i,j} \colon [s_{i,j}] \to \mathcal{S}_{i,j}$ be an arbitrary bijection. Clearly $s_{i,j} \leq 4^k k^2$.

The graph H consists of a permutation gadget Y_k and, for each $1 \leq i < j \leq k$, a choice gadget $C_{i,j}$ of order $s_{i,j}$. For $S \subseteq [k]$ we use shorthand $Y_k[S] = \{y_i \mid i \in S\}$. For $\ell \in [s_{i,j}]$ and $(S_1, S_2, S_3, S_4) = \rho_{i,j}(\ell)$ the vertices $C_{i,j}[g^1_\ell]$, $C_{i,j}[g^2_\ell]$, $C_{i,j}[g^3_\ell]$, $C_{i,j}[g^4_\ell]$ get connected to vertex sets $Y_k[S_1], Y_k[S_2], Y_k[S_3], Y_k[S_4]$, respectively. This finishes the construction of H. The number of vertices in H is clearly $2^{\mathcal{O}(k)}$ and the construction can be performed in time polynomial in the size of H. We set $p = 10 \cdot \sum_{1 \leq i < j \leq k} s_{i,j}$.

▷ Claim 5.8. If (G, k) admits a solution, then H has an interval deletion set of size p.

Proof. Let $\pi\colon [k] \to [k]$ be a permutation encoding a clique in G. By the construction, for each $1 \leq i < j \leq k$ we have $(\pi([i-1]), \pi([i]), \pi([j-1]), \pi([j]) \in \mathcal{S}_{i,j}$. Let $\ell \in [s_{i,j}]$ be the index mapped to this tuple by $\rho_{i,j}$. By Lemma 5.6(2) the choice gadget $C_{i,j}$ has an interval deletion set $X_{i,j} \subseteq V(C_{i,j})$ of size $10s_{i,j}$ such that $\{C_{i,j}[h^1_\ell], C_{i,j}[h^2_\ell], C_{i,j}[h^3_\ell], C_{i,j}[h^4_\ell]\} \subseteq X_{i,j}$ and $\{C_{i,j}[g^1_r], C_{i,j}[g^2_r], C_{i,j}[g^3_r], C_{i,j}[g^4_r]\} \subseteq X_{i,j}$ for each $r \neq \ell$. In other words, $X_{i,j}$ contains all vertices in $C_{i,j}$ which are adjacent to Y_k except for the $C_{i,j}$-copies of $g^1_\ell, g^2_\ell, g^3_\ell, g^4_\ell$ and $X_{i,j}$ also contains the neighbors of $C_{i,j}[g^1_\ell], C_{i,j}[g^2_\ell], C_{i,j}[g^3_\ell], C_{i,j}[g^4_\ell]$ in $C_{i,j}$.

We set $X = \bigcup_{1 \leq i < j \leq k} X_{i,j}$. Then the only connected component of $H - X$ which is not a connected component of any $C_{i,j} - X_{i,j}$ is given by Y_k together with an independent set of the vertices described above. The neighborhood of each such vertex in Y_k is of the form $Y_k[\pi([k'])]$ for some $0 \leq k' \leq k$. By Lemma 5.3 this component is an interval graph. This shows that X is indeed an interval deletion set. ◁

▷ Claim 5.9. If H has an interval deletion set of size at most p, then (G, k) admits a solution.

Proof. Let X be an interval deletion set in H. By Lemma 5.6(1) a minimum-size interval deletion set in $C_{i,j}$ has size $10s_{i,j}$. As the choice gadgets are vertex-disjoint subgraphs of H, the set X must contain exactly $10s_{i,j}$ vertices from $V(C_{i,j})$. This also implies that $V(Y_k) \cap X = \emptyset$.

Let $X_{i,j} = V(C_{i,j}) \cap X$. By Lemma 5.6(3) there exists $\ell \in [s_{i,j}]$ such that $\{C_{i,j}[g^1_\ell], C_{i,j}[g^2_\ell], C_{i,j}[g^3_\ell], C_{i,j}[g^4_\ell]\} \cap X_{i,j} = \emptyset$. Therefore for each pair (i,j) there is a tuple $(S^1_{i,j}, S^2_{i,j}, S^3_{i,j}, S^4_{i,j}) \in \mathcal{S}_{i,j}$ so that vertices from $C_{i,j}$ with neighborhoods $Y_k[S^1_{i,j}], Y_k[S^2_{i,j}], Y_k[S^3_{i,j}], Y_k[S^4_{i,j}]$ are present in $H - X$. By Lemma 5.3 there exists a single permutation $\pi\colon [k] \to [k]$ so that each set $S^\alpha_{i,j}$ is of the form $\pi([|S^\alpha_{i,j}|])$. By the definition of family $\mathcal{S}_{i,j}$ this implies that $(i, \pi(i))(j, \pi(j)) \in E(G)$ for each pair (i,j). Hence there is a k-clique in G. ◁

▷ Claim 5.10. The treedepth of H is $\mathcal{O}(k)$.

Proof. The treedepth of H is at most $|Y_k| = k + 2$ plus $\mathbf{td}(H - Y_k)$, which equals the maximum of $\mathbf{td}(C_{i,j})$ over all employed choice gadgets $C_{i,j}$. As $s_{i,j} \leq 4^k k^2$, Lemma 5.6(4) implies that $\mathbf{td}(C_{i,j}) \leq 2k + 2\log_2 k + \mathcal{O}(1)$. ◁

This concludes the proof of the proposition. ◀

6 Conclusion and open problems

We have obtained ETH-tight bounds for vertex-deletion problems into the classes of chordal and interval graphs, under the treewidth parameterization. The status of the corresponding edge-deletion problems remains unclear (see [64]). The related problem, Feedback Vertex Set, can be solved using representative families within the same running time as our algorithm for ChVD [37]. However, it admits a faster deterministic algorithm based on the determinant approach [69] and an even faster randomized algorithm based on the Cut & Count technique [35]. Could ChVD also be amenable to one of those techniques?

Our algorithm for ChVD is based on a novel connection between chordal graphs and graphic matroids, which might come in useful in other settings. In particular, we ask whether this insight can be leveraged to improve the running time for ChVD parameterized by the solution size k, where the current-best algorithm runs in time $2^{\mathcal{O}(k \log k)} n^{\mathcal{O}(1)}$ [29]. A direct avenue for a potential improvement would be to reduce the problem in time $2^{\mathcal{O}(k)} n^{\mathcal{O}(1)}$ to the case with treewidth $\mathcal{O}(k)$ and then apply Theorem 1.1. Such a strategy has been employed in the state-of-the-art algorithm for Planar Vertex Deletion parameterized by the solution size [47].

The Wrong Direction of Jensen's Inequality Is Algorithmically Right

Or Zamir ✉
Princeton University, NJ, USA

Abstract

Let $\mathcal{A}$ be an algorithm with expected running time e^X, conditioned on the value of some random variable X. We construct an algorithm $\mathcal{A}'$ with expected running time $O\left(e^{\mathsf{E}[X]}\right)$, that fully executes $\mathcal{A}$. In particular, an algorithm whose running time is a random variable T can be converted to one with expected running time $O\left(e^{\mathsf{E}[\ln T]}\right)$, which is never worse than $O(\mathsf{E}[T])$. No information about the distribution of X is required for the construction of $\mathcal{A}'$.

1 Introduction

Let $\mathcal{A}$ be a *Las Vegas*[1] randomized algorithm. Assume that conditioned on the value of some random variable X, the expected running time of $\mathcal{A}$ is e^X. By Jensen's inequality, $\mathsf{E}[e^X] \geq e^{\mathsf{E}[X]}$, and in fact $\mathcal{A}$'s expected running time might be much larger than $e^{\mathsf{E}[X]}$: Consider for example X that gets the value $\frac{1}{p}\mathsf{E}[X]$ with probability p and 0 otherwise, for any choice of $p > 0$; While the expectation of X is always $\mathsf{E}[X]$, the expectation of e^X is $p \cdot e^{\frac{1}{p}\mathsf{E}[X]}$ which can be arbitrarily large. We show that, surprisingly, any such $\mathcal{A}$ can be converted to a different Las-Vegas randomized algorithm $\mathcal{A}'$ that gives the same answer yet runs in expected time $O\left(e^{\mathsf{E}[X]}\right)$. Transforming $\mathcal{A}$ to $\mathcal{A}'$ does not require any assumption or knowledge about the distribution of X.

▶ **Theorem 1.** *There exists an algorithm T that receives as an input a randomized* Las Vegas *algorithm $\mathcal{A}$, and fully executes it. If the expected running time of $\mathcal{A}$ is e^X when conditioned on the value of some random variable X, then the expected running time of $T(A)$ is $O\left(e^{\mathsf{E}[X]}\right)$.*

As a corollary, any algorithm whose running time is a random variable T can be converted to one with expected running time $O\left(e^{\mathsf{E}[\ln T]}\right)$, which is never worse than $O(\mathsf{E}[T])$.

Recently we used the following simple version of Theorem 1 in a late revision of [10] to substantially simplify the analysis in the paper. The paper improves the running time of exact exponential-time algorithms for general Constraint Satisfaction Problems.

[1] A randomized algorithm is called *Las Vegas* if it always returns the correct answer, but its running time is a random variable.

▶ **Lemma 2** (from an up-to-date version of [10]). *Let $\mathcal{A}$ be an algorithm with expected running time 2^X conditioned on the value of a random variable X. There exists an algorithm $\mathcal{A}'$ that fully executes $\mathcal{A}$ and has an expected running time of $O\left(2^{\mathsf{E}[X]} \cdot \mathsf{E}[X]\right)$. Transforming $\mathcal{A}$ to $\mathcal{A}'$ requires knowing $\mathsf{E}[X]$.*

In this paper we focus on Theorem 1 itself, obtaining an optimal version of it.

We transform an algorithm $\mathcal{A}$ by using a sequence of *truncated evaluations*. A *truncated evaluation* of an algorithm $\mathcal{A}$ for t steps is the process of running algorithm $\mathcal{A}$ and aborting its run if it did not fully execute in the first t computational steps of its run. Each of the algorithms we present is thus a sequence of values $t_1, t_2, \ldots, t_i, \ldots$ which we use as thresholds for truncated evaluations of $\mathcal{A}$. We stop at the first time $\mathcal{A}$ is fully executed. These thresholds can be defined deterministically or be random variables. In the simpler algorithms we present, the thresholds depend on $\mathsf{E}[X]$ or even on the entire distribution X. For the proof of Theorem 1 the thresholds are completely independent of X and $\mathcal{A}$.

Truncated evaluations are frequently used in complexity theory (for example, see the proof of the time and space hierarchies in [2]). The first algorithmic use of such a sequence of truncated evaluations that we are aware of, is by Alt, Guibas, Mehlhorn, Karp and Wigderson [1]. They used it to convert *Las Vegas* randomized algorithms to *Monte Carlo* randomized algorithms, with success probability larger than what Markov's inequality gives. Luby, Sinclair and Zuckerman [5] then introduced a universal strategy for truncated evaluations. That is a sequence that is guaranteed to run in time $O(s \log s)$ if there exists any sequence that runs in time $O(s)$ for the same algorithm. Our contribution thus is two-fold: first, we prove the existence of good strategies in terms of $\mathsf{E}[X]$, and second, we show that these strategies can be explicitly constructed (i.e., without paying additional logarithmic factors). Not paying additional factors guarantees, due to Jensen's inequality, that our transformed algorithm is never worse than the original algorithm.

A natural use for such theorems is the regime of exponential-time algorithms. Consider the following toy example. As part of the classic algorithm of Schöning [9] it was shown that given an assignment α and a 3-SAT formula φ it is possible to test in $O\left(2^r\right)$ expected time whether φ has a satisfying assignment α_0 with $HAM\left(\alpha_0, \alpha\right) \leq r$, where $HAM(\cdot,\cdot)$ is the standard Hamming distance. This claim was also derandomized later [6]. We can use this primitive naively to obtain a non-trivial 3-SAT algorithm: Pick a random assignment α, and then run the above procedure of Schöning. Let X be the Hamming distance between α and a satisfying assignment α_0 of the input formula φ, this is a random variable. Conditioned on X, the expected running time of our algorithm is 2^X. The expected running time of our algorithm is thus $\mathsf{E}\left[2^X\right] = \sum_{r=0}^{n} \binom{n}{r} 2^{-n} 2^r = 2^{-n}(1+2)^n = \left(\frac{3}{2}\right)^n$. Using this paper's main Theorem, on the other hand, we can notice that $E[X] = \frac{n}{2}$ and thus we can convert the above algorithm in a black-box manner into one with expected running time $2^{\mathsf{E}[X]} = \left(\sqrt{2}\right)^n < \left(\frac{3}{2}\right)^n$. We note that Schöning already presented an algorithm using this procedure that is faster than both of the algorithms above.

Another similar example is the famous PPSZ algorithm for solving k-SAT, including its recent improvements, and generalizations for CSPs [7, 4, 3, 10]. In these algorithms, a randomly chosen permutation determines the number of input variables that we need to *guess* the values of. The expectation of this number of variables is then analyzed. The success probability or running time is exponential in this number. In the original PPSZ algorithm the analyzed quantity is the success probability and thus Jensen's inequality is applicable to bound this probability from below. In other variations (including [10]), the analyzed quantity is the running time and then Jensen's inequality is no longer applicable and either a more complicated analysis or the statement of this paper is necessary. Further discussion on possible applications and in particular possible implications for SAT algorithms appears in Section 3.

1.1 Preliminaries

We use standard notation throughout the paper. The notation $\ln x$ is used for the natural logarithm, and $\log x$ is used for the base two logarithm.

▶ **Definition 3** (Iterated functions). *Let $f : \mathbb{R} \to \mathbb{R}$ be a function. We define the iterated functions $f^{(k)} : \mathbb{R} \to \mathbb{R}$ recursively as follows. $f^{(0)}(x) := x$, and for any $k > 0$ we let $f^{(k)}(x) := f\left(f^{(k-1)}(x)\right)$.*

▶ **Definition 4** (Star functions). *Let $f : \mathbb{R} \to \mathbb{R}$ be a function. Assume f is strictly increasing and strictly shrinking[2] for all $x \geq x_0$. The star function of f, defined with respect to x_0 for every $x \geq x_0$, is*

$$f^{\star}(x) = \min\{k \mid f^{(k)}(x) \leq x_0\}.$$

The (general) Tower function $Tower_b(n,\, x) : \mathbb{N} \times \mathbb{R} \to \mathbb{R}$ is defined as $f^{(n)}(x)$ where $f(x) = b^x$. The standard Tower function $Tower : \mathbb{N} \to \mathbb{N}$ is defined as $Tower(n) = Tower_2(n, 1)$. The discrete inverse of the Tower function is $\log^{\star}$, defined with respect to $x_0 = 2$. That is, $\log^{\star} n$ is the smallest integer such that $Tower(\log^{\star} n) \geq n$.

2 Proof of Theorem 1

We begin by presenting a simple proof of Lemma 2.

Let $\mathcal{A}$ be an algorithm whose expected running time is e^X when we condition on the value of some non-negative random variable X. We observe, by Markov's inequality, that

$$\Pr\left(X > \mathsf{E}[X] + 1\right) \leq \frac{\mathsf{E}[X]}{\mathsf{E}[X]+1} = 1 - \frac{1}{\mathsf{E}[X]+1}.$$

Hence, consider the following algorithm.

Algorithm 1 Simple repetition.

Input: $\mathcal{A}$, $\mathsf{E}[X]$.
1: **repeat**
2: Run $\mathcal{A}$ for $2e^{\mathsf{E}[X]+1}$ computational steps.
3: **until** $\mathcal{A}$ completed a run.

▶ **Lemma 5.** *Algorithm 1 is expected to terminate in $O\left(e^{\mathsf{E}[X]} \cdot \mathsf{E}\left[X\right]\right)$ time.*

Proof. If $X \leq \mathsf{E}[X]+1$ then the expected running time of $\mathcal{A}$ is at most $e^{\mathsf{E}[X]+1}$, and hence by Markov's inequality a truncated evaluation of $\mathcal{A}$ for $2e^{\mathsf{E}[X]+1}$ steps concludes with probability at least $\frac{1}{2}$. By another application of Markov's inequality we got $\Pr\left(X \leq \mathsf{E}[X]+1\right) > \frac{1}{\mathsf{E}[X]+1}$. Hence, the expected number of iterations until the truncated evaluations concludes is at most $2\left(\mathsf{E}\left[X\right]+1\right)$. Each iteration takes $O\left(e^{\mathsf{E}[X]}\right)$ time. ◀

[2] That is, $f(x) < x$.

2.1 Optimal bound when the distribution of X is known

The bound given by Markov's inequality in

$$\Pr\left(X \geq \mathsf{E}[X]+1\right) \leq \frac{\mathsf{E}[X]}{\mathsf{E}[X]+1} = 1 - \frac{1}{\mathsf{E}[X]+1}$$

is attained *only* by the following distribution of X:

$$\Pr\left(X=k\right) := \begin{cases} \frac{1}{\mathsf{E}[X]+1} & k=0 \\ 1-\frac{1}{\mathsf{E}[X]+1} & k=\mathsf{E}[X]+1 \end{cases}.$$

In this distribution, on the other hand, the value of X is very small with a relatively high probability. In particular, in the case where $X < \mathsf{E}[X]+1$ we need to run $\mathcal{A}$ for much less than $e^{\mathsf{E}[X]+1}$ computational steps. Hence, it is sensible to hope that every distribution X has some threshold other than $\mathsf{E}[X]+1$ for which an algorithm similar to Algorithm 1 results in a better bound. Consider the following algorithm, which is a generalization of Algorithm 1 in which the threshold can be arbitrary.

Algorithm 2 Simple repetition with variable threshold.

Input: $\mathcal{A}$, t.
1: **repeat**
2: Run $\mathcal{A}$ for $2e^t$ computational steps.
3: **until** $\mathcal{A}$ completed a run.

▶ **Lemma 6.** *Let X be a non-negative random variable. There exists $t \in [0, \mathsf{E}[X]+1]$ such that $\frac{e^t}{\Pr(X<t)} \leq e^{\mathsf{E}[X]+1}$.*

Proof. Assume by contradiction that $\frac{e^t}{\Pr(X<t)} > e^{\mathsf{E}[X]+1}$ for every $t \in [0, \mathsf{E}[X]+1]$. Equivalently,

$$\Pr\left(X \geq t\right) = 1 - \Pr\left(X < t\right) > 1 - e^{t-(\mathsf{E}[X]+1)}.$$

Therefore,

$$\begin{aligned} \mathsf{E}[X] &= \int_0^\infty \Pr(X \geq t)\,\mathrm{d}t \geq \int_0^{\mathsf{E}[X]+1} \Pr(X \geq t)\,\mathrm{d}t \\ &> \int_0^{\mathsf{E}[X]+1} \left(1 - e^{t-(\mathsf{E}[X]+1)}\right)\mathrm{d}t \\ &= (\mathsf{E}[X]+1) - \left(1 - e^{-(\mathsf{E}[X]+1)}\right) = \mathsf{E}[X] + e^{-(\mathsf{E}[X]+1)} \\ &> \mathsf{E}[X], \end{aligned}$$

which is a contradiction. ◀

Lemma 6 implies the following.

▶ **Corollary 7.** *For every distribution X there exists a value of $t = t(X)$ for which Algorithm 2 runs in $O\left(e^{\mathsf{E}[X]}\right)$ time.*

We note that the additive constant $+1$ in the exponent in Lemma 6 is necessary. For a parameter E, consider the random variable X supported on $[0, E+1+\ln\left(1+e^{-(E+1)}\right)]$ and distributed with density $f(x) := e^{x-(E+1)}$; Its expectation is

$$\begin{aligned}\mathsf{E}[X] &= \int_0^{E+1+\ln\left(1+e^{-(E+1)}\right)} x f(x)\,\mathrm{d}x \\ &= \left((x-1)\,e^{x-(E+1)}\right)\Big|_0^{E+1+\ln\left(1+e^{-(E+1)}\right)} \\ &= \left(E+\ln\left(1+e^{-(E+1)}\right)\right)\cdot\left(1+e^{-(E+1)}\right)+e^{-(E+1)} \\ &= E+O\left(e^{-(E+1)}\right) = E+o(1),\end{aligned}$$

where the $o(1)$ term is vanishing when $E \to \infty$. On the other hand, for any $t \geq 0$ we have

$$\frac{e^t}{\Pr\left(X<t\right)} = \frac{e^t}{\min\left(1,\ e^{t-(E+1)}-e^{-(E+1)}\right)} > \frac{e^t}{e^{t-(E+1)}} = e^{E+1}.$$

2.2 Optimal algorithm when the distribution of X is unknown

If the only thing known about the distribution of X is its expectation $\mathsf{E}[X]$, then there is no fixed value of t for which Algorithm 2 is better than Algorithm 1. Fix a value of $\mathsf{E}[X]$ and a choice of t. If $t < \mathsf{E}[X]$ then with the constant distribution $X \equiv \mathsf{E}[X]$ Algorithm 2 never terminates. Otherwise, $t \geq \mathsf{E}[X]$ and we consider the following distribution X:

$$\Pr\left(X=k\right) := \begin{cases} 1-\frac{\mathsf{E}[X]}{t+1} & k=0 \\ \frac{\mathsf{E}[X]}{t+1} & k=t+1 \end{cases}.$$

For this distribution, the expected running time of Algorithm 2 is

$$\frac{e^t}{1-\frac{\mathsf{E}[X]}{t+1}} = e^{\mathsf{E}[X]}\cdot\frac{e^s}{\left(\frac{s+1}{\mathsf{E}[X]+s+1}\right)} = e^{\mathsf{E}[X]}\left(1+\frac{\mathsf{E}[X]}{s+1}\right)e^s \geq e^{\mathsf{E}[X]}\mathsf{E}[X]\cdot\frac{e^s}{s+1} \geq e^{\mathsf{E}[X]}\mathsf{E}[X],$$

where $s := t-\mathsf{E}[X] \geq 0$ and the last inequality follows as $e^s \geq s+1$ for any s.

To improve Algorithm 1 then, we need to consider *several thresholds*. We demonstrate this idea with the following Lemma.

▶ **Lemma 8.** *Let X be a non-negative random variable. It holds that either $\Pr\left(X \leq \mathsf{E}\left[X\right]-\ln\mathsf{E}\left[X\right]\right) > \frac{1}{\mathsf{E}[X]+1}$ or $\Pr\left(X \leq \mathsf{E}\left[X\right]+2\right) > \frac{1}{\ln\mathsf{E}[X]+2}$.*

Proof. Assume that $p := \Pr\left(X \leq \mathsf{E}\left[X\right]-\ln\mathsf{E}\left[X\right]\right) \leq \frac{1}{\mathsf{E}[X]+1}$. We observe that

$$\begin{aligned}\mathsf{E}\left[X\right] &= p\,\mathsf{E}\left[X \mid X \leq \mathsf{E}\left[X\right]-\ln\mathsf{E}\left[X\right]\right] + (1-p)\,\mathsf{E}\left[X \mid X > \mathsf{E}\left[X\right]-\ln\mathsf{E}\left[X\right]\right] \\ &\geq (1-p)\,\mathsf{E}\left[X \mid X > \mathsf{E}\left[X\right]-\ln\mathsf{E}\left[X\right]\right],\end{aligned}$$

and hence

$$\begin{aligned}\mathsf{E}\left[X \mid X > \mathsf{E}\left[X\right]-\ln\mathsf{E}\left[X\right]\right] &\leq \frac{1}{1-p}\mathsf{E}[X] \\ &\leq \frac{1}{1-\frac{1}{\mathsf{E}[X]+1}}\mathsf{E}[X] \\ &= \mathsf{E}[X]+1.\end{aligned}$$

Denote by $Y := X - (\mathsf{E}[X] - \ln \mathsf{E}[X])$. The above can now be rephrased as $\mathsf{E}[Y \mid Y > 0] \leq \ln \mathsf{E}[X] + 1$. Applying Markov's inequality to Y conditioned on $Y > 0$, we get

$$\Pr(Y > \ln \mathsf{E}[X] + 2 \mid Y > 0) \leq \frac{\ln \mathsf{E}[X] + 1}{\ln \mathsf{E}[X] + 2} = 1 - \frac{1}{\ln \mathsf{E}[X] + 2}.$$

We conclude by noting that

$$\Pr(X > \mathsf{E}[X] + 2) = \Pr(Y > \ln \mathsf{E}[X] + 2) \leq \Pr(Y > \ln \mathsf{E}[X] + 2 \mid Y > 0). \quad \blacktriangleleft$$

Consider the following Algorithm.

Algorithm 3 Two thresholds algorithm.

Input: $\mathcal{A}$, $\mathsf{E}[X]$.
1: **repeat**
2: **for** $\lceil \mathsf{E}[X] + 1 \rceil$ **times do**
3: Run $\mathcal{A}$ for $2e^{\mathsf{E}[X] - \ln \mathsf{E}[X]}$ computational steps.
4: **for** $\lceil \ln \mathsf{E}[X] + 2 \rceil$ **times do**
5: Run $\mathcal{A}$ for $2e^{\mathsf{E}[X]+2}$ computational steps.
6: **until** $\mathcal{A}$ completed a run.

Due to Lemma 8, each iteration of the outermost loop of Algorithm 3 succeeds to fully execute $\mathcal{A}$ with probability larger than $1 - e^{-1}$. Thus, in expectation we run this loop for a constant number of iterations. The first **for** loop takes $O\left(\mathsf{E}[X] \cdot e^{\mathsf{E}[X] - \ln \mathsf{E}[X]}\right) = O\left(e^{\mathsf{E}[X]}\right)$ expected time, and the second takes $O\left(e^{\mathsf{E}[X]} \ln \mathsf{E}[X]\right)$. We conclude the following.

▶ **Corollary 9.** *Algorithm 3 runs in expected time* $O\left(e^{\mathsf{E}[X]} \ln \mathsf{E}[X]\right)$.

Intuitively, the *proof* of Lemma 8 can be viewed as a reduction from the variable X to the variable $Y \mid (Y > 0)$, that has a much lower expectation: $\mathsf{E}[Y \mid Y > 0] \leq \ln \mathsf{E}[X] + 1$. We can thus hope that iterating the proof for $\ln^\star \mathsf{E}[X]$ times would result in reducing X to a variable with constant expectation. A natural implementation of this idea would result in an algorithm that runs in expected time $O\left(e^{\mathsf{E}[X]} \ln^\star \mathsf{E}[X]\right)$. We next formalize this intuition, and do so in a more careful manner to avoid the $\ln^\star \mathsf{E}[X]$ factor.

▶ **Definition 10.** *Let* $\lambda(x) := 3\ln(x)$ *and note it is strictly increasing and shrinking for all* $x \geq 5$. *We define* $\lambda^\star(x)$, *for* $x \geq 5$, *to be the smallest* $k \in \mathbb{N}$ *such that* $\lambda^{(k)}(x) \leq 5$.

▷ Claim 11. The following hold for all $x \geq 5$:
1. $\lambda^\star(x) = \Theta(\log^\star x)$.
2. $\lambda^{(\lambda^\star(x))}(x) > 4$.
3. $\sum_{i=0}^{\lambda^\star(x)} \frac{1}{\lambda^{(i)}(x)} < 2$.

Proof. (1) We have that $\lambda^{(2)}(x) \leq \log x \leq \lambda(x)$ for all $x \geq 410$. In particular, $\log^\star x \leq \lambda^\star(x) \leq 2\log^\star x + \lambda^\star(410)$.

(2) $\lambda^{(\lambda^\star(x)-1)}(x) > 5$ and hence $\lambda^{(\lambda^\star(x))}(x) > \lambda(5) > 4.82$.

(3) For all $x \geq 17$ it holds that $\lambda(x) \leq \frac{x}{2}$. Let k' be the smallest integer such that $\lambda^{(k')}(x) < 17$. We thus have

$$\sum_{i=0}^{k'-1} \frac{1}{\lambda^{(i)}(x)} < \frac{1}{17} \sum_{i=0}^{\infty} 2^{-i} = \frac{2}{17}.$$

On the other hand, there are at most $\lambda^\star(17)$ summands that are strictly larger than $\frac{1}{17}$, thus by (2) we have

$$\sum_{i=k'}^{\lambda^\star(x)} \frac{1}{\lambda^{(i)}(x)} < \frac{\lambda^\star(17)}{4} = \frac{5}{4}. \qquad \lhd$$

We are now ready to prove a generalized version of Lemma 8, that is going to be the core of our final algorithm.

▶ **Lemma 12.** *Let X be a non-negative distribution and $E \geq \max(\mathsf{E}[X], 5)$ be an upper bound on its expectation. There either exists $1 \leq k \leq \lambda^\star(E)$ such that $\Pr\left(X < E - \lambda^{(k)}(E)\right) \geq \left(\left(\lambda^{(k-1)}(E)+2\right)^2+1\right)^{-1}$, or it holds that $\Pr(X < E+10) \geq \frac{1}{2}$.*

Proof. We recursively denote by $E_0 := E$ and by $E_k := \lambda^{(k)}(E) + \sum_{i=0}^{k-1} \frac{1}{E_i}$ for $1 \leq k \leq \lambda^\star(E)$. Note that $E_k \geq \lambda^{(k)}(E)$ and hence also

$$E_k = \lambda^{(k)}(E) + \sum_{i=0}^{k-1} \frac{1}{E_i} \leq \lambda^{(k)}(E) + \sum_{i=0}^{k-1} \frac{1}{\lambda^{(i)}(E)} < \lambda^{(k)}(E) + 2,$$

where the last inequality follows from Claim 11. In particular, $\lambda^{(k)}(E) \leq E_k < \lambda^{(k)}(E) + 2$.

Assume that $\Pr\left(X < E - \lambda^{(k)}(E)\right) < \left(\left(\lambda^{(k-1)}(E)+2\right)^2+1\right)^{-1} < \frac{1}{(E_{k-1})^2+1}$ for every $1 \leq k \leq \lambda^\star(E)$.

Denote by $Y_k := X - \left(E - \lambda^{(k)}(E)\right)$ for $k \geq 0$. We prove by induction on k that $\mathsf{E}[Y_k \mid Y_k \geq 0] \leq E_k$. For $k = 0$ the claim is straightforward as $Y_0 = X$ and $E_0 = E$. For the inductive step, we assume the hypothesis holds for $k-1$ and show it holds for k. We note that $Y_{k-1} > Y_k$ and hence if $Y_k \geq 0$ then $Y_{k-1} \geq 0$ as well. Hence,

$$\begin{aligned}\mathsf{E}[Y_{k-1} \mid Y_{k-1} \geq 0] &\geq \Pr(Y_k \geq 0 \mid Y_{k-1} \geq 0)\, \mathsf{E}[Y_{k-1} \mid Y_k \geq 0] \\ &\geq \Pr(Y_k \geq 0)\, \mathsf{E}[Y_{k-1} \mid Y_k \geq 0].\end{aligned}$$

Thus, by the induction hypothesis we have

$$\begin{aligned}\mathsf{E}[Y_{k-1} \mid Y_k \geq 0] &\leq \frac{\mathsf{E}[Y_{k-1} \mid Y_{k-1} \geq 0]}{\Pr(Y_k \geq 0)} \\ &\leq \frac{E_{k-1}}{1 - \frac{1}{(E_{k-1})^2+1}} \\ &= E_{k-1} + \frac{1}{E_{k-1}}.\end{aligned}$$

Therefore,

$$\begin{aligned}\mathsf{E}[Y_k \mid Y_k \geq 0] &= \mathsf{E}[Y_{k-1} \mid Y_k \geq 0] + \lambda^{(k)}(E) - \lambda^{(k-1)}(E) \\ &\leq E_{k-1} + \frac{1}{E_{k-1}} + \lambda^{(k)}(E) - \lambda^{(k-1)}(E) \\ &= E_k.\end{aligned}$$

In particular, we have that $\mathsf{E}\left[Y_{\lambda^\star(E)} \mid Y_{\lambda^\star(E)} \geq 0\right] \leq E_{\lambda^\star(E)} < \lambda^{(\lambda^\star(E))}(E) + 2 \leq 7$.

Therefore,

$$\begin{aligned}\Pr\left(X \geq E+10\right) &\leq \Pr\left(X \geq E+10 \;\middle|\; X \geq E-\lambda^{(\lambda^\star(E))}(E)\right)\\ &= \Pr\left(Y_{\lambda^\star(E)} \geq \lambda^{(\lambda^\star(E))}(E)+10 \;\middle|\; Y_{\lambda^\star(E)} \geq 0\right)\\ &\leq \Pr\left(Y_{\lambda^\star(E)} \geq 14 \;\middle|\; Y_{\lambda^\star(E)} \geq 0\right) < \frac{7}{14} = \frac{1}{2}.\end{aligned}$$

◀

Consider the following algorithm.

Algorithm 4 Multiple thresholds algorithm.

Input: $\mathcal{A}$, E.

1: **repeat**
2: **for** $k = 1$ to $\lambda^\star(E)$ **do**
3: **for** $2\lceil\left(\lambda^{(k-1)}(E)+2\right)^2+1\rceil$ **times do**
4: Run $\mathcal{A}$ for $2e^{E-\lambda^{(k)}(E)}$ computational steps.
5: **for** 2 **times do**
6: Run $\mathcal{A}$ for $2e^{E+10}$ computational steps.
7: **until** $\mathcal{A}$ completed a run.

▶ **Corollary 13** (of Lemma 12). *Each* ***repeat*** *loop of Algorithm 4 fully executes $\mathcal{A}$ with probability at least $\frac{3}{4}$.*

▶ **Lemma 14.** *Let $E \geq \max\left(\mathsf{E}[X],\ 5\right)$, Algorithm 4 runs in $O\left(e^E\right)$ expected time.*

Proof. By Corollary 13 we enter the **repeat** loop a constant number of times in expectation. We thus analyze the computational cost of a single **repeat** loop. The evaluations in Lines $5-6$ take $O\left(e^E\right)$ time. The evaluations in Lines $2-4$ take

$$\sum_{k=1}^{\lambda^\star(E)} 2\lceil\left(\lambda^{(k-1)}(E)+2\right)^2+1\rceil \cdot 2e^{E-\lambda^{(k)}(E)} = O\left(e^E \cdot \sum_{k=1}^{\lambda^\star(E)} \left(\lambda^{(k-1)}(E)\right)^2 e^{-\lambda^{(k)}(E)}\right)$$

time. By the definition of $\lambda(x)$, we have $e^{-\lambda^{(k)}(x)} = e^{-3\ln\left(\lambda^{(k-1)}(x)\right)} = \left(\lambda^{(k-1)}(x)\right)^{-3}$. In particular,

$$\sum_{k=1}^{\lambda^\star(E)} \left(\lambda^{(k-1)}(E)\right)^2 e^{-\lambda^{(k)}(E)} = \sum_{k=1}^{\lambda^\star(E)} \left(\lambda^{(k-1)}(E)\right)^{-1} < 2,$$

where the last inequality follows from Claim 11. ◀

Finally, we also get rid of the necessity to provide the algorithm with E or $\mathsf{E}[X]$.

▶ **Theorem 15.** *Algorithm 5 runs in expected time $O\left(e^{\mathsf{E}[X]}\right)$.*

Proof. By Lemma 14 the iteration of the outermost **for** loop corresponding to E takes at most $C \cdot e^E$ time, for some global constant C. All iterations in which $E < \mathsf{E}[X]$ thus take $O\left(e^{\mathsf{E}[X]}\right)$ time. By Corollary 13, each subsequent iteration succeeds with probability at least $\frac{3}{4}$. Thus the expected running time is bounded by

$$Ce^{\mathsf{E}[X]} \cdot \sum_{t=0}^{\infty} e^t \left(\frac{1}{4}\right)^t = O\left(e^{\mathsf{E}[X]}\right).$$

◀

Algorithm 5 Final algorithm.

Input: $\mathcal{A}$.

for $E = 5$ to ∞ **do**
  for $k = 1$ to $\lambda^\star(E)$ **do**
    for $2\lceil\left(\lambda^{(k-1)}(E)+2\right)^2+1\rceil$ **times do**
      Run $\mathcal{A}$ for $2e^{E-\lambda^{(k)}(E)}$ computational steps.
  for 2 **times do**
    Run $\mathcal{A}$ for $2e^{E+10}$ computational steps.
  return if $\mathcal{A}$ completed a run.

3 Conclusions and Open Problems

We showed that a Las-Vegas algorithm with expected running e^X conditioned on the value of some random variable X, can always be converted to a Las-Vegas algorithm with expected running time $O\left(e^{\mathsf{E}[X]}\right)$. In particular, an algorithm whose running time is a random variable T can be converted to one with expected running time $O\left(e^{\mathsf{E}[\ln T]}\right)$, which is never worse than $O(\mathsf{E}[T])$.

We demonstrated a use of this theorem to simplify a proof in the regime of exponential time algorithms [10]. It is interesting to try applying it to other exponential and non-exponential time algorithms and see if it can simplify or even improve the analysis.

3.1 Considering the variance

In terms of $\mathsf{E}[X]$ only, we can not get any better than $O\left(e^{\mathsf{E}[X]}\right)$ as the distribution of X might be constant. In that case though, the variance of X is zero. Can we get a better bound just by assuming that the variance of X is large? Unfortunately, with the standard definition of variance this is not the case. For any choice of E and $V \geq 2E^2e^{-E}$ consider the following distribution:

$$\Pr(X=k) := \begin{cases} e^{-E} & k=0 \\ 1-\frac{Ve^{-E}}{V-E^2e^{-E}} & k=E \\ \frac{\left(Ee^{-E}\right)^2}{V-E^2e^{-E}} & k=\frac{V}{Ee^{-E}} \end{cases}.$$

Its expectation is E, its variance is V, which can be arbitrarily large, and nevertheless $\Pr(X < E) = e^{-E}$ so no strategy can beat $O\left(e^E\right)$.

On the other hand, the wishful thinking above is true with some other notions of deviation. For example, if we consider mean absolute deviation instead of standard deviation (i.e., $\mathsf{E}\left[\,|X-\mathsf{E}[X]|\,\right]$), then *it is* true that if the deviation is large then we can get a better running time. It is intriguing to find useful notion of deviation for which such a statement is true, with the goal of improving the running time of algorithms by analyzing the deviation of X.

In particular, consider the PPSZ algorithm for solving k-SAT [7] [4]. The algorithm uses randomization in two ways: first, a random permutation of the variables in the input formulas is drawn; Then, the chosen permutation determines the number of variables we need to *guess* the value of. In a recent improvement of the PPSZ analysis, Scheder [8] showed that in some large subset of permutations the number of guessed variables is smaller than what we expect when taking a uniformly random permutation. In particular, this implies that there is some non-negligible variance in the original algorithm's running time. Can we get better SAT algorithms by analyzing this variance?

A Hyperbolic Extension of Kadison-Singer Type Results

Ruizhe Zhang
The University of Texas at Austin, TX, USA

Xinzhi Zhang
University of Washington, Seattle, WA, USA

Abstract

In 2013, Marcus, Spielman, and Srivastava resolved the famous Kadison-Singer conjecture. It states that for n independent random vectors $v_1, \cdots, v_n$ that have expected squared norm bounded by ϵ and are in the isotropic position in expectation, there is a positive probability that the determinant polynomial $\det(xI - \sum_{i=1}^n v_i v_i^\top)$ has roots bounded by $(1+\sqrt{\epsilon})^2$. An interpretation of the Kadison-Singer theorem is that we can always find a partition of the vectors $v_1, \cdots, v_n$ into two sets with a low discrepancy in terms of the spectral norm (in other words, rely on the determinant polynomial).

In this paper, we provide two results for a broader class of polynomials, the hyperbolic polynomials. Furthermore, our results are in two generalized settings:

- The first one shows that the Kadison-Singer result requires a weaker assumption that the vectors have a bounded sum of hyperbolic norms.
- The second one relaxes the Kadison-Singer result's distribution assumption to the Strongly Rayleigh distribution.

To the best of our knowledge, the previous results only support determinant polynomials [Anari and Oveis Gharan'14, Kyng, Luh and Song'20]. It is unclear whether they can be generalized to a broader class of polynomials. In addition, we also provide a sub-exponential time algorithm for constructing our results.

1 Introduction

Introduced by [30], the Kadison-Singer problem was a long-standing open problem in mathematics. It was resolved by Marcus, Spielman, and Srivastrava in their seminal work [43]: For any set of independent random vectors $u_1, \cdots, u_n$ such that each u_i has finite support, and $u_1, \cdots, u_n$ are in isotropic positions in expectation, there is positive probability that $\sum_{i=1}^n u_i u_i^*$ has spectral norm bounded by $1 + O(\max_{i\in[n]} \|u_i\|)$. The main result of [43] is as follows:

▶ **Theorem 1** (Main result of [43]). *Let $\epsilon > 0$ and let $v_1, \cdots, v_n \in \mathbb{C}^m$ be n independent random vectors with finite support, such that $\mathbb{E}[\sum_{i=1}^n v_i v_i^*] = I$, and $\mathbb{E}[\|v_i\|^2] \leq \epsilon$, $\forall i \in [n]$. Then*

$$\Pr\left[\left\|\sum_{i\in[n]} v_i v_i^*\right\| \leq (1+\sqrt{\epsilon})^2\right] > 0.$$

The Kadison-Singer problem is closely related to discrepancy theory, which is an essential area in mathematics and theoretical computer science. A classical discrepancy problem is as follows: given n sets over n elements, can we color each element in red or blue such that each set has roughly the same number of elements in each color? More formally, for vectors $a_1, \ldots, a_n \in \mathbb{R}^n$ with $\|a_i\|_\infty \leq 1$ and a coloring $s \in \{\pm 1\}^n$, the discrepancy is defined by $\mathrm{Disc}(a_1, \ldots, a_n; s) := \|\sum_{i\in[n]} s_i a_i\|_\infty$. The famous Spencer's Six Standard Deviations Suffice Theorem [57] shows that there exists a coloring with discrepancy at most $6\sqrt{n}$, which beats the standard Chernoff bound showing that a random coloring has discrepancy $\sqrt{n \log n}$. More generally, we can consider the "matrix version" of discrepancy: for matrices $A_1, \ldots, A_n \in \mathbb{R}^{d\times d}$ and a coloring $s \in \{\pm 1\}^n$,

$$\mathrm{Disc}(A_1, \ldots, A_n; s) := \left\|\sum_{i\in[n]} s_i A_i\right\|.$$

Theorem 1 is equivalent to the following discrepancy result for rank-1 matrices:

▶ **Theorem 2** ([43]). *Let $u_1, \ldots, u_n \in \mathbb{C}^m$ and suppose $\max_{i\in[n]} \|u_i u_i^*\| \leq \epsilon$ and $\sum_{i=1}^n u_i u_i^* = I$. Then,*

$$\min_{s\in\{\pm1\}^n} \mathrm{Disc}(u_1 u_1^*, \ldots, u_n u_n^*; s) \leq O(\sqrt{\epsilon}).$$

In other words, the minimum discrepancy of rank-1 isotropic matrices is bounded by $O(\sqrt{\epsilon})$, where ϵ is the maximum spectral norm. This result also beats the matrix Chernoff bound [60], which shows that a random coloring for matrices has discrepancy $O(\sqrt{\epsilon \log d})$. The main techniques in [43] are the method of interlacing polynomials and the barrier methods developed in [42].

Several generalizations of the Kadison-Singer-type results, which have interesting applications in theoretical computer science, have been established using the same technical framework as described in [43]. In particular, Kyng, Luh, and Song [36] provided a "four derivations suffice" version of Kadison-Singer conjecture: Instead of assuming every independent random vector has a bounded norm, the main result in [36] only requires that the sum of the squared spectral norm is bounded by σ^2, and showed a discrepancy bound of 4σ:

▶ **Theorem 3** ([36]). *Let $u_1, \ldots, u_n \in \mathbb{C}^m$ and $\sigma^2 = \|\sum_{i=1}^n (u_i u_i^*)^2\|$. Then, we have*

$$\Pr_{\xi\sim\{\pm1\}^n}\left[\left\|\sum_{i=1}^n \xi_i u_i u_i^*\right\| \leq 4\sigma\right] > 0.$$

This result was recently applied by [38] to approximate solutions of generalized network design problems.

Moreover, Anari and Oveis-Gharan [6] generalized the Kadison-Singer conjecture into the setting of real-stable polynomials. Instead of assuming the random vectors are independent, [6] assumes that the vectors are sampled from any homogeneous strongly Rayleigh distribution with bounded marginal probability, have bounded norm, and are in an isotropic position:

▶ **Theorem 4** ([6]). *Let μ be a homogeneous strongly Rayleigh probability distribution on $[n]$ such that the marginal probability of each element is at most ϵ_1, and let $u_1, \cdots, u_n \in \mathbb{R}^m$ be vectors in an isotropic position, $\sum_{i=1}^n u_i u_i^* = I$, such that $\max_{i\in[n]} \|u_i\|^2 \le \epsilon_2$. Then*

$$\Pr_{S\sim\mu}\left[\left\|\sum_{i\in S} u_i u_i^*\right\| \le 4(\epsilon_1+\epsilon_2)+2(\epsilon_1+\epsilon_2)^2\right] > 0.$$

Theorem 4 has a direct analog in spectral graph theory: Given any (weighted) connected graph $G = (V, E)$ with Laplacian L_G. For any edge $e = (u, v) \in E$, define the vector corresponding to e as $v_e = L_G^{\dagger/2}(\mathbf{1}_u - \mathbf{1}_v)$ (here $L_G^\dagger$ is the Moore-Penrose inverse). Then the set of $\{v_e : e \in E\}$ are in isotropic position, and $\|v_e\|^2$ equals to the graph effective resistance with respect to e. Also, any spanning tree distribution of the edges in E is homogeneous strongly Rayleigh. It follows from Theorem 4 that any graph with bounded maximum effective resistance has a spectrally-thin spanning tree [6]. Moreover, [7] provided an exciting application to the asymmetric traveling salesman problem and obtained an $O(\log\log n)$-approximation.

Another perspective of generalizing the Kadison-Singer theorem is to study the discrepancy with respect to a more general norm than the spectral norm, which is the largest root of a determinant polynomial. A recent work by Bränden [19] proved a high-rank version of Theorem 2 for *hyperbolic* polynomial, which is a larger class of polynomials including the determinant polynomial. Moreover, the hyperbolic norm on vectors is a natural generalization of the matrix spectral norm. We will introduce hyperbolic polynomials in the full version of our paper. From this perspective, it is very natural to ask:

Can we also extend Theorem 3 and Theorem 4 to a more general class of polynomials, e.g., hyperbolic polynomials?

1.1 Our results

In this work, we provide an affirmative answer by generalizing both Theorem 3 and Theorem 4 into the setting of hyperbolic polynomials. Before stating our main results, we first introduce some basic notation of hyperbolic polynomials below.

Hyperbolic polynomials form a broader class of polynomials that encompasses determinant polynomials and homogeneous real-stable polynomials. An m-variate, degree-d homogeneous polynomial $h \in \mathbb{R}[x_1, \cdots, x_m]$ is *hyperbolic* with respect to a direction $e \in \mathbb{R}^m$ if the univariate polynomial $t \mapsto h(te - x)$ has only real roots for all $x \in \mathbb{R}^m$. The set of $x \in \mathbb{R}^m$ such that all roots of $h(te - x)$ are non-negative (or strictly positive) is referred to as the hyperbolicity cone $\Gamma_+^h(e)$ (or $\Gamma_{++}^h(e)$). It is a widely recognized result [16] that any vector x in the open hyperbolicity cone $\Gamma_{++}^h(e)$ is itself hyperbolic with respect to the polynomial h and have the same hyperbolicity cone as e, meaning that $\Gamma_{++}^h(e) = \Gamma_{++}^h(x)$. Therefore, the unique hyperbolicity cone of h can simply be expressed as Γ_+^h.

The hyperbolic polynomials have similarities to determinant polynomials of matrices, as they both can be used to define trace, norm, and eigenvalues. Given a hyperbolic polynomial $h \in \mathbb{R}[x_1, \cdots, x_m]$ and any vector $e \in \Gamma_{++}^h$, we can define a norm with respect to $h(x)$ and e as follows: for any $x \in \mathbb{R}^m$, its *hyperbolic norm* $\|x\|_h$ is equal to the largest root (in absolute value) of the linear restriction polynomial $h(te - x) \in \mathbb{R}[t]$. Similar to the eigenvalues of matrices, we define the *hyperbolic eigenvalues* of x to be the d roots of $h(te - x)$, denoted by $\lambda_1(x) \ge \cdots \ge \lambda_d(x)$. We can also define the *hyperbolic trace* and the *hyperbolic rank*:

$$\mathrm{tr}_h[x] := \sum_{i=1}^d \lambda_i(x), \quad \text{and} \quad \mathrm{rank}(x)_h := |\{i \in [d] : \lambda_i(x) \neq 0\}|.$$

Recall that both Theorem 3 and Theorem 4 upper-bound the spectral norm of the sum $\|\sum_{i=1}^n \xi_i v_i v_i^\top\|$. In the setting of hyperbolic polynomials, we should upper bound the hyperbolic norm $\|\sum_{i=1}^n \xi_i v_i\|_h$ for vectors $v_1, \ldots, v_n$ in the hyperbolicity cone, which is the set of vectors with all non-negative hyperbolic eigenvalues.

Our main results are as follows:

▶ **Theorem 5** (Main Result I, informal hyperbolic version of Theorem 1.4, [36]). *Let $h \in \mathbb{R}[x_1, \ldots, x_m]$ denote a hyperbolic polynomial in direction $e \in \mathbb{R}^m$. Let $v_1, \ldots, v_n \in \Gamma_+^h$ be n vectors in the closed hyperbolicity cone. Let $\xi_1, \ldots, \xi_n$ be n independent random variables with finite supports and $\mathbb{E}[\xi_i] = \mu_i$ and $\mathbf{Var}[\xi_i] = \tau_i^2$. Suppose $\sigma := \|\sum_{i=1}^n \tau_i^2 \operatorname{tr}_h[v_i] v_i\|_h$. Then there exists an assignment $(s_1, \ldots, s_n)$ with s_i in the support of ξ_i for all $i \in [n]$, such that*

$$\left\| \sum_{i=1}^n (s_i - \mu_i) v_i \right\|_h \leq 4\sigma.$$

We remark that Theorem 5 does not require the isotropic position condition of $v_1, \cdots, v_n$ as in [19]. In addition, we only need the sum of $\operatorname{tr}_h[v_i]v_i$'s hyperbolic norm to be bounded, while [19]'s result requires each vector's trace to be bounded individually.

We would also like to note that the class of hyperbolic polynomials is much broader than that of determinant polynomials, which were used in the original Kadison-Singer-type theorems. Lax conjectured in [39] that every 3-variate hyperbolic/real-stable polynomial could be represented as a determinant polynomial, this was later resolved in [28, 40]. However, the Lax conjecture is false when the number of variables exceeds 3, as demonstrated in [17, 20] with counterexamples of hyperbolic/real-stable polynomials $h(x)$ for which even $(h(x))^k$ cannot be represented by determinant polynomials for any $k > 0$.

Our second main result considers the setting where the random vectors are not independent, but instead, sampled from a strongly Rayleigh distribution. We say a distribution μ over the subsets of $[n]$ is *strongly Rayleigh* if its generating polynomial $g_\mu(z) := \sum_{S \subseteq [n]} \mu(S) z^S \in \mathbb{R}[z_1, \ldots, z_n]$ is a *real-stable polynomial*, which means $g_\mu(z)$ does not have any root in the upper-half of the complex plane, i.e., $g_\mu(z) \neq 0$ for any $z \in \mathbb{C}^n$ with $\Re(z) \succ 0$.

▶ **Theorem 6** (Main Result II, informal hyperbolic version of Theorem 1.2, [6]). *Let $h \in \mathbb{R}[x_1, \ldots, x_m]$ denote hyperbolic polynomial in direction $e \in \mathbb{R}^m$. Let μ be a homogeneous strongly Rayleigh probability distribution on $[n]$ such that the marginal probability of each element is at most ϵ_1.*

Suppose $v_1, \cdots, v_n \in \Gamma_+^h$ are in the hyperbolicity cone of h such that $\sum_{i=1}^n v_i = e$, and for all $i \in [n]$, $\|v_i\|_h \leq \epsilon_2$. Then there exists $S \subseteq [n]$ in the support of μ, such that

$$\left\| \sum_{i \in S} v_i \right\|_h \leq 4(\epsilon_1 + \epsilon_2) + 2(\epsilon_1 + \epsilon_2)^2.$$

It is worth mentioning that the previous paper [36, 6] focused on the determinant polynomial, leaving the question of whether their techniques could be extended to the hyperbolic/real-stable setting unresolved. In our paper, we address this gap by developing new techniques specifically tailored to hyperbolic polynomials.

In addition, we follow the results from [11] and give an algorithm that can find the approximate solutions of both Theorem 5 and Theorem 6 in time sub-exponential to m:

▶ **Proposition 7** (Sub-exponential algorithm for Theorem 5, informal). *Let $h \in \mathbb{R}[x_1, \ldots, x_m]$ denote a hyperbolic polynomial with direction $e \in \mathbb{R}^m$. Let $v_1, \ldots, v_n \in \Gamma_+^h$ be n vectors in the hyperbolicity cone Γ_+^h of h. Suppose $\sigma = \|\sum_{i=1}^n \operatorname{tr}_h[v_i] v_i\|_h$.*

Let $\mathcal{P}$ be the interlacing family used in the proof of Theorem 6. Then there exists an sub-exponential time algorithm KadisonSinger$(\delta, \mathcal{P})$*, such that for any $\delta > 0$, it returns a sign assignment $(s_1, \cdots, s_n) \in \{\pm 1\}^n$ satisfying*

$$\left\| \sum_{i=1}^{n} s_i u_i \right\|_h \leq 4(1+\delta)\sigma.$$

▶ **Proposition 8** (Sub-Exponential algorithm for Theorem 6, informal)**.** *Let $h \in \mathbb{R}[x_1, \ldots, x_m]$ denote a hyperbolic polynomial in direction $e \in \mathbb{R}^m$. Let μ be a homogeneous strongly Rayleigh probability distribution on $[n]$ such that the marginal probability of each element is at most ϵ_1, and let $v_1, \cdots, v_n \in \Gamma_+^h$ be n vectors such that $\sum_{i=1}^n v_i = e$, and for all $i \in [n]$, $\|v_i\|_h \leq \epsilon_2$.*

Let $\mathcal{Q}$ be the interlacing family used in the proof of Theorem 6. Then there exists an sub-exponential time algorithm KadisonSinger$(\delta, \mathcal{Q})$*, such that for any $\delta > 0$, it returns a set S in the support of μ satisfying*

$$\left\| \sum_{i \in S} u_i \right\|_h \leq (1+\delta) \cdot \left(4(\epsilon_1 + \epsilon_2) + 2(\epsilon_1 + \epsilon_2)^2\right).$$

2 Related work

Real-Stable Polynomials

Real-stability is an important property for multivariate polynomials. In [13], the authors used the real-stability to give a unified framework for Lee-Yang type problems in statistical mechanics and combinatorics. Real-stable polynomials are also related to the permanent. Gurvits [25] proved the Van der Waerden conjecture, which conjectures that the permanent of n-by-n doubly stochastic matrices are lower-bounded by $n!/n^n$, via the capacity of real-stable polynomials. Recently, [26] improved the capacity lower bound for real-stable polynomials, which has applications in matrix scaling and metric TSP. In addition, real-stable polynomials are an important tool in solving many counting and sampling problems [46, 9, 8, 58, 10, 5, 12, 3, 4].

Hyperbolic Polynomials

Hyperbolic polynomial was originally defined to study the stability of partial differential equations [23, 29, 34]. In theoretical computer science, Güler [24] first introduced hyperbolic polynomial for optimization (hyperbolic programming), which is a generalization of LP and SDP. Later, a few algorithms [50, 44, 53, 51, 45, 52] were designed for hyperbolic programming. On the other hand, a significant effort has been put into the equivalence between hyperbolic programming and SDP, which is closely related to the "Generalized Lax Conjecture" (which conjectures that every hyperbolicity cone is spectrahedral) and its variants [28, 40, 18, 35, 54, 2, 48].

Strongly Rayleigh Distribution

The strongly Rayleigh distribution was introduced by [14]. The authors also proved numerous basic properties of strongly Rayleigh distributions, including negative association, and closure property under operations such as conditioning, product, and restriction to a subset. [47] proved a concentration result for Lipschitz functions of strongly Rayleigh variables. [37] showed a matrix concentration for strongly Rayleigh random variables, which implies that adding a small number of uniformly random spanning trees gives a graph spectral sparsifier.

Strongly Rayleigh distribution also has many algorithmic applications. [9] exploited the negative dependence property of homogeneous strongly Rayleigh distributions, and designed efficient algorithms for generating approximate samples from Determinantal Point Process using Monte Carlo Markov Chain. The strongly Rayleigh property of spanning tree distribution is a key component for improving the approximation ratios of TSP [31, 32] and k-edge connected graph problem [33].

Other generalizations of the Kadison-Singer-type results

The upper bound of the rank-one Kadison-Singer theorem was improved by [15, 49]. [1] further extended [49]'s result to prove a real-stable version of Anderson's paving conjecture. However, they used a different norm for real-stable polynomials, and hence their results and ours are incomparable. In the high-rank case, [21] also proved a Kadison-Singer result for high-rank matrices. [56] relaxed [19]'s result to the vectors in sub-isotropic position. In addition, they proved a hyperbolic Spencer theorem for constant-rank vectors.

Another direction of generalizing the Kadison-Singer-type result is to relax the $\{+1,-1\}$-coloring to $\{0,1\}$-coloring, which is called the one-sided version of Kadison-Singer problem in [61]. More specifically, given n isotropic vectors $v_1,\ldots,v_n \in \mathbb{R}^m$ with norm $\frac{1}{\sqrt{N}}$, the goal is to find a subset $S \subset [n]$ of size k such that $\|\sum_{i\in S} v_i v_i^\top\| \leq \frac{k}{n} + O(1/\sqrt{N})$. Unlike the original Kadison-Singer problem, Weaver [61] showed that this problem can be solved in polynomial time. Very recently, Song, Xu and Zhang [55] improved the time complexity of the algorithm via an efficient inner product search data structure.

Applications of Kadison-Singer Problem

There are many interesting results developed from the Kadison-Singer theorem. In spectral graph theory, [27] exploited the same proof technique of interlacing families to show a sufficient condition of the spectrally thin tree conjecture. [6] used the strongly-Rayleigh extension of Kadison-Singer theorem to show a weaker sufficient condition. Based on this result, [7] showed that any k-edge-connected graph has an $O(\frac{\log\log(n)}{k})$-thin tree, and gave a $\mathrm{poly}(\log\log(n))$-integrality gap of the asymmetric TSP. [41, 22] used the Kadison-Singer theorem to construct bipartite Ramanujan graphs of all sizes and degrees. In the network design problem, [38] exploited the result in [36], and built a spectral rounding algorithm for the general network design convex program, which has applications in weighted experimental design, spectral network design, and additive spectral sparsifier.

3 Proof Overview

3.1 Hyperbolic Deviations

In this section, we will sketch the proof of our hyperbolic generalization of the Kadison-Singer theorem (Theorem 5). Details of the proof are deferred to the full version of the paper. We will use the same strategy as the original Kadison-Singer theorem (Theorem 1) in [42, 43], following three main technical steps.

For simplicity, we assume that the random variables $\xi_1,\ldots,\xi_n \in \{\pm 1\}$ are independent Rademacher random variables, i.e., $\Pr[\xi_i = 1] = \frac{1}{2}$ and $\Pr[\xi_i = -1] = \frac{1}{2}$ for all $i \in [n]$.

To generalize the Kadison-Singer statement into the hyperbolic norm, one main obstacle is to define the variance of the hyperbolic norm of the sum of random vectors $\sum_{i=1}^n \xi_i v_i$. In the determinant polynomial case, each v_i corresponds to a rank-1 matrix $u_i u_i^*$, and it is easy

to see that the variance of the spectral norm is $\|\sum_{i=1}^n (u_i u_i^*)^2\|$. However, there is no analog of "matrix square" in the setting of hyperbolic/real-stable polynomials. Instead, we define the *hyperbolic variance*:

$$\left\|\sum_{i=1}^n \mathrm{tr}_h[v_i]v_i\right\|_h$$

in terms of the hyperbolic trace, and show that *four hyperbolic deviations suffice*.

Defining interlacing family of characteristic polynomials

In the first step, we construct a family of *characteristic polynomials* $\{p_s : s \in \{\pm 1\}^t, t \in \{0, \cdots, n\}\}$ as follows: For each $\mathbf{s} \in \{\pm 1\}^n$, define the leaf-node-polynomial:

$$p_{\mathbf{s}}(x) := \left(\prod_{i=1}^n p_{i,s_i}\right) \cdot h\left(xe + \sum_{i=1}^n s_i v_i\right) \cdot h\left(xe - \sum_{i=1}^n s_i v_i\right),$$

and for all $\ell \in \{0, \ldots, n-1\}$, $\mathbf{s}' \in \{\pm 1\}^\ell$, we construct an inner node with a polynomial that corresponds to the bit-string $\mathbf{s}'$:

$$p_{\mathbf{s}'}(x) := \sum_{\mathbf{t} \in \{\pm 1\}^{n-\ell}} p_{(\mathbf{s}',\mathbf{t})}(x).$$

where $(\mathbf{s}', \mathbf{t}) \in \{\pm 1\}^n$ is the bit-string concatenated by $\mathbf{s}'$ and $\mathbf{t}$.

We will then show that the above family of characteristic polynomials forms an *interlacing family*. By basic properties of interlacing family, we can always find a leaf-root-polynomial p_s (where $s \in \{\pm 1\}^n$) whose largest root is upper bounded by the largest root of the top-most polynomial.

$$p_\emptyset(x) = \mathop{\mathbb{E}}_{\xi_1,\cdots,\xi_n}\left[h\Big(xe + \sum_{i=1}^n \xi_i v_i\Big) \cdot h\Big(xe - \sum_{i=1}^n \xi_i v_i\Big)\right].$$

(we call $p_\emptyset$ to be the *mixed characteristic polynomial*). Notice that by rewriting the largest root of p_s to be the expected hyperbolic norm of $\sum_{i=1}^n s_i v_i$, we get that

$$\lambda_{\max}(p_\emptyset) = \left\|\sum_{i=1}^n s_i v_i\right\|_h. \tag{1}$$

Also, we will take $s \in \{\pm 1\}^n$ as the corresponding sign assignment in the main theorem (Theorem 5) It then suffices to upper-bound the largest root of the mixed characteristic polynomial.

From mixed characteristic polynomial to multivariate polynomial

In the second step, we will show that the mixed characteristic polynomial that takes the average on n random variables

$$p_\emptyset(x) = \mathop{\mathbb{E}}_{\xi_1,\ldots,\xi_n}\left[h\Big(xe + \sum_{i=1}^n \xi_i v_i\Big) \cdot h\Big(xe - \sum_{i=1}^n \xi_i v_i\Big)\right]$$

is equivalent to a polynomial with n extra variables $z_1, \cdots, z_n$:

$$\prod_{i=1}^n \Big(1 - \frac{1}{2}\frac{\partial^2}{\partial z_i^2}\Big)\Big|_{z=0} \left(h\Big(xe + \sum_{i=1}^n z_i v_i\Big)\right)^2. \tag{2}$$

Thus, we can reduce the upper bound of $\chi_{\max}(p_\emptyset)$ to an upper bound of the largest root in (2). The latter turns out to be easier to estimate with the help of a barrier argument [43].

To show such equivalence holds, we use induction on the random variables $\xi_1, \ldots, \xi_n$. More specifically, we start from ξ_1 and are conditioned on any fixed choice of $\xi_2, \ldots, \xi_n$. We prove that taking expectation over ξ_1 is equivalent to applying the operator $(1 - \frac{\partial^2}{\partial z_1^2})$ to the polynomial

$$\left(h(xe + z_1 v_1 + \sum_{i=2}^{n} \xi_i v_i)\right)^2$$

and setting $z_1 = 0$. Here we use the relation between expectation and the second derivatives: for any Rademacher random variable ξ,

$$\mathop{\mathbb{E}}_{\xi}[h(x_1 - \xi v) \cdot h(x_2 + \xi v)] = \left(1 - \frac{1}{2}\frac{\mathrm{d}^2}{\mathrm{d}t^2}\right)\Big|_{t=0} h(x_1 + tv)h(x_2 + tv).$$

Repeating this process and removing one random variable at a time. After n iterations, we obtain the desired multivariate polynomial.

We also need to prove the real-rootedness of the multivariate polynomial (Eqn. (2)). We first consider an easy case where h itself is a real-stable polynomial, as in the determinant polynomial case. Then the real-rootedness easily follows from the closure properties of the real-stable polynomial. More specifically, we can show that $(h(xe + \sum_{i=1}^n z_i v_i))^2$ is also a real-stable polynomial. Furthermore, applying the operators $(1 - \frac{1}{2}\frac{\partial^2}{\partial z_i^2})$ and restricting $z = 0$ preserve the real-stability. Therefore, the multivariate polynomial is a univariate real-stable polynomial, which is equivalent to being real-rooted.

Next, we show that when h is a hyperbolic polynomial, the multivariate polynomial (Eqn. (2)) is also real-rooted. our approach is to show that the linear restriction of h: $h(xe + \sum_{i=1}^n z_i v_i)$ is a real-stable polynomial in $\mathbb{R}[x, z_1, \ldots, z_n]$. A well-known test for real-stability is that if for any $a \in \mathbb{R}^{n+1}_{>0}, b \in \mathbb{R}^{n+1}$, the one-dimensional restriction $p(at+b) \in \mathbb{R}[t]$ is non-zero and real-rooted, then $p(x)$ is real-stable. We test $h(xe + \sum_{i=1}^n z_i v_i)$ by restricting to $at + b$, and get the following polynomial:

$$h\Big((a_1 e + \sum_{i=1}^{n} a_{i+1} v_i)t + y\Big) \in \mathbb{R}[t],$$

where y is a fixed vector depending on b. Since $a_i > 0$ for all $i \in [n+1]$ and $e, v_1, \ldots, v_n$ are vectors in the hyperbolicity cone, it implies that the vector $a_1 e + \sum_{i=1}^n a_{i+1} v_i$ is also in the hyperbolicity cone. Then, by the definition of hyperbolic polynomial, we immediately see that $h((a_1 e + \sum_{i=1}^n a_{i+1} v_i)t + y)$ is real-rooted for any $a \in \mathbb{R}^{n+1}_{>0}$ and $b \in \mathbb{R}^{n+1}$. Hence, we can conclude that the restricted hyperbolic polynomial $h(xe + \sum_{i=1}^n z_i v_i)$ is real-stable and the remaining proof is the same as the real-stable case.

Applying barrier argument

Finally, we use *barrier argument* to find an "upper barrier vector" whose components lie above any roots of multivariate polynomial can take. In particular, we consider the multivariate polynomial $P(x, z) = (h(xe + \sum_{i=1}^n z_i v_i))^2$. Define the *barrier function* of any variable $i \in [n]$ as the following:

$$\Phi_P^i(\alpha(t), -\delta) = \frac{\partial_{z_i} P(x, z)}{P(x, z)}\Big|_{x=\alpha(t), z=-\delta},$$

where $\delta \in \mathbb{R}^n$ where $\delta_i = t \operatorname{tr}_h[v_i]$ for $i \in [n]$ and $\alpha(t) > t$ is a parameter that depends on t.

As a warm-up, consider the case when $\sigma = 1$ and assuming $\|\sum_{i=1}^n \mathrm{tr}_h[v_i]v_i\|_h \le 1$. It is easy to show that $(\alpha(t), -\delta)$ is an upper barrier of P, from the linearity of the hyperbolic eigenvalues and the assumption. Next, we upper-bound the barrier function's value at $(\alpha(t), -\delta)$. When h is a determinant polynomial, this step is easy because the derivative of $\log\det$ is the trace of the matrix. For a general hyperbolic polynomial, we will rewrite the partial derivative ∂_{z_i} as a directional derivative D_{v_i} and get

$$\Phi_P^i(\alpha(t), -\delta) = 2 \cdot \frac{(D_{v_i}h)(\alpha e - te + t(e - \sum_{j=1}^n \mathrm{tr}_h[v_j]v_j))}{h(\alpha e - te + t(e - \sum_{j=1}^n \mathrm{tr}_h[v_j]v_j))}.$$

We observe that our assumption $\|\sum_{i=1}^n \mathrm{tr}_h[v_i]v_i\|_h \le 1$ implies that $e - \sum_{j=1}^n \mathrm{tr}_h[v_j]v_j \in \Gamma_+^h$. By the concavity of the function $\frac{h(x)}{D_{v_i}h(x)}$ in the hyperbolicity cone, we can prove that

$$\Phi_P^i(\alpha(t), -\delta) \le \frac{2\,\mathrm{tr}_h[v_i]}{\alpha(t) - t}.$$

Now, we can apply the barrier update lemma in [36] with $\alpha(t) = 2t = 4$ to show that

$$\Phi^j_{(1-\frac{1}{2}\partial^2_{z_i})P}(4, -\delta + \delta_i \mathbf{1}_i) \le \Phi_P^j(4, -\delta).$$

In other words, the partial differential operator $(1 - \frac{1}{2}\partial_{z_i}^2)$ shifts the upper-barrier by $(0, \cdots, 0, \delta_i, 0, \cdots, 0)$. Using induction for the variables $\delta_1, \cdots, \delta_n$, we can finally finally get an upper-barrier of

$$(4, -\delta + \sum_{i=1}^n \delta_i \mathbf{1}_i) = (4, 0, \ldots, 0),$$

which implies that $(4, 0, \ldots, 0)$ is above the roots of

$$\prod_{i=1}^n \Big(1 - \frac{1}{2}\frac{\partial^2}{\partial z_i^2}\Big) \left(h\Big(xe + \sum_{i=1}^n z_i\tau_i v_i\Big)\right)^2 \tag{3}$$

A challenge in this process is ensuring that the barrier function remains nonnegative. To achieve this, we use the multidimensional convexity of the hyperbolic barrier function as established in [59]. For cases where $\sigma \neq 1$, this requirement is satisfied through a simple scaling argument.

Combining the above three steps together, we can prove that $\Pr_{\xi_1,\cdots,\xi_n}[\|\sum_{i=1}^n \xi_i v_i\|_h \le 4\sigma] > 0$ for vectors $v_1, \ldots, v_n$ in the hyperbolicity cone with $\|\sum_{i=1}^n \mathrm{tr}_h[v_i]v_i\|_h = \sigma^2$.

3.2 Generalization to Strongly Rayleigh Distributions

Our main technical contribution to Theorem 6 is a more universal and structured method to characterize the mixed characteristic polynomial. Define the mixed characteristic polynomial as

$$q_S(x) = \mu(S) \cdot h\left(xe - \sum_{i\in S} v_i\right). \tag{4}$$

we want to show that it is equivalent to the restricted multivariate polynomial:

$$\prod_{i=1}^n (1 - \frac{1}{2}\frac{\partial^2}{\partial z_i^2})\Big(h(xe + \sum_{i=1}^n z_i v_i) g_\mu(x\mathbf{1} + z)\Big)\Big|_{z=0} \in \mathbb{R}[x, z_1, \cdots, z_n]. \tag{5}$$

Although Eqn. (4) and Eqn. (5) are the hyperbolic generalization of [6], we are unable to apply the previous techniques. This is because [6] computes the mixed characteristic polynomial explicitly, which heavily relies on the fact that the characteristic polynomial is a determinant. It is unclear how to generalize this method to hyperbolic/real-stable characteristic polynomials.

The key step in [6] is to show the following equality between mixed characteristic polynomial and multivariate polynomial:

$$\begin{aligned}&x^{d_\mu-d}\cdot \mathop{\mathbb{E}}_{S\sim\mu}\left[\det\left(x^2I-\sum_{i\in S}2v_iv_i^\top\right)\right]\\&=\prod_{i=1}^n(1-\partial_{z_i}^2)\left(g_\mu(x\mathbf{1}+z)\cdot\det(xI+\sum_{i=1}^n z_iv_iv_i^\top)\right)\Big|_{z=\mathbf{0}}\end{aligned}$$

where d_μ is the degree of the homogeneous strongly-Rayleigh distribution μ (i.e. the degree of g_μ), and m is the dimension of v_i.

Then they expand the right-hand side to get:

$$\begin{aligned}\text{RHS}&=\sum_{k=0}^m(-1)^kx^{d_\mu+m-2k}\sum_{S\in\binom{[n]}{k}}\Pr_{T\sim\mu}[S\subseteq T]\cdot\sigma_k(\sum_{i\in S}2v_iv_i^\top)\\&=x^{d_\mu-m}\cdot\mathop{\mathbb{E}}_{S\sim\mu}\left[\det\left(x^2I-\sum_{i\in S}2v_iv_i^\top\right)\right]=\text{LHS},\end{aligned}$$

where $\sigma_k(M)$ equals to the sum of all $k\times k$ principal minors of $M\in\mathbb{R}^{m\times m}$. The first step comes from expanding the product $\prod_{i=1}^n(1-\partial^2z_i)$, and the second step comes from that

$$\det(x^2I-\sum_{i=1}^n v_iv_i^\top)=\sum_{k=0}^m(-1)^{2k}x^{2m-2k}\sum_{S\in\binom{[n]}{k}}\sigma_k(\sum_{i\in S}v_iv_i^\top).$$

The naive generalization of a technique to hyperbolic/real-stable polynomial h faces challenges. One such challenge is the absence of an explicit form for h, unlike in the case of $h=\det$ where the determinant can be expressed as a combination of minors. This lack of a well-defined minor presents difficulty in rewriting the hyperbolic/real-stable polynomial. To tackle this issue, we devised a new and structured proof that relies on induction, offering a novel solution to this problem.

Inductive step

We first rewrite the expectation over the Strongly-Rayleigh distribution $T\sim\mu$ as follows:

$$\begin{aligned}x^{d_\mu}\cdot2^{-n}\cdot\mathop{\mathbb{E}}_{T\sim\mu}[h(xe-\sum_{i\in T}v_i)]=\frac{1}{2}\mathop{\mathbb{E}}_{\xi_2,\cdots,\xi_n\sim\{0,1\}^{n-1}}\Big[&(1-\partial_{z_1})h(x_2+z_1v_1)x\partial_{z_1}g_2(x+z_1)\\&+h(x_2)(1-x\partial_{z_1})g_2(x+z_1)\Big|_{z_1=0}\Big]\end{aligned}$$

where g_2 is defined as

$$\begin{aligned}g_2(t):=x^{\sum_{i=2}^n\xi_i}&\cdot\\&\prod_{i=2}^n\Big(\xi_i\partial_{z_i}+(1-\xi_i)(1-x\partial_{z_i})\Big)g_\mu(t,x+z_2,x+z_3,\cdots,x+z_n)\Big|_{z_2,\ldots,z_n=0}\end{aligned}$$

and $x_2 = x^2 e - \sum_{i=2}^{n} \xi_i v_i$. The main observation is that the marginals of a homogeneous Strongly-Rayleigh distribution can be computed from the derivatives of its generating polynomial.

Then, we can expand the term inside the expectation as

$$(1 - \frac{x}{2}\partial_{z_1}^2)\Big(h(x_2 + z_1 v_1) g_2(x + z_1)\Big)\Big|_{z_1=0},$$

using the fact that $\mathrm{rank}(v_1)_h \le 1$ and the degree of $g_2(t)$ is at most 1.

Hence, we obtain our inductive step as

$$\begin{aligned} & x^{d_\mu} \cdot 2^{-n} \cdot \mathop{\mathbb{E}}_{\xi\sim\mu}\left[h(xe - \sum_{i=1}^{n} \xi_i v_i)\right] \\ = & \frac{1}{2}(1 - \frac{x}{2}\partial_{z_1}^2)\left(\mathop{\mathbb{E}}_{\xi_2,\cdots,\xi_n}\left[h(xe - \sum_{i=2}^{n} \xi_i v_i + z_1 v_1) \cdot g_2(x + z_1)\right]\right)\Big|_{z_1=0}. \end{aligned}$$

Applying the step inductively

Repeating the above process for n times, we finally get

$$x^{d_\mu} \cdot \mathop{\mathbb{E}}_{\xi\sim\mu}\left[h(x^2 e - (\sum_{i=1}^{n} \xi_i v_i))\right] = \sum_{T\subseteq[n]} (-\frac{x}{2})^{|T|} \partial_{z^T}^2 \Big(h(x^2 e + \sum_{i=1}^{n} z_i v_i) g_\mu(x\mathbf{1} + z)\Big)\Big|_{z=0}.$$

Then, we rewrite the partial derivatives as directional derivatives. For any subset $T \subseteq [n]$ of size k, we have

$$\begin{aligned} & (-\frac{x}{2})^k \partial_{z^T}^2 \Big(h(x^2 e + \sum_{i=1}^{n} z_i v_i) g_\mu(x\mathbf{1} + z)\Big)\Big|_{z=0} \\ = & (-\frac{x}{2})^k \cdot 2^k \cdot \left(\prod_{i\in T} D_{v_i}\right) h(x^2 e) \cdot g_\mu^{(T)}(x\mathbf{1}), \end{aligned}$$

where $g_\mu^{(T)}(x\mathbf{1}) = \prod_{i\in T} \partial_{z_i} g_\mu(x\mathbf{1} + z)\Big|_{z=0}$. And by the homogeneity of h, it further equals to

$$x^d \cdot (-\frac{1}{2})^k \partial_{z^T}^2 \left(h(xe + \sum_{i=1}^{n} z_i v_i) g_\mu(x\mathbf{1} + z)\right)\Big|_{z=0}.$$

Therefore, we prove the following formula that relates the characteristic polynomial under SR distribution to the multivariate polynomial:

$$x^{d_\mu} \cdot \mathop{\mathbb{E}}_{\xi\sim\mu}\left[h(x^2 e - (\sum_{i=1}^{n} \xi_i v_i))\right] = x^d \cdot \prod_{i=1}^{n} (1 - \frac{1}{2}\partial_{z_i}^2)\Big(h(xe + \sum_{i=1}^{n} z_i v_i) g_\mu(x\mathbf{1} + z)\Big)\Big|_{z=0}.$$

On Semantically-Deterministic Automata

Abstract

Nondeterminism is a fundamental notion in Theoretical Computer Science. A nondeterministic automaton is *semantically deterministic* (SD) if different nondeterministic choices in the automaton lead to equivalent states. Semantic determinism is interesting as it is a natural relaxation of determinism, and as some applications of automata in formal methods require deterministic automata, yet in fact can use automata with some level of nondeterminism, tightly related to semantic determinism.

In the context of finite words, semantic determinism coincides with determinism, in the sense that every pruning of an SD automaton to a deterministic one results in an equivalent automaton. We study SD automata on infinite words, focusing on Büchi, co-Büchi, and weak automata. We show that there, while semantic determinism does not increase the expressive power, the combinatorial and computational properties of SD automata are very different from these of deterministic automata. In particular, SD Büchi and co-Büchi automata are exponentially more succinct than deterministic ones (in fact, also exponentially more succinct than history-deterministic automata), their complementation involves an exponential blow up, and decision procedures for them like universality and minimization are PSPACE-complete. For weak automata, we show that while an SD weak automaton need not be pruned to an equivalent deterministic one, it can be determinized to an equivalent deterministic weak automaton with the same state space, implying also efficient complementation and decision procedures for SD weak automata.

1 Introduction

Automata are among the most studied computation models in theoretical computer science. Their simple structure has made them a basic formalism for the study of fundamental notions, such as *determinism* and *nondeterminism* [35]. While a deterministic computing machine examines a single action at each step of its computation, nondeterministic machines are allowed to examine several possible actions simultaneously. Understanding the power of nondeterminism is at the core of open fundamental questions in theoretical computer science (most notably, the P vs. NP problem).

A prime application of *automata on infinite words* is specification, verification, and synthesis of nonterminating systems. The automata-theoretic approach reduces questions about systems and their specifications to questions about automata [28, 41], and is at the heart of many algorithms and tools. A run of an automaton on infinite words is an infinite

sequence of states, and acceptance is determined with respect to the set of states that the run visits infinitely often. For example, in *Büchi* automata, some of the states are designated as accepting states, and a run is accepting iff it visits states from the set α of accepting states infinitely often [9]. Dually, in *co-Büchi* automata, a run is accepting if it visits the set α only finitely often. Then, *weak* automata are a special case of both Büchi and co-Büchi automata in which every strongly connected component in the graph induced by the automaton is either contained in α or is disjoint from α. We use DBW and NBW to denote determinisitic and nondeterministic Büchi word automata, respectively, and similarly for D/NCW, D/NWW, and D/NFW, for co-Büchi, weak, and automata on finite words, respectively.

For automata on infinite words, nondeterminism not only leads to exponential succinctness, but may also increase the expressive power. This is the case, for example, in Büchi and weak automata, thus NBWs are strictly more expressive than DBWs [29], and NWWs are strictly more expressive than DWWs [6]. On the other hand, NCWs are as expressive as DCWs [32], and in fact, also as NWWs [27]. In some applications of the automata-theoretic approach, such as model checking, algorithms can be based on nondeterministic automata, whereas in other applications, such as synthesis and reasoning about probabilistic systems, they cannot. There, the advantages of nondeterminism are lost, and algorithms involve a complicated determinization construction [36] or acrobatics for circumventing determinization [26, 21].

In a deterministic automaton, the transition function maps each state and letter to a single successor state. In recent years there is growing research on weaker types of determinism. This includes, for example, *unambiguous automata*, which may have many runs on each word, yet only one accepting run [10, 12], automata that are *deterministic in the limit*, where each accepting run should eventually reach a deterministic sub-automaton [40], and automata that are *determinizable by pruning* (DBP), thus embody an equivalent deterministic automaton [4].

In terms of applications, some weaker types of determinism have been defined and studied with specific applications in mind. Most notable are *history-deterministic* automata (HD), which can resolve their nondeterministic choices based on the history of the run [18, 8, 23][1], and can therefore replace deterministic automata in algorithms for synthesis and control, and *good-for-MDPs* automata (GFM), whose product with Markov decision processes maintains the probability of acceptance, and can therefore replace deterministic automata when reasoning about stochastic behaviors [16, 39].

The different levels of determinism induce classes of automata that differ in their succinctness and in the complexity of operations and decision problems on them. Also, some classes are subclasses of others. For example, it follows quite easily from the definitions that every automaton that is deterministic in the limit is GFM, and every automaton that is DBP is HD.

In this paper we study the class of *semantically deterministic* automata (SD). An automaton $\mathcal{A}$ is SD if its nondeterministic choices lead to equivalent states. Formally, if $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$, with a transition function $\delta : Q \times \Sigma \to 2^Q$, then $\mathcal{A}$ is SD if for every state $q \in Q$, letter $\sigma \in \Sigma$, and states $q_1, q_2 \in \delta(q, \sigma)$, the set of words accepted from $\mathcal{A}$ with initial state q_1 is equal to the set of words accepted from $\mathcal{A}$ with initial state q_2. Since all nondeterministic choices lead to equivalent states, one may be tempted to think that SD automata are DBP or at least have similar properties to deterministic automata. This is

[1] The notion used in [18] is *good for games* (GFG) automata, as they address the difficulty of playing games on top of a nondeterministic automaton. As it turns out, the property of being good for games varies in different settings and HD is good for applications beyond games. Therefore, we use the term *history determinism*, introduced by Colcombet in the setting of quantitative automata with cost functions [11].

indeed the case for SD-NFWs, namely when one considers automata on finite words. There, it is not hard to prove that any pruning of an SD-NFW to a DFW results in an equivalent DFW. Thus, SD-NFWs are not more succinct than DFWs, and operations on them are not more complex than operations on DFWs.

Once, however, one considers automata on infinite words, the simplicity of SD automata is lost. In order to understand the picture in the setting of infinite words, let us elaborate some more on HD automata, which are strongly related to SD automata. Formally, a nondeterministic automaton $\mathcal{A}$ is HD if there is a strategy g that maps each finite word $u \in \Sigma^*$ to a transition to be taken after u is read, and following g results in accepting all the words in the language of $\mathcal{A}$. Obviously, every DBP automaton is HD – the strategy g can suggest the same transition in all its visits in a state. On the other hand, while HD-NWWs are always DBP [25, 33], this is not the case for HD-NBWs and HD-NCWs [7]. There, the HD strategy may need to suggest different transitions in visits (with different histories) to the same state.

It is easy to see that a strategy g as above cannot choose a transition to states whose language is strictly contained in the language of states that are reachable by other transitions. Thus, all HD automata can be pruned in polynomial time to SD automata [20, 5]. The other direction, however, does not hold: it is shown in [3] that an SD-NWW need not be HD (hence, SD-NBWs and SD-NCWs need not be HD too). Moreover, while all all HD-NWWs are DBP, this is not the case for all SD-NWWs.

In this work we study the succinctness of SD automata with respect to deterministic ones, as well as the complexity of operations on them and decision problems about them. Our goal is to understand the difference between determinism and semantic determinism, and to understand how this difference varies among different acceptance conditions. Our study is further motivated by the applications of automata with different levels of nondeterminism in algorithms for synthesis and for reasoning in a stochastic setting. In particular, beyond the connection to HD automata discussed above, as runs of an SD-NBW on words in the language are accepting with probability 1, all SD-NBWs are GFM [3].

We study semantic determinism for Büchi, co–Büchi, and weak automata. We consider automata with both *state-based* acceptance conditions, as defined above, and *transition-based* acceptance conditions. In the latter, the acceptance condition is given by a subset α of transitions, and a run is required to traverse transitions in α infinitely often (in Büchi automata, termed tD/tNBW) or finitely often (in co-Büchi automata, termed tD/tNCW). As it turns out, especially in the context of HD automata, automata with transition-based acceptance conditions may differ in their properties from automata with traditional state-based acceptance conditions. For example, while HD-tNCWs can be minimized in PTIME [1], minimization of HD-NCWs is NP-complete [38]. In addition, there is recently growing use of transition-based automata in practical applications, with evidences they offer a simpler translation of LTL formulas to automata and enable simpler constructions and decision procedures [14, 15, 13, 40, 30]. Our results for all types of acceptance conditions are summarized in Table 1 below, where we also compare them with known results about deterministic and HD automata.

Let us highlight the results we find the most interesting and surprising. While all three types of SD automata are not DBP, we are able to determinize SD-NWWs in polynomial time, and end up with a DWW whose state space is a subset of the state space of the original SD-NWW. Essentially, rather than pruning transitions, the construction redirects transitions to equivalent states in deep strongly connected components of the SD-NWW, which we prove

Table 1 Succinctness (determinization blow-up), complementation (blow-up in going from an automaton to a complementing one), universality (deciding whether an automaton accepts all words), and minimization (deciding whether an equivalent automaton of a given size exists, and the described results apply also for the case the given automaton is deterministic). All blow-ups are tights, except for HD-NBW determinization, where the quadratic bound has no matching lower bound; all NL, NP, and PSPACE bounds are complete.

	Deterministic	HD	SD
Succinctness	n (B,C,W)	n^2 (B), 2^n (C), n (W) [20, 25, 33]	2^n (B,C), n (W) Theorems 5, 14, 22
Complementation	n (B,C,W) [22]	n (B), 2^n (C), n (W) [20]	2^n (B,C), n (W) Theorems 7, 16, 23
Universality	NL (B,C,W) [22]	P (B,C,W) [17, 20]	PSPACE (B,C), P (W) Theorems 9, 17, 24
Minimization (state based)	NP (B,C), P (W) [37, 31]	NP (B,C), P (W) [38, 25, 31]	PSPACE (B,C), P (W) Theorems 10, 18, 24
Minimization (transition based)	open (B,C), P (W) [31]	open (B), P (C,W) [1, 25, 31]	PSPACE (B,C), P (W) Theorems 10, 18, 24

to result in an equivalent deterministic DWW[2]. This suggests that despite the "not DBP anomaly" of SD-NWWs, they are very similar in their properties to DWWs. On the other hand, except for their expressive power, SD-NBWs and SD-NCWs are not at all similar to DBWs and DCWs: while HD-NBWs are only quadratically more succinct than DBWs, succinctness jumps to exponential for SD-NBWs. This also shows that SD-NBWs may be exponentially more succinct than HD-NBWs, and we show this succinctness gap also for co-Büchi automata, where exponential succinctness with respect to DCWs holds already in the HD level.

The succinctness results are carried over to the blow-up needed for complementation, and to the complexity of decision procedures. Note that this is not the case for HD automata. There, for example, complementation of HD-NBWs results in an automaton with the same number of states [20]. Moreover, even though HD-NCWs are exponentially more succinct than DCWs, language-containment for HD-NCWs can be solved in PTIME [17, 20], and HD-tNCWs can be minimized in PTIME [1]. For SD automata, we show that complementation involves an exponential blow-up. Also, universality and minimization of SD Büchi and co-Büchi automata, with either state-based or transition-based acceptance conditions, is PSPACE-complete, as it is for NBWs and NCWs. We also study the *D-to-SD minimization problem*, where we are given a deterministic automaton $\mathcal{A}$ and a bound $k \geq 1$, and need to decide whether $\mathcal{A}$ has an equivalent SD automaton with at most k states. Thus, the given automaton is deterministic, rather than SD. By [19], the D-to-N minimization problem for automata on finite words (that is, given a DFW, minimize it to an NFW) is PSPACE-complete. It is easy to see that the D-to-SD minimization problem for for automata on finite words can be solved in PTIME. We show that while this is the case also for weak automata, D-to-SD minimization for Büchi and co-Büchi automata is PSPACE-complete.

[2] Our result implies that checking language-equivalence between states in an SD-NWW can be done in PTIME, as the check can be performed on the equivalent DWWs. We cannot, however, use this complexity result in our algorithm, as this involves a circular dependency. Consequently, our construction of the equivalent DWWs involves a language-approximation argument.

Our results show that in terms of combinatorial and computational properties, semantic determinism is very similar to determinism in weak automata, whereas for Büchi and co-Büchi automata, semantic determinism is very similar to nondeterminism.

Due to the lack of space, some proofs are missing, and can be found in the full version [2].

2 Preliminaries

2.1 Languages and Automata

For a finite nonempty alphabet Σ, an infinite *word* $w = \sigma_1 \cdot \sigma_2 \cdots \in \Sigma^\omega$ is an infinite sequence of letters from Σ. A *language* $L \subseteq \Sigma^\omega$ is a set of words. For $1 \leq i \leq j$, we use $w[i,j]$ to denote the infix $\sigma_i \cdot \sigma_{i+1} \cdots \sigma_j$ of w, use $w[i]$ to denote the letter σ_i, and use $w[i,\infty]$ to denote the infinite suffix $\sigma_i \cdot \sigma_{i+1} \cdots$ of w. We also consider languages $R \subseteq \Sigma^*$ of finite words, denote the empty word by ϵ, and denote the set of nonempty words over Σ by Σ^+; thus $\Sigma^+ = \Sigma^* \setminus \{\epsilon\}$. For a set S, we denote its complement by $\overline{S}$. In particular, for languages $R \subseteq \Sigma^*$ and $L \subseteq \Sigma^\omega$, we have $\overline{R} = \Sigma^* \setminus R$ and $\overline{L} = \Sigma^\omega \setminus L$.

A *nondeterministic automaton* is a tuple $\mathcal{A} = \langle \Sigma, Q, Q_0, \delta, \alpha \rangle$, where Σ is an alphabet, Q is a finite set of *states*, Q_0 is a set of *initial states*, $\delta : Q \times \Sigma \to 2^Q \setminus \emptyset$ is a *transition function*, and α is an *acceptance condition*, to be defined below. For states q and s and a letter $\sigma \in \Sigma$, we say that s is a *σ-successor* of q if $s \in \delta(q, \sigma)$. Note that the transition function of $\mathcal{A}$ is total, thus for all states $q \in Q$ and letters $\sigma \in \Sigma$, q has at least one σ-successor. If $|Q_0| = 1$ and every state q has a single σ-successor, for all letters σ, then $\mathcal{A}$ is *deterministic*. The transition function δ can be viewed as a transition relation $\Delta \subseteq Q \times \Sigma \times Q$, where for every two states $q, s \in Q$ and letter $\sigma \in \Sigma$, we have that $\langle q, \sigma, s \rangle \in \Delta$ iff $s \in \delta(q, \sigma)$. We define the *size* of $\mathcal{A}$, denoted $|\mathcal{A}|$, as its number of states, thus, $|\mathcal{A}| = |Q|$.

Given an input word $w = \sigma_1 \cdot \sigma_2 \cdots$, a *run* of $\mathcal{A}$ on w is a sequence of states $r = r_0, r_1, r_2, \ldots$, such that $r_0 \in Q_0$, and for all $i \geq 0$, we have that $r_{i+1} \in \delta(r_i, \sigma_{i+1})$, i.e, the run starts in some initial state and proceeds according to the transition function. If the word in the input is infinite, then so is the run. We sometimes view the run $r = r_0, r_1, r_2, \ldots$ on $w = \sigma_1 \cdot \sigma_2 \cdots$ as a sequence of successive transitions $\langle r_0, \sigma_1, r_1 \rangle, \langle r_1, \sigma_2, r_2 \rangle, \ldots$. Note that a deterministic automaton has a single run on an input w. We sometimes extend δ to sets of states and finite words. Then, $\delta : 2^Q \times \Sigma^* \to 2^Q$ is such that for every $S \in 2^Q$, finite word $u \in \Sigma^*$, and letter $\sigma \in \Sigma$, we have that $\delta(S, \epsilon) = S$, $\delta(S, \sigma) = \bigcup_{s \in S} \delta(s, \sigma)$, and $\delta(S, u \cdot \sigma) = \delta(\delta(S, u), \sigma)$. Thus, $\delta(S, u)$ is the set of states that $\mathcal{A}$ may reach when it reads u from some state in S.

The acceptance condition α determines which runs are "good". For automata on finite words, $\alpha \subseteq Q$, and a run is *accepting* if it ends in a state in α. For automata on infinite words, we consider *state-based* and *transition-based* acceptance conditions. Let us start with *state-based* conditions. Here, $\alpha \subseteq Q$, and we use the terms *α-states* and *$\overline{\alpha}$-states* to refer to states in α and in $Q \setminus \alpha$, respectively. For a run $r \in Q^\omega$, let $\mathit{sinf}(r) \subseteq Q$ be the set of states that r visits infinitely often. Thus, $\mathit{sinf}(r) = \{q : q = r_i \text{ for infinitely many } i\text{'s}\}$. In *Büchi* automata, r is *accepting* iff $\mathit{sinf}(r) \cap \alpha \neq \emptyset$, thus if r visits states in α infinitely often. Dually, in *co-Büchi* automata, r is *accepting* iff $\mathit{sinf}(r) \cap \alpha = \emptyset$, thus if r visits states in α only finitely often.

We proceed to *transition-based* conditions. There, $\alpha \subseteq \Delta$ and acceptance depends on the set of transitions that are traversed infinitely often during the run. We use the terms *α-transitions* and *$\bar{\alpha}$-transitions* to refer to transitions in α and in $\Delta \setminus \alpha$, respectively. For a run $r \in \Delta^\omega$, we define $\mathit{tinf}(r) = \{\langle q, \sigma, s \rangle \in \Delta : q = r_i, \sigma = \sigma_{i+1}, \text{ and } s = r_{i+1}, \text{ for infinitely many } i\text{'s}\}$. As expected, in transition-based Büchi automata, r is accepting iff $\mathit{tinf}(r) \cap \alpha \neq \emptyset$, and in transition-based co-Büchi automata, r is accepting iff $\mathit{tinf}(r) \cap \alpha = \emptyset$.

Consider an automaton $\mathcal{A} = \langle \Sigma, Q, Q_0, \delta, \alpha \rangle$. In all automata classes, a run of $\mathcal{A}$ that is not accepting is *rejecting*. A word w is accepted by an automaton $\mathcal{A}$ if there is an accepting run of $\mathcal{A}$ on w. The language of $\mathcal{A}$, denoted $L(\mathcal{A})$, is the set of words that $\mathcal{A}$ accepts.

Consider a directed graph $G = \langle V, E \rangle$. A *strongly connected set* in G (SCS, for short) is a set $C \subseteq V$ such that for every two vertices $v, v' \in C$, there is a path from v to v'. An SCS is *maximal* if for every non-empty set $C' \subseteq V \setminus C$, it holds that $C \cup C'$ is not an SCS. The *maximal strongly connected sets* are also termed *strongly connected components* (SCCs, for short). An automaton $\mathcal{A} = \langle \Sigma, Q, Q_0, \delta, \alpha \rangle$ induces a directed graph $G_{\mathcal{A}} = \langle Q, E \rangle$, where $\langle q, q' \rangle \in E$ iff there is a letter $\sigma \in \Sigma$ such that $\langle q, \sigma, q' \rangle \in \Delta$. The SCSs and SCCs of $\mathcal{A}$ are those of $G_{\mathcal{A}}$.

An automaton $\mathcal{A} = \langle \Sigma, Q, Q_0, \delta, \alpha \rangle$ with a state-based acceptance condition $\alpha \subseteq Q$ is *weak* [34] if for each SCC C of $\mathcal{A}$, either $C \subseteq \alpha$ in which case C is *accepting*, or $C \cap \alpha = \emptyset$ in which case C is *rejecting*. We view $\mathcal{A}$ as a Büchi automaton, yet note that a weak automaton can be viewed as both a Büchi and a co-Büchi automaton. Indeed, a run of $\mathcal{A}$ visits α infinitely often iff it gets trapped in an SCC that is contained in α iff it visits states in $Q \setminus \alpha$ only finitely often. Note also that when $\mathcal{A}$ uses a transition-based acceptance condition, we can ignore the membership in α of transitions between SCCs (indeed, such transitions are traversed only finitely often), and say that $\mathcal{A}$ is weak if the transitions in each SCC are all in α or all disjoint from α.

Consider two automata $\mathcal{A}_1$ and $\mathcal{A}_2$. We say that $\mathcal{A}_1$ is *contained in* $\mathcal{A}_2$ if $L(\mathcal{A}_1) \subseteq L(\mathcal{A}_2)$. Then, $\mathcal{A}_1$ and $\mathcal{A}_2$ are *equivalent* if $L(\mathcal{A}_1) = L(\mathcal{A}_2)$, and $\mathcal{A}_1$ is *universal* if $L(\mathcal{A}_1) = \Sigma^\omega$ (or $L(\mathcal{A}_1) = \Sigma^*$, in case it runs on finite words). Finally, $\mathcal{A}_1$ is *minimal* (with respect to a class of automata, say state-based deterministic Büchi automata) if for all automata $\mathcal{A}_2$ equivalent to $\mathcal{A}_1$, we have that $|\mathcal{A}_1| \leq |\mathcal{A}_2|$.

2.2 SD and HD Automata

Consider an automaton $\mathcal{A} = \langle \Sigma, Q, Q_0, \delta, \alpha \rangle$. For a state $q \in Q$ of $\mathcal{A}$, we define $\mathcal{A}^q = \langle \Sigma, Q, \{q\}, \delta, \alpha \rangle$, as the automaton obtained from $\mathcal{A}$ by setting the set of initial states to be $\{q\}$. We say that two states $q, s \in Q$ are *equivalent*, denoted $q \sim_{\mathcal{A}} s$, if $L(\mathcal{A}^q) = L(\mathcal{A}^s)$. We say that q *is reachable* if there is a finite word $x \in \Sigma^*$ with $q \in \delta(Q_0, x)$, and say that q *is reachable from* s if q is reachable in $\mathcal{A}^s$. We say that $\mathcal{A}$ is *semantically deterministic* (SD, for short) if different nondeterministic choices lead to equivalent states. Thus, all initial states are equivalent, and for every state $q \in Q$ and letter $\sigma \in \Sigma$, all the σ-successors of q are equivalent. Formally, if $s, s' \in \delta(q, \sigma)$, then $s \sim_{\mathcal{A}} s'$. The following proposition, termed the *SDness property*, follows immediately from the definitions and implies that in SD automata, for all finite words x, all the states in $\delta(Q_0, x)$ are equivalent. Intuitively, it means that a run of an SD automaton can take also bad nondeterministic choices, as long as it does so only finitely many times.

▶ **Proposition 1.** *Consider an SD automaton $\mathcal{A} = \langle \Sigma, Q, Q_0, \delta, \alpha \rangle$, and states $q, s \in Q$. If $q \sim_{\mathcal{A}} s$, then for every $\sigma \in \Sigma$, $q' \in \delta(q, \sigma)$, and $s' \in \delta(s, \sigma)$, we have that $q' \sim_{\mathcal{A}} s'$.*

An automaton $\mathcal{A}$ is *history deterministic* (*HD*, for short) if its nondeterminism can be resolved based on the past, thus on the prefix of the input word read so far. Formally, $\mathcal{A}$ is *HD* if there exists a *strategy* $f : \Sigma^* \to Q$ such that the following hold:

1. The strategy f is consistent with the transition function. That is, $f(\epsilon) \in Q_0$, and for every finite word $u \in \Sigma^*$ and letter $\sigma \in \Sigma$, we have that $f(u \cdot \sigma) \in \delta(f(u), \sigma)$.
2. Following f causes $\mathcal{A}$ to accept all the words in its language. That is, for every word $w = \sigma_1 \cdot \sigma_2 \cdots$, if $w \in L(\mathcal{A})$, then the run $f(\epsilon), f(w[1,1]), f(w[1,2]), \ldots$ is an accepting run of $\mathcal{A}$ on w.

We say that the strategy f *witnesses* $\mathcal{A}$'s HDness. Note that, by definition, we can assume that every SD and HD automaton $\mathcal{A}$ has a single initial state. Thus, we sometimes abuse notation and write $\mathcal{A}$ as $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$, where q_0 is the single initial state of the SD (or HD) automaton $\mathcal{A}$.

For an automaton $\mathcal{A}$, we say that a state q of $\mathcal{A}$ is *HD*, if $\mathcal{A}^q$ is HD. Note that every deterministic automaton is HD. Also, while not all HD automata can be pruned to deterministic ones [7], removing of transitions that are not used by a strategy f that witnesses $\mathcal{A}$'s HDness does not reduce the language of $\mathcal{A}$ and results in an SD automaton. Moreover, since every state that is used by f is HD, the removal of non-HD states does not affect $\mathcal{A}$'s language nor its HDness. Accordingly, we have the following [20, 5].

▶ **Proposition 2.** *Every HD automaton $\mathcal{A}$ can be pruned to an equivalent SD automaton all whose states are HD.*

We use three-letter acronyms in $\{\mathrm{D}, \mathrm{N}\} \times \{\mathrm{B}, \mathrm{C}, \mathrm{W}, \mathrm{F}\} \times \{\mathrm{W}\}$ to denote the different automata classes. The first letter stands for the branching mode of the automaton (deterministic or nondeterministic); the second for the acceptance condition type (Büchi, co-Büchi, weak, or an automaton that runs over finite inputs); and the third indicates that we consider automata on words. For transition-based automata, we start the acronyms with the letter "t", and for HD or SD automata, we add an HD or SD prefix, respectively. For example, an HD-tNBW is a transition-based HD nondeterministic Büchi automaton, a DFW is a state-based deterministic automaton on finite words, and an SD-NWW is a state-based weak SD automaton.

3 Semantically Deterministic Büchi Automata

In this section we examine SD-tNBWs and SD-NBWs. Our results use the following definitions and constructions: For a language $R \subseteq \Sigma^*$ of finite words, we use ∞R to denote the language of infinite words that contain infinitely many disjoint infixes in R. Thus, $w \in \infty R$ iff $\epsilon \in R$ or there are infinitely many indices $i_1 \leq i'_1 < i_2 \leq i'_2 < \cdots$ such that $w[i_j, i'_j] \in R$, for all $j \geq 1$. For example, taking $\Sigma = \{a, b\}$, we have that $\infty\{ab\}$ is the language of words with infinitely many ab infixes, namely all words with infinitely many a's and infinitely many b's. We say that a finite word $x \in \Sigma^*$ is a *good prefix* for a language $R \subseteq \Sigma^*$ if for all finite words $y \in \Sigma^*$, we have that $x \cdot y \in R$. For example, while the language $(a + b)^* \cdot a$ does not have a good prefix, the word a is a good prefix for the language $a \cdot (a + b)^*$.

Theorem 3 below suggests that one can encode an NFW-recognizable language R in an SD-tNBW $\mathcal{A}$ for ∞R, and Theorem 4 suggests that one can decode an NFW for R from an SD-tNBW for $\infty(\$ \cdot R \cdot \$)$, where $\$ \notin \Sigma$. The blow-up in the sizes of the automata is constant, and both theorems play a major rule in the rest of this section.

▶ **Theorem 3.** *Given an NFW $\mathcal{N}$, one can obtain, in polynomial time, an SD-tNBW $\mathcal{A}$ such that $L(\mathcal{A}) = \infty L(\mathcal{N})$ and $|\mathcal{A}| = |\mathcal{N}|$.*

Proof. Let $\mathcal{N} = \langle \Sigma, Q, Q_0, \delta, F \rangle$. Then, $\mathcal{A} = \langle \Sigma, Q, Q_0, \delta', \alpha \rangle$ is obtained from $\mathcal{N}$ by adding transitions to Q_0 from all states with all letters. A new σ-transition is in α if $Q_0 \cap F \neq \emptyset$ or when $\mathcal{N}$ could transit with σ to a state in F. Formally, for all $s \in Q$ and $\sigma \in \Sigma$, we have that $\delta'(s, \sigma) = \delta(s, \sigma) \cup Q_0$, and $\alpha = \{\langle s, \sigma, q \rangle : q \in Q_0 \text{ and } (Q_0 \cap F \neq \emptyset \text{ or } \delta(s, \sigma) \cap F \neq \emptyset)\}$.

It is easy to see that $|\mathcal{A}| = |\mathcal{N}|$. In order to prove that $\mathcal{A}$ is SD and $L(\mathcal{A}) = \infty L(\mathcal{N})$, we prove in the full version that for every state $q \in Q$, it holds that $L(\mathcal{A}^q) = \infty L(\mathcal{N})$. ◀

▶ **Theorem 4.** *Consider a language $R \subseteq \Sigma^*$ and a letter $\$ \notin \Sigma$. For every SD-tNBW $\mathcal{A}$ such that $L(\mathcal{A}) = \infty(\$ \cdot R \cdot \$)$, there exists an NFW $\mathcal{N}$ such that $L(\mathcal{N}) = R$ and $|\mathcal{N}| \leq |\mathcal{A}| + 1$. In addition, if R has no good prefixes, then $|\mathcal{N}| \leq |\mathcal{A}|$.*

Proof. If R is trivial, then one can choose $\mathcal{N}$ to be a one-state NFW. Assume that R is nontrivial. Let $\mathcal{A} = \langle \Sigma \cup \{\$\}, Q, q_0, \delta, \alpha \rangle$ be an SD-tNBW for $\infty(\$ \cdot R \cdot \$)$, W.l.o.g we assume that all the states of $\mathcal{A}$ are reachable. For a nonempty set of states $S \in 2^Q \setminus \emptyset$, we define the *universal $\overline{\alpha}$ language* of S as

$$L_{u\overline{\alpha}}(S) = \{w \in (\Sigma \cup \{\$\})^\omega : \text{for all } q \in S, \text{ all the runs of } \mathcal{A}^q \text{ on } w \text{ do not traverse } \alpha\}.$$

We say that S is *hopeful* when $(\$ \cdot \overline{R})^\omega \subseteq L_{u\overline{\alpha}}$. Note that S is hopeful iff for every state $q \in S$, it holds that $\{q\}$ is hopeful. Also, if S is hopeful, $x \in \Sigma^*$ is a finite word, and there is a run from S on $\$ \cdot x$ that traverses α, then $x \in R$. Then, we say that S is *good* when for all words $x \in \Sigma^*$, it holds that $x \in \overline{R}$ iff all the runs from S on $\$ \cdot x$ do not traverse α, and the set $\delta(S, \$ \cdot x)$ is hopeful. Note that as R is nontrivial, there exists a word x in $\overline{R}$, and thus by definition, all the \$-labled transitions going out from a good set S are in $\overline{\alpha}$.

Good sets in $\mathcal{A}$ characterize the language R, and as we argue below, their existence induces an NFW for R. In the full version, we prove that a good set exists. We show now that a good set in $\mathcal{A}$ induces an NFW $\mathcal{N}$ for R with the required properties. Let $S \in 2^Q \setminus \emptyset$ be a good set. We define the NFW $\mathcal{N} = \langle \Sigma, Q \cup \{q_{acc}\}, Q_0^S, \delta_S, F_S \rangle$, where $Q_0^S = \delta(S, \$)$, $F_S = \{q_{acc}\} \cup \{q \in Q : \text{the set } \{q\} \text{ is not hopeful}\}$, and the transition function δ_S is defined as follows. For every two states $q, s \in Q$ and letter $\sigma \in \Sigma$, it holds that $s \in \delta_S(q, \sigma)$ iff $\langle q, \sigma, s \rangle \in \overline{\alpha}$. Also, $q_{acc} \in \delta_S(q, \sigma)$ iff there is a σ-labeled α-transition going out from q in $\mathcal{A}$. Also, for all letters $\sigma \in \Sigma$, it holds that $\delta(q_{acc}, \sigma) = \{q_{acc}\}$; that is, q_{acc} is an accepting sink. Thus, $\mathcal{N}$ behaves as the states in $\delta(S, \$)$ as long as it reads $\overline{\alpha}$ transitions of $\mathcal{A}$, moves to the accepting sink q_{acc} whenever an α-transition is encountered, and accepts also whenever it reaches a state in Q that is not hopeful.

In the full version, we prove that $L(\mathcal{N}) = R$. Essentially, this follows from the fact that if we consider a word $x \in \Sigma^*$ such that all the runs from Q_0^S on x in $\mathcal{A}$ do not traverse α, then S being a good set implies that $x \in R$ iff $\delta(S, \$ \cdot x) \cap F_S \neq \emptyset$.

Since the state space of $\mathcal{N}$ is $Q \cup \{q_{acc}\}$, then $|\mathcal{N}| = |\mathcal{A}| + 1$. Moreover, as q_{acc} is an accepting sink, a word $x \in L(\mathcal{N})$ that has a run that ends in q_{acc} is a good prefix for $L(\mathcal{N})$. Hence, as $L(\mathcal{N}) = R$, if R has no good prefixes, then q_{acc} is not reachable in $\mathcal{N}$ and thus can be removed without affecting $\mathcal{N}$'s language. Thus, in this case, we get an NFW $\mathcal{N}$ for R whose size is at most $|\mathcal{A}|$. ◀

3.1 Succinctness and Complementation

In this section we study the succinctness of SD Büchi automata with respect to deterministic ones, and the blow-up involved in their complementation. We show that SD-tNBWs are exponentially more succinct than tDBWs, matching the known upper bound [3], and in fact, also from HD-tNBWs. We also prove an exponential lower bound for complementation. Similar results for SD-NBWs follow, as the transition between the two types of acceptance conditions is linear.

▶ **Theorem 5.** *There is a family $L_1, L_2, L_3, \ldots$ of languages such that for every $n \geq 1$, there is an SD-tNBW with $3n + 3$ states that recognizes L_n, yet every tDBW or HD-tNBW that recognizes L_n needs at least 2^n states.*

Proof. For $n \geq 1$, let $[n] = \{1, \ldots, n\}$, and let $\Sigma_n = \{1, \ldots, n, \$, \#\}$. We say that a word $z \in \Sigma_n^*$ is *good* if $z = \$ \cdot x \cdot \# \cdot i$, where $x \in [n]^+$ and i appears in x. Let $R_n \subseteq \Sigma_n^*$ be the language of all good words. We define $L_n = \infty R_n$. First, it is not hard to see that R_n can be recognized by an NFW $\mathcal{N}_n$ with $3n + 3$ states. Essentially, $\mathcal{N}_n$ guesses the last letter i in the input word and then checks that the guess is correct (see sketch in Figure 1). By Theorem 3, there is an SD-tNBW for L_n with $3n + 3$ states.

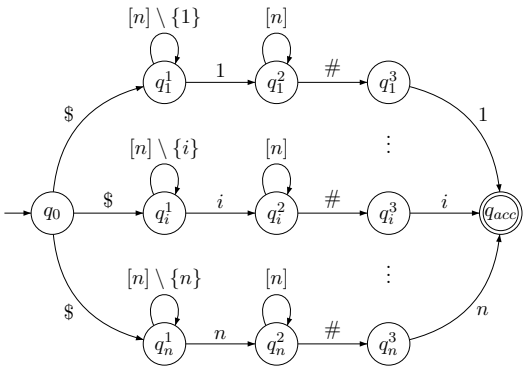

Figure 1 The NFW $\mathcal{N}_n$. Missing transitions lead to a rejecting-sink.

Before we prove that every tDBW or HD-tNBW that recognizes L_n needs at least 2^n states, let us note that it is already known that going from a DFW for a language $R \subseteq \Sigma^*$ to a tDBW for ∞R, may involve a blow-up of $2^{n-2-log_2(n)}$[24]. Thus, Theorem 3 implies an exponential gap between SD-tNBWs and tDBWs. Moreover, as HD-tNBWs are at most quadratically more succinct than tDBWs [20], the above can be extended to a $2^{\frac{n-2-log_2(n)}{2}}$ lower bound for the succinctness of SD-tNBWs with respect to HD-tNBWs. Our example here is tighter.

It is left to prove that every HD-tNBW that recognizes L_n needs at least 2^n states. Assume towards contradiction that $\mathcal{A} = \langle \Sigma_n, Q, q_0, \delta, \alpha \rangle$ is an HD-tNBW for L_n with $|Q| < 2^n$ states. In the full version, we iteratively define infinite sequences of finite words $x_1, x_2, x_3, \ldots$ and states $q_0, q_1, \ldots$ such that for all $k \geq 1$, the word x_k starts with \$, has no good infixes, and there is a run of the form $r_k = q_{k-1} \xrightarrow{x_k} q_k$ in $\mathcal{A}$ on x_k that traverses α. The challenging part in the construction is to make it valid also for HD (and not only deterministic) automata. For this, the definition of the words in the sequence is defined with respect to a strategy that attempts to witness the HDness of $\mathcal{A}$. To see why such sequences imply a contradiction, note that the concatenation of the runs $r_1, r_2, \ldots$ is an accepting run of $\mathcal{A}$ on the word $x = x_1 \cdot x_2 \cdots$. As $\mathcal{A}$ recognizes $L_n = \infty R_n$, it follows that $x \in \infty R_n$. On the other hand, x has no good infixes, and so $x \notin \infty R_n$. Indeed, if there is a good infix in x, then it must contain letters from different x_k's; in particular, it must contain at least two \$'s. ◀

▶ Remark 6. In order to get a slightly tighter bound, one can show that a minimal tDBW for L_n needs at least 2^{n+1} states and that the language L_n is not *HD-helpful*. That is, a minimal HD-tNBW for L_n is not smaller than a minimal tDBW for L_n, and so the 2^{n+1} bound holds also for a minimal HD-tNBW. The proof starts with a tDBW for L_n that has 2^{n+1} states, considers its complement tDCW, and shows that the application of the polynomial minimization algorithm of [1] on it, namely the algorithm that returns an equivalent minimal HD-tNCW, does result in a smaller automaton. The result then follows from the fact that a minimal HD-tNCW for a language is smaller than a minimal HD-tNBW for its complement [20]. The proof involves many notions and observations from [1] about minimal HD-tNCWs.

In the full version, we still describe a tDBW with 2^{n+1} states for L_n, and readers familiar with [1] can observe that the application of the HD-tNCW minimization algorithm on its dual tDCW does not make it smaller.

▶ **Theorem 7.** *There is a family $L_1, L_2, L_3, \ldots$ of languages such that for every $n \geq 1$, there is an SD-tNBW with $O(n)$ states that recognizes L_n, yet every SD-tNCW that recognizes $\overline{L_n}$ needs at least $2^{O(n)}$ states.*

Proof. Let $\Sigma = \{0, 1\}$. For $n \geq 1$, let $R_n = \{w : w \in 0 \cdot (0+1)^{n-1} \cdot 1 + 1 \cdot (0+1)^{n-1} \cdot 0\}$. It is easy to see that R_n can be recognized by an NFW $\mathcal{N}_n$ with $O(n)$ states. We define $L_n = \infty R_n$. First, by Theorem 3, there is an SD-tNBW with $O(n)$ states for L_n. In order to prove that an SD-tNCW for $\overline{L_n}$ needs at least $2^{O(n)}$ states, we prove that in fact every tNCW for $\overline{L_n}$ needs that many states. For this, note that $\overline{L_n}$ consists of all words w for which there is $u \in (0+1)^n$ such that $w \in (0+1)^* \cdot u^\omega$. Indeed, for such words w, the suffix u^ω contains no infix in R_n. Also, if a word contain only finitely many infixes in R_n, then it must have a suffix with no such infixes, namely a suffix of the form u^ω for some $u \in (0+1)^n$. Then, the proof that a tNCW for $\overline{L_n}$ needs exponentially many states is similar to the proof that an NFW for $\{u \cdot u : u \in (0+1)^n\}$ needs exponentially many states. Indeed, it has to remember the last n letters read. ◀

3.2 Decision Problems

We continue to decision problems about SD-tNBWs and SD-NBWs, and show that the exponential succinctness comes with a price: the complexity of all the problems we study coincides with the one known for tNBWs and NBWs. Accordingly, we only prove lower bounds for SD-tNBWs. Matching upper bounds follow from the known complexity for tNBWs, and same bounds for SD-NBWs follow from linear translations between SD-tNBWs and SD-NBWs. The problems we study are *language containment:* given two SD-tNBWs $\mathcal{A}_1$ and $\mathcal{A}_2$, decide whether $L(\mathcal{A}_1) \subseteq L(\mathcal{A}_2)$, *universality:* given an SD-tNBW $\mathcal{A}_1$, decide whether $L(\mathcal{A}_1) = \Sigma^\omega$, and *minimization:* given an SD-tNBW $\mathcal{A}_1$ and an integer $k \geq 1$, decide whether there is an SD-tNBW $\mathcal{A}_2$ such that $L(\mathcal{A}_1) = L(\mathcal{A}_2)$ and $|\mathcal{A}_2| \leq k$.

The exponential succinctness of SD automata motivates also the study of the *D-to-SD minimization problem*. Here, we are given a tDBW $\mathcal{A}_1$ and an integer $k \geq 1$, and we need to decide whether there is an SD-tNBW $\mathcal{A}_2$ such that $L(\mathcal{A}_1) = L(\mathcal{A}_2)$ and $|\mathcal{A}_2| \leq k$. For automata on finite words, the D-to-N minimization problem is known to be PSPACE-complete [19].

Note that a lower bound for universality implies a lower bound also for language containment. We still start with language containment, as it is much simpler.

▶ **Theorem 8.** *The language-containment problem for SD-tNBWs is PSPACE-hard.*

Proof. We describe a reduction from the universality problem for NFWs. Given an NFW $\mathcal{N}$ over Σ, let $\mathcal{N}'$ be an NFW over $\Sigma \cup \{\$\}$ such that $L(\mathcal{N}') = \$ \cdot L(\mathcal{N}) \cdot \$$. Now, let $\mathcal{A}_1$ be a 1-state tDBW over $\Sigma \cup \{\$\}$ such that $L(\mathcal{A}_1) = \infty\$$, and let $\mathcal{A}_2$ be the SD-tNBW obtained by applying the operation from Theorem 3 on $\mathcal{N}'$. Note that $L(\mathcal{A}_2) = \infty(\$ \cdot L(\mathcal{N}) \cdot \$)$ and $|\mathcal{A}_2| = |\mathcal{N}| + 3$.

We claim that $\mathcal{N}$ is universal iff $L(\mathcal{A}_1) \subseteq L(\mathcal{A}_2)$. First, if $L(\mathcal{N}) = \Sigma^*$, then $L(\mathcal{A}_2) = \infty(\$ \cdot \Sigma^* \cdot \$) = \infty\$$ and so $L(\mathcal{A}_1) \subseteq L(\mathcal{A}_2)$. Conversely, if there is a word $x \in \Sigma^* \setminus L(\mathcal{N})$, then the word $w = (\$ \cdot x)^\omega$ is in $L(\mathcal{A}_1) \setminus L(\mathcal{A}_2)$. Indeed, w has infinitely many \$'s, yet for every infix $\$ \cdot y \cdot \$$ of w, we have that $y \notin L(\mathcal{N})$, and so $w \notin L(\mathcal{A}_2)$. ◀

The proof in Theorem 8 uses $\infty\$$ as the "contained language". For the universality problem, where we cannot relay on hints from words in the contained language, we have to work much harder and generate such hints from runs of Turing machines. Specifically, we prove PSPACE hardness by a generic reduction from polynomial space Turing machines. Such reductions associate with a Turing machine T an automaton $\mathcal{A}$ that recognizes the language R of words that do not encode legal rejecting computations of T, and so $R = \Sigma^*$ iff the machine has no rejecting computations. The automaton $\mathcal{A}$ is nondeterministic, as it has to guess violations of attempts to encode legal accepting computations. In order to replace $\mathcal{A}$ by an SD automaton, we manipulate the Turing machine so that the language of the generated automaton is of the form ∞R, for which we can construct an SD-tNBW.

▶ **Theorem 9.** *The universality problem for SD-tNBWs is PSPACE-hard.*

Proof. We do a reduction from polynomial-space Turing machines. Given a Turing machine T with space complexity $s : \mathbb{N} \to \mathbb{N}$, we construct in time polynomial in $|T|$ and $s(0)$, an SD-tNBW $\mathcal{A}$ of size polynomial in T and $s(0)$, such that $\mathcal{A}$ is universal iff T accepts the empty tape[3]. Let $n_0 = s(0)$. Thus, each configuration in the computation of T on the empty tape uses at most n_0 cells. We assume that T halts from all configurations (that is, not just from these reachable from an initial configuration of T); Indeed, by adding a polynomial-space counter to T, one can transform a polynomial-space Turing machine that need not halt from all configurations to one that does halt. We also assume, without loss of generality, that once T reaches a final (accepting or rejecting) state, it erases the tape, moves with its reading head to the leftmost cell, and moves to the initial state. Thus, all computations of T are infinite and after visiting a final configuration for the first time, they eventually consists of repeating the same finite computation on the empty tape that uses at most n_0 tape cells.

We define $\mathcal{A}$ so that it accepts a word w iff (C1) no suffix of w is an encoding of a legal computation of T that uses at most n_0 tape cells, or (C2) w has infinitely many infixes that encode the accepting state of T.

It is not hard to see that T accepts the empty tape iff $\mathcal{A}$ is universal. Indeed, if T accepts the empty tape, and there is a word w that does not satisfy (C1), thus w has a suffix that is an encoding of a legal computation of T that uses at most n_0 cells, then the encoded computation eventually reaches a final configuration, from which it eventually repeats the accepting computation of T on the empty tape infinitely many times, and so w satisfies (C2). Conversely, If T rejects the empty tape, then the word w that encodes the computation of T on the empty tape does not satisfy (C1) nor (C2), and so $\mathcal{A}$ does not accept w.

Finally, the fact that T is a polynomial-space Turing machine enables us to define $\mathcal{A}$ with polynomially many states, as we detail in the full version. ◀

We continue to the minimization problem. Note that here, a PSPACE upper bound does not follow immediately from the known PSPACE upper bound for tNBWs, as the candidate automata need to be SD. Still, as SDness can be checked in PSPACE [3], a PSPACE upper bound follows. Also note that here, the case of SD-NBWs is easy, as a non-empty SD-NBW

[3] This is sufficient, as one can define a generic reduction from every language L in PSPACE as follows. Let T_L be a Turing machine that decides L in polynomial space $f(n)$. On input w for the reduction, the reduction considers the machine T_w that on every input, first erases the tape, writes w on its tape, and then runs as T_L on w. Then, the reduction outputs an automaton $\mathcal{A}$, such that T_w accepts the empty tape iff $\mathcal{A}$ is SD. Note that the space complexity of T_w is $s(n) = \max(n, f(|w|))$, and that w is in L iff T_w accepts the empty tape. Since $\mathcal{A}$ is constructed in time polynomial in $s(0) = f(|w|)$ and $|T_w| = \text{poly}(|w|)$, it follows that the reduction is polynomial in $|w|$.

is universal iff it has an equivalent SD-NBW with one state. For transition-based acceptance, the language of a single-state SD-tNBW need not be trivial, and so we have to examine the specific language used for the universality PSPACE-hardness proof (see proof in the full version):

▶ **Theorem 10.** *The minimization problem for SD-tNBWs is PSPACE-hard.*

As we show below, the minimization problem stays hard even when we start from a deterministic automaton:

▶ **Theorem 11.** *The D-to-SD minimization problem for Büchi automata is PSPACE-hard.*

Proof. We start with Büchi automata with transition-based acceptance, and describe a reduction from the D-to-N minimization problem for automata on finite words: given a DFW $\mathcal{A}_1$, and an integer $k \geq 1$, decide whether there is an NFW $\mathcal{A}_2$ such that $L(\mathcal{A}_1) = L(\mathcal{A}_2)$ and $|\mathcal{A}_2| \leq k$. In [19], the authors prove that the problem is PSPACE-hard, in fact PSPACE-hard already for DFWs that recognize a language that has no good prefixes.

Consider a language $R \subseteq \Sigma^*$. The reduction is based on a construction that turns an NFW for R into an SD-tNBW for $\infty(\$ \cdot R \cdot \$)$, for a letter $\$ \notin \Sigma$. Note that by applying the construction from Theorem 3 on the language $\$ \cdot R \cdot \$$, we can get an SD-tNBW for $\infty(\$ \cdot R \cdot \$)$. The construction there, however, does not preserve determinism. Therefore, we need a modified polynomial construction, which takes advantage of the \$'s. We describe the modified construction below.

Given an NFW $\mathcal{A} = \langle \Sigma, Q, Q_0, \delta, F \rangle$, and a letter $\$ \notin \Sigma$, we construct the tNBW $\mathcal{A}' = \langle \Sigma \cup \{\$\}, Q, Q_0, \delta', \alpha \rangle$, where for all states $q \in Q$ and letters $\sigma \in \Sigma$, we have that $\delta'(q, \sigma) = \delta(q, \sigma)$. Also, $\delta'(q, \$) = Q_0$, and $\alpha = \{\langle s, \sigma, q \rangle : q \in Q_0 \text{ and } s \in F\}$. Thus, $\mathcal{A}'$ is obtained from $\mathcal{A}$ by adding \$-transitions from all states to Q_0. A new transition is in α iff its source is an accepting state of $\mathcal{A}$. In the full version, we prove that $\mathcal{A}'$ is an SD-tNBW and $L(\mathcal{A}') = \infty(\$ \cdot L(\mathcal{A}) \cdot \$)$. Also, as we only added transitions labeled \$ to Q_0, it is easy to see that if $\mathcal{A}$ is deterministic, then so is $\mathcal{A}'$.

We now describe the reduction. Given a DFW $\mathcal{A}$ over Σ such that $L(\mathcal{A})$ has no good prefixes, and given an integer k, the reduction returns the polynomial tDBW $\mathcal{A}'$ and the integer k. We prove next that the reduction is correct. Thus, the DFW $\mathcal{A}$ has an equivalent NFW with at most k states iff the tDBW $\mathcal{A}'$ has an equivalent SD-tNBW with at most k states. For the first direction, if $\mathcal{B}$ is an NFW equivalent to $\mathcal{A}$ whose size is at most k, then by the above construction, it holds that $\mathcal{B}'$ is an SD-tNBW whose size is at most k, and $L(\mathcal{B}') = \infty(\$ \cdot L(\mathcal{B}) \cdot \$) = \infty(\$ \cdot L(\mathcal{A}) \cdot \$) = L(\mathcal{A}')$.

Conversely, if $\mathcal{B}'$ is an SD-tNBW for $\infty(\$ \cdot L(\mathcal{A}) \cdot \$)$ whose size is at most k, then as $L(\mathcal{A})$ has no good prefixes, we get by Theorem 4 that there is an NFW $\mathcal{B}$ for $L(\mathcal{A})$ whose size is at most k, and we are done.

Finally, since the transitions between automata with transition-based and state-based acceptance may involve a linear blow-up, here we need to be careful in extending the result to the state-based setting. In the full version, we prove that the arguments in Theorem 11 can be adapted to automata with state-based acceptance, thus PSPACE-completeness holds also for Büchi automata with state-based acceptance. ◀

4 Semantically Deterministic co-Büchi Automata

In this section we study SD co-Büchi automata. Here too, our results are based on constructions that involve encodings of NFWs by SD-tNCWs. Here, however, the constructions are more complicated, and we first need some definitions and notations.

Consider a tNCW $\mathcal{A} = \langle \Sigma, Q, Q_0, \delta, \alpha \rangle$. We refer to the SCCs we get by removing $\mathcal{A}$'s α-transitions as the $\overline{\alpha}$-*components* of $\mathcal{A}$; that is, the $\overline{\alpha}$-*components* of $\mathcal{A}$ are the SCCs of the graph $G_{\mathcal{A}^{\overline{\alpha}}} = \langle Q, E^{\overline{\alpha}} \rangle$, where $\langle q, q' \rangle \in E^{\overline{\alpha}}$ iff there is a letter $\sigma \in \Sigma$ such that $\langle q, \sigma, q' \rangle \in \overline{\alpha}$. We say that $\mathcal{A}$ is *normal* if there are no $\overline{\alpha}$-transitions connecting different $\overline{\alpha}$-components. That is, for all states q and s of $\mathcal{A}$, if there is a path of $\overline{\alpha}$-transitions from q to s, then there is also a path of $\overline{\alpha}$-transitions from s to q. Note an accepting run of $\mathcal{A}$ eventually gets trapped in one of $\mathcal{A}$'s $\overline{\alpha}$-components. In particular, accepting runs in $\mathcal{A}$ traverse transitions that leave $\overline{\alpha}$-components only finitely often. Hence, we can add transitions among $\overline{\alpha}$-components to α without changing the language of the automaton. Accordingly, in the sequel we assume that given tNCWs are normal.

We proceed to encoding NFWs by SD-tNCWs. For a language $R \subseteq \Sigma^*$, we define the language $\bowtie_{\$}(R) \subseteq (\Sigma \cup \{\$\})^\omega$, by

$$\bowtie_{\$}(R) = \{w : \text{if } w \text{ has infinitely many } \$, \text{ then it has a suffix in } (\$R)^\omega\}.$$

Also, we say that a finite word $x \in \Sigma^*$ is a *bad infix* for R if for all words $w \in \Sigma^*$ that have x as an infix, it holds that $w \in \overline{R}$.

Note that for every language $R \subseteq \Sigma^*$, we have that $\bowtie_{\$}(R) = \overline{\infty(\$ \cdot \overline{R} \cdot \$)}$. Thus, $\bowtie_{\$}(R)$ complements $\infty(\$ \cdot \overline{R} \cdot \$)$. Yet, unlike tDCWs and tDBWs, which dualize each other, SD-tNBWs and SD-tNCWs are not dual. Hence, adjusting Theorems 3 and 4 to the co-Büchi setting, requires different, in fact more complicated, constructions.

▶ **Theorem 12.** *Given an NFW $\mathcal{N}$, one can obtain, in linear time, an SD-tNCW $\mathcal{A}$ such that $L(\mathcal{A}) = \bowtie_{\$}(L(\mathcal{N}))$ and $|\mathcal{A}| = |\mathcal{N}|$.*

Proof. Given $\mathcal{N} = \langle \Sigma, Q, Q_0, \delta, F \rangle$, we obtain $\mathcal{A}$ by adding \$-transitions from all states to Q_0. The new transitions are in α iff they leave a state in $Q \setminus F$. Formally, $\mathcal{A} = \langle \Sigma \cup \{\$\}, Q, Q_0, \delta', \alpha \rangle$, where for all $s \in Q$ and $\sigma \in \Sigma$, we have that $\delta'(s, \sigma) = \delta(s, \sigma)$, and $\delta'(s, \$) = Q_0$. Then, $\alpha = \{\langle s, \$, q \rangle : q \in Q_0 \text{ and } s \in Q \setminus F\}$. It is easy to see that $|\mathcal{A}| = |\mathcal{N}|$. In order to prove that $\mathcal{A}$ is SD and $L(\mathcal{A}) = \bowtie_{\$}(L(\mathcal{N}))$, we prove in the full version that for every state $q \in Q$, it holds that $L(\mathcal{A}^q) = \bowtie_{\$}(L(\mathcal{N}))$. Essentially, this follows from the fact that $\mathcal{A}$ can avoid traversing α when it reads an input of the form $x \cdot \$$, only when $x \in L(\mathcal{N})$. ◀

▶ **Theorem 13.** *Consider a language $R \subseteq \Sigma^*$ and a letter $\$ \notin \Sigma$. For every tNCW $\mathcal{A}$ such that $L(\mathcal{A}) = \bowtie_{\$}(R)$, there exists an NFW $\mathcal{N}$ such that $L(\mathcal{N}) = R$ and $|\mathcal{N}| \leq |\mathcal{A}| + 1$. In addition, if R has bad infixes, then $|\mathcal{N}| \leq |\mathcal{A}|$.*

Proof. Let $\mathcal{A} = \langle \Sigma \cup \{\$\}, Q, Q_0, \delta, \alpha \rangle$ be a tNCW for $\bowtie_{\$}(R)$. We assume that $\mathcal{A}$ is normal and all of its states are reachable. We define the NFW $\mathcal{N} = \langle \Sigma, Q \cup \{q_{rej}\}, Q_0^{\mathcal{N}}, \delta_{\mathcal{N}}, F_{\mathcal{N}} \rangle$, where

- $Q_0^{\mathcal{N}} = \{q \in Q : \text{there is a state } q' \text{ such that } \langle q', \$, q \rangle \in \overline{\alpha}\}$.
- $F_{\mathcal{N}} = \{q \in Q : \text{there is a state } q' \text{ such that } \langle q, \$, q' \rangle \in \overline{\alpha}\}$.
- The transition function $\delta_{\mathcal{N}}$ is defined as follows: for every two states $q, s \in Q$ and letter $\sigma \in \Sigma$, it holds that $s \in \delta_{\mathcal{N}}(q, \sigma)$ iff $\langle q, \sigma, s \rangle \in \overline{\alpha}$. Also, if $\{q\} \times \{\sigma\} \times \delta(q, \sigma) \subseteq \alpha$, then $\delta_{\mathcal{N}}(q, \sigma) = q_{rej}$. Finally, for all letters $\sigma \in \Sigma$, it holds that $\delta_{\mathcal{N}}(q_{rej}, \sigma) = q_{rej}$; that is, q_{rej} is a rejecting sink.

Thus, $\mathcal{N}$ tries to accept words $x \in \Sigma^*$ for which there is a run in $\mathcal{A}$ that does not traverse α on the word $\$ \cdot x \cdot \$$.

We prove that $L(\mathcal{N}) = R$. We first prove that $R \subseteq L(\mathcal{N})$. Consider a word $x \in R$, and let $r = r_0, r_1, r_2, \ldots$ be an accepting run of $\mathcal{A}$ on $(\$ \cdot x)^\omega$. As r is accepting, there are $i < j$ such that $r_i, r_{i+1}, \ldots, r_j$ is a run that does not traverse α on $\$ \cdot x \cdot \$$. By the definition of $\delta_{\mathcal{N}}$, $r_{i+1} \in Q_0^{\mathcal{N}}, r_{j-1} \in F_{\mathcal{N}}$, and so $r_{i+1}, r_{i+2}, \ldots, r_{j-1}$ is an accepting run of $\mathcal{N}$ on x.

We prove next that $L(\mathcal{N}) \subseteq R$. Consider a word $x = \sigma_1 \cdot \sigma_2 \cdots \sigma_n \in L(\mathcal{N})$ and let $r = r_0, r_1, \ldots r_n$ be an accepting run of $\mathcal{N}$ on x. As r ends an accepting state of $\mathcal{N}$, then it does not visit q_{rej}. Hence, the definition of $\delta_{\mathcal{N}}$ implies that r is a run that does not traverse α in $\mathcal{A}$. Also, as $r_0 \in Q_0^{\mathcal{N}}$ and $r_n \in F_{\mathcal{N}}$, there are states $q_1, q_2 \in Q$ such that $\langle q_1, \$, r_0\rangle, \langle r_n, \$, q_2\rangle \in \overline{\alpha}$. Hence, $q_1, r_0, r_1, \ldots, r_n, q_2$ is a run that does not traverse α in $\mathcal{A}$ on the word $\$ \cdot x \cdot \$$. As $\mathcal{A}$ is normal, there is a word $y \in (\Sigma \cup \{\$\})^*$ such that there is a run that does not traverse α of $\mathcal{A}^{q_2}$ on y that reaches q_1. Therefore, $(\$ \cdot x \cdot \$ \cdot y)^\omega \in L(\mathcal{A}^{q_1})$. As all the states of $\mathcal{A}$ are reachable, it follows that there is a word $z \in (\Sigma \cup \{\$\})^*$ such that $q_1 \in \delta(Q_0, z)$, and thus $z \cdot (\$ \cdot x \cdot \$ \cdot y)^\omega \in L(\mathcal{A})$. Hence, as $L(\mathcal{A}) = \bowtie_{\$}(R)$, we get that $x \in R$.

Since the state space of $\mathcal{N}$ is $Q \cup \{q_{rej}\}$, we have that $|\mathcal{N}| = |\mathcal{A}| + 1$. Moreover, if R has a bad infix x, then $x \in \overline{R}$. Hence, if we consider the word x^ω, then as it has no \$'s, it is accepted by $\mathcal{A}$. Hence, there is a state $q \in Q$ such that $\mathcal{A}^q$ has a run on x^ω that does not leave the $\overline{\alpha}$-component of q. As we detail in the full version, the fact that x is a bad infix of R implies that the $\overline{\alpha}$-component of q does not contain \$-transitions. Hence, since the only states in Q that are reachable in $\mathcal{N}$ lie in $\overline{\alpha}$-components that contain a \$-transition, we can remove the state q_{rej} from $\mathcal{N}$ and make q a rejecting sink instead. Hence, in this case, we have that $|\mathcal{N}| \leq |\mathcal{A}|$, and we are done. ◀

4.1 Succinctness and Complementation

In this section we study the succinctness of SD co-Büchi automata with respect to deterministic ones, and the blow-up involved in their complementation. Recall that unlike Büchi automata, for co-Büchi automata, HD automata are exponentially more succinct than deterministic ones. Accordingly, our results also refer to the succinctness of SD automata with respect to HD ones:

▶ **Theorem 14.** *There is a family $L_1, L_2, L_3, \ldots$ of languages such that for every $n \geq 1$, there is an SD-tNCW with $3n + 3$ states that recognizes L_n, yet every tDCW or HD-tNCW that recognizes L_n needs at least 2^n states.*

Proof. For $n \geq 1$, consider the alphabet $\Sigma_n = [n] \cup \{\#\}$, and the language $R_n = \{x \cdot \# \cdot i : x \in [n]^+ \text{ and } i \text{ appears in } x\} \subseteq \Sigma_n^*$. We define $L_n = \bowtie_{\$}(R_n)$. Recall that a word over $z \in (\Sigma_n \cup \{\$\})^*$ is good if $z = \$ \cdot x \cdot \# \cdot i$, where $x \in [n]^+$ and i appears in x, and note that L_n consists of exactly the words with finitely many \$'s, or that have a suffix that is a concatenation of good words. First, it is not hard to see that R_n can be recognized by an NFW $\mathcal{N}_n$ with $3n + 3$ states, for example, a candidate for $\mathcal{N}_n$ can be obtained from the NFW in Figure 1 by removing the \$-transitions from q_0, and letting q_0 guess to behave as any state in $\bigcup_{i \in [n]} \{q_i^1\}$. By Theorem 12, there is an SD-tNCW for L_n with $3n + 3$ states.

In order to show that an HD-tNCW for L_n needs at least 2^n states, we rely on properties of HD-tNCWs [20, 1] and argue that (1) an HD-tNCW for L_n has a state q such that $L_{\overline{\alpha}}(q) = \{w : \text{there is a run from } q \text{ on } w \text{ that does not traverse } \alpha\}$ is such that $(\$ \cdot R_n)^\omega \subseteq L_{\overline{\alpha}}(q)$, and (2) the $\overline{\alpha}$-component of q is of size at least 2^n. As we detail in the full version, the first claim follows from the fact that HD-tNCWs can be assumed to be $\overline{\alpha}$ *deterministic*, thus all their $\bar{\alpha}$-transitions are deterministic [20, 1]. The second claim follows from the fact that the $\overline{\alpha}$-component of q should detect good subwords, and should remember for this subsets of $[n]$. ◀

▶ Remark 15. As has been the case with Büchi automata, here too, an analysis of the application of the HD-tNCW minimization algorithm on a tDCW for L_n leads to a slightly tighter bound. Specifically, in the full version, we describe a tDCW for L_n with $2^{n+1} + 1$ states, such that the application of the HD-tNCW minimization algorithm on it does not make it smaller.

▶ **Theorem 16.** *There is a family $L_1, L_2, L_3, \ldots$ of languages such that for every $n \geq 1$, there is an SD-tNCW with $O(n)$ states that recognizes L_n, yet every SD-tNBW that recognizes $\overline{L_n}$ needs at least $2^{O(n)}$ states.*

Proof. Let $\Sigma = \{0, 1\}$, and let $R_n = \{w : w \in (0+1)^* \cdot (0 \cdot (0+1)^{n-1} \cdot 1 + 1 \cdot (0+1)^{n-1} \cdot 0) \cdot (0+1)^*\}$. Thus, R_n is the language of all words that contain two letters that are at distance n and are different. We define $L_n = {\bowtie_\$}(R_n)$.

It is easy to see that R_n can be recognized by an NFW with $O(n)$ states. Hence, by Theorem 12, there is an SD-tNCW with $O(n)$ states for L_n. We prove next that every SD-tNBW for $\overline{L_n}$ needs at least $2^{O(n)}$ states. For this, note that $\overline{L_n}$ consists of all words w such that w contains infinitely many \$'s yet has no suffix in $(\$R_n)^\omega$. Thus, w contains infinitely many infixes in $\$\overline{R_n}\$$. Therefore, $\overline{L_n} = \infty(\$ \cdot \overline{R_n} \cdot \$)$. It is not hard to prove that an NFW for $\overline{R_n}$ needs at least $2^{O(n)}$ states. Then, by Theorem 4, this bound is carried over to a $2^{O(n)}$ lower bound on an SD-tNBW for $\overline{L_n}$. ◀

4.2 Decision Problems

We continue to decision problems for SD-tNCWs and SD-NCWs. As in Section 3.2, we state only the lower bounds, and for SD-tNCWs. Matching upper bounds and similar results for SD-NCWs follow from the known upper bounds for tNCWs and the known linear translations between state-based and transition-based automata.

We start with language-containment and universality.

▶ **Theorem 17.** *The language-containment and universality problems for SD-tNCWs are PSPACE-hard.*

Proof. We describe a reduction from universality of NFWs to universality of SD-tNCWs. Given an NFW $\mathcal{N}$ over Σ, the reduction returns the SD-tNCW $\mathcal{A}$ over $\Sigma \cup \{\$\}$ that is obtained by applying the operation from Theorem 12 on $\mathcal{N}$. Thus, $L(\mathcal{A}) = {\bowtie_\$}(L(\mathcal{N}))$.

First, if $L(\mathcal{N}) = \Sigma^*$, then $(\Sigma \cup \{\$\})^* \cdot (\$L(\mathcal{N}))^\omega = \infty\$$, and so $L(\mathcal{A}) = (\Sigma \cup \{\$\})^\omega$. Conversely, if there is a word $x \in \Sigma^* \setminus L(\mathcal{N})$, then the word $w = (\$x)^\omega$ is not in $L(\mathcal{A})$. Indeed, w has infinitely many \$'s, yet it has a word not in $L(\mathcal{N})$ between every two consecutive \$'s. ◀

We continue to the minimization problem. Note that while minimization is PSPACE-complete for NCWs, it is NP-complete for DCWs and in PTIME for HD-tNCWs. Thus, our PSPACE lower bound suggests a significant difference between SD and HD automata. Note also that, as has been the case with Büchi automata, the case of SD-NCWs is easy, as a non-empty SD-NCW is universal iff it has an equivalent SD-NCW with one state, which is not the case for SD-tNCWs (see proof in the full version):

▶ **Theorem 18.** *The minimization problem for SD-tNCWs is PSPACE-hard.*

We continue to the D-to-SD minimization problem, showing it stays PSPACE-hard.

▶ **Theorem 19.** *The D-to-SD minimization problem for co-Büchi automata is PSPACE-hard.*

Proof. We reduce from the D-to-N minimization problem for automata on finite words, which is already PSPACE-hard for languages that have bad infixes[19]. We start with co-Büchi automata with transition-based acceptance.

Consider the construction from Theorem 12. Recall it takes an NFW $\mathcal{A}$ as input, returns an SD-tNCW $\mathcal{A}'$ of the same size for ${\bowtie_\$}(L(\mathcal{A}))$, and preserves determinism.

Consider a DFW $\mathcal{A}$ over Σ such that $L(\mathcal{A})$ has a bad infix, and an integer k. The reduction returns the SD-tNCW $\mathcal{A}'$ constructed from $\mathcal{A}$ in Theorem 12, and the integer k. Recall that $L(\mathcal{A}') = \bowtie_{\$}(L(\mathcal{A}))$, and that the construction in Theorem 12 preserves determinism. Thus, the automaton $\mathcal{A}'$ is really a tDCW.

We prove next that the reduction is correct. That is, the DFW $\mathcal{A}$ has an equivalent NFW with at most k states iff the tDCW $\mathcal{A}'$ has an equivalent SD-tNCW with at most k states. For the first direction, if $\mathcal{B}$ is an NFW equivalent to $\mathcal{A}$ whose size is at most k, then, by applying to it the construction from Theorem 12, we get an SD-tNCW $\mathcal{B}'$ whose size is at most k, and $L(\mathcal{B}') = \bowtie_{\$}(L(\mathcal{B})) = \bowtie_{\$}(L(\mathcal{A})) = L(\mathcal{A}')$.

Conversely, if $\mathcal{B}'$ is an SD-tNCW for $\bowtie_{\$}(L(\mathcal{A}))$ whose size is at most k, then as $L(\mathcal{A})$ has bad infixes, we get by Theorem 13 that there is an NFW $\mathcal{B}$ for $L(\mathcal{A})$ whose size is at most k, and we are done.

In the full version, we extend the proof to co-Büchi automata with state-based acceptance. ◀

5 Semantically Deterministic Weak Automata

By [3], SD-NWWs need not be DBP or even HD. For completeness we describe here the example from [3], as it highlights the challenges in SD-NWW determinization. Consider the automaton $\mathcal{A}$ in Figure 2.

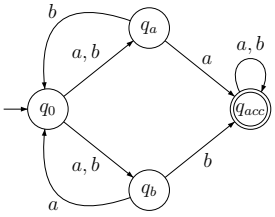

Figure 2 An SD-NWW that is not DBP.

It is easy to see that $\mathcal{A}$ is weak, and all its states are universal, and so it is SD. On the other hand, $\mathcal{A}$ is not HD as every strategy has a word with which it does not reach q_{acc} – a word that forces every visit in q_a and q_b to be followed by a visit in q_0. Below we show that despite not being DBP, SD-NWWs can be determinized in polynomial time. Essentially, our proof is based on redirecting transitions of the SD-NWW to deep components in the automaton. In our example, note that while the SD-NWW $\mathcal{A}$ is not HD, it has a deterministic state q_{acc} that recognizes $L(\mathcal{A})$.

Consider an SD-NWW $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$. We denote the set of $\mathcal{A}$'s SCCs by $\mathcal{C}(\mathcal{A})$, and the SCC containing a state q by $C(q)$. Let $C_1 \leq C_2 \leq \cdots \leq C_m$ be a total order on the SCCs of $\mathcal{A}$, extending the partial order induced by δ. That is, if $q' \in \delta(q, \sigma)$, for some letter σ, then $C(q) \leq C(q')$. When $C \leq C'$, we say that C' is *deeper than* C. Thus, states along runs of a weak automaton proceed from SCCs to deeper ones, and eventually get stuck in some SCC.

If we had an algorithm that checks language equivalence between states in $\mathcal{A}$ in polynomial time, we could have a polynomial determinization algorithm that defines the σ-successor of a state as the deepest state among all states equivalent to its σ-successors (since $\mathcal{A}$ is SD, all these successors agree on their language). Since we still do not have such an algorithm (in fact, it would follow from our construction), we approximate language equivalence by an equivalence that follows from the semantic determinism of $\mathcal{A}$.

For two states $s_1, s_2 \in Q$, we say that s_1 and s_2 are *δ-close*, if there is a state $q \in Q$ and a word $w \in \Sigma^*$ such that $s_1, s_2 \in \delta(q, w)$. Note that the δ-close relation refines equivalence, yet the converse does not hold. Indeed, the SDness property implies that $s_1 \sim_{\mathcal{A}} s_2$ for all δ-close states s_1 and s_2.

▶ **Lemma 20.** *If s_1 and s_2 are δ-close, then there is a state q and word w of length at most $|Q|^2$ such that $s_1, s_2 \in \delta(q, w)$.*

In order to calculate the δ-close relation in polynomial time, we define a sequence $H_0, H_1, H_2, \ldots \subseteq Q \times Q$ of relations, where $\langle s_1, s_2 \rangle \in H_i$ iff there is a state q and word w of length at most i such that $s_1, s_2 \in \delta(q, w)$. By Lemma 20 (see proof in the full version), we are guaranteed to reach a fixed point after at most $|Q|^2$ iterations. The relations H_i are defined as follows.

- $H_0 = \{\langle q, q \rangle : q \in Q\}$.
- For $i \geq 0$, we define $H_{i+1} = H_i \cup \{\langle s_1, s_2 \rangle :$ there is $\langle q_1, q_2 \rangle \in H_i$ and letter $\sigma \in \Sigma$ such that $s_1 \in \delta(q_1, \sigma)$ and $s_2 \in \delta(q_2, \sigma)\}$.

Let $j \geq 0$ be such that $H_{j+1} = H_j$. It is not hard to see that H_j is the δ-close relation. While the δ-close relation is reflexive and symmetric, it is not transitive. Now, let $H \subseteq Q \times Q$ be the closure of H_j under transitivity. That is, $\langle s_1, s_2 \rangle \in H$ iff there is $k \geq 2$ and states $q_1, q_2, \ldots, q_k$ such that $q_1 = s_1$, $q_k = s_2$ and $\langle q_i, q_{i+1} \rangle \in H_j$ for all $1 \leq i < k$.

The following lemma implies that H propagates to successor states (see proof in the full version):

▶ **Lemma 21.** *If $H(s, s')$, then for every letter $\sigma \in \Sigma$ and states $q \in \delta(s, \sigma)$ and $q' \in \delta(s', \sigma)$, we have that $H(q, q')$.*

It is easy to see that H is an equivalence relation. Let $\mathcal{P} = \{P_1, \ldots, P_k\}$ be the set of the equivalence classes of H. For each equivalence class $P \in \mathcal{P}$, we fix the *representative of* P as some state in $P \cap C$, where $C \in \mathcal{C}(\mathcal{A})$ is the deepest SCC that intersects P. Let $p_1, \ldots, p_k$ be the representatives of the sets in $\mathcal{P}$. For a state $q \in Q$, let $\widetilde{q}$ denote the representative of the set $P \in \mathcal{P}$ with $q \in P$. Note that as H refines $\sim_{\mathcal{A}}$, we have that $q \sim_{\mathcal{A}} \widetilde{q}$.

▶ **Theorem 22.** *Given an SD-NWW $\mathcal{A}$ with state space Q, we can construct, in polynomial time, an equivalent DWW $\mathcal{D}$ with state space Q', for $Q' \subseteq Q$.*

Proof. Given $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$, we define $\mathcal{D} = \langle \Sigma, Q', q'_0, \delta', \alpha \cap Q' \rangle$, where

- $Q' = \{p_1, \ldots, p_k\}$. Note that indeed $Q' \subseteq Q$.
- $q'_0 = \widetilde{q_0}$.
- For $p \in Q'$ and $\sigma \in \Sigma$, we define $\delta'(p, \sigma) = \tilde{q}$, for some $q \in \delta(p, \sigma)$. Note that all the states in $\delta(p, \sigma)$ are δ-close, and thus belong to the same set in $\mathcal{P}$. Hence, the choice of q is not important, as $\delta'(p, \sigma)$ is the representative of this set.

We prove that $\mathcal{D}$ is a DWW equivalent to $\mathcal{A}$. First, in order to see that $\mathcal{D}$ is weak, consider states p, p' such that $p' \in \delta'(p, \sigma)$. Thus, p' is the representative of a state $q \in \delta(p, \sigma)$. As $\mathcal{A}$ is weak, we have that $C(p) \leq C(q)$. As $p' = \tilde{q}$, we have that $C(q) \leq C(p')$. Hence $C(p) \leq C(p')$, and we are done.

We continue and prove that $L(\mathcal{A}) = L(\mathcal{D})$. We first prove that $L(\mathcal{A}) \subseteq L(\mathcal{D})$. Consider a word w and assume that $w \in L(\mathcal{A})$. Let $r = q_0, q_1, q_2, \ldots$ be an accepting run of $\mathcal{A}$ on w, and let $r' = s_0, s_1, s_2, \ldots$ be the run of $\mathcal{D}$ on w. If r' is accepting, we are done. Otherwise, namely if r' is rejecting, we point to a contradiction. Let $j \geq 0$ be the index in which r'

visits only states in $sinf(r')$. Note that all the states $s_j, s_{j+1}, s_{j+2}, \ldots$ belong to some SCC C of $\mathcal{A}$. Since we assume that r' is rejecting, and acceptance in $\mathcal{D}$ is inherited from $\mathcal{A}$, we get that C is a rejecting SCC of $\mathcal{A}$. We claim that all the runs of $\mathcal{A}^{s_j}$ on the suffix $w[j+1,\infty]$ of w are stuck in C. Thus, $w[j+1,\infty] \notin L(\mathcal{A}^{s_j})$. On the other hand, we claim that for all $i \geq 0$, we have that $q_i \sim_{\mathcal{A}} s_i$. Then, however, $w[j+1,\infty] \notin L(\mathcal{A}^{q_j})$, contradicting the fact that r is accepting:

The easy part is to prove that for all $i \geq 0$, we have that $q_i \sim_{\mathcal{A}} s_i$. Indeed, it follows from the fact that for all $i \geq 0$, we have that $H(q_i, s_i)$ and the fact that H refines $\sim_{\mathcal{A}}$. The proof proceeds by an induction on i. First, as for every state $q \in Q$, we have that $H(q, \widetilde{q})$, then $H(q_0, q'_0)$, and so the claim follows from s_0 being q'_0. Assume now that $H(q_i, s_i)$. Recall that s_{i+1} is $\widetilde{q}$ for some $q \in \delta(s_i, w[i+1])$. Also, $q_{i+1} \in \delta(q_i, w[i+1])$. Then, by Lemma 21, we have that $H(q_{i+1}, q)$. Since, in addition, we have that $H(q, \widetilde{q})$, then the transitivity of H implies that $H(q_{i+1}, s_{i+1})$, and we are done.

We proceed to the other part, namely, proving that all the runs of $\mathcal{A}^{s_j}$ on the suffix $w[j+1,\infty]$ of w are stuck in C. Let $u_{j+1}, u_{j+2}, \ldots$ be such that for all $i \geq 1$, it holds that $u_{j+i} \in \delta(s_{j+i-1}, w[j+i])$ and $H(u_{j+i}, s_{j+i})$. Note that such states exist, as $s_{j+i-1} \xrightarrow{w[j+i]} s_{j+i}$ is a transition of $\mathcal{D}$ and so $s_{j+i} = \widetilde{q}$ for all $q \in \delta(s_{j+i-1}, w[j+i])$. Consider a run $r'' = v_0, v_1, v_2, \ldots$ of $\mathcal{A}^{s_j}$ on $w[j+1,\infty]$. Note that $v_0 = s_j$, and so $H(v_0, s_j)$. Therefore, by Lemma 21, we have that $H(v_1, u_{j+1})$, implying $H(v_1, s_{j+1})$. By repeated applications of Lemma 21, we get that $H(v_i, u_{j+i})$, implying $H(v_i, s_{j+i})$, for all $i \geq 1$. Assume now by way of contradiction that the run r'' leaves the SCC C, and so there is $i \geq 1$ such that $C(v_i) \not\leq C(s_{j+i})$. As $H(v_i, s_{j+i})$, the states v_i and s_{j+i} are in the same equivalence class $P \in \mathcal{P}$. Then, the definition of Q' implies that $C(s_{j+i}) \geq C(v_i)$, and we have reached a contradiction.

It is left to prove that $L(\mathcal{D}) \subseteq L(\mathcal{A})$. Consider a word $w \in L(\mathcal{D})$. Let $r' = s_0, s_1, s_2, \ldots$ be the run of $\mathcal{D}$ on w, and let $j \geq 0$ be the index in which r' visits only states in $sinf(r')$; in particular, as argued above, $sinf(r')$ is included in some SCC C of $\mathcal{A}$. Thus, all the states $s_j, s_{j+1}, s_{j+2}, \ldots$ are in C. Since $w \in L(\mathcal{D})$, then r' is accepting, and so C is an accepting SCC of $\mathcal{A}$. As in the previous direction, it holds that s_j is $\mathcal{A}$-equivalent to all the states in $\delta(q_0, w[1,j])$. Hence, to conclude that $w \in L(\mathcal{A})$, we show that there is an accepting run of $\mathcal{A}^{s_j}$ on $w[j+1,\infty]$. Assume by way of contradiction that all the runs of $\mathcal{A}^{s_j}$ on $w[j+1,\infty]$ are rejecting. In particular, all these runs leave the SCC C. As in the previous direction, this contradicts the choice of the states $s_j, s_{j+1}, s_{j+2}, \ldots$ as representatives of equivalence classes in $\mathcal{P}$. ◀

Since DWWs can be complemented by dualization (that is, by switching α and $\bar{\alpha}$), Theorem 22 implies the following.

▶ **Theorem 23.** *Given an SD-NWW $\mathcal{A}$ with n states, we can construct, in polynomial time, an SD-NWW (in fact, a DWW) that complements $\mathcal{A}$.*

Since the language-containment problem for DWW can be solved in NLOGSPACE, and minimization for DWW is similar to minimization of DFWs and can be solved in polynomial time [31], we have the following.

▶ **Theorem 24.** *The language-containment, universality, and minimality problems for SD-NWWs can be solved in polynomial time.*

Abstract

In the language-theoretic approach to refinement verification, we check that the language of traces of an implementation all belong to the language of a specification. We consider the refinement verification problem for asynchronous programs against specifications given by a Dyck language. We show that this problem is EXPSPACE-complete – the same complexity as that of language emptiness and for refinement verification against a regular specification. Our algorithm uses several technical ingredients. First, we show that checking if the coverability language of a succinctly described vector addition system with states (VASS) is contained in a Dyck language is EXPSPACE-complete. Second, in the more technical part of the proof, we define an ordering on words and show a downward closure construction that allows replacing the (context-free) language of each task in an asynchronous program by a regular language. Unlike downward closure operations usually considered in infinite-state verification, our ordering is not a well-quasi-ordering, and we have to construct the regular language ab initio. Once the tasks can be replaced, we show a reduction to an appropriate VASS and use our first ingredient. In addition to the inherent theoretical interest, refinement verification with Dyck specifications captures common practical resource usage patterns based on reference counting, for which few algorithmic techniques were known.

1 Introduction

Asynchronous programs are a common programming idiom for multithreaded shared memory concurrency. An asynchronous program executes tasks atomically; each task is a sequential recursive program that can read or write some shared state, emit events (such as calling an API), and, in addition, can spawn an arbitrary number of new tasks for future execution. A cooperative scheduler iteratively picks a previously spawned task and executes it atomically to completion. Asynchronous programs occur in many software systems with stringent correctness requirements. At the same time, they form a robustly decidable class of infinite-state systems closely aligned with other concurrency models. Thus, algorithmic verification of asynchronous programs has received a lot of attention from both theoretical and applied perspectives [25, 13, 10, 8, 9, 15, 11, 16, 20].

We work in the language-theoretic setting, where we treat asynchronous programs as generators of languages, and reduce verification questions to decision problems on these languages. Thus, an execution of a task yields a word over the alphabet of its events and task names. An execution of the asynchronous program concatenates the words of executing tasks and further ensures that any task executing in the concatenation was spawned before and not already executed. The trace of an execution projects the word to the alphabet of events and the language of the program is the set of all traces. With this view, reachability or safety verification questions reduce to language emptiness, and refinement verification reduces to language inclusion of a program in a given specification language over the alphabet of events.

We consider the language inclusion problem for asynchronous programs when the specification language is given by a Dyck language. Our main result shows that this problem is EXPSPACE-complete. The language emptiness problem for asynchronous programs, as well as language inclusion in a regular language, are already EXPSPACE-complete [10]. Thus, there is no increase in complexity even when the specifications are Dyck languages. However, as we shall see below, our proof of membership in EXPSPACE requires several new ingredients.

In addition to the inherent language-theoretic interest, the problem is motivated by the practical "design pattern" of reference counting and barrier synchronization in concurrent event-driven programs. In this pattern, each global shared resource maintains a counter of *how many* processes have access to it. Before working with the shared resource, a task acquires access to the resource by incrementing a counter (the reference count). Later, a possibly different task can release the resource by decrementing the reference count. When the count is zero, the system can garbage collect the resource. For example, device drivers in the kernel maintain such reference counts, and there are known bugs arising out of incorrect handling of reference counts [21]. Here is a small snippet that shows the pattern in asynchronous code:

```
start :   { t := inc(); if (t) spawn(work); }
          // arbitrarily many requests may start concurrently
work :    { in this code, we can assert that the reference count is positive ;
            spawn(cleanup); }
cleanup : { dec(); if zeroref() { garbage collect the resource }}
```

Here, `inc` and `dec` increment and decrement the reference count associated with a shared resource, `inc` succeeds if the resource has not been garbage collected. `spawn` starts a new task, and `zeroref` checks if the reference count is zero. There are three tasks, `start`, `work`, and `cleanup`; each invocation of a task executes atomically. Initially, an arbitrary number of `start` tasks are spawned.

Our goal is to ensure the device is not garbage collected while some instance of `work` is pending. Intuitively, the reason for this is clear: each `work` is spawned by a previous `start` that takes a reference count and this reference is held until a later `cleanup` runs. However,

it is difficult for automated model checking tools to perform this reasoning, and existing techniques require manual annotations of invariants [11, 15]. Dyck languages allow specifying correct handling of reference counts [1], and our algorithm provides as a special case an algorithmic analysis of correct reference counting for asynchronous programs.

Since there is a simple reduction from language emptiness to inclusion, we immediately inherit EXPSPACE-hardness. Let us therefore focus on the challenges in obtaining an EXPSPACE upper bound. The EXPSPACE algorithm for language emptiness proceeds as follows (see [10, 20]). First, we can ignore the alphabet of events and only consider words over the alphabet of task names. Second, we notice that (non-)emptiness is preserved if we "lose" some spawns along an execution; this allows us to replace the language of each task by its downward closure. By general results about well-quasi orderings, the downward closure is a regular language which, moreover, has a succinct representation. Thus, we can reduce the language emptiness problem to checking (coverability) language emptiness of an associated vector addition system with states (VASS). This problem can be solved in EXPSPACE, by a result of Rackoff [22].

Unfortunately, this outline is not sufficient in our setting. First, unlike for language emptiness or regular language inclusion, we cannot simply replace tasks with their downward closures (w.r.t. the subword ordering). While we can drop spawns as before, dropping letters from the event alphabet does not preserve membership in a Dyck language. Second, even if each handler is regular, we are left with checking if a VASS language is contained in a Dyck language. We provide new constructions to handle these challenges.

Our starting point is the characterization of inclusion in Dyck languages [23]: A language L is not included in a Dyck language if and only if there is a word $w \in L$ with either an *offset violation* (number of open brackets does not match the number of closed brackets), a *dip violation* (some prefix with more closed brackets than open ones), or a *mismatch violation* (an open bracket of one kind matched with a closed bracket of a different kind).

Checking VASS Language Inclusion. Our first technical construction shows how to check language inclusion of a VASS coverability language in a Dyck language in EXPSPACE. (In a *coverability language*, acceptance is defined by reaching a final control state.) In fact, our result carries over when the control states of the VASS are *succinctly represented*, for example by using transducers and binary encodings of numbers.

We first check that the VASS language is *offset-uniform*, that is, every word in the language has exactly the same offset (difference between open brackets and closed brackets), and that this offset is actually zero. (If this condition is not true, there is already an offset violation.) We show that the offset of every prefix of a word in any offset-uniform VASS language is bounded by a doubly exponential number, and therefore, this number can be tracked by adding double exponentially bounded counters (as in Lipton's construction [18]) in the VASS itself. Moreover, we can reduce the checking of dip or mismatch violations to finding a *marked Dyck factor*: an infix of the form $\#w\bar{\#}$ for a Dyck word w. Finally, for offset-uniform VASS, finding a marked Dyck factor reduces to coverability in succinctly represented VASS, which can be checked in EXPSPACE [2]. Offset uniformity is important – finding a marked Dyck factor in an arbitrary VASS language is equivalent to VASS reachability, which is Ackermann-complete [7, 17]. In fact, checking whether a given VASS language is included in the set of *prefixes* of the one-letter Dyck language is already equivalent to VASS reachability (see the long version of the paper for a proof).

A consequence of our result is that given a VASS coverability language K and a *reachability language* (i.e. acceptance requires all counters to be zero in the end) L of a *deterministic* VASS, deciding whether $K \subseteq L$ is EXPSPACE-complete. This is in contrast (but not in contradiction[1]) to recent Ackermann-completeness results for settings where both K and L are drawn from subclasses of VASS coverability languages [6].

Downward Closure of Tasks. Next, we move to asynchronous programs. We define a composite ordering on words that is a combination of two different orderings: the subword ordering for task names, and the syntactic preorder on the events projected to a single set $\{x, \bar{x}\}$ of Dyck letters. In our case, the latter means a word u is less than v iff they both have the same offset, but v has at most the dip of u. The composite order is defined so as to preserve the existence of marked Dyck factors. In contrast to the subword ordering, this (composite) ordering is not a well-quasi-ordering (since, e.g., $\bar{x}x, \bar{x}\bar{x}xx, \bar{x}\bar{x}\bar{x}xxx, \ldots$ forms an infinite descending chain). Nevertheless, our most difficult technical construction shows that for any context-free language (satisfying an assumption, which we call tame-pumping) there exists a regular language with the same downward closure in this ordering. The case of general context-free languages reduces to this special case since the presence of a non-tame pump immediately results in a Dyck-violation and can easily be detected in PSPACE. For the tame-pumping grammars, a succinct description of the corresponding automaton can be computed in PSPACE. This key observation allows us to replace the context-free languages of tasks with regular sets, and thereby reduce the problem to checking VASS language inclusion.

Related Work. Language inclusion in Dyck languages is a well-studied problem. For example, inclusion in a Dyck language can be checked in polynomial time for context-free languages [26] or for ranges of two-copy tree-to-string transducers [19]. Our work extends the recent result that the language noninclusion problem for context-bounded multi-pushdown systems in Dyck languages is NP-complete [1]. Our result is complementary to that of [1]: their model considers a *fixed* number of threads but allows the threads to be interrupted and context-switched a fixed number of times. In contrast, we allow dynamic spawning of threads but assume each thread is atomically run to completion. A natural open question is whether our results continue to hold if threads can be interrupted up to a fixed number of times.

Inclusion problems have recently also been studied when both input languages are given as VASS coverability languages [6]. Since in our setting, the supposedly larger language is always a Dyck language (which is not a coverablity VASS language), those results are orthogonal.

2 Language-Theoretic Preliminaries

General Definitions. We assume familiarity with basic language theory, see the textbook [14] for more details. For an alphabet $\Sigma \subseteq \Theta$, let $\pi_\Sigma \colon \Theta^* \to \Sigma^*$ denote the projection onto Σ^*. In other words, for $w \in \Theta^*$, the word $\pi_\Sigma(w)$ is obtained from w by deleting every occurrence of a letter in $\Theta \setminus \Sigma$. If Σ contains few elements, e.g. $\Sigma = \{x, y\}$, then instead of writing $\pi_{\{x,y\}}$ we also write $\pi_{x,y}$, leaving out the set brackets. We write $|w|_\Sigma$ for the number of occurrences of letters $x \in \Sigma$ in w, and similarly $|w|_x$ if $\Sigma = \{x\}$.

[1] For general VASS, every coverability language is also a reachability language. However, *deterministic* VASS with reachability acceptance cannot accept all coverability languages.

Context-Free Languages. A *context-free grammar* (CFG) $\mathcal{G} = (N, \Theta, P, S)$ consists of an alphabet of *nonterminals* N, an alphabet of *terminals* Θ with $N \cap \Theta = \emptyset$, a finite set of *productions* $P \subseteq N \times (N \cup \Theta)^*$, and the start symbol $S \in N$. We usually write $A \to v$ to denote a production $(A, v) \in P$. The size of the CFG $\mathcal{G}$ is defined as $|\mathcal{G}| = \sum_{A \to v \in P}(|v| + 1)$. We denote the *derivation relation* by $\Rightarrow_{\mathcal{G}}$ and its reflexive, transitive closure by $\overset{*}{\Rightarrow}_{\mathcal{G}}$. We drop the subscript $\mathcal{G}$ if it is clear from the context. We also use *derivation trees* labelled by $N \cup \Theta$ for derivations of the form $A \overset{*}{\Rightarrow} w$ for some $A \in N$. Here we start with the root labelled by A, and whenever we apply a production $B \to v$ with $v = a_1 \dots a_n$, we add n children labelled by $a_1, \dots, a_n$ (in that order from left to right) to a leaf labelled by B. A *pump* is a derivation of the form $A \overset{*}{\Rightarrow} uAv$ for some nonterminal A. A derivation tree which is pumpfree, i.e., in which no path contains multiple occurrences of the same nonterminal, is referred to as a *skeleton*. We will often see an arbitrary derivation tree as one which is obtained by inserting pumps into a skeleton.

The *language* $L(\mathcal{G}, A)$ of $\mathcal{G}$ starting from nonterminal $A \in N$ contains all words $w \in \Theta^*$ such that there exists a derivation $A \overset{*}{\Rightarrow}_{\mathcal{G}} w$. The language of $\mathcal{G}$ is $L(\mathcal{G}) = L(\mathcal{G}, S)$. A *context-free language* (CFL) L is a language for which there exists a CFG $\mathcal{G}$ with $L = L(\mathcal{G})$.

A CFG $\mathcal{G} = (N, \Theta, P, S)$ is said to be in *Chomsky normal form* if all of its productions have one of the forms $A \to BC$, $A \to a$, or $S \to \varepsilon$, where $B, C \in N \setminus \{S\}$, $a \in \Theta$, and the last form only occurs if $\varepsilon \in L(\mathcal{G})$. It is well known that every CFG can be transformed in polynomial time into one in Chomsky normal form with the same language.

An *extended* context-free grammar (ECFG) $\mathcal{G} = (N, \Theta, P, S)$ is a CFG, which may additionally have productions of the form $A \to \Gamma^* \in P$ for some alphabet $\Gamma \subseteq \Theta$. Productions of this form induce derivations $uAs \Rightarrow_{\mathcal{G}} uvs$, where $u, s \in (N \cup \Theta)^*$ and $v \in \Gamma^*$. Chomsky normal form for ECFG is defined as for CFG, but also allows productions of the form $A \to \Gamma^*$. An ECFG can still be transformed into Chomsky normal form using the same algorithm as for a CFG, treating expressions Γ^* like single terminal symbols. Since the extended productions can be simulated by conventional CFG productions, the language of an ECFG is still a CFL.

Dyck Language. Let X be an alphabet and let $\bar{X} = \{\bar{x} \mid x \in X\}$ be a disjoint copy of X. The *Dyck language (over X)* $\mathsf{Dyck}_X \subseteq (X \cup \bar{X})^*$ is defined by the following context-free grammar:

$$S \to \varepsilon \mid S \to SS \mid S \to xS\bar{x} \quad \text{for } x \in X.$$

Let $\Theta \supseteq X \cup \bar{X}$ be an alphabet. For $w \in \Theta^*$ we define $\mathsf{offset}(w) = |w|_X - |w|_{\bar{X}}$. A language $L \subseteq \Theta^*$ is called *offset-uniform* if for any $u, v \in L$, we have $\mathsf{offset}(u) = \mathsf{offset}(v)$.

The *dip* of $w \in \Theta^*$ is defined as $\mathsf{dip}(w) = \max\{-\mathsf{offset}(u) \mid u \text{ is a prefix of } w\}$. We define $e(w) = (\mathsf{dip}(w), \mathsf{offset}(w))$. Observe that for $w \in (X \cup \bar{X})^*$ with $|X| = 1$ we have $w \in \mathsf{Dyck}_X$ if and only if $e(w) = (0, 0)$.

A language $L \subseteq (X \cup \bar{X})^*$ is *not* included in Dyck_X if and only if there exists a word $w \in L$ that satisfies one of the following violation conditions [23]:

(OV) an *offset violation* $\mathsf{offset}(w) \neq 0$,

(DV) a *dip violation*, where $\mathsf{dip}(w) > 0$, i.e., there is a prefix u of w with $\mathsf{offset}(u) < 0$, or

(MV) a *mismatch violation*, where there exists a pair $x, \bar{y}$ (for some $x \neq y$) of *mismatched* letters in w, i.e., w contains an infix $xv\bar{y}$ where $e(v) = (0, 0)$.

For example, $w_1 = x\bar{x}\bar{x}x$ has a dip violation due to the prefix $u = x\bar{x}\bar{x}$; $w_2 = xx\bar{x}$ has an offset violation and $w_3 = xx\bar{x}\bar{y}$ has a mismatch violation.

3 Asynchronous Programs

An *asynchronous program* [10], henceforth simply called a *program*, is a tuple $\mathscr{P} = (Q, \Sigma, \Gamma, \mathcal{G}, \Delta, q_0, q_f, \gamma_0)$, where Q is a finite set of *global states*, Σ is an alphabet of *event letters*, Γ is an alphabet of *handler names* with $\Sigma \cap \Gamma = \emptyset$, $\mathcal{G}$ is a CFG over the terminal symbols $\Sigma \cup \Gamma$, Δ is a finite set of transition rules (described below), $q_0 \in Q$ is the *initial state*, $q_f \in Q$ is the *final state*, and γ_0 is the *initial handler*.

Transition rules in Δ are of the form $q \xhookrightarrow{a,A} q'$, where $q, q' \in Q$ are global states, $a \in \Gamma$ is a handler name, and A is a nonterminal symbol in $\mathcal{G}$.

Let $\mathbb{M}[S]$ denote the set of all multisets of elements from the set S. A *configuration* $(q, \mathbf{m}) \in Q \times \mathbb{M}[\Gamma]$ of $\mathscr{P}$ consists of a global state q and a multiset $\mathbf{m} : \Gamma \to \mathbb{N}$ of pending handler instances. The *initial* configuration of $\mathscr{P}$ is $c_0 = (q_0, [\![\gamma_0]\!])$, where $[\![\gamma_0]\!]$ denotes the singleton multiset containing γ_0. A configuration is considered *final* if its global state is q_f. The rules in Δ induce a transition relation on configurations of $\mathscr{P}$: We have $(q, \mathbf{m}) \xrightarrow{w} (q', \mathbf{m}')$ iff there is a rule $q \xhookrightarrow{a,A} q' \in \Delta$ and a word $u \in L(\mathcal{G}, A)$ such that $\pi_\Sigma(u) = w$ and $\mathbf{m}' = (\mathbf{m} \ominus [\![a]\!]) \oplus \mathsf{Parikh}(\pi_\Gamma(u))$, where $\mathbf{m}'' = \mathbf{m} \oplus \mathbf{m}'$ is the multiset which satisfies $\mathbf{m}''(a) = \mathbf{m}'(a) + \mathbf{m}(a)$ for each $a \in \Gamma$. Similarly $\mathbf{m}'' = \mathbf{m} \ominus \mathbf{m}'$ is the multiset which satisfies $\mathbf{m}''(a) = \mathbf{m}'(a) - \mathbf{m}(a)$ for each $a \in \Gamma$ with the implicit assumption that $\mathbf{m}'(a) \geq \mathbf{m}(a)$. Here, $\mathsf{Parikh}(w) : \Gamma \to \mathbb{N}$ is the *Parikh image* of w that maps each handler in Γ to its number of occurrences in w. Note that the transition is feasible only if $\mathbf{m}$ contains at least one instance of the handler a.

Intuitively, a program consists of a set of atomic event handlers that communicate over a shared global state Q. Each handler is a piece of sequential code that generates a word over a set of events Σ and, in addition, posts new instances of handlers from Γ. A configuration $(q, \mathbf{m})$ represents the current value of the shared state q and a task buffer $\mathbf{m}$ containing the posted, but not yet executed, handlers. At each step, a scheduler non-deterministically picks and removes a handler from the multiset of posted handlers and "runs" it. Running a handler changes the global state and produces a sequence of events over Σ as well as a multiset of newly posted handlers. The newly posted handlers are added to the task buffer.

We consider asynchronous programs as generators of words over the set of events. A *run* of $\mathscr{P}$ is a finite sequence of configurations $c_0 = (q_0, [\![\gamma_0]\!]) \xrightarrow{w_1} c_1 \xrightarrow{w_2} \ldots \xrightarrow{w_\ell} c_\ell$. It is an *accepting* run if it ends in a final configuration.

The *language* of $\mathscr{P}$ is defined as

$$L(\mathscr{P}) = \{w \in \Sigma^* \mid w = w_1 \cdots w_\ell, \text{ there is an accepting run } c_0 \xrightarrow{w_1} \ldots \xrightarrow{w_\ell} c_\ell\}.$$

The size of the program $\mathscr{P}$ is defined as $|\mathscr{P}| = |Q| + |\mathcal{G}| + |\Delta|$, i.e., the combined size of states, grammar, and transitions.

The *Dyck inclusion problem* for programs asks, given a program $\mathscr{P}$ over a set $(X \cup \bar{X})$ of events, whether every word in $L(\mathscr{P})$ belongs to the Dyck language Dyck_X. We show the following main result.

▶ **Theorem 3.1** (Main Theorem). *Given a program $\mathscr{P}$ with $L(\mathscr{P}) \subseteq (X \cup \bar{X})^*$, deciding if $L(\mathscr{P}) \subseteq \mathsf{Dyck}_X$ is* EXPSPACE*-complete.*

EXPSPACE-hardness follows easily from the following result on language emptiness (by simply adding a loop with a letter $\bar{x} \in \bar{X}$ at the final state). Therefore, the rest of the paper focuses on the EXPSPACE upper bound.

▶ **Proposition 3.2** (Theorem 6.2, Ganty and Majumdar [10]). *Given a program $\mathscr{P}$, checking if $L(\mathscr{P}) = \emptyset$ is* EXPSPACE*-complete.*

A nonterminal B in the grammar $\mathcal{G}$ of a program $\mathscr{P}$ is called *useful* if there exists a run ρ of $\mathscr{P}$ reaching q_f in which there exists a derivation tree containing B. More precisely, there are two successive configurations $(q, \mathbf{m}) \xrightarrow{w} (q', \mathbf{m}')$ in ρ such that there is a rule $q \xhookrightarrow{a,A} q'$ and a word $u \in L(\mathcal{G}, A)$ with $\pi_\Sigma(u) = w$, $\mathbf{m}' = (\mathbf{m} \ominus [\![a]\!]) \oplus \mathsf{Parikh}(\pi_\Gamma(u))$, and B occurs in some derivation tree with root A and yield u. There is a simple reduction from checking if a nonterminal is useful to checking language emptiness (see the full version) so we can check if a nonterminal is useful also in EXPSPACE. Therefore, in the following, we shall assume that all nonterminals are useful.

4 Checking Dyck Inclusion for VASS Coverability Languages

As a first technical construction, we show how to check Dyck inclusion for (succinctly defined) VASS languages. We shall reduce the problem for programs to this case.

4.1 Models: VASS and Succinct Versions

Vector Addition Systems with States. A *vector addition system with states* (VASS) is a tuple $\mathcal{V} = (Q, \Sigma, I, E, q_0, q_f)$ where Q is a finite set of *states*, Σ is a finite alphabet of *input letters*, I is a finite set of *counters*, $q_0 \in Q$ is the *initial state*, $q_f \in Q$ is the *final state*, and E is a finite set of *edges* of the form $q \xrightarrow{x,\delta} q'$, where $q, q' \in Q$, $x \in \Sigma \cup \{\varepsilon\}$, and $\delta \in \{-1, 0, 1\}^I$.[2]

A *configuration* of $\mathcal{V}$ is a pair $(q, \mathbf{u}) \in Q \times \mathbb{M}[I]$. The elements of $\mathbb{M}[I]$ and $\{-1, 0, 1\}^I$ can also be seen as vectors of length $|I|$ over $\mathbb{N}$ and $\{-1, 0, 1\}$, respectively, and we sometimes denote them as such. The edges in E induce a transition relation on configurations: there is a transition $(q, \mathbf{u}) \xrightarrow{x} (q', \mathbf{u}')$ if there is an edge $q \xrightarrow{x,\delta} q'$ in E such that $\mathbf{u}'(i) = \mathbf{u}(i) + \delta(i) \geq 0$ for all $i \in I$. A *run* of the VASS is a finite sequence of configurations $c_0 \xrightarrow{x_1} c_1 \xrightarrow{x_2} \dots \xrightarrow{x_\ell} c_\ell$ where $c_0 = (q_0, \mathbf{0})$. A run is said to reach a state $q \in Q$ if the last configuration in the run is of the form $(q, \mathbf{m})$ for some multiset $\mathbf{m}$. An *accepting* run is a run whose final configuration has state q_f. The *(coverability) language* of $\mathcal{V}$ is defined as

$$L(\mathcal{V}) = \{w \in \Sigma^* \mid \text{there exists a run } (q_0, \mathbf{0}) = c_0 \xrightarrow{x_1} \dots \xrightarrow{x_\ell} c_\ell = (q_f, \mathbf{u}) \text{ with } w = x_1 \cdots x_\ell\}.$$

The size of the VASS $\mathcal{V}$ is defined as $|\mathcal{V}| = |I| \cdot |E|$.

Models with Succinct Control. In this paper we need various models with *doubly succinct* control, i.e., models with doubly exponentially many states. Informally speaking, a machine with finite control $\mathcal{B}$, e.g. an NFA or a VASS, is doubly succinct if its set of control states is Λ^M where $M \in \mathbb{N}$ is an exponential number given in binary encoding, and Λ is a finite alphabet. The initial and final state of $\mathcal{B}$ are the states 0^M and 1^M for some letters $0, 1 \in \Lambda$. Finally, the transitions of $\mathcal{B}$ are given by *finite-state transducers* $\mathcal{T}$, i.e., asynchronous multitape automata recognizing relations $R \subseteq (\Lambda^M)^k$. For example, a *doubly succinct* NFA (dsNFA in short) contains binary transducers $\mathcal{T}_a$ for each $a \in \Sigma \cup \{\varepsilon\}$ where Σ is the input alphabet, and $\mathcal{B}$ contains a transition $p \xrightarrow{x} q$ if and only if (p, q) is accepted by $\mathcal{T}_x$. A *doubly succinct VASS* (dsVASS, for short) contains binary transducers $\mathcal{T}_{x,i}, \mathcal{T}_{x,\bar{i}}, \mathcal{T}_{x,\varepsilon}$ for each $x \in \Sigma \cup \{\varepsilon\}$ and $i \in I$, where I is the set of counters. A state pair (p, q) accepted by $\mathcal{T}_{x,i}$ specifies

[2] A more general definition of VASS would allow each transition to add an arbitrary vector over the integers. We instead restrict ourselves to the set $\{-1, 0, 1\}$, since this suffices for our purposes, and the EXPSPACE-hardness result by Lipton [18] already holds for VASS of this form.

a transition $p \xrightarrow{x,\mathbf{e}_i} q$ in $\mathcal{B}$, where $\mathbf{e}_i$ only increments counter i and leaves other counters the same. Similarly $\mathcal{T}_{x,\bar{i}}$ and $\mathcal{T}_{x,\varepsilon}$ specify decrementing transitions and transitions without counter updates.

Later we will also use *(singly) succinct* ECFGs, which are extended context-free grammars whose set of nonterminals is Λ^M where M is a unary encoded number. The set of productions is given in a suitable fashion by transducers. Let us remark that the precise definition of (doubly) succinct automata or grammars is not important for our paper, e.g. one could also use circuits instead of transducers to specify the transitions/productions.

4.2 Checking Dyck Inclusion for dsVASS

We prove our first technical contribution: an EXPSPACE procedure to check non-inclusion of a VASS language in a Dyck language. This involves checking if one of (OV), (DV), or (MV) occurs. We begin by showing how these violations can be detected for a (non-succinct) VASS.

To this end, first we show that offset-uniformity of a VASS language implies a doubly exponential bound B on the offset values for prefixes of accepted words (Theorem 4.1). Given an alphabet X and a number $k \in \mathbb{N}$, we define the language

$$\mathscr{B}(X,k) = \{w \in (X \cup \bar{X})^* \mid \text{for every prefix } v \text{ of } w\colon\ |\mathsf{offset}(v)| \leq k\}.$$

▶ **Theorem 4.1.** *Let $\mathcal{V}$ be a* VASS *with $L(\mathcal{V}) \subseteq (X \cup \bar{X})^*$. If $L(\mathcal{V})$ is offset-uniform, then $L(\mathcal{V}) \subseteq \mathscr{B}(X, 2^{2^{p(|\mathcal{V}|)}})$ for some polynomial function p.*

Proof. Let $\mathcal{V} = (Q, X \cup \bar{X}, I, E, q_0, q_f)$ be a VASS where $L(\mathcal{V}) \neq \emptyset$ is offset-uniform. The unique offset of $L(\mathcal{V})$ is bounded double exponentially in $|\mathcal{V}|$ since $L(\mathcal{V})$ contains some word that is at most double exponentially long, a fact that follows from Rackoff's bound on covering runs [22]. Let $C \subseteq Q \times \mathbb{M}[I]$ be the set of configurations that are reachable from $(q_0, \mathbf{0})$ and from which the final state can be reached. Observe that for any configuration $c \in C$ the language $L(c) = \{w \in (X \cup \bar{X})^* \mid \exists \mathbf{u}\colon c \xrightarrow{w} (q_f, \mathbf{u})\}$ is also offset-uniform since $L(c) \subseteq \{w \in (X \cup \bar{X})^* \mid vw \in L(\mathcal{V})\}$ where $v \in (X \cup \bar{X})^*$ is any word with $(q_0, \mathbf{0}) \xrightarrow{v} c$. Define the function $f\colon C \to \mathbb{Z}$ where $f(c)$ is the unique offset of the words in $L(c)$. It remains to show that $|f(c)|$ is bounded double exponentially for all $c \in C$.

Let M be the set of all configurations from which the final state can be reached (hence $C \subseteq M$). Consider the following order on VASS configurations $Q \times \mathbb{M}[I]$: $(q, \mathbf{u}) \leq (q', \mathbf{u}')$ iff $q = q'$ and $\mathbf{u}(i) \leq \mathbf{u}'(i)$ for each $i \in I$. The cardinality of the set $\min(M)$ of minimal elements in M with respect to this order is bounded doubly exponentially in the size of $\mathcal{V}$. This follows directly from the fact that Rackoff's doubly-exponential bound [22] on the length of a covering run does not depend on the start configuration (but only the size of the VASS and the final configuration). An explicit bound for $|\min(M)|$ is given in [4, Theorem 2].

Observe that if $c_1 \in M$ and $c_2 \in C$ with $c_1 \leq c_2$ then $L(c_1) \subseteq L(c_2)$ and therefore $L(c_1)$ is also offset-uniform, having the same offset as $L(c_2)$. Hence, if for two configurations $c_1, c_2 \in C$ there exists a configuration $c \in M$ with $c \leq c_1$ and $c \leq c_2$, then $f(c_1) = f(c_2)$. Since for every $c_2 \in C$ there exists $c_1 \in \min(M)$ with $c_1 \leq c_2$, the function f can only assume doubly exponentially many values on C.

Finally, we claim that $f(C) \subseteq \mathbb{Z}$ is an interval containing 0, which proves that the norms of elements in $f(C)$ are bounded by the number of different values, i.e., double exponentially. Since we assumed $L(\mathcal{V}) \neq \emptyset$, some final configuration $(q_f, \mathbf{u}) \in C$ is reachable from $(q_0, \mathbf{0})$, and therefore $0 \in f(C)$ since $\varepsilon \in L((q_f, \mathbf{u}))$. Consider the configuration graph $\mathcal{C}$ of $\mathcal{V}$ restricted to C. For any edge $c_1 \to c_2$ in $\mathcal{C}$ we have $|f(c_1) - f(c_2)| \leq 1$ since VASS transitions consume at most one input symbol. Moreover, the underlying undirected graph of $\mathcal{C}$ is connected since any configuration is reachable from $(q_0, \mathbf{0}) \in C$. Therefore $f(C)$ is an interval, which concludes the proof. ◀

Note that although $\mathscr{B}(X,k)$ is a regular language for each X and k, Theorem 4.1 does not imply that every offset-uniform VASS language is regular. For example, the VASS language $\{(x\bar{x})^m(y\bar{y})^n \mid m \geq n\}$ is offset-uniform, but it is not regular. This is because Theorem 4.1 only implies boundedness of the number of occurrences of letters in the input words, but the VASS's own counters might be unbounded.

The main consequence of Theorem 4.1 is that in a VASS we can track the offset using a doubly succinct control state. Thus, we have the following corollary.

▶ **Corollary 4.2.** *The following problems can be decided in* EXPSPACE*: Given a* VASS *or* dsVASS $\mathcal{V}$*, does* $\mathsf{offset}(w) = 0$ *hold for all* $w \in L(\mathcal{V})$*?*

Proof. First assume $\mathcal{V}$ is a VASS. We show that the problem can be reduced to the intersection non-emptiness problem for a VASS and a doubly succinct NFA, i.e., given a VASS $\mathcal{V}$ and a doubly succinct NFA $\mathcal{A}$, is the intersection $L(\mathcal{V}) \cap L(\mathcal{A})$ nonempty? One can construct in polynomial time a doubly succinct VASS for $L(\mathcal{V}) \cap L(\mathcal{A})$, as a product construction between $\mathcal{V}$ and $\mathcal{A}$. Since the emptiness problem for dsVASS is in EXPSPACE ([2, Theorem 5.1]), we can also decide emptiness of $L(\mathcal{V}) \cap L(\mathcal{A})$ in EXPSPACE.

Define the number $M = 2^{2^{p(|\mathcal{V}|)}}$ where p is the polynomial from Theorem 4.1. Let $K_0 = \{w \in (X \cup \bar{X})^* \mid \mathsf{offset}(w) = 0\}$. According to Theorem 4.1, we have $L(\mathcal{V}) \subseteq K_0$ if and only if $L(\mathcal{V}) \subseteq K_0 \cap \mathscr{B}(X,M)$. By the remarks above, it suffices to construct a doubly succinct NFA for the complement of $K_0 \cap \mathscr{B}(X,M)$. The following doubly succinct deterministic finite automaton $\mathcal{A}$ recognizes $K_0 \cap \mathscr{B}(X,M)$: Given an input word over $X \cup \bar{X}$, the automaton tracks the current offset in the interval $[-M,M]$, stored in the control state as a binary encoding of length $\log M = 2^{p(|\mathcal{V}|)}$ together with a bit indicating the sign. If the absolute value of the offset exceeds M, the automaton moves to a rejecting sink state. The state representing offset 0 is the initial and the only final state. Finally, we complement $\mathcal{A}$ to obtain a doubly succinct NFA $\bar{\mathcal{A}}$, with a unique final state, for the complement of $K_0 \cap \mathscr{B}(X,M)$.

Now assume $\mathcal{V}$ is a dsVASS. Using Lipton's construction simulating doubly exponential counter values [18], we can construct a (conventional) VASS $\mathcal{V}'$, size polynomial in $|\mathcal{V}|$, with the same language (similar to [2, Theorem 5.1]). We can now apply the above construction. ◀

Next, we check for (DV) or (MV), assuming offset uniformity. We will reduce both kinds of violations to the problem of searching for *marked Dyck factors*. A word of the form $u\#v\bar{\#}w$ is called a *marked Dyck factor* if $u,v,w \in \{x,\bar{x}\}^*$ and $v \in \mathsf{Dyck}_x$.

Intuitively, if a (DV) occurs in a word w, there is a first time that the offset reaches -1. Placing a $\bar{\#}$ at the place where this happens, and a $\#$ right at the beginning, we have a word of the form $\#u\bar{\#}v$ where $u \in \mathsf{Dyck}_x$. Similarly for (MV), we replace two letters $z \in X$ and $\bar{y} \in X$ with $z \neq y$ by $\#$ and $\bar{\#}$, respectively, and look for a word $u\#v\bar{\#}w$, where $v \in \mathsf{Dyck}_x$.

▶ **Proposition 4.3.** *The following problems can be decided in* EXPSPACE*: Given an offset-uniform* VASS *or* dsVASS $\mathcal{V}$*, does* $L(\mathcal{V})$ *contain a marked Dyck factor?*

Proof. As in Corollary 4.2, given a dsVASS, we can convert to a polynomial-sized VASS with the same language and apply the following algorithm.

We again reduce to the intersection nonemptiness problem between a VASS and a doubly succinct NFA, and use the fact that nonemptiness of dsVASS is in EXPSPACE [2, Theorem 5.1]. As above, define the number $M = 2^{2^{p(|\mathcal{V}|)}}$ where p is the polynomial from Theorem 4.1. The automaton keeps track of the offset and also verifies that the input has the correct format $u\#v\bar{\#}w$ where $u,v,w \in \{x,\bar{x}\}^*$. Furthermore, upon reaching $\#$ it starts tracking the current offset and verifies that (i) the offset stays nonnegative, (ii) the offset never exceeds $2M$,

and (iii) the offset is zero when reaching $\bar{\#}$. If $L(\mathcal{V})$ intersects $L(\mathcal{A})$, then clearly $\mathcal{V}$ is a positive instance of the problem. Conversely, assume that $L(\mathcal{V})$ contains a word $u\#v\bar{\#}w$ with $v \in \mathsf{Dyck}_x$. By offset-uniformity of $\mathcal{V}$ and by Theorem 4.1, each prefix v' of v satisfies $\mathsf{offset}(v') = \mathsf{offset}(uv') - \mathsf{offset}(u) \leq M - (-M) = 2M$. Therefore $u\#v\bar{\#}w \in L(\mathcal{A})$. ◀

Let us put everything together. Let $\rho\colon (X \cup \bar{X})^* \to \{x, \bar{x}\}^*$ be the morphism that replaces all letters from X (resp., $\bar{X}$) by the letter x (resp., $\bar{x}$). Given a dsVASS $\mathcal{V}$ over $X \cup \bar{X}$ we can construct in polynomial time three dsVASS $\mathcal{V}_\mathsf{o}, \mathcal{V}_\mathsf{d}, \mathcal{V}_\mathsf{m}$ where

$$L(\mathcal{V}_\mathsf{o}) = \rho(L(\mathcal{V})),$$
$$L(\mathcal{V}_\mathsf{d}) = \{\#\rho(v)\bar{\#}\rho(\bar{y}w) \mid v\bar{y}w \in L(\mathcal{V}) \text{ for some } v, w \in (X \cup \bar{X})^*,\ y \in X\},$$
$$L(\mathcal{V}_\mathsf{m}) = \{\rho(u)\#\rho(v)\bar{\#}\rho(w) \mid uyv\bar{z}w \in L(\mathcal{V}) \text{ for some } u, v, w \in (X \cup \bar{X})^*,\ y \neq z \in X\}.$$

Observe that $L(\mathcal{V}) \subseteq \mathsf{Dyck}_x$ if and only if $L(\mathcal{V}_\mathsf{o})$ has uniform offset 0 and $L(\mathcal{V}_\mathsf{d})$ and $L(\mathcal{V}_\mathsf{m})$ do not contain marked Dyck factors.

Hence, to decide whether $L(\mathcal{V}) \subseteq \mathsf{Dyck}_X$ we first test that $L(\mathcal{V}_\mathsf{o})$ has uniform offset 0, using Corollary 4.2, rejecting if not. Otherwise, we can apply Proposition 4.3 to test whether $L(\mathcal{V}_\mathsf{d})$ or $L(\mathcal{V}_\mathsf{m})$ contain marked Dyck factors. If one of the tests is positive, we know $L(\mathcal{V}) \not\subseteq \mathsf{Dyck}_X$, otherwise $L(\mathcal{V}) \subseteq \mathsf{Dyck}_X$.

▶ **Theorem 4.4.** *Given a* dsVASS $\mathcal{V}$ *over the alphabet* $X \cup \bar{X}$*, checking whether* $L(\mathcal{V}) \subseteq \mathsf{Dyck}_X$ *is* EXPSPACE*-complete.*

Let us remark that Theorem 4.4 can also be phrased slightly more generally. Above, we have defined the language of a VASS to be the set of input words for which a final state is reached. Such languages are also called *coverability languages*. Another well-studied notion is the *reachability language* of a VASS, which consists of those words for which a configuration $(q_f, \mathbf{0})$ is reached. Moreover, a VASS is *deterministic* if for each input letter x and each state q, there is at most one x-labeled transition starting in q (and there are no ε-transitions). We can now phrase Theorem 4.4 as follows: Given a VASS coverability language K and a reachability language L of a deterministic VASS, it is EXPSPACE-complete to decide whether $K \subseteq L$. This is in contrast to inclusion problems where K is drawn from a subclass of the coverability languages: This quickly leads to Ackermann-completeness [6]. In fact, even if we replace Dyck_X in Theorem 4.4 with the set of prefixes of $\mathsf{Dyck}_{\{x\}}$, the problem becomes Ackermann-complete (see the full version of this work).

5 Checking Dyck Inclusion for Programs

We now describe our algorithm for checking inclusion in Dyck_X for programs. Our argument is similar to the case of dsVASS: we first construct three auxiliary programs $\mathscr{P}_\mathsf{o}$, $\mathscr{P}_\mathsf{d}$, and $\mathscr{P}_\mathsf{m}$, and then we use them to detect each type of violation in the original program. We construct the program $\mathscr{P}_\mathsf{o}$ for checking offset violation by projecting the Dyck letters to the one-dimensional Dyck alphabet $\{x, \bar{x}\}$. The programs $\mathscr{P}_\mathsf{d}$ and $\mathscr{P}_\mathsf{m}$ are constructed by first placing two markers like for VASS, and then projecting to $\{x, \bar{x}\}$.

As in the algorithm for VASS, we check whether $L(\mathscr{P}_\mathsf{o})$ has uniform offset 0, and whether $L(\mathscr{P}_\mathsf{d})$ and $L(\mathscr{P}_\mathsf{m})$ contain marked Dyck factors. For these checks, we convert the three programs into dsVASS $\mathcal{V}_\mathsf{o}$, $\mathcal{V}_\mathsf{d}$, and $\mathcal{V}_\mathsf{m}$, respectively, in such a way that violations are preserved. To be more precise, this conversion from programs to dsVASS will preserve the *downward closure* with respect to a specific order that we define below. The global downward closure procedure is obtained by composing a local downward closure procedure applied to each task.

On the task level, the order $\sqsubseteq$ is a combination of the subword order on the handler names in Γ and the syntactic order of Dyck_X over the event letters. The core technical result is a transformation from context-free grammars into dsNFA which preserve the downward closure with respect to $\sqsubseteq$.

One key aspect of our downward closure construction is an important condition on the pumps that appear in the context-free grammar.

▶ **Definition 5.1.** *A context-free grammar $\mathcal{G}$ is* tame-pumping *if for every pump $A \overset{*}{\Rightarrow} uAv$, we have $\mathsf{offset}(u) \geq 0$ and $\mathsf{offset}(v) = -\mathsf{offset}(u)$. A derivation $A \overset{*}{\Rightarrow} uAv$ is called an* increasing pump *if $\mathsf{offset}(u) > 0$, otherwise it is called a* zero pump*. An asynchronous program is* tame-pumping *if its grammar is tame-pumping.*

Note that while our definition of a tame-pumping grammar is syntactic, it actually only depends on the generated language, assuming every nonterminal occurs in a derivation: In that case, a grammar is tame-pumping if and only if (i) the set of offsets and (ii) the set of dips of words in its language are both finite.

The following lemma summarizes some properties of tame-pumping and why it is useful for our algorithm. The proof can be found in the full version.

▶ **Lemma 5.2.**

1. *We can check in* coNP *whether a given context-free grammar over $\{x, \bar{x}\}$ is tame-pumping. Furthermore, given a nonterminal A_0, we can check in* NP *whether A_0 has a zero pump (resp., increasing pump).*
2. *There exists a polynomial p such that, if $\mathcal{G}$ is tame-pumping, then for every nonterminal A of $\mathcal{G}$ and every $w \in L(\mathcal{G}, A)$ we have $\mathsf{dip}(w) \leq 2^{p(|\mathcal{G}|)}$.*
3. *If $\mathscr{P}$ does not have tame-pumping, then $L(\mathscr{P}) \not\subseteq \mathsf{Dyck}_X$.*

Thus, if $\mathscr{P}$ is not tame-pumping, the refinement checking algorithm rejects immediately. From now on, we assume that $\mathscr{P}$ is tame-pumping.

5.1 Combining the subword order and the syntactic order

Suppose Γ is an alphabet and let $\Theta = \Gamma \cup \{x, \bar{x}\}$. Define $\bar{a} = a$ for $a \in \Gamma$. By $\preccurlyeq$, we denote the *subword ordering* on Γ^*, i.e. $u \preccurlyeq v$ if and only if u can be obtained from v by deleting some letters. Formally there exist words $u_1, \ldots, u_n, v_0, \ldots, v_n \in \Gamma^*$ such that $u = u_1 \cdots u_n$ and $v = v_0 u_1 v_1 \cdots u_n v_n$. For $u, v \in \{x, \bar{x}\}^*$, we write $u \trianglelefteq v$ if $\mathsf{offset}(u) = \mathsf{offset}(v)$ and $\mathsf{dip}(u) \geq \mathsf{dip}(v)$. In fact, $\trianglelefteq$ is the *syntactic order* with respect to the Dyck language, i.e. if $u \trianglelefteq v$ and $rus \in \mathsf{Dyck}_x$ then $rvs \in \mathsf{Dyck}_x$ for all r, s. We define the ordering $\sqsubseteq'$ on Θ^* by $z_1 \sqsubseteq' z_2$ if and only if $\pi_{x,\bar{x}}(z_1) \trianglelefteq \pi_{x,\bar{x}}(z_2)$, and $\pi_\Gamma(z_1) \preccurlyeq \pi_\Gamma(z_2)$. For example, $a\bar{x}xc \sqsubseteq' xabc\bar{x}$ because ac is a subword of abc, and both $\bar{x}x$ and $x\bar{x}$ have offset 0, but $\bar{x}x$ has a larger dip.

Let $\#, \bar{\#}$ be two fresh letters, called *markers*. The set of *marked words* is defined as

$$\mathscr{M} = \Theta^*\{\varepsilon, \#\}\Theta^*\{\varepsilon, \bar{\#}\}\Theta^*.$$

A marked word should be viewed as an infix of a larger word $u\#v\bar{\#}w$. The set of *admissible* marked words, denoted by $\mathscr{A}$, consists of those words $z \in \mathscr{M}$ which are an infix of a word $u\#v\bar{\#}w$ where $v \in \mathsf{Dyck}_x$. For example, a marked word $u\#v$ is admissible if v is a prefix of a Dyck word.

On the set of admissible marked words, we define an ordering $\sqsubseteq$. To do so, we first define for each marked word $z \in \mathscr{M}$ two words $\mathsf{inside}(z)$ and $\mathsf{outside}(z)$ in Θ^* as follows: Let $u, v, w \in \Theta^*$ such that either $z = v$, $z = u\#v$, $z = v\bar{\#}w$, or $z = u\#v\bar{\#}w$. Then we define $\mathsf{inside}(z) = v$ and $\mathsf{outside}(z) = uw$ (here, $u = \varepsilon$ if it is not part of z, same for w). Given

two admissible marked words $z_1, z_2 \in \mathscr{A}$ we define $w \sqsubseteq w'$ if and only if z_1 and z_2 contain the same markers, and $\mathsf{inside}(z_1) \sqsubseteq' \mathsf{inside}(z_2)$, and $\mathsf{outside}(z_1) \sqsubseteq' \mathsf{outside}(z_2)$. For example, $a\bar{x}xc\#a \sqsubseteq xabc\bar{x}\#ab$ because $a\bar{x}xc \sqsubseteq' xabc\bar{x}$ and $a \sqsubseteq' ab$.

For a language $L \subseteq \mathscr{M}$ we denote by $L{\downarrow}$ the downward closure of L within $\mathscr{A}$ with respect to the ordering $\sqsubseteq$. Thus, we define:

$$L{\downarrow} = \{u \in \mathscr{A} \mid \exists v \in L \cap \mathscr{A} \colon u \sqsubseteq v\}.$$

▶ **Theorem 5.3.** *Given a tame-pumping* CFG $\mathcal{G}$*, we can compute in polynomial space a doubly succinct* NFA $\mathcal{A}$ *such that* $L(\mathcal{A}){\downarrow} = L(\mathcal{G}){\downarrow}$ *and* $|\mathcal{A}|$ *is polynomially bounded in* $|\mathcal{G}|$*.*

We explain how to prove Theorem 5.3 in Section 6. Let us make a few remarks. While downward closed sets with respect to the subword ordering are always regular, this does not hold for $\sqsubseteq$. Consider the language $L = (ax)^*$ where $a \in \Gamma$ is a handler name and $x \in X$ is an event letter. Then $L{\downarrow}$ consists of all words $w \in \{a, x, \bar{x}\}^*$ where $|w|_a \leq |w|_x - |w|_{\bar{x}}$, which is not a regular language. Furthermore, the automaton in Theorem 5.3 may indeed require double exponentially many states. For example, given a number n, consider the language $L = \{u\bar{x}^{2^n}\#x^{2^n}\bar{u} \mid u \in \{ax, bx\}^*\}$ where $\Gamma = \{a, b\}$ is the set of handler names and $X = \{x\}$. Here we define $\overline{a_1 a_2 \cdots a_n} = \bar{a}_n \cdots \bar{a}_2 \bar{a}_1$ for a word $a_1 \cdots a_n \in \{a, b, x\}^*$ where $\bar{a} = a$ and $\bar{b} = b$. This is generated by a tame-pumping context-free grammar of size linear in n. However, for any $\mathcal{A}$ with $L(\mathcal{A}){\downarrow} = L{\downarrow}$, projecting to just a and b yields the language $K = \{uu^{\mathsf{rev}} \mid u \in \{a, b\}^*,\ |u| \leq 2^n\}{\downarrow}$, for which an NFA requires at least 2^{2^n} states.

Finally, note that the restriction to admissible words is crucial: If we defined the ordering $\sqsubseteq$ on all words of $\mathscr{M}$, then for the tame-pumping language $L = \{x^n\#\bar{x}^n \mid n \in \mathbb{N}\}$, the downward closure would not be regular, because an NFA would be unable to preserve the unbounded offset at the separator $\#$. A key observation in this work is that in combination with tame pumping, admissibility guarantees that the offset at the borders $\#$ and $\bar{\#}$ is bounded (see Lemma 6.7), which enables a finite automaton to preserve it.

Given a tame-pumping asynchronous program $\mathscr{P}$, we can now compute a dsVASS $\mathcal{V}$ with the same downward closure: Its counters are the handler names $a \in \Gamma$ in $\mathscr{P}$. For each nonterminal A we apply Theorem 5.3 to $\mathcal{G}_A$, which is the grammar of $\mathscr{P}$ with start symbol A, and obtain a dsNFA $\mathcal{B}_A$. We replace each transition $q \xhookrightarrow{a,A} q'$ by the following gadget: First, it decrements the counter for the handler name a. Next, the gadget simulates the dsNFA $\mathcal{B}_A$ where handlers $b \in \Gamma$ are interpreted as counter increments. Finally, when reaching the final state of $\mathcal{B}_A$ we can non-deterministically switch to q'.

▶ **Corollary 5.4.** *Given an asynchronous program* $\mathscr{P}$ *with tame-pumping, we can compute in polynomial space a doubly succinct* VASS $\mathcal{V}$ *such that* $L(\mathscr{P}){\downarrow} = L(\mathcal{V}){\downarrow}$ *and* $|\mathcal{V}|$ *is polynomially bounded in* $|\mathscr{P}|$*.*

The details of the proof are given in the full version.

5.2 The algorithm

We are now ready to explain the whole algorithm. Given an asynchronous program $\mathscr{P} = (Q, X \cup \bar{X}, \Gamma, \mathcal{G}, \Delta, q_0, q_f, \gamma_0)$, we want to check if $L(\mathscr{P}) \subseteq \mathsf{Dyck}_X$. Recall that, wlog, we can assume all nonterminals are useful, meaning every nonterminal is involved in some accepting run. The algorithm is presented in Algorithm 1. As a first step, the algorithm verifies that $\mathscr{P}$ is tame-pumping using Lemma 5.2. Next we construct the following auxiliary asynchronous programs $\mathscr{P}_{\mathsf{o}}$, $\mathscr{P}_{\mathsf{d}}$, $\mathscr{P}_{\mathsf{m}}$, to detect offset, dip, and mismatch violations in $L(\mathscr{P})$.

Algorithm 1 Checking non-inclusion of $L(\mathscr{P})$ in the Dyck language Dyck_X in EXPSPACE.

```
Asynchronous program 𝒫 for a language L ⊆ (X ∪ X̄)*
if 𝒫 does not have tame-pumping (Lemma 5.2) then return L ⊈ Dyck_X;
Construct asynchronous programs 𝒫_o, 𝒫_d, 𝒫_m (Equation (1)).
Construct dsVASS 𝒱_o, 𝒱_d, 𝒱_m with L(𝒱_x)↓ = L(𝒫_x)↓ for x ∈ {o, d, m} (Corollary 5.4).
if 𝒱_o does not have uniform offset 0 (Corollary 4.2) then return L ⊈ Dyck_X;
if L(𝒱_d) or L(𝒱_m) contains a marked Dyck factor (Proposition 4.3) then return
  L ⊈ Dyck_X;
return L ⊆ Dyck_X
```

Let $\rho\colon (X \cup \bar{X})^* \to \{x, \bar{x}\}^*$ be the morphism which replaces all letters in X by unique letter x and all letters in $\bar{X}$ by unique letter $\bar{x}$. The programs $\mathscr{P}_\mathsf{o}$, $\mathscr{P}_\mathsf{d}$, $\mathscr{P}_\mathsf{m}$ recognize the following languages over the alphabet $\{x, \bar{x}, \#, \bar{\#}\}$:

$$\begin{aligned} L(\mathscr{P}_\mathsf{o}) &= \{\rho(w) \mid w \in L(\mathscr{P})\}, \\ L(\mathscr{P}_\mathsf{d}) &= \{\#\rho(v)\bar{\#}\rho(\bar{y}w) \mid v\bar{y}w \in L(\mathscr{P}) \text{ for some } v, w \in (X \cup \bar{X})^*,\ y \in X\}, \\ L(\mathscr{P}_\mathsf{m}) &= \{\rho(u)\#\rho(v)\bar{\#}\rho(w) \mid uyv\bar{z}w \in L(\mathscr{P}), \\ &\qquad\qquad \text{for some } u, v, w \in (X \cup \bar{X})^*,\ y \neq z \in X\}. \end{aligned} \tag{1}$$

In fact, if the original asynchronous program $\mathscr{P}$ is tame-pumping, we can ensure that $\mathscr{P}_\mathsf{o}$, $\mathscr{P}_\mathsf{d}$, $\mathscr{P}_\mathsf{m}$ are also tame-pumping (see the full version for details).

It remains to verify whether $L(\mathscr{P}_\mathsf{o})$ has uniform offset 0, and $L(\mathscr{P}_\mathsf{d})$ and $L(\mathscr{P}_\mathsf{m})$ do not contain marked Dyck factors. By Corollary 5.4 we can compute for each $\mathsf{x} \in \{\mathsf{o}, \mathsf{d}, \mathsf{m}\}$ a dsVASS $\mathcal{V}_\mathsf{x}$ with $L(\mathcal{V}_\mathsf{x})\downarrow = L(\mathscr{P}_\mathsf{x})\downarrow$. Since $\sqsubseteq$ preserves offsets we know that $L(\mathscr{P}_\mathsf{o})$ has uniform offset 0 if and only if $L(\mathcal{V}_\mathsf{o})$ has uniform offset 0, which can be decided in exponential space by Corollary 4.2. Finally, we check whether $L(\mathcal{V}_\mathsf{d})$ or $L(\mathcal{V}_\mathsf{m})$ contain a marked Dyck factor by Proposition 4.3. This is correct, because a language L contains a marked Dyck factor if and only if $L\downarrow$ contains a marked Dyck factor: On the one hand, the "only if" direction is clear because $L \subseteq L\downarrow$. On the other hand, if $u\#v\bar{\#}w \in L\downarrow$ is a marked Dyck word then there exists a word $u'\#v'\bar{\#}w' \in L$ with $v \trianglelefteq v'$, and therefore $v' \in \mathsf{Dyck}_x$.

6 Computing Downward Closures and the Proof of Theorem 5.3

It remains to show how the automaton $\mathcal{A}$ for the downward closure in Theorem 5.3 is constructed. As a warm-up, let us illustrate how to construct from a context-free grammar $\mathcal{G}$ an NFA $\mathcal{A}$ for the subword closure of $L(\mathcal{G})$, cf. [5]. Here, *subword closure* refers to the downward closure with respect to the subword ordering $\preccurlyeq$. Notice that this is a special case of Theorem 5.3, namely where $L(\mathcal{G}) \subseteq \Gamma^*$. The basic idea is that every derivation tree of $\mathcal{G}$ can be obtained by inserting pumps into a *skeleton* – a derivation tree without vertical repetitions of nonterminals. The skeleton can be guessed by an (exponentially large) automaton $\mathcal{A}$ and the effects of pumps are abstracted as follows: For each nonterminal A one can compute the subalphabets $\Gamma_{A,\mathsf{L}}, \Gamma_{A,\mathsf{R}} \subseteq \Gamma$ containing all letters occurring on the left side u and the right side v of a pump $A \overset{*}{\Rightarrow} uAv$. Instead of inserting pumps, the automaton for the subword closure inserts arbitrary words $u' \in \Gamma_{A,\mathsf{L}}^*$ and $v' \in \Gamma_{A,\mathsf{R}}^*$ on the left or right side of A, respectively. This is sufficient because for any word w, the subword closure of the language w^* contains exactly those words that consist only of letters present in w.

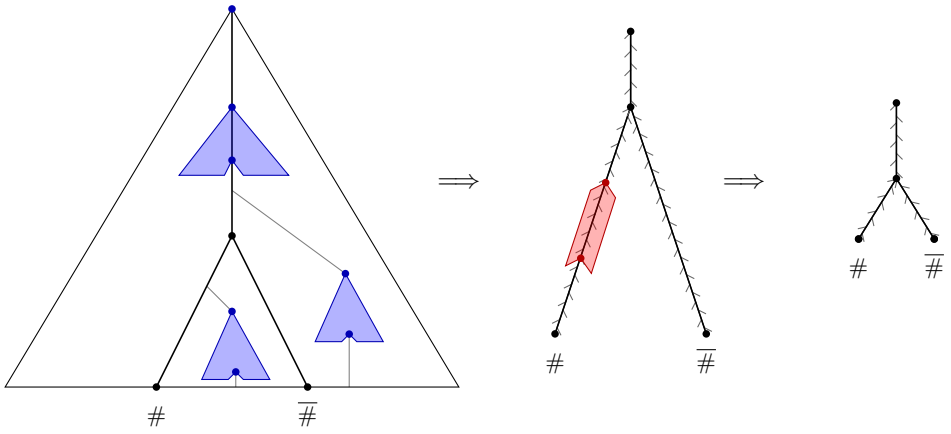

Figure 1 Abstracting undivided pumps (in blue) and divided pumps (in red).

The difficulty in proving Theorem 5.3 is to preserve, not only the subword closure, but also the downward closure with respect to the syntactic order $\trianglelefteq$ on the letters $\{x, \bar{x}\}$. To do so, we need to distinguish between two types of pumps. Consider the derivation tree for a marked word $z = u\#v\bar{\#}w$, depicted left in Figure 1. Observe that removing one of the three pumps in blue does not change the offset of $\mathsf{inside}(z) = v$ or $\mathsf{outside}(z) = uw$, because $\mathcal{G}$ is tame-pumping. Such pumps, which are completely contained in $\mathsf{inside}(z)$ or $\mathsf{outside}(z)$, will be called *undivided*. However, one needs to be more careful when removing *divided* pumps, e.g., the red pump in the second derivation tree of Figure 1. Removing the red pump decreases the offset of $\mathsf{outside}(z)$, while increasing the offset of $\mathsf{inside}(z)$ by the same amount.

We will proceed in two transformations, which preserve the downward closure w.r.t. $\sqsubseteq$. In the first transformation we obtain a grammar whose derivation trees do not contain any undivided pumps. In the second step we additionally eliminate divided pumps.

6.1 Abstracting undivided pumps

Recall that $\mathscr{M} = \Theta^*\{\#, \varepsilon\}\Theta^*\{\bar{\#}, \varepsilon\}\Theta^*$ where $\Theta = \Gamma \cup \{x, \bar{x}\}$. In the following we only consider *uniformly marked* grammars $\mathcal{G}$, that is, we assume $L(\mathcal{G})$ is contained in one of the subsets $\Theta^*\#\Theta^*\bar{\#}\Theta^*$, $\Theta^*\#\Theta^*$, $\Theta^*\bar{\#}\Theta^*$, or Θ^*. This is not a restriction since we can split the given grammar $\mathcal{G}$ into four individual grammars, covering the four types of marked words, and treat them separately. This allows us to partition the set of nonterminals N into $N_{\#\bar{\#}} \cup N_{\#} \cup N_{\bar{\#}} \cup N_0$ where $N_{\#\bar{\#}}$-nonterminals only produce marked words in $\Theta^*\#\Theta^*\bar{\#}\Theta^*$, $N_{\#}$-nonterminals only produce marked words in $\Theta^*\#\Theta^*$, etc. A pump $A \overset{*}{\Rightarrow} uAv$ is *undivided* if $A \in N_{\#\bar{\#}} \cup N_0$, and *divided* otherwise. Our first goal will be to eliminate undivided pumps. A derivation tree without undivided pumps may still contain exponentially large subtrees below N_0-nonterminals. Such subtrees will also be "flattened" in this step, see the first transformation step in Figure 1.

▶ **Definition 6.1.** *A context-free grammar $\mathcal{G} = (N, \Theta \cup \{\#, \bar{\#}\}, P, S)$ is* almost-pumpfree *iff*
(C1) *$\mathcal{G}$ does not have undivided pumps, and*
(C2) *for all productions $A \to \alpha$ with $A \in N_0$ either $\alpha = a \in \Theta$ or $\alpha = (\Gamma')^*$ for some $\Gamma' \subseteq \Gamma$.*

We will now explain how to turn any uniformly marked CFG into an almost-pumpfree one. The resulting (extended) grammar will be exponentially large but can be represented succinctly. Recall that a *succinct ECFG* (sECFG) is an extended context-free grammar

$\mathcal{G}$ whose nonterminals are polynomially long strings and whose productions are given by finite-state transducers. For example, one of the transducers accepts the finite relation of all triples (A, B, C) such that there exists a production $A \to BC$. Productions either adhere to Chomsky normal form or have the form $A \to B$. The latter enables us to simulate PSPACE-computations in the grammar without side effects, see Observation 6.5 below.

▶ **Proposition 6.2.** *Given a uniformly marked tame-pumping* CFG $\mathcal{G}$*, one can compute in polynomial space a tame-pumping almost-pumpfree* sECFG $\mathcal{G}'$ *such that* $L(\mathcal{G})\downarrow = L(\mathcal{G}')\downarrow$ *and* $|\mathcal{G}'|$ *is polynomially bounded in* $|\mathcal{G}|$*.*

To prove Proposition 6.2, we first need some auxiliary results, which are mainly concerned with computing the minimal dips and letter occurrences within undivided pumps of a grammar $\mathcal{G}$. Recall that for the subword closure we computed for each nonterminal A the subalphabets $\Gamma_{\mathsf{L},A}$ and $\Gamma_{\mathsf{R},A}$, and inserted arbitrary words over $\Gamma_{\mathsf{L},A}$ and $\Gamma_{\mathsf{R},A}$ left and right to the nonterminal A. For the refined order $\sqsubseteq$ we may only use a letter $a \in \Gamma$ after simulating the minimal dip which is required to produce the letter a.

For a word $w \in \Theta^*$ we define the set $\psi(w)$ of all pairs $(n, m) \in \mathbb{N}^2$ such that $n \geq \mathsf{dip}(w)$ and $m = n + \mathsf{offset}(w)$. In other words, $\psi(w)$ is the reachability relation induced by w, interpreted as counter instructions. Recall that *Presburger arithmetic* is the first-order theory of $(\mathbb{N}, +, <, 0, 1)$. As an auxiliary step, we will compute existential Presburger formulas capturing the relation $\psi(u) \times \psi(v)$ for all pumps $A \overset{*}{\Rightarrow} uAv$ of a nonterminal A.

In the following lemma, when we say that we can *compute a formula for a relation* $R \subseteq \mathbb{N}^k$ *in polynomial space*, we mean that there is non-deterministic polynomial-space algorithm, where each non-deterministic branch computes a polynomial-size formula for a relation R_i such that if $R_1, \ldots, R_n$ are the relations of all the branches, then $R = \bigcup_{i=1}^{n} R_i$. Here we tacitly use the fact that NPSPACE = PSPACE [24].

▶ **Lemma 6.3.** *Given an offset-uniform* CFG *with* $L(\mathcal{G}) \subseteq \Theta^*\$\Theta^*$*, where* $\$ \notin \Theta$*, we can compute in polynomial space an existential Presburger formula for the relation*

$$\bigcup_{u\$v \in L} \psi(u) \times \psi(v) \subseteq \mathbb{N}^4.$$

Proof sketch. The result of Lemma 6.3 was already proved in [1, Proposition 3.8], under the additional assumption that the given context-free grammar $\mathcal{G}$ for L is *annotated* (they even show that in this case the formula can be computed in NP). We call $\mathcal{G}$ annotated if for every nonterminal A the minimal dip that can be achieved by a word in $L(\mathcal{G}, A)$ is given as an input, denoted by $\mathsf{mindip}(A)$. Hence, it remains to show how to compute the annotation of an offset-uniform grammar in PSPACE, which is possible using a simple saturation algorithm. For each nonterminal A, the algorithm stores a number $D(A)$ satisfying $D(A) \geq \mathsf{mindip}(A)$. Initially, $D(A)$ is set to an upper bound for $\mathsf{mindip}(A)$, which by Lemma 5.2 (2) can be chosen to be exponentially large in $|\mathcal{G}|$. In each round the function D is updated as follows: For each production $A \to BC$ we set $D(A)$ to the minimum of $D(A)$ and $\max\{D(B), D(C) - \mathsf{offset}(B)\}$, where $\mathsf{offset}(B)$ is the unique offset of $L(\mathcal{G}, B)$. Clearly, the algorithm can be implemented in polynomial space since the numbers are bounded exponentially. Termination of the algorithm is guaranteed since the numbers $D(A)$ are non-increasing. ◀

With Lemma 6.3 in hand, we can now prove the following lemma, which allows us to check whether pumps with certain letter occurrences exist for certain minimal dips.

▶ **Lemma 6.4.** *Given a tame-pumping* CFG $\mathcal{G}$ *such that* $L(\mathcal{G}) \subseteq \mathscr{M}$*, a nonterminal* A *in* $\mathcal{G}$*, a letter* $a \in \Gamma$ *and two numbers* $d_{\mathsf{L}}, d_{\mathsf{R}} \in \mathbb{N}$*, we can decide in* PSPACE *if there exists a derivation* $A \overset{*}{\Rightarrow} uAv$ *such that* u *contains the letter* a *(or symmetrically, whether* v *contains the letter* a*),* $\mathsf{dip}(u) \leq d_{\mathsf{L}}$*, and* $\mathsf{dip}(v) \leq d_{\mathsf{R}}$*. Furthermore, we can also decide in* PSPACE *whether a derivation with the above properties exists that also satisfies* $\mathsf{offset}(u) > 0$*.*

Proof sketch. We first construct the CFG $\mathcal{G}_A$ for the language of pumps of the nonterminal A, meaning for $L(\mathcal{G}_A) = \{u\$v \mid A \overset{*}{\Rightarrow}_{\mathcal{G}} uAv\}$. Then we intersect with the regular language $\Theta^* a \Theta^* \$ \Theta^*$, and apply Lemma 6.3 to the resulting grammar. This is possible, because tame-pumping implies that the grammar for the pumps has a uniform offset of zero. We can modify the resulting Presburger formula from Lemma 6.3 to check for the required dips, and modify it further to check for the positive offset for u. Finally, we use the fact that testing satisfiability of an existential Presburger formula is in NP [3]. ◀

Now we are almost ready to prove Proposition 6.2. The last thing we need is for an sECFG to perform PSPACE-computations on paths in its derivation trees:

▶ **Observation 6.5.** *An* sECFG *can simulate* PSPACE*-computations on exponentially long paths in its derivation trees. This is because the nonterminals are polynomially long strings and can therefore act as polynomial space Turing tape configurations. Moreover, the transducers of the* sECFG *can easily be constructed to enforce the step-relation of a Turing machine. If we apply this enforcement to productions of the form* $A \to B$*, then the path that simulates the* PSPACE*-computation will not even have any additional side paths until after the computation is complete. Thus, only the result of the computation will affect the derived word.*

Since grammars and transducers are non-deterministic (and NPSPACE = PSPACE*), we can even implement non-determinism and guessing within such computations.*

We are ready to present a proof sketch of Proposition 6.2. The main idea is that $\mathcal{G}'$ simulates derivation trees of $\mathcal{G}$ by keeping track of at most polynomially many nodes, and abstracting away pumps via the previous auxiliary results.

If a nonterminal A of $\mathcal{G}$ does not belong to N_0 (i.e., it produces a marker), then $\mathcal{G}'$ guesses a production $A \to BC$ to apply. If A furthermore belongs to $N_{\#\bar{\#}}$, then $\mathcal{G}'$ also guesses a pump to apply in the form of a 4-tuple consisting of two dip values $d_{\mathsf{L}}, d_{\mathsf{R}} \in \mathbb{N}$ and two alphabets $\Gamma_{\mathsf{L}}, \Gamma_{\mathsf{R}} \subseteq \Gamma$. Guessing and storing the dip values is possible in PSPACE, since they are exponentially bounded by Lemma 5.2 (2). For each $a \in \Gamma_{\mathsf{L}}$, Lemma 6.4 is used on input $A, a, d_{\mathsf{L}}, d_{\mathsf{R}}$ to check in PSPACE whether a matching pump exists. A symmetric version of Lemma 6.4 is also used for each $a \in \Gamma_{\mathsf{R}}$. Then, if all checks succeed, $\mathcal{G}'$ simulates the pump as $A \to \bar{x}^{d_{\mathsf{L}}} x^{d_{\mathsf{L}}} \Gamma_{\mathsf{L}}^* BC \bar{x}^{d_{\mathsf{R}}} x^{d_{\mathsf{R}}} \Gamma_{\mathsf{R}}^*$. This simulation clearly preserves minimal dips and handler names, whereas by tame-pumping the combined offset of a pump is zero anyway, and therefore need not be computed.

If a nonterminal A belongs to N_0, then $\mathcal{G}'$ abstracts away its entire subtree. To this end it generates a pumpfree subtree on-the-fly using depth-first search, which is possible in PSPACE since without pumps the tree has polynomial height. During this process pumps are simulated using the same strategy as before.

We also need to ensure that nonterminals of $\mathcal{G}'$ in N_0 only have productions that allow for a single leaf node below them. To this end $\mathcal{G}'$ only ever derives letters and alphabets Γ'^* one at a time. Consider the up to two *main paths* in a derivation tree of $\mathcal{G}'$, by which we mean the paths leading from the root to a marker. Whenever $\mathcal{G}'$ simulates a pump as $A \to u'Av'$ in the above process, it extends the main path by $|uv|$ and in each step only derives a single nonterminal from N_0 to the left or right. When $\mathcal{G}'$ abstracts an entire subtree of a nonterminal in N_0, then this subtree is also produced to the left or right of the main path, without leaving said path.

Additionally, whenever $\mathcal{G}'$ simulates a pump of some A, then $\mathcal{G}'$ assumes that this pump is the combination of all pumps that occur in the original derivation tree for that instance of A. Thus, below such a pump, it remembers in polynomial space, that A is not allowed to occur anymore. Finally, whenever $\mathcal{G}'$ checks by Lemma 6.4 that a pump exists with $\mathsf{offset}(u) > 0$, then this is a so-called increasing pump, and it can be repeated to achieve an infix with arbitrary high offset. Thus, dip values below this pump cannot make up for this offset and therefore will no longer be simulated.

6.2 Abstracting divided pumps

We have now removed all the undivided pumps and are left with derivation trees as in the middle picture of Figure 1. In this subsection, we will show the following:

▶ **Lemma 6.6.** *Given a tame-pumping almost-pumpfree* sECFG $\mathcal{G}$ *with* $L(\mathcal{G}) \subseteq \mathscr{M}$*, one can construct in polynomial space a* dsNFA $\mathcal{B}$ *such that* $L(\mathcal{B})\downarrow = L(\mathcal{G})\downarrow$ *and* $|\mathcal{B}|$ *is polynomially bounded in* $|\mathcal{G}|$*.*

We give a proof sketch here, the details can be found in the full version of the paper. Our starting point in the proof of Lemma 6.6 is the following key observation: The offsets which occur during the production of any *admissible* marked word w which contains exactly one marker are bounded. This allows us to keep track of the offset precisely, which is necessary for us to solve the marked Dyck factor (MDF) problem.

For a node t in a derivation tree T, let $w(t)$ denote the word derived by the subtree rooted at t and let $u(t) = \mathsf{inside}(w(t))$, $v(t) = \mathsf{outside}(w(t))$.

▶ **Lemma 6.7.** *There exists a polynomial p such that for any uniformly marked, tame-pumping, almost-pumpfree* sECFG $\mathcal{G}$ *the following holds. Let T be a derivation tree of $\mathcal{G}$ which produces an admissible marked word containing $\#$ or $\bar{\#}$, but not both. Then we have* $|\mathsf{offset}(u(t))|, |\mathsf{offset}(v(t))| \leq 2^{p(|\mathcal{G}|)}$*.*

Proof. We consider the case when the word derived is of the form $u\#v$, the case for $v\bar{\#}w$ being symmetric. Our derivation tree T has a skeleton T' into which pumps are inserted to form T. This means $u\#v = u'_k\hat{u}_k \cdots u'_1\hat{u}_1u'_0\#v'_0\hat{v}_1v'_1 \cdots \hat{v}_kv'_k$, where $u'_k \cdots u'_0\#v'_0 \cdots v'_k$ is the word generated by T' and each pair $(\hat{u}_i, \hat{v}_i)$ is derived using a pump. Then we have

$$\mathsf{offset}(u) = \overbrace{\mathsf{offset}(u'_k \cdots u'_0)}^{=:U_0} + \overbrace{\sum_{i=1}^{k} \mathsf{offset}(\hat{u}_i)}^{=:U_1},$$

$$\mathsf{offset}(v) = \underbrace{\mathsf{offset}(v'_0 \cdots v'_k)}_{=:V_0} + \underbrace{\sum_{i=1}^{k} \mathsf{offset}(\hat{v}_i)}_{=:V_1}.$$

We claim that each of the numbers $|U_0|, |U_1|, |V_0|, |V_1|$ is bounded by $n(\mathcal{G})$, the number of nonterminals of $\mathcal{G}$. This clearly implies the lemma: Since $\mathcal{G}$ is a succinct grammar, it has at most exponentially many nonterminals in the size of its description. We begin with U_0, V_0. The tree T' contains each nonterminal of $\mathcal{G}$ at most once, and by property (C2) in Definition 6.1, we know that the subtree under each nonterminal in T' not containing $\#$ has offset -1, 0, or 1. Thus, $|U_0|, |V_0| \leq n(\mathcal{G})$. The bound on $|U_1|, |V_1|$ is due to admissibility of $u\#v$: It yields $V_0 + V_1 = \mathsf{offset}(v) \geq 0$ and thus $V_1 \geq -V_0$. Moreover, by tame-pumping, we know that $\mathsf{offset}(\hat{v}_i) \leq 0$ for each $i \in [1, k]$, and thus $V_1 \leq 0$. Together, we obtain $V_1 \in [-V_0, 0]$. Finally, tame-pumping also implies $\mathsf{offset}(\hat{u}_i) = -\mathsf{offset}(\hat{v}_i)$ for each $i \in [1, k]$ and hence $U_1 = -V_1$. ◀

▶ Remark 6.8. Note that the bound only holds under the condition of admissibility. An easy counterexample is the tame-pumping language $L = \{x^n \# \bar{x}^n \mid n \in \mathbb{N}\}$.

The dsNFA $\mathcal{B}$ of Lemma 6.6 can now be constructed in three steps as follows:

Step I: Tracking counter effects. We first observe that since $\mathcal{G}$ is almost-pumpfree, its pumps $A \overset{*}{\Rightarrow} uAv$ can be simulated by a transducer that traverses the derivation tree bottom-up. Thus, we can construct a *singly* succinct finite-state transducer $\mathcal{T}_A$ with size polynomial in $|\mathcal{G}|$ that captures all pumps $A \overset{*}{\Rightarrow} uAv$. To be precise, $\mathcal{T}_A$ accepts exactly those pairs (u, v) for which $A \overset{*}{\Rightarrow} u^{\mathsf{rev}}Av$. The transducer $\mathcal{T}_A$ has one state for each nonterminal of $\mathcal{G}$.

Since $\mathcal{B}$ will need to preserve offset and dip, we need to expand $\mathcal{T}_A$ to track them as well. Here, it is crucial that we only need to do this for $A \in N_{\#} \cup N_{\bar{\#}}$ and pumps $A \overset{*}{\Rightarrow} uAv$ that are used to derive an admissible word. According to Lemma 6.7 tells us that in such a pump, the absolute values of offsets and dips of u and v are bounded by $2^{q(|\mathcal{G}|)}$ for some polynomial q. Thus, we can modify $\mathcal{T}_A$ so as to track the dip and offset of the two words it reads. Therefore, for each $A \in N_{\#} \cup N_{\bar{\#}}$ and each quadruple $\mathbf{x} = (d_{\mathsf{L}}, \delta_{\mathsf{L}}, d_{\mathsf{R}}, \delta_{\mathsf{R}})$ of numbers with absolute value at most $2^{q(\mathcal{G})}$, we can construct in PSPACE a transducer $\mathcal{T}_{A,\mathbf{x}}$ with

$$(u, v) \text{ is accepted by } \mathcal{T}_{A,\mathbf{x}} \quad \text{iff} \quad A \overset{*}{\Rightarrow} u^{\mathsf{rev}}Av \text{ and } e(u^{\mathsf{rev}}) = (d_{\mathsf{L}}, \delta_{\mathsf{L}}), \text{ and } e(v) = (d_{\mathsf{R}}, \delta_{\mathsf{R}}).$$

Moreover, $\mathcal{T}_{A,\mathbf{x}}$ is singly succinct, polynomial-size, and can be computed in PSPACE. Observe that by Lemma 6.7, if a pump $A \overset{*}{\Rightarrow} uAv$ is used in a derivation of an admissible word, then for some quadruple $\mathbf{x}$, the pair (u^{rev}, v) is accepted by $\mathcal{T}_{A,\mathbf{x}}$.

Step II: Skeleton runs. The automaton $\mathcal{B}$ has to read words from left to right, rather than two factors in parallel as $\mathcal{T}_A$ and $\mathcal{T}_{A,\mathbf{x}}$ do. To this end, it will guess a run of $\mathcal{T}_{A,\mathbf{x}}$ without state repetitions; such a run is called a *skeleton run*. For a fixed skeleton run ρ, the set of words read in each component of $\mathcal{T}_{A,\mathbf{x}}$ is of the shape $\Gamma_0^*\{a_1, \varepsilon\}\Gamma_1^* \cdots \{a_k, \varepsilon\}\Gamma_k^*$, where each a_i is read in a single step of ρ and Γ_i is the set of letters from Γ seen in cycles in a state visited in ρ. Sets of this shape are called *ideals* [12]. The ideal for the left (right) component is called the *left* (*right*) *ideal* of the skeleton run. Note that since $\mathcal{T}_{A,\mathbf{x}}$ has exponentially many states, the skeleton run is at most exponentially long.

Step III: Putting it together. The dsNFA $\mathcal{B}$ guesses and verifies an exponential size skeleton T of the sECFG $\mathcal{G}$. Moreover, for each node t that is above $\#$ or $\bar{\#}$—but not both—it guesses a quadruple $\mathbf{x} = (d_{\mathsf{L}}, \delta_{\mathsf{L}}, d_{\mathsf{R}}, \delta_{\mathsf{R}})$ with $d_{\mathsf{L}}, d_{\mathsf{R}} \in [0, 2^{q(|\mathcal{G}|)}]$, $\delta_{\mathsf{L}}, \delta_{\mathsf{R}} \in [-2^{q(\mathcal{G})}, 2^{q(\mathcal{G})}]$ and a skeleton run ρ_t of the transducer $\mathcal{T}_{A,\mathbf{x}}$, where A is t's label. The automaton $\mathcal{B}$ then traverses the skeleton T in-order; i.e. node, left subtree, right subtree, node; meaning each inner node is visited exactly twice. Whenever $\mathcal{B}$ visits a node t as above, it produces an arbitrary word from an ideal of ρ_t: For the first (resp. second) visit of t, it uses the left (resp. right) ideal of ρ_t. Moreover, in addition to the word from the left ideal, $\mathcal{B}$ outputs a string $w \in \{x, \bar{x}\}^*$ with $e(w) = (d_{\mathsf{L}}, \delta_{\mathsf{L}})$, where $\mathbf{x} = (d_{\mathsf{L}}, \delta_{\mathsf{L}}, d_{\mathsf{R}}, \delta_{\mathsf{R}})$ is the quadruple guessed for t (and similarly for the right ideal). This way, it preserves offset and dip at the separators $\#$ and $\bar{\#}$.

Since the skeleton T has exponentially many nodes (in $|\mathcal{G}|$) and each skeleton run ρ_t requires exponentially many bits, the total number of bits that $\mathcal{B}$ has to keep in memory is also bounded by an exponential in $|\mathcal{G}|$.

Abstract

We define the *adjacent fragment* $\mathcal{AF}$ of first-order logic, obtained by restricting the sequences of variables occurring as arguments in atomic formulas. The adjacent fragment generalizes (after a routine renaming) two-variable logic as well as the fluted fragment. We show that the adjacent fragment has the finite model property, and that its satisfiability problem is no harder than for the fluted fragment (and hence is TOWER-complete). We further show that any relaxation of the adjacency condition on the allowed order of variables in argument sequences yields a logic whose satisfiability and finite satisfiability problems are undecidable. Finally, we study the effect of the adjacency requirement on the well-known guarded fragment ($\mathcal{GF}$) of first-order logic. We show that the satisfiability problem for the guarded adjacent fragment ($\mathcal{GA}$) remains 2EXPTIME-hard, thus strengthening the known lower bound for $\mathcal{GF}$.

1 Introduction

The quest to find fragments of first-order logic for which satisfiability is algorithmically decidable has been a central undertaking of mathematical logic since the appearance of Hilbert and Ackermann's *Grundzüge der theoretischen Logik* [15, 16] almost a century ago. The great majority of such fragments so far discovered, however, belong to just three families: (i) quantifier prefix fragments [8], where we are restricted to prenex formulas with a specified quantifier sequence; (ii) two-variable logics [13], where the only logical variables occurring as arguments of predicates are x_1 and x_2; and (iii) guarded logics [1], where quantifiers are relativized by atomic formulas featuring all the free variables in their scope.

There is, however, a fourth family of decidable logics, originating in the work of W.V.O. Quine [33], and based on restricting the allowed sequences of variables occurring as arguments in atomic formulas. This family of logics, which includes the *fluted fragment*,

the *ordered fragment* and the *forward fragment*, has languished in relative obscurity. In this paper, we investigate the potential for obtaining decidable fragments in this way, identifying a new fragment, which we call the *adjacent fragment*. This fragment not only includes the fluted, ordered and forward fragments, but also subsumes, in a sense we make precise, the two-variable fragment. We show that the satisfiability problem for the adjacent fragment is decidable, and determine bounds on its complexity.

To explain how restrictions on argument orderings work, we consider presentations of first-order logic without equality over purely relational signatures, employing individual variables from the alphabet $\{x_1, x_2, x_3, \ldots\}$. Any atomic formula in this logic has the form $p(\bar{x})$, where p is a predicate of arity $m \geq 0$ and $\bar{x}$ is a word over the alphabet of variables of length m. Call a first-order formula φ *index-normal* if, for any quantified sub-formula $Qx_k\,\psi$ of φ, ψ is a Boolean combination of formulas that are either atomic with free variables among $x_1, \ldots, x_k$, or have as their major connective a quantifier binding x_{k+1}. By re-indexing variables, any first-order formula can easily be written as a logically equivalent index-normal formula. In the *fluted fragment*, denoted $\mathcal{FL}$, as defined by W. Purdy [32], we confine attention to index-normal formulas, but additionally insist that any atom occurring in a context in which x_k is quantified have the form $p(x_{k-m+1} \cdots x_k)$, i.e. $p(\bar{x})$ with $\bar{x}$ a *suffix* of $x_1 \cdots x_k$. In the *ordered fragment*, due to A. Herzig [14], by contrast, we insist that $\bar{x}$ be a *prefix* of $x_1 \cdots x_k$. In the *forward fragment* [2], we insist only that $\bar{x}$ be an *infix* of $x_1 \cdots x_k$.

All these logics have the finite model property, and hence are decidable for satisfiability. Denoting by $\mathcal{FL}^k$ the sub-fragment of $\mathcal{FL}$ involving at most k variables (free or bound), the satisfiability problem for $\mathcal{FL}^k$ is known to be in $(k{-}2)$-NExpTime for all $k \geq 3$, and $\lfloor k/2 \rfloor$-NExpTime-hard for all $k \geq 2$ [30]. Thus, satisfiability for the whole fluted fragment is Tower-complete, in the system of trans-elementary complexity classes due to [35]. By contrast, the satisfiability problem for the ordered fragment is known to be PSpace-complete [14, 18]. On the other hand, the apparent liberalization afforded by the forward fragment yields no difference in expressive power [4], and moreover there is a polynomial time satisfiability-preserving reduction of the forward fragment to the fluted fragment [2]. The term "fluted" originates with Quine [34], and presumably invites us to imagine the atoms in formulas aligned in such a way that the variables form columns. Note that none of these fragments can state that a relation is reflexive or symmetric (see [4] for a discussion of their expressivity).

Say that a word $\bar{x}$ over the alphabet $\{x_1, \ldots, x_k\}$ $(k \geq 0)$ is *adjacent* if the indices of neighbouring letters differ by at most 1. For example, $x_3x_2x_1x_2x_2x_2x_3x_4x_3$ is adjacent, but $x_1x_3x_2$ is not. The *adjacent fragment*, denoted $\mathcal{AF}$, is analogous to the fluted, ordered and forward fragments, but we allow any atom $p(\bar{x})$ to occur in a context where x_k is available for quantification as long as $\bar{x}$ is an adjacent word over $\{x_1, \ldots, x_k\}$. (A formal definition is given in Sec. 2.) As a simple example, the formula

$$\forall x_1 \forall x_2 \forall x_3 \exists x_4 \forall x_5 \; \big(p(x_1x_2x_3x_2x_3x_4x_5) \rightarrow p(x_1x_2x_3x_4x_3x_4x_5)\big) \tag{1}$$

is a validity of $\mathcal{AF}$, as can be seen by assigning x_4 the same value as x_2. Evidently, $\mathcal{AF}$ includes the fluted, ordered and forward fragments; the inclusion is strict, since the formulas $\forall x_1\, r(x_1x_1)$ and $\forall x_1x_2(r(x_1x_2) \rightarrow r(x_2x_1))$, stating that r is reflexive and symmetric, respectively, are in $\mathcal{AF}$. As every word over $\{x_1, x_2\}$ is adjacent, we may transform any formula of the two-variable fragment without equality, FO^2, in polynomial time, to a logically equivalent formula of $\mathcal{AF}$. The converse is true over signatures with predicates of arity at most two. Since the system of basic multimodal propositional logic is, under the standard translation to first-order logic, included within FO^2, this logic is similarly subsumed by $\mathcal{AF}$, as indeed is its notational variant, the description logic $\mathcal{ALC}$ (see, e.g. [17]).

We show that the satisfiability problem for the restriction of the adjacent fragment to formulas involving at most k variables (free or bound) is in $(k-2)$-NExpTime for all $k \geq 3$ – and hence no more difficult than the k-variable fluted fragment, which it properly contains. The critical step in our analysis is a lemma on the combinatorics of strings (Theorem 3.1), which may be of independent interest. We also consider minimal relaxations of adjacency involving the fragment with just three variables, and show that, in all cases of interest, the satisfiability and finite satisfiability problems for the resulting logics are undecidable. Thus, adjacency is as far as we can go in seeking decidable fragments based on straightforward argument ordering restrictions of the type envisaged by Quine.

The adjacent fragment is incomparable in expressive power to the guarded fragment. Moreover, the satisfiability problem for the union of $\mathcal{GF}$ and $\mathcal{AF}$ is undecidable, as one can use adjacent formulas to introduce any k-ary universal relations, which makes $\mathcal{GF}$ as expressive as first-order logic. Therefore, we study the effect of the adjacency restriction on $\mathcal{GF}$. We investigate the complexity of satisfiability for the resulting logic, $\mathcal{GA}$, showing that the problem is 2ExpTime-complete, thus sharpening the existing 2ExpTime-hardness proof for $\mathcal{GF}$ [11].

2 Preliminaries

Let m and k be non-negative integers. For any integers i and j, we write $[i, j]$ to denote the set of integers h such that $i \leq h \leq j$. A function $f\colon [1, m] \to [1, k]$ is *adjacent* if $|f(i+1)-f(i)| \leq 1$ for all i $(1 \leq i < m)$. We write $\mathbf{A}_k^m$ to denote the set of adjacent functions $f\colon [1, m] \to [1, k]$. Since $[1, 0] = \emptyset$, we have $\mathbf{A}_k^0 = \{\emptyset\}$, and $\mathbf{A}_0^m = \emptyset$ if $m > 0$. Let A be a non-empty set. A word $\bar{a}$ over the alphabet A is simply a tuple of elements from A; we alternate freely in the sequel between these two ways of speaking as the context requires. Accordingly, A^k denotes the set of words over A having length exactly k, and A^* is the set of all finite words over A. If $\bar{a} \in A^*$, denote the length of $\bar{a}$ by $|\bar{a}|$, and the reversal of $\bar{a}$ by $\bar{a}^{-1}$. Any function $f\colon [1, m] \to [1, k]$ (adjacent or not) induces a natural map from A^k to A^m defined by $\bar{a}^f = a_{f(1)} \cdots a_{f(m)}$, where $\bar{a} = a_1 \cdots a_k$. If $f \in \mathbf{A}_k^m$ (i.e. if f is adjacent), we may think of $\bar{a}^f$ as the result of a "walk" on the tuple $\bar{a}$, starting at the element $a_{f(1)}$, and moving left, right, or remaining stationary according to the sequence of values $f(i+1)-f(i)$ $(1 \leq i < m)$.

For any $k \geq 0$, denote by $\mathbf{x}_k$ the fixed word $x_1 \cdots x_k$ (if $k = 0$, this is the empty word). A *k-atom* is an expression $p(\mathbf{x}_k^f)$, where p is a predicate of some arity $m \geq 0$, and $f\colon [1, m] \to [1, k]$. Thus, in a k-atom, each argument is a variable chosen from $\mathbf{x}_k$. If f is adjacent, we speak of an *adjacent k-atom*. Thus, in an adjacent k-atom, the indices of neighbouring arguments differ by at most one. When $k \leq 2$, the adjacency requirement is vacuous, and in this case we prefer to speak simply of *k-atoms*. Proposition letters (predicates of arity $m = 0$) count as (adjacent) k-atoms for all $k \geq 0$, taking f to be the empty function. When $k = 0$, we perforce have $m = 0$, since otherwise, there are no functions from $[1, m]$ to $[1, k]$; thus the 0-atoms are precisely the proposition letters.

We define the sets of first-order formulas $\mathcal{AF}^{[k]}$ by simultaneous structural induction:

1. every adjacent k-atom is in $\mathcal{AF}^{[k]}$;
2. $\mathcal{AF}^{[k]}$ is closed under Boolean combinations;
3. if φ is in $\mathcal{AF}^{[k+1]}$, $\exists x_{k+1}\, \varphi$ and $\forall x_{k+1}\, \varphi$ are in $\mathcal{AF}^{[k]}$.

Now let $\mathcal{AF} = \bigcup_{k \geq 0} \mathcal{AF}^{[k]}$ and define $\mathcal{AF}^k$ to be the set of formulas of $\mathcal{AF}$ featuring no variables other than $\mathbf{x}_k$, free or bound. We call $\mathcal{AF}$ the *adjacent fragment* and $\mathcal{AF}^k$ the *k-variable adjacent fragment*. Note that formulas of $\mathcal{AF}$ contain no individual constants, function symbols or equality. The primary objects of interest here are the languages $\mathcal{AF}$

and $\mathcal{AF}^k$; however, the sets of formulas $\mathcal{AF}^{[k]}$ play an important auxiliary role in their analysis. Thus, for example, formula (1) is in $\mathcal{AF}^k$ for all $k \geq 5$, but in $\mathcal{AF}^{[k]}$ only for $k = 0$. On the other hand, the *quantifier-free* formulas of $\mathcal{AF}^{[k]}$ and $\mathcal{AF}^k$ are the same.

We silently assume the variables $\mathbf{x}_k = x_1 \cdots x_k$ to be ordered in the standard way. That is: if φ is a formula of $\mathcal{AF}^{[k]}$, $\mathfrak{A}$ a structure interpreting its signature, and $\bar{a} = a_1 \cdots a_k \in A^k$, we say simply that $\bar{a}$ *satisfies* φ in $\mathfrak{A}$, and write $\mathfrak{A} \models \varphi[\bar{a}]$ to mean that $\bar{a}$ satisfies φ in $\mathfrak{A}$ under the assignment $x_i \leftarrow a_i$ $(1 \leq i \leq k)$. (This does not necessarily mean that each of the variables of $\mathbf{x}_k$ actually appears in φ.) If φ is true under all assignments in all structures, we write $\models \varphi$; the notation $\varphi \models \psi$ means the same as $\models \varphi \to \psi$ (i.e. variables are consistently instantiated in φ and ψ). The notation $\varphi(\bar{v})$, where $\bar{v} = v_1 \cdots v_k$ are variables, will always be used to denote the formula that results from substituting v_i for x_i $(1 \leq i \leq k)$ in φ. We write $\forall \mathbf{x}_{k;\ell}$ in place of $\forall x_k \forall x_{k+1} \cdots \forall x_\ell$ (and just $\forall \mathbf{x}_\ell$ if $k = 1$). A *sentence* is a formula with no free variables. Necessarily, all formulas of $\mathcal{AF}^{[0]}$ are sentences. For a sentence φ we write simply $\mathfrak{A} \models \varphi$ to mean that φ is true in $\mathfrak{A}$. We call the set of predicates used in φ *the signature of* φ (denoted $\mathsf{sig}(\varphi)$). By routine renaming of variables we establish:

▶ **Lemma 2.1.** *Every* FO^2*-formula is logically equivalent to an* $\mathcal{AF}$*-formula. The converse holds for* $\mathcal{AF}$*-formulas featuring predicates of arity at most two.*

We adapt the standard notion of (atomic) k-types for the fragments studied here. Fix some signature σ. An *adjacent k-literal over σ* is an *adjacent k-atom* or its negation, featuring a predicate in σ. An *adjacent k-type over σ* is a maximal consistent set of adjacent k-literals over σ. Reference to σ is suppressed where clear from context. We use the letters ζ and η to range over adjacent k-types for various k. We denote by Atp_k^σ the set of all adjacent k-types over σ. For finite σ, we identify members of Atp_k^σ with their conjunctions, and treat them as (quantifier-free) $\mathcal{AF}^k$-formulas, writing ζ instead of $\bigwedge \zeta$. When $k \leq 2$, the adjacency requirement is vacuous, and in this case we shall simply speak simply of *k-types*. It is obvious that every quantifier-free $\mathcal{AF}^k$-formula χ is logically equivalent to a disjunction of adjacent k-types, in essence the adjacent disjunctive normal form of χ. In particular, if χ is satisfiable, then there is an adjacent k-type which entails it. If $\mathfrak{A}$ is a σ-structure and $\bar{a}$ a k-tuple of elements from A, there is a unique adjacent k-type ζ such that $\mathfrak{A} \models \zeta[\bar{a}]$; we denote this adjacent k-type by $\mathrm{atp}^{\mathfrak{A}}[\bar{a}]$, and call it the *adjacent type of $\bar{a}$ in $\mathfrak{A}$*. If $\tau \subseteq \sigma$, we use $\mathrm{atp}_\tau^{\mathfrak{A}}[\bar{a}]$ to denote the adjacent type of $\bar{a}$ in $\mathfrak{A}$ restricted to predicates from τ. It is not required that the elements $\bar{a}$ be distinct. Again, if $k \leq 2$, adjacency is vacuous, and we write $\mathrm{tp}^{\mathfrak{A}}[\bar{a}]$ rather than $\mathrm{atp}^{\mathfrak{A}}[\bar{a}]$, and refer to $\mathrm{tp}^{\mathfrak{A}}[\bar{a}]$ as the *type of $\bar{a}$ in $\mathfrak{A}$*.

Since adjacent formulas do not contain equality, we may freely duplicate elements in their models. Let $\mathfrak{B}$ be a σ-structure, and I a non-empty set of indices. We define the structure $\mathfrak{B} \times I$ over the Cartesian product $B \times I$ by setting, for any $p \in \sigma$ of arity m, and any m-tuples $b_1 \cdots b_m$ from B and $i_1 \cdots i_m$ from I^m, $\mathfrak{B} \times I \models p[\langle b_1, i_1 \rangle \cdots \langle b_m, i_m \rangle]$ if and only if $\mathfrak{B} \models p[b_1 \cdots b_m]$. By routine structural induction:

▶ **Lemma 2.2.** *Let ψ be an equality-free first-order formula all of whose free variables occur in $\mathbf{x}_k$, $\mathfrak{B}$ a structure interpreting the signature of ψ, and I a non-empty set. Then, for any tuples $\bar{b} = b_1 \cdots b_k$ from B and $i_1 \cdots i_k$ from I, $\mathfrak{B} \models \psi[\bar{b}]$ if and only if $\mathfrak{B} \times I \models \psi[\langle b_1, i_1 \rangle \cdots \langle b_k, i_k \rangle]$.*

The following combinatorial lemma allows us to extend the technique of "circular witnessing" [12], frequently used in the analysis of two-variable logics, to the languages $\mathcal{AF}^k$.

▶ **Lemma 2.3.** *For any integer $k > 0$ there is a set J with $|J| = (k^2 + k + 1)^{k+1}$ and a function $g\colon J^k \to J$ such that, for any tuple $\bar{t} \in J^k$ consisting of the elements $t_1, \ldots, t_k$ in some order:* (i) *$g(\bar{t})$ is not in $\bar{t}$;* (ii) *if $\bar{t}' \in J^k$ consists of the elements $\{t_2, \ldots, t_k, g(\bar{t})\}$ in some order, then $g(\bar{t}')$ is not in $\bar{t}$ either.*

3 Primitive generators of words

The upper complexity bounds obtained below depend on an observation concerning the combinatorics of words, which may be of independent interest. For words $\bar{a}, \bar{c} \in A^*$ with $|\bar{a}| = k$ and $|\bar{c}| = m$, say that $\bar{a}$ *generates* $\bar{c}$ if $\bar{c} = \bar{a}^f$ for some *surjective* function $f \in \mathbf{A}_k^m$. As explained above, it helps to think of $\bar{a}^f$ as the sequence of letters encountered on an m-step "walk" backwards and forwards on the tuple $\bar{a}$, with $f(i)$ giving the index of our position in $\bar{a}$ at the ith step. The condition that f is adjacent ensures that we never change position by more than one letter at a time; the condition that f is surjective ensures that we visit every position of $\bar{a}$. We may picture a walk as a piecewise linear function, with the generat*ed* word superimposed on the abscissa and the generat*ing* word on the ordinate, c.f. Figure 1.

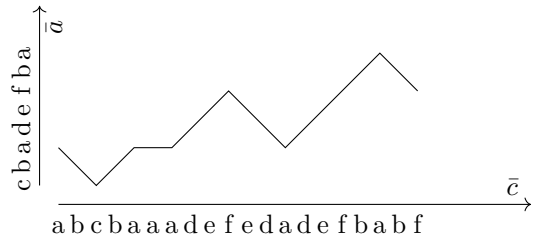

Figure 1 Generation of abcbaaadefedadefbabf from cbadefba.

Every word generates both itself and its reversal. Moreover, if $\bar{a}$ generates $\bar{c}$, then $|\bar{c}| \geq |\bar{a}|$; in fact, $\bar{a}$ and $\bar{a}^{-1}$ are the only words of length $|\bar{a}|$ generated by $\bar{a}$. Finally, generation is transitive: if $\bar{a}$ generates $\bar{b}$ and $\bar{b}$ generates $\bar{c}$, then $\bar{a}$ generates $\bar{c}$. We call $\bar{a}$ *primitive* if it is not generated by any word shorter than itself, equivalently, if it is generated only by itself and its reversal. For example, *babcd* and *abcbcd* are not primitive, because they are generated by *abcd*; but *abcbda* is primitive. Note that an infix (factor) of a primitive word need not be primitive. Define a *primitive generator* of $\bar{c}$ to be a generator of $\bar{c}$ that is itself primitive. From the foregoing remarks, it is obvious that every word $\bar{c}$ has some primitive generator $\bar{a}$, and indeed, $\bar{a}^{-1}$ as well, since the reversal of a primitive generator is clearly a primitive generator. The following result, by contrast, is anything but obvious. Notwithstanding the naturalness of the question it answers, we believe it to be new. Since it is concerned only with the combinatorics of strings, however, we refer the reader to [29] for the proof.

▶ **Theorem 3.1.** *The primitive generator of any word is unique up to reversal.*

Remarkably, while primitive generators are unique up to reversal, modes of generation are not. The word $\bar{c} = abcbcbd$ has primitive generator $\bar{a} = abcbd$. But there are *distinct* surjective functions $f, g \in \mathbf{A}_5^7$ such that $\bar{c} = \bar{a}^f = \bar{a}^g$, as is easily verified. Define the *primitive length* of any word $\bar{c}$ to be the length of any primitive generator of $\bar{c}$. By Theorem 3.1, this notion is well-defined; it will play a significant role in our analysis of the adjacent fragment. Obviously, the primitive length of $\bar{c}$ is at most $|\bar{c}|$, but will be strictly less if $\bar{c}$ is not primitive.

Let χ be a quantifier-free $\mathcal{AF}^\ell$-formula, and let $g \in \mathbf{A}_k^\ell$. We denote by χ^g the formula $\chi(x_{g(1)} \cdots x_{g(\ell)})$. We claim that $\chi^g \in \mathcal{AF}^k$. Indeed, any atom α appearing in χ is of the form $p(\mathbf{x}_k^f)$, where p is a predicate of some arity m and $f \in \mathbf{A}_\ell^m$. But then the corresponding atom in χ^g has the form $\beta \coloneqq \alpha(x_{g(1)} \cdots x_{g(\ell)}) = p(x_{g(f(1))} \cdots x_{g(f(m))}) = p(\mathbf{x}_k^{(g \circ f)})$. Since the composition of adjacent functions is adjacent, the claim follows. The following (almost trivial) lemma is useful when manipulating adjacent formulas. Recall in this regard that any function $g \in \mathbf{A}_k^\ell$ maps a k-tuple $\bar{a}$ over some set to an ℓ-tuple $\bar{a}^g$ over the same set.

▶ **Lemma 3.2.** *Let χ be a quantifier-free formula of $\mathcal{AF}^\ell$, and $g \in \mathbf{A}_k^\ell$. For any $\mathsf{sig}(\chi)$-structure $\mathfrak{A}$ and any $\bar{a} \in A^k$, we have $\mathfrak{A} \models \chi^g[\bar{a}]$ if and only if $\mathfrak{A} \models \chi[\bar{a}^g]$.*

Proof. We may assume without loss of generality that $\chi = p(\mathbf{x}_k^f)$ is atomic, with $f \in \mathbf{A}_\ell^m$; the general case follows by an easy structural induction. But then, writing $\bar{a} = a_1 \cdots a_m$, both sides of the bi-conditional amount to the statement $a_{g(f(1))} \cdots a_{g(f(m))} \in p^{\mathfrak{A}}$. ◀

The adjacent type of any tuple in $\mathfrak{A}$ is thus completely determined by that of its primitive generator. Indeed, let $\mathfrak{A}$ be a σ-structure, and $\bar{a}$ an ℓ-tuple from A. Then $\bar{a}$ has a primitive generator, say $\bar{b}$ of length $k \leq \ell$, with $\bar{a} = \bar{b}^g$ for some surjective $g \in \mathbf{A}_k^\ell$. Now consider any atomic $\mathcal{AF}^\ell$-formula α. By Lemma 3.2 we have $\mathfrak{A} \models \alpha[\bar{a}]$ if and only if $\mathfrak{A} \models \alpha^g[\bar{b}]$.

When evaluating $\mathcal{AF}^\ell$-formulas, for fixed ℓ, we can disregard any tuples whose primitive length is greater than ℓ. Indeed, consider a pair of σ-structures $\mathfrak{A}$ and $\mathfrak{A}'$ over a common domain A. We write $\mathfrak{A} \approx_\ell \mathfrak{A}'$, if, for any predicate p (of any arity $m \geq 0$), and any m-tuple $\bar{a}$ from A of primitive length at most ℓ, $\bar{a} \in p^{\mathfrak{A}}$ if and only if $\bar{a} \in p^{\mathfrak{A}'}$. That is, $\mathfrak{A} \approx_\ell \mathfrak{A}'$ just in case $p^{\mathfrak{A}}$ and $p^{\mathfrak{A}'}$ agree on all those m-tuples whose primitive length is at most ℓ. The following may be proved by structural induction, using Lemma 3.2.

▶ **Lemma 3.3.** *Let φ be an $\mathcal{AF}^\ell$-sentence, and suppose $\mathfrak{A}$ and $\mathfrak{A}'$ are $\mathsf{sig}(\varphi)$-structures over a common domain A such that $\mathfrak{A} \approx_\ell \mathfrak{A}'$. Then $\mathfrak{A} \models \varphi \Rightarrow \mathfrak{A}' \models \varphi$.*

Proof. Let ψ be a *formula* of $\mathcal{AF}^\ell$ (possibly featuring free variables), and let k ($0 \leq k \leq \ell$) be such that $\psi \in \mathcal{AF}^{[k]}$. (We may as well take the smallest such k.) We claim that, for any k-tuple of elements $\bar{a}$, $\mathfrak{A} \models \psi[\bar{a}]$ if and only if $\mathfrak{A}' \models \psi[\bar{a}]$. To see this, suppose first that ψ is atomic. We may write $\psi := p(\mathbf{x}_k^f)$, where p is a predicate (of arity, say, m), and $f \in \mathbf{A}_k^m$. If $\bar{a}$ is a k-tuple of elements from A, then $\mathfrak{A} \models \psi[\bar{a}]$ if and only if $\bar{a}^f \in p^{\mathfrak{A}}$. But the primitive length of $\bar{a}^f$ is certainly at most $k = |\bar{a}|$. This proves our claim for all k ($0 \leq k \leq \ell$) and for all *atomic* $\psi \in \mathcal{AF}^{[k]}$. The general case follows simply by structural induction. The statement of the lemma is the special case where ψ has no free variables. ◀

In view of Lemma 3.3, when considering models of $\mathcal{AF}^\ell$-sentences, it will be useful to take the extensions of predicates (of whatever arity) to be *undefined in respect of tuples whose primitive length is greater than ℓ*, since these cannot affect the outcome of semantic evaluation. That is, where ℓ is clear from context, we typically suppose any model $\mathfrak{A}$ of φ to determine whether $\bar{a} \in p^{\mathfrak{A}}$ for any m-ary predicate p and any m-tuple $\bar{a}$ *of primitive length at most ℓ*; but with respect to m-tuples $\bar{a}$ having greater primitive length, $\mathfrak{A}$ remains agnostic. To make it clear that the structure $\mathfrak{A}$ need not be fully defined, we speak of such a structure $\mathfrak{A}$ as a *layered* structure, and we refer to ℓ as its *primitive length*. Notice that the notion of primitive length is independent of the arities of the predicates interpreted. A layered structure $\mathfrak{A}$ may have primitive length, say 3, but still interpret a predicate p of arity, say, 5. In this case, it is determined whether $\mathfrak{A} \models p[babcc]$, because the primitive generator of *babcc* is *abc*; however, it will not be determined whether $\mathfrak{A} \models p[abcab]$, because *abcab* is primitive.

One of the intriguing aspects of layered structures is that they allow us to build up models of $\mathcal{AF}$-formulas layer by layer. Suppose $\mathfrak{A}$ has primitive length k; and we wish to construct a layered structure $\mathfrak{A}^+$ of primitive length $k{+}1$ over the same domain A, agreeing with the assignments made by $\mathfrak{A}$. Clearly, it suffices to fix the adjacent type of each primitive $(k{+}1)$-tuple $\bar{b}$ from A. To fix the adjacent type of $\bar{b}$ – and hence that of its reversal, $\bar{b}^{-1}$ – we consider each predicate p in turn – of arity, say, m – and decide, for any m-tuple $\bar{c}$ from A whose primitive generator is $\bar{b}$, whether $\mathfrak{A} \models p[\bar{c}]$. Now repeat this process for all pairs of mutually inverse primitive words $(\bar{b}, \bar{b}^{-1})$ from A having primitive length $k{+}1$. Since every

tuple $\bar{c}$ considered for inclusion in the extension of some predicate has primitive length $k+1$, these assignments will not clash with any previously made in the original structure $\mathfrak{A}$. Moreover, since, by Theorem 3.1, every m-tuple $\bar{c}$ assigned in this process has a unique primitive generator $\bar{b}$ (up to reversal), these assignments will not clash with each other. Thus, to increment the primitive length of $\mathfrak{A}$, one takes each inverse pair $(\bar{b}, \bar{b}^{-1})$ of primitive $(k+1)$-tuples in turn, and fixes the adjacent type of each $\bar{b}$ consistently with the existing assignments of all tuples generated by proper infixes of $\bar{b}$, as given in the original structure $\mathfrak{A}$.

We finish this section with an easy technical observation that will be needed in the sequel. Denote by $\vec{\mathbf{A}}_k^m$ the set of all functions $f \in \mathbf{A}_k^m$ such that $f(m) = k$. Thus, if $f \in \vec{\mathbf{A}}_k^m$ is used to define a walk of length m on some word $\bar{a}$ of length k, then the walk in question ends at the final position of $\bar{a}$.

▶ **Lemma 3.4.** *Let $\bar{c}$ be a word of length $m \geq 0$ over some alphabet A, and d an element of A that does not appear in $\bar{c}$. If $\bar{c}d$ is not primitive, then neither is $\bar{c}$. In fact, there is a word $\bar{a}$ of length $k < m$ and a function $f \in \vec{\mathbf{A}}_k^m$ such that $\bar{a}^f = \bar{c}$.*

Proof. Suppose $\bar{c}d = \bar{b}^g$ for some word $\bar{b}$ of length $k+1 \leq m$ and some surjective $g \in \mathbf{A}_{k+1}^{m+1}$. Since d does not occur in $\bar{c}$, it is immediate that d occupies either the first or last position in $\bar{b}$ for, otherwise, it would be encountered again in the entire traversal of $\bar{b}$ (as g is adjacent and surjective). By reversing $\bar{b}$ if necessary, assume the latter, so that we may write $\bar{b} = \bar{a}d$, with $g(m+1) = k+1$. By adjacency, $g(m) = k$, so that setting $f = g \setminus \{\langle m+1, k+1\rangle\}$, we have the required $\bar{a}$ and f. ◀

Finally, we remark that, if $f \in \vec{\mathbf{A}}_k^m$, then the function $f^+ = f \cup \langle m+1, k+1\rangle$ satisfies $f^+ \in \vec{\mathbf{A}}_{k+1}^{m+1}$. That is, we can extend f by setting $f(m+1) = k+1$, retaining adjacency.

4 Upper bounds for $\mathcal{AF}$ and $\mathcal{AF}^k$

In this section, we establish a small model property for each of the fragments $\mathcal{AF}^k$ with $k \geq 3$. Define the function $\mathfrak{t}(k, n)$ inductively by $\mathfrak{t}(0, n) = n$ and $\mathfrak{t}(k+1, n) = 2^{\mathfrak{t}(k,n)}$. We show that, for some fixed polynomial p, if φ is a satisfiable formula of $\mathcal{AF}^k$, then φ is satisfied in a structure of size at most $\mathfrak{t}(k-2, p(\|\varphi\|))$. We proceed by induction, establishing first the base case for $k = 3$, and then reducing the case $k+1$ to the case k. It follows that the satisfiability problem (= finite satisfiability problem) for $\mathcal{AF}^k$ is in $(k-2)$-NExpTime for all $k \geq 3$. The best lower complexity bound is $\lfloor k/2 \rfloor$-NExpTime-hard, from the k-variable fluted fragment [30]. For $k \leq 2$, the adjacency restriction has no effect on the complexity of satisfiability. Thus satisfiability for $\mathcal{AF}^2$ is NExpTime-complete, while for $\mathcal{AF}^1$ and $\mathcal{AF}^0$ it is NPTime-complete. We begin by establishing a normal form lemma for $\mathcal{AF}$.

▶ **Lemma 4.1.** *Let φ be a sentence of $\mathcal{AF}^{\ell+1}$, where $\ell \geq 2$. We can compute, in polynomial time, an $\mathcal{AF}^{\ell+1}$-formula ψ satisfiable over the same domains as φ, of the form*

$$\bigwedge_{i \in I} \forall \mathbf{x}_\ell \exists x_{\ell+1}\, \gamma_i \wedge \forall \mathbf{x}_{\ell+1}\, \delta, \tag{2}$$

where I is a finite index set, the formulas γ_i and δ are quantifier-free.

Let φ be a normal-form $\mathcal{AF}^{\ell+1}$-formula as given in (2), over signature σ. Recall the operation $\cdot^f$ on quantifier-free adjacent formulas employed in Lemma 3.2, as well as the sets of functions $\vec{\mathbf{A}}_k^\ell$ employed in Lemma 3.4. For any $f \in \vec{\mathbf{A}}_k^\ell$, we continue to write f^+ for the function (in $\vec{\mathbf{A}}_{k+1}^{\ell+1}$) extending f by setting $f(\ell+1) = k+1$. Now define the *adjacent closure of* φ, denoted $\varphi^\#$, to be:

$$\bigwedge_{i\in I}\bigwedge_{k=1}^{\ell-1}\bigwedge_{f\in\vec{\mathbf{A}}_k^\ell}\forall\mathbf{x}_k\exists x_{k+1}\,\gamma_i^{f^+}\wedge\bigwedge_{k=1}^{\ell}\bigwedge_{g\in\mathbf{A}_k^{\ell+1}}\forall\mathbf{x}_k\,\delta^g.$$

Observe that the conjunctions for the $\forall^\ell\exists$-formulas range over $\vec{\mathbf{A}}_k^\ell$, while the conjunctions for the purely universal formula range over the whole of $\mathbf{A}_k^{\ell+1}$. Up to trivial logical rearrangement and re-indexing of variables, $\varphi^\#$ is actually a normal-form $\mathcal{AF}^\ell$-formula. In effect, $\varphi^\#$ is the result of identifying various universally quantified variables in φ in a way which preserves adjacency. The following lemma is therefore immediate.

▶ **Lemma 4.2.** *Let $\varphi\in\mathcal{AF}^{\ell+1}$ be in normal-form. Then $\varphi\models\varphi^\#$.*

The following notation will be useful. If χ is any quantifier-free $\mathcal{AF}^{\ell+1}$-formula, we denote by χ^{-1} the formula $\chi(x_{\ell+1},\ldots,x_1)$ obtained by simultaneously replacing each variable x_h by $x_{\ell-h+2}$ $(1\leq h\leq\ell+1)$; and we denote by $\hat{\chi}$ the formula $\chi\wedge\chi^{-1}$. Obviously χ^{-1} and $\hat{\chi}$ are also in $\mathcal{AF}^{\ell+1}$. If η is an adjacent ℓ-type, we denote by η^+ the quantifier-free $\mathcal{AF}^{\ell+1}$-formula $\eta(x_2,\ldots,x_{\ell+1})$ obtained by incrementing the index of each variable. Finally, if χ is a quantifier-free $\mathcal{AF}^{\ell+1}$-formula over some signature σ (which we take to be given by context), we denote by χ° the quantifier-free $\mathcal{AF}^\ell$-formula $\bigvee\{\eta\in\mathrm{Atp}_\ell^\sigma\mid\chi\wedge\eta^+\text{ is consistent}\}$. The intuition in this last case is that, if a is an element and $\bar{a}$ an ℓ-tuple of elements such that $a\bar{a}$ satisfies χ in some structure, then χ° is the strongest statement that follows regarding $\bar{a}$.

Now we are in a position to tackle the main task of this section, namely, to bound the complexity of the satisfiability problem for $\mathcal{AF}^k$ $(k\geq 3)$. Certainly the satisfiability problem for $\mathcal{AF}^2$ is in NExpTime, since any normal-form $\mathcal{AF}^2$-formula is in FO^2. Here, we strengthen that result to $\mathcal{AF}^3$ (which will sharpen the bound of Theorem 4.9 by one exponential). The proof is similar to an analogous result for the three-variable *fluted* fragment, $\mathcal{FL}^3$ [30, Lemma 4.5]

Let σ be a relational signature. If π is a 1-type over σ, define the 2-type π^2, over the same signature, to be $\{\lambda\mid\lambda\text{ a literal in }\mathcal{AF}^{[2]}\text{ s.t. }\lambda(x_1,x_1)\in\pi\}$. The intuition here is that if π is the type of an element a in some structure, then π^2 is the type of the pair aa. A *connector-type* (*over* σ) is a set ω of 2-types over σ subject to the condition that there exists some 1-type π over σ such that $\pi^2\in\omega$ and $\zeta\models\pi$ for all $\zeta\in\omega$. This 1-type π is clearly unique, and we denote it by $\mathrm{tp}(\omega)$. If $\mathfrak{A}$ is any structure interpreting σ and $a\in A$, then a defines a connector-type ω over σ in a natural way by setting $\omega=\{\mathrm{tp}^{\mathfrak{A}}[a,b]\mid b\in A\}$. We refer to ω as *the connector-type of a in $\mathfrak{A}$*, and denote it $\mathrm{con}^{\mathfrak{A}}[a]$. It follows immediately from the above definitions that $\mathrm{tp}(\mathrm{con}^{\mathfrak{A}}[a])=\mathrm{tp}^{\mathfrak{A}}[a]$. When speaking of connector-types, we suppress reference to σ if irrelevant or clear from context.

Let φ be a normal-form formula of $\mathcal{AF}^3$, as given in (2), with $\ell=2$, with $\sigma=\mathsf{sig}(\varphi)$. In the sequel we refer freely to the subformulas γ_i $(i\in I)$ and δ of φ. Say that a connector-type ω is *compatible* with φ if the following conditions hold:

L$\exists_1$: for all $i\in I$, there exists $\eta\in\omega$ s.t. $\eta\models\gamma_i(x_1,x_1,x_2)$.

L$\exists_2$: for all ζ such that $\zeta^{-1}\in\omega$ and all $i\in I$, there exists $\eta\in\omega$ such that the $\mathcal{AF}^3$-formula $\zeta\wedge\eta^+\wedge\gamma_i\wedge\hat{\delta}$ is consistent;

L$\forall_1$: for all $\eta\in\omega$ and all $f\in\mathbf{A}_2^3$, $\eta\models\delta^f$;

L$\forall_2$: for all ζ such that $\zeta^{-1}\in\omega$ and all $\eta\in\omega$, the $\mathcal{AF}^3$-formula $\zeta\wedge\eta^+\wedge\hat{\delta}$ is consistent.

The proofs of Lemmas 4.3–4.5 are straightforward and will be omitted.

▶ **Lemma 4.3.** *If φ is a normal-form $\mathcal{AF}^3$-formula, $\mathfrak{A}\models\varphi$ and $a\in A$, then $\mathrm{con}^{\mathfrak{A}}[a]$ is compatible with φ.*

A set Ω of connector-types is said to be *coherent* if the following conditions hold:
G$\exists$: for all $\omega \in \Omega$ and all $\zeta \in \omega$, there exists $\omega' \in \Omega$ such that $\zeta^{-1} \in \omega'$;
G$\forall$: for all $\omega, \omega' \in \Omega$, there exists a 2-type ζ such that $\zeta \in \omega$ and $\zeta^{-1} \in \omega'$.

▶ **Lemma 4.4.** *Let $\mathfrak{A}$ be a structure. Then $\Omega = \{\mathrm{con}^{\mathfrak{A}}[a] \mid a \in A\}$ is coherent.*
Define a *certificate* for φ to be a non-empty, coherent set of connector-types, all of which are compatible with φ.

▶ **Lemma 4.5.** *Any satisfiable normal-form $\mathcal{AF}^3$-formula has a certificate Ω such that both $|\Omega|$ and $|\bigcup \Omega|$ are $2^{O(\|\varphi\|)}$.*

We are now in a position to obtain a bound on the size of models of $\mathcal{AF}^3$-formulas.

▶ **Lemma 4.6.** *Let φ be a normal-form $\mathcal{AF}^3$-formula over a signature σ. If φ is satisfiable, then it has a model of size $2^{O(\|\varphi\|)}$.*

Proof. We may assume without loss of generality that σ features no proposition letters. Let φ be as given by (2). By Lemma 4.5, φ has a certificate Ω of cardinality at most $2^{O(\|\varphi\|)}$; moreover the set of 2-types T occurring anywhere in Ω is $2^{O(\|\varphi\|)}$. Let $H = \{0, 1, 2\}$, let I be the index set occurring in φ, let J be a set of cardinality $343 = 7^3$, and let $g\colon J^2 \to J$ a function satisfying the conditions of Lemma 2.3 with $k = 2$. Defining $A = \Omega \times T \times H \times I \times J$, we see that $|A|$ is $2^{O(\|\varphi\|)}$, as required by the lemma. We write any element $a \in A$ as (ω, ζ, h, i, j). We shall construct a layered model $\mathfrak{A} \models \varphi$ of primitive length 3 over this domain, proceeding layer by layer. In the sequel, bear in mind that a pair or triple of elements is primitive if and only if those elements are distinct.

Stage 1. We set the 1-type of any $a = (\omega, \zeta, h, i, j)$ to be $\mathrm{tp}^{\mathfrak{A}}[a] = \mathrm{tp}(\omega)$. Clearly, all these determinations can be made independently, since σ features no proposition letters. At this point, we have a layered structure of primitive length 1.

Stage 2. Now consider any $a = (\omega, \zeta, h, i, j) \in A$ and any $\eta \in \omega$. By (G$\exists$), there exists $\omega_\eta \in \Omega$ such that $\eta^{-1} \in \omega_\eta$. For each $i' \in I$ and $j' \in J$ set $\mathrm{tp}^{\mathfrak{A}}[a, a_{i',j'}] = \eta$, where $a_{i',j'}$ denotes the element $(\omega_\eta, \eta, h{+}1, i', j')$. (Here the addition in "$h{+}1$" is taken modulo 3.) The index η ensures that the $a_{i',j'}$ are chosen to be distinct for distinct $\eta \in \omega$. Moreover, the index $h{+}1$ ensures that this process can be carried out for every $a \in A$ without danger of clashes. (This is the familiar technique of "circular witnessing" [12].) Finally, suppose $a = (\omega, \zeta, h, i, j)$ and $a' = (\omega', \zeta', h', i', j')$ are distinct elements of A for which $\mathrm{tp}^{\mathfrak{A}}[a, a']$ has not yet been defined. By (G$\forall$), there exists $\eta \in \omega$ such that $\eta^{-1} \in \omega'$, and we set $\mathrm{tp}^{\mathfrak{A}}[a, a'] = \eta$. At the end of this process, all 1- and 2-types have been defined, and we thus have a layered structure of primitive length 2. From the foregoing construction, if $a = (\omega, \zeta, h, i, j) \in A$ and $\eta \in \omega$, then there exists a constructor-type ω' such that $\mathrm{tp}^{\mathfrak{A}}[a, b] = \eta$ for each $b \in A$ of the form $(\omega', \eta, h + 1, i', j')$ (where $i' \in I$, $j' \in J$); moreover, for all $a = (\omega, \zeta, h, i, j)$ and $b = (\omega', \zeta', h', i', j')$ with $\mathrm{tp}^{\mathfrak{A}}[a, b] = \eta$, we are guaranteed that $\eta \in \omega$ and $\eta^{-1} \in \omega'$. We remark that, in particular, $\mathrm{con}^{\mathfrak{A}}[a] = \omega$. It follows from L$\exists_1$ that, for every $a \in A$ and every $i \in I$, there exists $b \in A$ such that $\gamma_i[a, a, b]$. Another way of saying this is that, for every pair of elements a_1, a_2 whose primitive length is 1 (i.e. $a_1 = a_2$), $\mathfrak{A}$ provides a witness for the formula $\exists x_3\, \gamma_i$. Likewise, it follows from L$\forall_1$ that, for every triple $\bar{a}$ whose primitive length is either 1 or 2, $\mathfrak{A} \models \delta[\bar{a}]$. Indeed, if $\bar{a} = \bar{b}^f$ where $|\bar{b}| \leq 2$, we have $\mathfrak{A} \models \delta^f[\bar{b}]$, whence $\mathfrak{A} \models \delta[\bar{a}]$ by Lemma 3.2.

Stage 3. We now increment the primitive length of $\mathfrak{A}$ to 3 by setting the adjacent 3-types of all primitive triples in $\mathfrak{A}$. Fix any pair of distinct elements $a = (\omega, \tau, h, i, j)$ and $a' = (\omega', \tau', h', i', j')$. Let us write $\zeta = \mathrm{tp}^{\mathfrak{A}}[a, a']$, so that, by construction of $\mathfrak{A}$ in the previous stage, $\zeta \in \omega$ and $\zeta^{-1} \in \omega'$. By (L$\exists_2$), there exists some $\eta \in \omega'$ such that the $\mathcal{AF}^3$-formula $\psi \coloneqq \zeta \wedge \eta^+ \wedge \gamma_i \wedge \hat{\delta}$ is consistent; let θ_i be an adjacent 3-type entailing this formula. By the construction of the previous stage again, we can find an element $b_i \coloneqq (\omega'', \eta, h' + 1, i, g(j, j')) \in A$ such that $\mathrm{tp}^{\mathfrak{A}}[a', b_i] = \eta$. We shall set $\mathrm{atp}^{\mathfrak{A}}[a, a', b_i] = \theta_i$ for all $i \in I$. From the index i, the elements b_i are distinct, and so these assignments do not clash with each other. Since θ_i entails $\zeta \wedge \eta^+$, they do not clash with the 2-types assigned so far. Since θ_i entails γ_i, the pair a, a' now has a witness in respect of the formula $\exists x_3\, \gamma_i$. From property (i) of g secured by Lemma 2.3, the triple a, a', b_i is primitive; hence the only primitive triples whose adjacent types are thereby defined are a, a', b_i and b_i, a', a. But since θ_i entails $\hat{\delta}$, neither of these triples violates $\forall x_1 x_2 x_3\, \delta$. Now repeat this construction for all pairs of distinct elements $a = (\omega, \tau, h, i, j)$ and $a' = (\omega', \tau', h', i', j')$. We claim that no tuple $\bar{c}$ is assigned to the extensions of any predicates twice in this process. Since $\bar{c}$ must have some primitive generators $a_1a_2a_3$ and $a_3a_2a_1$, the only possibility for double assignment of $\bar{c}$ is if a_3 is chosen as some witness for the pair a_1, a_2, and a_1 is chosen as some witness for the pair a_3, a_2. Remembering that a_1, a_2 and a_3 are actually quintuples, let their final components be, respectively, j, j', j''. By the choice of witnesses, $j'' = g(j, j')$ and $j = g(j'', j')$. But this contradicts property (ii) of g secured by Lemma 2.3, thus establishing the claim that no primitive triple is assigned to extensions of predicates twice. At this point, for every pair of elements a_1a_2 (of primitive length either 1 or 2) and every $i \in I$, $\mathfrak{A}$ provides a witness for the formula $\exists x_3\, \gamma_i$. Moreover, no adjacent 3-type so-far assigned violates δ. To complete the extension of $\mathfrak{A}$ to primitive length 3, it remains only to assign adjacent types to all remaining primitive triples without violating δ. Suppose, then a, a', a'' are distinct elements whose adjacent type in $\mathfrak{A}$ has not yet been defined. Let $\zeta = \mathrm{tp}^{\mathfrak{A}}[a_1, a_2]$ and $\eta = \mathrm{tp}^{\mathfrak{A}}[a_2, a_3]$. By the previous stage, $\zeta \wedge \eta^+ \wedge \hat{\delta}$ is consistent, so let θ be an adjacent 3-type entailing this formula, and set $\mathrm{tp}^{\mathfrak{A}}[a_1, a_2, a_3] = \theta$. Observe that we are also thereby assigning the adjacent 3-type of $\mathrm{tp}^{\mathfrak{A}}[a_3, a_2, a_1]$, but are assigning no other adjacent 3-types. Since θ entails $\zeta \wedge \eta^+$, this assignment does not clash with the assignments of the previous step. Since θ entails $\hat{\delta}$, no newly assigned triple violates δ. This completes the construction of the model $\mathfrak{A}$. ◀

Extending Lemma 4.6 to the whole of $\mathcal{AF}$ represents a greater challenge. For the next two lemmas (4.7 and 4.8), fix a normal-form $\mathcal{AF}^{\ell+1}$-formula φ over some signature σ, as given in (2), with $\ell \geq 3$. We construct a normal-form formula $\varphi' \in \mathcal{AF}^{\ell}$ such that: (i) if φ is satisfiable over some domain A, then so is φ'; and (ii) if φ' is satisfiable over some domain B, then φ is satisfiable over a domain A, with $|A|/|B|$ bounded by some exponential function of $\|\varphi\|$.

Recall that the adjacent closure, $\varphi^{\#}$ of φ, may be regarded as a normal-form $\mathcal{AF}^{\ell}$-formula over the same signature. For every adjacent ℓ-type ζ over σ, let p_ζ be a fresh predicate of arity $\ell{-}1$. Intuitively, we shall think of $p(x_2 \cdots x_\ell)$ as stating "*for some* x_1, the ℓ-tuple $\mathbf{x}_\ell = x_1 \cdots x_\ell$ is of adjacent type ζ". Now define φ' to be the conjunction of $\varphi^{\#}$ with the following $\mathcal{AF}^{\ell}$-formulas:

$$\bigwedge_{\zeta \in \mathrm{Atp}^{\sigma}_{\ell}} \forall \mathbf{x}_\ell \big(\zeta \to p_\zeta(x_2 \cdots x_\ell)\big) \tag{3}$$

$$\bigwedge_{\zeta \in \mathrm{Atp}^{\sigma}_{\ell}} \bigwedge_{i \in I} \forall \mathbf{x}_{\ell-1} \exists x_\ell \big(p_\zeta(\mathbf{x}_{\ell-1}) \to (\zeta \wedge \hat{\delta} \wedge \gamma_i)^{\circ}\big) \tag{4}$$

$$\bigwedge_{\zeta \in \mathrm{Atp}^{\sigma}_{\ell}} \forall \mathbf{x}_{\ell} \big(p_{\zeta}(\mathbf{x}_{\ell-1}) \to (\zeta \wedge \hat{\delta})^{\circ} \big) \tag{5}$$

▶ **Lemma 4.7.** *Suppose $\mathfrak{A} \models \varphi$. Then we can expand $\mathfrak{A}$ to a model $\mathfrak{A}^{+} \models \varphi'$.*

Proof. Set $p_{\zeta}^{\mathfrak{A}^{+}} = \{\bar{a} \in A^{\ell-1} \colon \mathfrak{A} \models \zeta[a\bar{a}] \text{ for some } a \in A\}$, for every $\zeta \in \mathrm{Atp}^{\sigma}_{\ell}$. The truth of (3) in $\mathfrak{A}^{+}$ is then immediate. To see the same for (4), fix $\zeta \in \mathrm{Atp}^{\sigma}_{\ell}$ and $i \in I$, and suppose $\mathfrak{A}^{+} \models p_{\zeta}(\bar{a})$, where $\bar{a} \in A^{\ell-1}$. Then there exists $a \in A$ such that $\mathfrak{A} \models \zeta[a\bar{a}]$. Moreover, since $\mathfrak{A} \models \varphi$, there exists $b \in A$ such that $\mathfrak{A} \models \gamma_i[a\bar{a}b]$ and $\mathfrak{A} \models \hat{\delta}[a\bar{a}b]$. Now let $\eta = \mathrm{atp}^{\mathfrak{A}}[\bar{a}b]$. Writing χ for $\zeta \wedge \hat{\delta} \wedge \gamma_i$, we have $\mathfrak{A} \models \chi[a\bar{a}b]$, whence χ is consistent; and since $\mathfrak{A} \models \eta[\bar{a}b]$, it follows that $\eta \models \chi^{\circ}$. Thus, b is a witness for the $(\ell-1)$-tuple $\bar{a}$ required by the relevant conjunct of (4). This secures the truth of (4) in $\mathfrak{A}^{+}$. Formula (5) is handled similarly. ◀

▶ **Lemma 4.8.** *Suppose $\mathfrak{B} \models \varphi'$. Then we can construct a model $\mathfrak{C}^{+} \models \varphi$ such that $|C^{+}|/|B| \leq |I| \cdot (\ell^2 + \ell + 1)^{\ell}$.*

Proof. Since $\varphi' \in \mathcal{AF}^{\ell}$, we may assume by Lemma 3.3 that $\mathfrak{B}$ is a layered structure of primitive length ℓ – that is, does not specify the extensions of predicates in respect of tuples whose primitive length is greater than ℓ. Let $\mathfrak{B}^{-}$ be the reduct of $\mathfrak{B}$ to the signature σ (i.e. we forget the predicates p_{ζ}). Thus, every ℓ-tuple from B satisfies a unique element of $\mathrm{Atp}^{\sigma}_{\ell}$. We first define a collection of "witness" functions $v_i \colon B^{\ell} \to B$, where $i \in I$. For any ℓ-tuple $\bar{b} = b_1 \cdots b_{\ell}$, let $\zeta = \mathrm{atp}^{\mathfrak{B}^{-}}[\bar{b}]$. By (3), $\mathfrak{B} \models p_{\zeta}[b_2 \cdots b_{\ell}]$, whence, by (4), we may select $b \in B$ such that $\mathfrak{B} \models (\zeta \wedge \hat{\delta} \wedge \gamma_i)^{\circ}[(b_2 \cdots b_k b)]$. Set $v_i(\bar{b}) = b$. Now let J be a set of cardinality $\ell^2 + \ell + 1$ and let $g \colon J^{\ell} \to J$ a function satisfying conditions (i) and (ii) guaranteed by Lemma 2.3. We inflate the structure $\mathfrak{B}^{-}$ using the product construction of Lemma 2.2. Specifically, we define $\mathfrak{C} = \mathfrak{B}^{-} \times (I \times J)$, writing elements of $\mathfrak{C}$ as triples (b, i, j), where $b \in B$, $i \in I$ and $j \in J$. Now, predicate extensions featuring tuples of primitive length greater than ℓ can be safely disregarded in the structure $\mathfrak{C}$. We next define a collection of witness functions $w_i \colon C^{\ell} \to C$, based on the functions v_i defined above. The motivation is that these functions will allow us to choose witnesses in $\mathfrak{C}$ for the conjuncts (4) that do not, as it were, tread on each others' toes. Consider any ℓ-tuple $\bar{c} = c_1 \cdots c_{\ell}$ of elements in C, with $c_h = (b_h, i_h, j_h)$ for each h $(1 \leq h \leq \ell)$. Writing $\bar{b} = b_1 \cdots b_{\ell}$, we define $w_i(\bar{c})$ to be the element $(v_i(\bar{b}), i, g(j_1 \cdots j_{\ell}))$. Since $\mathfrak{B}^{-} \models (\zeta \wedge \hat{\delta} \wedge \gamma_i)^{\circ}[b_2 \cdots b_{\ell}\, w_i(\bar{b})]$, it follows from Lemma 2.2 that $\mathfrak{C} \models (\zeta \wedge \hat{\delta} \wedge \gamma_i)^{\circ}[c_2 \cdots c_{\ell}\, w_i(\bar{c})]$. In addition, the functions w_i satisfy the following two additional properties:

(w1) for fixed $\bar{c}$, the $w_i(\bar{c})$ are distinct as i varies over I;
(w2) $w_i(\bar{c})$ does not occur in $\bar{c}$;
(w3) if $\bar{c}'$ is an ℓ-tuple consisting of the elements $c_2, \ldots, c_{\ell}, w_i(\bar{c})$ in some order, then $w_{i'}(\bar{c}')$ does not occur in $\bar{c}$ for any $i' \in I$.

Indeed, (w1) is immediate from the fact $w_i(\bar{c})$ contains i as its second element; (w2) and (w3) follow, respectively, from conditions (i) and (ii) on g guaranteed in Lemma 2.3.

We are now ready to extend $\mathfrak{C}$ to a structure $\mathfrak{C}^{+}$ of primitive length $\ell+1$ such that $\mathfrak{C}^{+} \models \varphi$. We first manufacture witnesses required by the conjuncts $\forall \bar{x} \exists x_{\ell+1} \gamma_i$, insofar as these are not already present. Fix any ℓ-tuple $\bar{c} = c_1 \cdots c_{\ell}$, and let $\zeta = \mathrm{atp}^{\mathfrak{C}}[\bar{c}]$. Now consider any $i \in I$, and write $c = w_i(\bar{c})$. We have two cases, depending on whether the word $\bar{c}c$ is primitive. Suppose first that it is not. By (w2), c is not an element of $\bar{c}$, whence by Lemma 3.4 there is some k-tuple $\bar{d}$ $(k < \ell)$ and $f \in \vec{\mathbf{A}}^{\ell}_{k}$ such that $\bar{d} = \bar{c}^{f}$. As before, define $f^{+} \in \vec{\mathbf{A}}^{\ell+1}_{k+1}$ extending f by setting $f(k+1) = \ell + 1$. Since $k < \ell$, and $\mathfrak{C} \models \varphi^{\#}$, there exists $c' \in C$ such that $\mathfrak{C} \models \gamma_i^{f^{+}}[\bar{d}c']$. By Lemma 3.2, $\mathfrak{C} \models \gamma_i[(\bar{d}c')^{f^{+}}]$, or in other words, $\mathfrak{C} \models \gamma_i[\bar{c}c']$, so that a witness c' is already present in respect of the tuple $\bar{c}$ and the index i. (Notice that we are throwing

our original witness, c, away.) Suppose on the other hand that $\bar{c}c$ is primitive. Since $\mathfrak{C}$ has primitive length ℓ, no tuple with primitive generator $\bar{c}c$ has been assigned to the extension of any predicate in $\mathfrak{C}$. Let $\eta = \mathrm{atp}^{\mathfrak{C}}[c_2 \cdots c_\ell c]$. Writing χ for the $\mathcal{AF}^\ell$-formula $\zeta \wedge \hat{\delta} \wedge \gamma_i$ it follows from the choice of c that $\mathfrak{C} \models \chi^\circ[\bar{c}c]$, whence, by the definition of the operator $(\cdot)^\circ$, the $\mathcal{AF}^{\ell+1}$-formula $\eta^+ \wedge (\zeta \wedge \hat{\delta} \wedge \gamma_i)$ is consistent. Therefore, there exists an adjacent $(\ell+1)$-type ω entailing it, and we may fix $\mathrm{atp}^{\mathfrak{C}^+}[\bar{c}c] = \omega$. To see that this assignment makes sense and extends $\mathfrak{C}$, recall that $\mathrm{atp}^{\mathfrak{C}^+}[\bar{c}c]$ specifies whether $\mathfrak{C}^+ \models q[\bar{d}]$ for any m-tuple $\bar{d}$ whose primitive generator is an infix, say $\bar{e}$, of $\bar{c}c$. If $\bar{e}$ is of length ℓ or less, then its adjacent type has already been fixed in $\mathfrak{C}$ consistently with ζ or η^+. Otherwise, the primitive generator of $\bar{d}$ is $\bar{c}c$, so that $\mathfrak{C}$ does not determine satisfaction of q by $\bar{d}$; writing $\bar{d} = (\bar{c}c)^f$, then, we may set $\mathfrak{C}^+ \models q[\bar{d}]$ if and only if $\models \omega \to q((\mathbf{x}_\ell x_{\ell+1})^f)$. Since $\omega \models \gamma_i$, we see that, following these assignments, $\mathfrak{C}^+$ has been provided with a witness in respect of the tuple $\bar{c}$ and the index i. We claim in addition that the newly assigned tuples do not violate $\forall \mathbf{x}_\ell x_{\ell+1}\, \delta$. For suppose that $\bar{d}$ is an $(\ell+1)$-tuple whose adjacent type in $\mathfrak{C}^+$ has been defined. If the primitive length of $\bar{d}$ is ℓ or less, then we have $\bar{d} = \bar{e}^g$ for some primitive $\bar{e}$ of length $k \leq \ell$ and some $g \in \mathbf{A}_k^{\ell+1}$. Since $\mathfrak{C} \models \varphi^\#$, we have $\mathfrak{C} \models \delta^g[\bar{e}]$, whence by Lemma 3.2, $\mathfrak{C} \models \delta[\bar{d}]$. If, however, the primitive length of $\bar{d}$ is $\ell+1$, then $\bar{d}$ is either $\bar{c}c$ or its reversal, and by the fact that $\omega \models \hat{\delta}$, we have $\mathfrak{C}^+ \models \delta[\bar{d}]$ as required. Still keeping $\bar{c}$ fixed for the moment, we may carry out the above procedure for all $i \in I$. To see that these assignments do not interfere with each other, we simply note property (w1) of the functions w_i.

Now make these assignments as just described for *each* word $\bar{c} \in C^\ell$. To ensure that these assignments do not interfere with each other, we make use of properties (w1) and (w3) of the functions w_i. If $\bar{d}$ is an m-tuple that has been assigned (or not) to the extensions of various predicates by the process described above, then the two primitive generators of $\bar{d}$ must be of the form $\bar{c}c$ and $(\bar{c}c)^{-1}$, where $c = w_i(\bar{c})$ for some $i \in I$. Since primitive generators are unique up to reversal by Theorem 3.1, it suffices to show that, for distinct pairs $(\bar{c}, i)$ and $(\bar{c}', i')$, the corresponding $(\ell{+}1)$-tuples $(\bar{c}\, w_i(\bar{c}))$ and $(\bar{c}'\, w_{i'}(\bar{c}'))$ are not the same up to reversal. Now $\bar{c}\, w_i(\bar{c}) = \bar{c}'\, w_{i'}(\bar{c}')$ implies $\bar{c} = \bar{c}'$, whence i and i' are distinct, whence $w_i(\bar{c}) \neq w_{i'}(\bar{c}')$ by (w1), a contradiction. On the other hand if $\bar{c}\, w_i(\bar{c}) = (\bar{c}'\, w_{i'}(\bar{c}))^{-1}$, then $\bar{c}' = w_i(\bar{c}), c_\ell \cdots c_2$, whence $w_{i'}(\bar{c}')$ does not occur in $\bar{c}$ by (w3), again a contradiction.

At this point, we have assigned a collection of tuples with primitive length $\ell{+}1$ to the extensions of predicates in σ so as to guarantee that $\mathfrak{C}^+ \models \forall \mathbf{x}_\ell \exists x_{\ell+1}\, \gamma_i$ for all $i \in I$. In addition, no adjacent $(\ell{+}1)$-types thus defined violate $\forall \mathbf{x}_{\ell+1}\, \delta$. It remains to complete the specification of $\mathfrak{C}^+$ by defining the adjacent types of all remaining primitive $\ell{+}1$-tuples, and showing that, in the resulting structure, every $(\ell{+}1)$-tuple (primitive or not) satisfies δ. Let $c_1 \cdots c_{\ell+1}$ be a primitive $(\ell{+}1)$-tuple whose adjacent type has not yet been defined. Let $\zeta = \mathrm{atp}^{\mathfrak{C}}[c_1 \cdots c_\ell]$ and $\eta = \mathrm{atp}^{\mathfrak{C}}[c_2 \cdots c_{\ell+1}]$. Writing $c_h = (b_h, i_h, j_h)$ for all h $(1 \leq h \leq \ell+1)$, we have $\zeta = \mathrm{atp}^{\mathfrak{B}^-}[b_1 \cdots b_\ell]$ and $\eta = \mathrm{atp}^{\mathfrak{B}^-}[b_2 \cdots b_{\ell+1}]$. By (3), $\mathfrak{B} \models p_\zeta[b_2 \cdots b_{\ell+1}]$, and hence by (5), $\mathfrak{B} \models (\zeta \wedge \hat{\delta})^\circ[b_2 \cdots b_{\ell+1}]$, whence $\zeta \wedge \eta^+ \wedge \hat{\delta}$ is consistent, by the definition of the operator $(\cdot)^\circ$. So let $\omega \in \mathrm{Atp}^\sigma_{\ell+1}$ entail this formula, and set $\mathrm{atp}^{\mathfrak{C}^+}[\bar{c}c] = \omega$. Carrying this procedure out for all remaining primitive $\ell{+}1$-tuples, we obtain a layered structure $\mathfrak{C}^+$ of primitive length $\ell+1$. Let $\bar{d}$ be any $(\ell{+}1)$-tuple of elements from C. If $\bar{d}$ is primitive, then we have just ensured that $\mathfrak{C}^+ \models \delta[\bar{d}]$. If, on the other hand, $\bar{d} = \bar{e}^f$ for some k-tuple $\bar{e}$ and some $f \in \mathbf{A}_k^{\ell+1}$, where $k \leq \ell$, then, since $\varphi^\#$, we have $\mathfrak{C} \models \delta^f[\bar{e}]$ and hence, by Lemma 3.2, $\mathfrak{C} \models \delta[\bar{d}]$. This completes the construction of $\mathfrak{C}^+$. We have shown that $\mathfrak{C}^+ \models \varphi$. ◀

Lemma 4.6 establishes the decidability of satisfiability for $\mathcal{AF}^3$. Lemmas 4.7 and 4.8, on the other hand, reduce the satisfiability problem for $\mathcal{AF}^{\ell+1}$ to that for $\mathcal{AF}^\ell$ $(\ell \geq 3)$, though with exponential blow-up. Putting these together, we obtain the decidability of satisfiability

for the whole of $\mathcal{AF}$. More precisely:

▶ **Theorem 4.9.** *If φ is a satisfiable $\mathcal{AF}^{\ell+1}$-formula, with $\ell \geq 2$, then φ is satisfied in a structure of size at most $\mathfrak{t}(\ell{-}1, O(\|\varphi\|))$. Hence the satisfiability problem for $\mathcal{AF}^{\ell}$ is in $(\ell{-}2)$-NExpTime for all $\ell \geq 3$, and the adjacent fragment is Tower-complete.*

Proof. Fix $\ell \geq 2$ and suppose φ is a satisfiable $\mathcal{AF}^{\ell+1}$-formula over a signature σ. By Lemma 4.1, we may assume that φ is in normal form. Writing $\varphi_{\ell+1}$ for φ, let φ_ℓ be the formula φ' given by the conjunction of $\varphi^{\#}$ and formulas (3)–(5) as described before Lemma 4.7. Repeating this process, we obtain a sequence of formulas $\varphi_{\ell+1}, \ldots, \varphi_3$. By Lemma 4.7, φ_3 is satisfiable. For all k, $(3 \leq k \leq \ell+1)$, let φ_k have signature σ_k, and for $k \leq \ell$, consider the construction of φ_k from φ_{k+1}. Since $\sum_{k'=1}^{k+1} |\mathbf{A}_{k'}^{k+1}|$ is bounded by a constant, we see that $\|\varphi_{k+1}^{\#}\|$ is $O(\|\varphi_{k+1}\|)$. Turning now to the formulas corresponding to (3)–(5), we employ the same technique used in the proof of Lemma 4.5. When considering the adjacent k-types over σ_{k+1}, we may disregard all adjacent atoms whose argument sequence is not a substitution instance of some argument sequence $\mathbf{x}_k^g$ occurring in an atom of φ_{k+1}, as these cannot affect the evaluation of φ_{k+1}. And since $k \leq \ell$, the number of functions from $\mathbf{x}_k$ to itself is again bounded by a constant, so that the number of adjacent k-atoms over σ_{k+1} that we need to consider is $O(\|\varphi_{k+1}\|)$. Thus, the number of adjacent k-types over σ_{k+1} that we need to consider is $2^{O(\|\varphi_{k+1}\|)}$; and this bounds the number of conjuncts in (3)–(5) taken together. Some care is needed when calculating the sizes of these conjuncts themselves, as they feature the subformulas $(\zeta \wedge \hat{\delta} \wedge \gamma_i)^\circ$ and $(\zeta \wedge \hat{\delta})^\circ$. However, these are simply, in effect, disjunctive normal forms over atoms contained in φ_{k+1}, and hence have cardinality $2^{O(\|\varphi_{k+1}\|)}$, whence $\|\varphi_k\|$ is $2^{O(\|\varphi_{k+1}\|)}$. By an easy induction, then, $\|\varphi_3\|$ is $\mathfrak{t}(\ell-2, O(\|\varphi_{\ell+1}\|))$, i.e. $\mathfrak{t}(\ell-2, O(\|\varphi\|))$.

By Lemma 4.6, φ_3 has a model of cardinality $\mathfrak{t}(\ell-1, O(\|\varphi\|))$. Moreover, by Lemma 4.7, each of the formulas φ_k $(3 \leq k \leq \ell)$ has a model over a set, say B_k, such that $|B_{k+1}| \leq |B_k| \cdot \|\varphi_{k+1}\| \cdot (\ell^2+\ell+1)^\ell$. Since $\|\varphi_k\|$ is $\mathfrak{t}(\ell-3, O(\|\varphi\|))$ for all k and remembering that ℓ is a constant, we see that $\varphi = \varphi_{\ell+1}$ has a model of cardinality $O(\|\varphi\|^{\ell-1}\mathfrak{t}(\ell-1, O(\|\varphi\|)))$, that is to say $\mathfrak{t}(\ell-1, O(\|\varphi\|))$. ◀

5 The Guarded Subfragment

We next shift our attention to the *guarded subfragment* of the adjacent fragment, denoted $\mathcal{GA}$, defined as the intersection of the guarded fragment $\mathcal{GF}$ and $\mathcal{AF}$. Recall that in $\mathcal{GF}$, quantification is relativized by atoms, e.g. all universal quantification takes the form $\forall \bar{x}(\alpha \to \psi)$, where α (a *guard*) is an atom featuring all the variables in $\bar{x}$ and all the free variables of ψ. We show that the satisfiability problem for $\mathcal{GA}$, in contrast to $\mathcal{GF}^2$ (the two-variable guarded fragment), is 2ExpTime-complete, and thus as difficult as full $\mathcal{GF}$.

Our proof employs the same strategy as the 2ExpTime-hardness proof for $\mathcal{GF}$ by Grädel [11]. The novel part of the reduction here concerns a feature characteristic of hardness results for guarded logics [11, 19]. However, the fact that we are working in the guarded *adjacent* fragment means that existing techniques are not directly available.

Let $m \in \mathbb{N}$ and consider the following adjacent functions (the upper index is mapped to the lower one):

$$\lambda_1 \coloneqq \begin{pmatrix} 1 & 2 & 3 & 4 & \ldots & m{+}2 \\ 1 & 2 & 2 & 3 & \ldots & m{+}1 \end{pmatrix}, \lambda_2 \coloneqq \begin{pmatrix} 1 & 2 & 3 & 4 & \ldots & m{+}2 \\ 1 & 2 & 1 & 2 & \ldots & m \end{pmatrix}, \lambda_3 \coloneqq \begin{pmatrix} 1 & 2 & 3 & 4 & \ldots & m{+}2 \\ 1 & 2 & 3 & 3 & \ldots & m{+}1 \end{pmatrix}.$$

We show that repeated application of λ_1–λ_3 on the bit-string $\mathbf{011}^m$ yields the whole of $\mathbf{01}\{\mathbf{0},\mathbf{1}\}^m$.

▶ **Lemma 5.1.** *Let* $W_0 \subseteq \{\mathbf{0},\mathbf{1}\}^*$ *contain* $\mathbf{011}^m$ *and* $W_i \coloneqq W_{i-1} \cup \{\bar{w}^{\lambda_1}, \bar{w}^{\lambda_2}, \bar{w}^{\lambda_3} \mid \bar{w} \in W_{i-1}\}$. *Setting* $W \coloneqq \bigcup_{i\geq 0} W_i$, *we have* $\mathbf{01}\{\mathbf{0},\mathbf{1}\}^m \subseteq W$.

Proof. We inductively prove that, for any $i \in [0,m]$ and any $\bar{c} \in \{\mathbf{0},\mathbf{1}\}^i$, we have $\mathbf{01}\bar{c}\mathbf{1}^{m-i} \in W$. The base case ($i = 0$) follows from the assumption that W_0 contains $\mathbf{011}^m$, so let $i > 0$. We aim at generating any word $u = \mathbf{01}x\bar{c}\mathbf{1}^{m-i-1}$ for $x \in \{\mathbf{0},\mathbf{1}\}$. By induction hypothesis both $\bar{v} = \mathbf{01}\bar{c}\mathbf{1}^{m-i-1}\mathbf{1}$ and $\bar{w} = \mathbf{01}\bar{d}\mathbf{1}^{m-i-1}\mathbf{11}$ (where $\bar{c} = c_1\bar{d}$) are in W. We consider cases: (i) if $x = \mathbf{1}$ then $\bar{u} = \bar{v}^{\lambda_1}$, (ii) if both x and $c_1 = \mathbf{0}$ then $\bar{u} = \bar{v}^{\lambda_3}$, and otherwise, (iii) $x = \mathbf{0}$, $c_1 = \mathbf{1}$ and $\bar{u} = \bar{w}^{\lambda_2}$. Thus $\bar{u} \in W$. ◀

Let G_m and P be, respectively, $(m+2)$-ary and binary predicates. We define ζ_m^P to be the sentence below:

$$\forall xy\,\Big(P(xy) \to G_m(xy\underbrace{y\cdots y}_{m})\Big) \wedge \bigwedge_{i=1,2,3} \forall \mathbf{z}_{m+2}\,\Big(G_m(\mathbf{z}_{m+2}) \to G_m(\mathbf{z}_{m+2}^{\lambda_i})\Big).$$

Let $\mathfrak{A}$ be a model of ζ_m^P, and take any $(a,b) \in P^{\mathfrak{A}}$. By Lemma 5.1 we conclude that $G_m^{\mathfrak{A}}$ contains every word of the form $ab\{a,b\}^m$. Let R be some 4-ary relation symbol. In the forthcoming proof we also consider a $(2m+4)$-ary predicate F_m described by ϵ_m^R which is a conjunction of the following two sentences:

$$\forall yxx'y'\,\Big(R(yxx'y') \to F_m(\underbrace{y\ldots y}_{m}yxx'y'\underbrace{y'\ldots y'}_{m})\Big)$$

$$\bigwedge_{i,j\in\{0,1,2,3\}} \forall \mathbf{z}_{m+2}^{-1}\mathbf{z}'_{m+2}\,\Big(F_m(\mathbf{z}_{m+2}^{-1}\mathbf{z}'_{m+2}) \to F_m(z_{\lambda_i(m+2)}\cdots z_{\lambda_i(1)}z'_{\lambda_j(1)}\cdots z'_{\lambda_j(m+2)})\Big).$$

Here λ_0 is the identity function (i.e. $k \mapsto k$ for each $k \in [1,m]$). The intended meaning is that whenever $\mathfrak{A} \models \zeta_m^R$ holds, this implies that for any quadruple $baa'b' \in R^{\mathfrak{A}}$ we have that $\mathfrak{A} \models G[\bar{c}baa'b'\bar{c}']$ holds for all $\bar{c} \in \{a,b\}^m$ and $\bar{c}' \in \{a',b'\}^m$.

ATMs. An *Alternating Turing Machine* (ATM) $\mathcal{M}$ is a tuple $\langle \mathcal{Q}, \mathcal{S}, \mathcal{T}_l, \mathcal{T}_r, q_0, \kappa\rangle$, where $\mathcal{Q}$ is a finite set of states, $\mathcal{S}$ is a finite alphabet containing an empty-cell symbol "␣", $\mathcal{T}_l, \mathcal{T}_r : \mathcal{Q}\times\mathcal{S} \to \mathcal{Q}\times\mathcal{S}\times[-1,1]$ are, respectively, the left and right transition functions, $q_0 \in Q$ is the initial state, and $\kappa : \mathcal{Q} \to \{\forall,\exists\}$ is the state descriptor function stating if a given state is, respectively, *universal* $\forall$ or *existential* $\exists$. We say that a state q is *accepting* if and only if $\kappa(q) = \forall$, and there are no possible transitions given by $\mathcal{T}_l(q,s)$ and $\mathcal{T}_r(q,s)$ for any symbol $s \in \mathcal{S}$. Dually, q is *rejecting* if and only if $\kappa(q) = \exists$, and, again, there are no possible transitions. By tracking every step of the computation by $\mathcal{M}$ on $\bar{w} \in \mathcal{S}^*$ we obtain a binary tree structure $\mathcal{G} = \langle \mathcal{V}, \mathcal{E}_l, \mathcal{E}_r\rangle$. Each vertex $v \in \mathcal{V}$ is labelled with some *configuration* $\langle q, \bar{s}, h\rangle$, where $q \in \mathcal{Q}$ is a machine state, $\bar{s} \in \mathcal{S}^m$ a word indicating the contents of the tape, and $h \in [0, m-1]$ an integer indicating the position of the head at some point in the computation. Each edge $(v,u) \in \mathcal{E}_\eta$ (where $\eta = l, r$) is labelled by a transition $\mathcal{T}_\eta(q, s_h)$, enabled in the configuration labelling of v. We call $\mathcal{G}$ the *configuration tree* of the computation by $\mathcal{M}$ on $\bar{w}$. Assuming $\mathcal{G}$ is finite, we say that it is *accepting* if no vertex is associated with a rejecting state. We identify the following three properties of $\mathcal{G}$. The root node is labelled with a configuration in which the machine is in state q_0, the head position is 0, and the tape is written with the string $\bar{w}$ followed by blanks. We call this property *initial configuration* (**IC**). Let u be a vertex labelled with a configuration in which the machine is in state q. If q is universal, then u will have two children; if q is existential, then u will have a single child;

if q is accepting, or rejecting then u will have no children. We call this property *successor existence* (**SE**). Suppose further that, in the configuration labelling of some node u we have that the head is reading the symbol s whilst in state q. Then any child v_η (s.t. $(u, v_\eta) \in \mathcal{T}_\eta$, where $\eta = l$ or $\eta = r$) represents the result of a single transition $\mathcal{T}_\eta(q, s) = (p, s', k)$, and thus is labelled with a configuration in which the machine state is p, s' is written in place of s, and the head is moved by a distance of k. We call this property *configuration succession* (**CS**).

Encoding numbers. Let $\text{BIN}^m_{x,y}$ be the canonical map from $[0, 2^n - 1]$ to bit-string representations of length $m \in \mathbb{N}$, using x as the *zero bit* and y as the *unit bit*. In the sequel, we will consider structures $\mathfrak{A}$ with elements labelled by a unary predicate O. If $\mathfrak{A} \models \neg O[a] \wedge O[b]$ we say that a, b *act as zero and unit bits*. We thus associate every word $\bar{c} \in \{a, b\}^+$ with an integer value given by the canonical map $\text{VAL}^{\mathfrak{A}}$ (this function depends on $\mathfrak{A}$, because it is $\mathfrak{A}$ that determines which is the zero bit and which is the unit bit.) Given two bit-strings $\bar{c}$ and $\bar{d}$ (not necessarily composed of the same elements) there is a classical way to define the following properties in the monadic fragment of FO (hence also in $\mathcal{GA}$):

- $\mathfrak{A} \models \text{LESS}(\bar{c}, \bar{d})$ iff $\text{VAL}^{\mathfrak{A}}(\bar{c}) < \text{VAL}^{\mathfrak{A}}(\bar{d})$
- $\mathfrak{A} \models \text{EQ}(\bar{c}, \bar{d})$ iff $\text{VAL}^{\mathfrak{A}}(\bar{c}) = \text{VAL}^{\mathfrak{A}}(\bar{d})$
- $\mathfrak{A} \models \text{EQ}(\bar{c}, \bar{d} + k)$ iff $\text{VAL}^{\mathfrak{A}}(\bar{c}) = \text{VAL}^{\mathfrak{A}}(\bar{d}) + k$, where $k \in [-1, 1]$.

Formally, the formulas are defined as follows:

$$\text{LESS}(\mathbf{z}_m, \mathbf{z}'_m) \coloneqq \bigvee_{i=1}^{m} \Big(\neg O(z_i) \wedge O(z'_i) \wedge \bigwedge_{j=i+1}^{m} \big(O(z_j) \leftrightarrow O(z'_j) \big) \Big)$$

$$\text{EQ}(\mathbf{z}_m, \mathbf{z}'_m) \coloneqq \bigwedge_{i=1}^{m} \Big(O(z_i) \leftrightarrow O(z'_i) \Big)$$

$$\text{EQ}(\mathbf{z}_m, \mathbf{z}'_m + 1) \coloneqq \bigwedge_{i=1}^{m} \Big(\big(O(z_i) \leftrightarrow O(z'_i) \big) \leftrightarrow \bigvee_{j=1}^{i-1} O(z_j) \Big)$$

and where $\text{EQ}(\mathbf{z}_m, \mathbf{z}'_m + 0) \coloneqq \text{EQ}(\mathbf{z}_m, \mathbf{z}'_m)$ and $\text{EQ}(\mathbf{z}_m, \mathbf{z}'_m - 1) \coloneqq \text{EQ}(\mathbf{z}'_m, \mathbf{z}_m + 1)$.

Fix an ATM $\mathcal{M}$ working in exponential space w.r.t any given input $\bar{w}$. Our goal is to construct a polynomial-size $\mathcal{GA}$-sentence $\varphi_{\mathcal{M},\bar{w}}$ which is satisfiable if and only if $\mathcal{M}$ has an accepting configuration tree on a given input $\bar{w}$. Utilising the fact that AExpSpace equals 2ExpTime, the reduction yields the desired bound on $\mathcal{GA}$. Now, take an accepting configuration tree $\mathcal{G} = (\mathcal{V}, \mathcal{E}_l, \mathcal{E}_r)$ for $\mathcal{M}$ and $\bar{w}$, and fix $n = |\bar{w}|$. We consider structures interpreting binary predicates V, R, Q_q (for each $q \in \mathcal{Q}$), quaternary predicates E_l, E_r and n-ary predicates H, S_s (for each $s \in \mathcal{S}$). We say that $\mathfrak{A}_0$ *embeds* $\mathcal{G}$ if there is $f : \mathcal{V} \to A_0^2$ such that for all $v \in \mathcal{V}$

(a) $\mathfrak{A}_0 \models V[f(v)]$,
(b) $\mathfrak{A}_0 \models R[f(v)]$ if v is the root node,
(c) $\mathfrak{A}_0 \models E_\eta[f(u)^{-1}, f(v)]$ if $(u, v) \in \mathcal{E}_\eta$, where $\eta = l, r$,
(d) $\mathfrak{A}_0 \models Q_q[f(v)]$ if the configuration v is in state q,
(e) $\mathfrak{A}_0 \models S_s[\text{BIN}^n_{f(v)}(i)]$ if v's i-th tape cell has symbol s,
(f) $\mathfrak{A}_0 \models H[\text{BIN}^n_{f(v)}(i)]$ if v's head is located over the i-th tape square.

We construct $\mathfrak{A}_0$ embedding $\mathcal{G}$ as follows: the domain A_0 is composed of fresh symbols $0_v, 1_v$ for each vertex $v \in \mathcal{V}$, for which we also put $f(v) = 0_v 1_v$. (Notice that $0_v 1_v$ is a word over A_0 of length 2.) We interpret the predicates V, R, E, Q_q, S_s and H as required by conditions (a)–(f). Then, we construct a $\varphi_{\mathcal{M},\bar{w}}$ in $\mathcal{GA}$ such that: (i) $\mathfrak{A}_0$ can be expanded to a model $\mathfrak{A}$ of $\varphi_{\mathcal{M},\bar{w}}$; and (ii) every model of $\varphi_{\mathcal{M},\bar{w}}$ embeds $\mathcal{G}$.

The first conjunct of $\varphi_{\mathcal{M},\bar{w}}$ requires pairs ab satisfying the predicate V to act as zero bits and unit bits, indicated by the predicate O:

$$\varphi_1 = \forall xy \Big(V(xy) \to \neg O(x) \wedge O(y) \Big)$$

We now add ζ_n^V and ζ_{2n}^V to the main formula $\varphi_{\mathcal{M},\bar{w}}$. Recall that the sentence ζ_m^V features an $(m+2)$-ary predicate G_m, and ensures that, if $\mathfrak{A} \models V[ab]$, then $\mathfrak{A} \models G_m[ab\bar{c}]$ for all $c \in \{a,b\}^m$. Writing φ_2, φ_3 and φ_4 as

$$\bigwedge_{p,q\in\mathcal{Q}}^{p\neq q} \forall xy \Big(V(xy) \to \big(\neg Q_p(xy) \vee \neg Q_q(xy) \big) \Big),$$

$$\bigwedge_{s,s'\in\mathcal{S}}^{s\neq s'} \forall xy\mathbf{z}_n \Big(G_n(xy\mathbf{z}) \to \neg \big(S_s(\mathbf{z}_n) \wedge S_{s'}(\mathbf{z}_n) \big) \Big),$$

$$\forall xy\mathbf{z}_n\mathbf{z}'_n \Big(G_{2n}(xy\mathbf{z}_n\mathbf{z}'_n) \to \Big(\big(H(\mathbf{z}_n) \wedge H(\mathbf{z}'_n) \big) \to \textsc{eq}(\mathbf{z}_n, \mathbf{z}'_n) \Big) \Big)$$

respectively, we ensure that every configuration is in at most one state at a time, every tape square of a configuration has at most one symbol, and the read-write head of any configuration is pointing to a single square at a time. Note that all of these formulas are guarded. However, the advertised behaviour of the guard predicates G_n and G_{2n} means, in essence, that the guards have no semantic effect.

We now secure the property (**IC**). Let μ_1 abbreviate the formula $Q_{q_0}(xy) \wedge H(\textsc{bin}^n_{xy}(0)) \wedge \bigwedge_{i=1}^{|\bar{w}|} S_{w_i}(\textsc{bin}^n_{x,y}(i{-}1))$, and μ_2 the formula $\textsc{less}(\textsc{bin}^n_{x,y}(|\bar{w}|{-}1), \mathbf{z}_n) \to S_{\sqcup}(\mathbf{z}_n)$. Writing

$$\varphi_5 \coloneqq \exists xy \Big(V(xy) \wedge R(xy) \Big) \wedge \forall xy \Big(R(xy) \to \big(\mu_1 \wedge \forall \mathbf{z}_n (G(xy\mathbf{z}_n) \to \mu_2) \big) \Big),$$

we ensure that there is a root configuration in which the machine state is q_0, the head is scanning square "0", and the tape is written with the string $\bar{w}$ followed by the requisite number of blanks.

Let $\mathrm{K}_\forall$ be the formula $\bigvee_{q\in\mathcal{Q}}^{\kappa(q)=\forall} Q_q(xy)$, and define $\mathrm{K}_\exists$ analogously. Similarly, we define $\mathrm{K}_\times$ to be a disjunction of rejecting states. The formula $\varphi_6 \coloneqq \forall xy(V(xy) \to \neg \mathrm{K}_\times(xy))$ ensures that no configuration is labelled with a rejecting state.

We next encode the transitions of $\mathcal{M}$, securing the property (**SE**). Let $\psi_\forall$ abbreviate the formula $\exists x'y' E_l(yxx'y') \wedge \exists x'y' E_r(yxx'y')$, and $\psi_\exists$ the formula $\exists x'y' E_l(yxx'y') \vee \exists x'y' E_r(yxx'y')$. Writing

$$\varphi_7 \coloneqq \bigwedge_{k=\forall,\exists} \forall yx \Big(V(xy) \to \Big(\mathrm{K}_k(xy) \to \psi_k \Big) \Big).$$

we ensure that, if $\mathfrak{A} \models V[a,b] \wedge \mathrm{K}_k[ab]$, then $\mathfrak{A}$ contains pairs encoding the appropriate successor configurations.

We next ensure that the transitions have the expected effect on the configurations they connect, securing the property (**CS**). For this, we need a further predicate, F_n, to act as a dummy guard. By adding $\epsilon_n^{E_\eta}$ to the main formula (for both $\eta = l, r$), we secure $\mathfrak{A} \models F_n[\bar{c}baa'b'\bar{c}']$ for all a, b, a', b' such that $\mathfrak{A} \models E_\eta[baa'b']$ with $\bar{c} \in \{a,b\}^n$, $\bar{c}' \in \{a',b'\}^n$. The formula φ_8 then ensures that any pair of parent and successor configurations have identical tape contents except (possibly) for the position scanned by the head, thus:

$$\varphi_8 \coloneqq \forall \mathbf{z}_n yxx'y'\mathbf{z}'_n \Big(F_n(\mathbf{z}_n yxx'y'\mathbf{z}'_n) \rightarrow \Big(\Big(\big(\neg H(\mathbf{z}_n) \wedge \textsc{eq}(\mathbf{z}_n, \mathbf{z}'_n)\big) \rightarrow \Big(\bigwedge_{s\in\mathcal{S}} \big(S_s(\mathbf{z}_n) \rightarrow S_s(\mathbf{z}'_n)\big)\Big)\Big)\Big).$$

Now let χ_1 abbreviate the formula $Q_p(x'y')$, χ_2 the formula $\textsc{eq}(\mathbf{z}'_n, \mathbf{z}_n) \rightarrow S_{s'}(\mathbf{z}'_n)$, and χ_3 the formula $\textsc{eq}(\mathbf{z}'_n, \mathbf{z}_n + k) \rightarrow H(\mathbf{z}'_n)$. In addition, we write ξ_{τ_η} for the sentence

$$\forall \mathbf{z}_n yxx'y'\mathbf{z}'_n \Big(G(\mathbf{z}_n yxx'y'\mathbf{z}'_n) \rightarrow \Big(\big(E_\eta(yxx'y') \wedge Q_q(xy) \wedge H(\mathbf{z}_n) \wedge S_s(\mathbf{z}_n)\big) \rightarrow \big(\chi_1 \wedge \chi_2 \wedge \chi_3\big)\Big)\Big).$$

Assuming the transition τ_η is of the form $(q, s) \mapsto (p, s', k)$, the formula ξ_{τ_η} states that, if in a certain configuration, the machine state is q and the head is reading symbol s, then in the η-side successor configuration defined by $\mathcal{T}_\eta$, the machine state will be p, the symbol s will have been replaced by s', and the head will have moved by k. To encode all possible transitions, we write φ_9 to be a conjunction of ξ_{τ_η} for each transition $\tau_\eta \in \mathcal{T}_\eta$ for both $\eta = l, r$.

Let $\mathfrak{A}_0$ embed some accepting $\mathcal{G}$ as described in (a)–(f). We expand $\mathfrak{A}_0$ to $\mathfrak{A}$ by setting $A = A_0$ with

1. $\mathfrak{A} \models \neg O[a]$ and $\mathfrak{A} \models O[b]$ if $\mathfrak{A}_0 \models V[ab]$,
2. $\mathfrak{A} \models G_m[ab\bar{c}]$ where $\mathfrak{A}_0 \models V[ab]$ and $\bar{c} \in \{a, b\}^m$ (for $m = n, 2n$),
3. $\mathfrak{A} \models F_n[\bar{c}baa'b'\bar{c}']$ where $\mathfrak{A}_0 \models S_\eta[baa'b']$, $\bar{c} \in \{a, b\}^n$ and $\bar{c}' \in \{a', b'\}^n$ (here $\eta = l, r$).

Recalling that $\mathcal{G}$ contains an initial configuration (**IC**), we have that $\mathfrak{A} \models \varphi_5$. Additionally, $\mathcal{G}$ has the property (**SE**), we see that $\mathfrak{A} \models \varphi_7$. Lastly, since $\mathcal{G}$ has the property (**CS**), we have that $\mathfrak{A} \models \varphi_8$. At this point it is easy to verify that $\mathfrak{A} \models \varphi_{\mathcal{M},\bar{w}}$.

Conversely, suppose $\mathfrak{A} \models \varphi_{\mathcal{M},\bar{w}}$. We construct an embedding $f\colon \mathcal{V} \rightarrow A^2$ for an accepting $\mathcal{G}$ by well-founded induction. The following observations will be used. Suppose $\mathfrak{A} \models V[ab]$. Intuitively, we think of the pair ab as a vertex of the computation tree labelled by some configuration, as determined by the predicates Q_q, S_s and H. By φ_2, there is a unique Q_q (for $q \in \mathcal{Q}$) satisfied by ab. Moreover, by φ_3, any bit-string $\bar{c} \in \{a, b\}^n$ satisfies a unique S_s (for $s \in \mathcal{S}$). Similarly, by φ_4, there is a unique $\bar{c}$ satisfying H.

Proceeding with the induction, for the base case, pick a, b s.t. $\mathfrak{A} \models R[ab]$. By φ_5 we see that $\mathfrak{A} \models Q_{q_0}[ab]$, $\mathfrak{A} \models H[\textsc{bin}^n_{a,b}(0)]$, and $\mathfrak{A} \models S_{w_i}[\bar{c}]$ for each $1 \leq i \leq |\bar{w}|$ with $\textsc{val}^{\mathfrak{A}}(\bar{c}) = i-1$ and $\mathfrak{A} \models S_\sqcup[\bar{c}]$ otherwise. We then set $\mathcal{V} = \{v\}$ and $f(v) = ab$. Labeling v with the state, tape and head position as suggested by (a)–(f), we have secured the property (**IC**).

For the inductive step, let u be vertex which has been added to the tree. Assume u is labelled with a configuration in which the machine state q is universal, and the head is at position h, reading symbol s. If q is accepting, then we stop. Otherwise, φ_7 guarantees that there are words $a_\eta b_\eta \in A^2$ such that $\mathfrak{A} \models S_\eta[f(u)^{-1} a_\eta b_\eta]$ for both $\eta = l, r$. Notice that by φ_8 if the configuration labelling u has the symbol s' written on tape square i (for $i \neq h$), then $\mathfrak{A} \models S_{s'}[\textsc{bin}^n_{a_\eta b_\eta}(i)]$. By φ_9 the pair $a_\eta b_\eta$ satisfies the predicate Q_p that is in accordance with the transition $\mathcal{T}_\eta(q, s) = (p, s', k)$. Additionally, $\mathfrak{A} \models S_{s'}[\textsc{bin}^n_{a_\eta b_\eta}(h)]$ and $\mathfrak{A} \models H[\textsc{bin}^n_{a_\eta b_\eta}(h + k)]$.

We thus set $\mathcal{V} \coloneqq \mathcal{V} \cup \{v_\eta\}$, $f(v_\eta) = (a_\eta, b_\eta)$ and $\mathcal{E}_\eta \coloneqq \mathcal{E}_\eta \cup \{(u, v_\eta)\}$ thus securing (**SE**). By interpreting the state, tape and head position of v_η as suggested by (a)–(f) we see that v_η is a proper successor of u as required by (**CS**). The case for when q is existential is similar.

Since there are no rejecting states in conf. tree (reference φ_6), there is an initial configuration by (**IC**), each parent has children complying with (**SE**), and each parent-child pair conforms to (**CS**), we conclude that $\mathcal{G}$ is an accepting configuration tree.

6 Conclusions

The adjacent fragment $\mathcal{AF}$ is defined as the union of the formulas sets $\mathcal{AF}^{[k]}$, each of which restricts the allowed argument sequences appearing in atomic formulas to *adjacent* words over the alphabet $\mathbf{x}_k$. The question arises as to whether these restrictions might be further relaxed without compromising the decidability of satisfiability. Under reasonable assumptions about the fragment in question, the answer must be no. Indeed, assume, for simplicity, that the argument sequence x_1x_2 is allowed in the 2-variable case, and x_2x_3 in the 3-variable case. Now the only non-adjacent words of length 2 over $\mathbf{x}_3$ are x_1x_3 and x_3x_1. In the first case, this allows us to write the formula $\forall x_1 \forall x_2 (r(x_1x_2) \to \forall x_3 (r(x_2x_3) \to r(x_1x_3)))$, which says that r is transitive. But even two-variable logic with (at least two) transitive relations yields a logic for which satisfiability and finite satisfiability are undecidable [20], since it is simple to write formulas all of whose models embed grids of unbounded size. Similar remarks apply to the formula $\forall x_1 \forall x_2 (r(x_1x_2) \to \forall x_3 (r(x_2x_3) \to r(x_3x_1)))$, and indeed to the case of formulas featuring ternary non-adjacent atoms such as $p(x_1x_3x_2)$. It is therefore difficult to conceive of meaningful fragments of first-order logic defined purely by reference to restrictions on the allowable argument sequences that do not define sub-fragments of the adjacent fragment, and that are at the same time decidable for satisfiability. In this respect, $\mathcal{AF}$ appears to be the end of the road.

On the other hand, the last two decades have witnessed concerted attempts to investigate the decidability of the satisfiability problem for FO^2 over various classes of structures, where some distinguished predicates are interpreted in a special way, e.g. as linear orders [24, 36, 37]; other such semantic constraints have also been investigated [25, 10, 21, 7, 9, 3]. It is therefore natural to ask whether the adjacent fragment remains decidable when subject to similar semantic constraints. Of course, since $\mathcal{AF}$ extends FO^2, all the undecidability results for FO^2 immediately transfer to $\mathcal{AF}$. Thus, $\mathcal{AF}$ extended with two transitive relations [20], or with three equivalence relations [22], or with one transitive and one equivalence relation [24], or with two linear orders and their two corresponding successor relations [25], must all be undecidable. (See [23] for a survey.) Regarding positive results, existing results on the fluted fragment give cause for some hope. Thus, for example, the fluted fragment remains decidable with the addition of one transitive relation (and equality) [31]; moreover, *finite* satisfiability for FO^2 with one transitive relation is also known to be decidable [27].

A second generalization of FO^2 which preserves decidability of satisfiability is the extension with counting quantifiers [26, 28, 6]. (Here, however, the finite model property is lost.) It has been shown that the corresponding extension of the fluted fragment retains the finite model property [28]. Extending the adjacent fragment with counting quantifiers certainly results in loss of the finite model property, because $\mathcal{AF}$ includes FO^2; however, the decidability of the satisfiability and finite satisfiability problems is left for future work.

Abstract

We investigate expansions of Presburger arithmetic ($\mathcal{P}\boldsymbol{a}$), i.e., the theory of the integers with addition and order, with additional structure related to exponentiation: either a function that takes a number to the power of 2, or a predicate $2^{\mathbb{N}}$ for the powers of 2. The latter theory, denoted $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot))$, was introduced by Büchi as a first attempt at characterizing the sets of tuples of numbers that can be expressed using finite automata; Büchi's method does not give an elementary upper bound, and the complexity of this theory has been open. The former theory, denoted as $\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$, was shown decidable by Semenov; while the decision procedure for this theory differs radically from the automata-based method proposed by Büchi, Semenov's method is also non-elementary. And in fact, the theory with the power function has a non-elementary lower bound. In this paper, we show that while Semenov's and Büchi's approaches yield non-elementary blow-ups for $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot))$, the theory is in fact decidable in triply exponential time, similarly to the best known quantifier-elimination algorithm for $\mathcal{P}\boldsymbol{a}$. We also provide a NExpTime upper bound for the existential fragment of $\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$, a step towards a finer-grained analysis of its complexity. Both these results are established by analyzing a single parameterized satisfiability algorithm for $\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$, which can be specialized to either the setting of $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot))$ or the existential theory of $\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$. Besides the new upper bounds for the existential theory of $\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$ and $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot))$, we believe our algorithm provides new intuition for the decidability of these theories, and for the features that lead to non-elementary blow-ups.

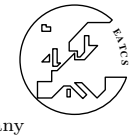
1 Introduction

This paper concerns decision problems involving first-order logic sentences over the integers. We are given a sentence in the logic, and want to know if it holds in a certain infinite structure over the integers – we refer to these as "satisfaction problems" below. If the sentence can mention "full arithmetic" – both addition and multiplication on the integers – then it is well-known that the satisfaction problem is undecidable [3]. On the other hand, if the sentence mentions only addition, inequality, and integer constants – *Presburger arithmetic* ($\mathcal{P}\boldsymbol{a}$) –



then the satisfaction problem is decidable [20]. Presburger arithmetic is by no means the maximal decidable arithmetic theory. For instance, adding a "bit predicate" to Presburger arithmetic – a binary predicate holding on (m, n) if m is the largest power of 2 dividing n – does not undermine decidability. This extension is known as *Büchi arithmetic*. A decision procedure for the satisfaction problem of this theory is based on translating each formula into a finite automaton over strings, representing the binary expansions of possible solutions to the formula [2]. Although both are decidable, there is a big difference between Presburger arithmetic and Büchi arithmetic: the satisfaction problem of the former can be decided in triply exponential time [17] and even in doubly exponential space [8], whereas the latter is known to have no elementary bound. See [1] and [25] for a finer-grained analysis of the complexity of Presburger arithmetic, in terms of alternating Turing machines.

Sitting in between Presburger arithmetic and Büchi arithmetic is the extension of $\boldsymbol{\mathcal{Pa}}$ with a predicate for the powers of 2: we refer to this set of numbers as $2^{\mathbb{N}}$ and to the theory as $\boldsymbol{\mathcal{Pa}}(2^{\mathbb{N}}(\cdot))$. This predicate is clearly definable in Büchi arithmetic, so the first-order theory of $\boldsymbol{\mathcal{Pa}}(2^{\mathbb{N}}(\cdot))$ is again decidable with automata. An alternative decision procedure, avoiding automata, was developed by Semenov in [23]. It proceeds by eliminating quantifiers, arriving at a quantifier-free formula in an enhanced signature – including, for example, a predicate for the highest power of 2 below a given integer. Semenov's procedure applies more broadly to extensions of Presburger arithmetic by a unary predicate satisfying a condition "effective sparseness": thus it isolates combinatorial properties of $2^{\mathbb{N}}$ that underlie decidability, rather than automata-theoretic constructions. Semenov's procedure has been refined and extended by Point; see, e.g., [19]. The complexity of the procedure and the complexity of $\boldsymbol{\mathcal{Pa}}(2^{\mathbb{N}}(\cdot))$ has, to our knowledge, received no attention.

Instead of adding a unary predicate, one can add to $\boldsymbol{\mathcal{Pa}}$ the function taking a number n to 2^n: the power function for short, rather than the powers predicate above. The theory, which we denote $\boldsymbol{\mathcal{Pa}}(\lambda x.2^{|x|})$, subsumes $\boldsymbol{\mathcal{Pa}}(2^{\mathbb{N}}(\cdot))$. Semenov proved decidability of this theory as well [24]. But in this case a non-elementary lower bound follows from [6], see [4]. We are not aware of any finer-grained analysis of the complexity of the theory. Note that $\boldsymbol{\mathcal{Pa}}(\lambda x.2^{|x|})$ is incomparable to Büchi arithmetic in expressiveness: in fact the union of the two is undecidable [4].

In this paper we show that the complexity of $\boldsymbol{\mathcal{Pa}}(2^{\mathbb{N}}(\cdot))$ is elementary, and is in fact contained in 3ExpTime. In this sense $\boldsymbol{\mathcal{Pa}}(2^{\mathbb{N}}(\cdot))$ is quite similar to Presburger arithmetic in complexity. We also show that the existential fragment of the theory $\boldsymbol{\mathcal{Pa}}(\lambda x.2^{|x|})$ has elementary complexity: its satisfaction problem is in NExpTime.

We show our results on extending $\boldsymbol{\mathcal{Pa}}$ with powers or the power function using a single parameterized algorithm. The algorithm can be applied to decide satisfaction of a $\boldsymbol{\mathcal{Pa}}(\lambda x.2^{|x|})$ sentence φ in time tower of $|\varphi|$, matching the prior non-elementary complexity. But it can be specialized to the context of either a $\boldsymbol{\mathcal{Pa}}(2^{\mathbb{N}}(\cdot))$ sentence or an existential $\boldsymbol{\mathcal{Pa}}(\lambda x.2^{|x|})$ sentence, giving in each case an elementary bound. The algorithm is based on eliminating quantifiers: it makes heavy use both of existing Presburger quantifier elimination algorithms [25] and the core of the method of Semenov, which involves removing "problematic occurrences" of a variable within a formula. Intuitively, an occurrence of a variable in an atomic formula is unproblematic if it occurs only outside of power functions, or if the atomic formula is just a comparison between two power terms. In the latter case, the exponentiation of the variable can be eliminated by taking logarithms. We factor this core Semenovian idea out into a self-contained subroutine. We give a short top-level procedure that interleaves calls to this subroutine with calls to a variant of Presburger quantifier elimination. The latter enables us to remove quantified variables completely. A meticulous complexity analysis that tracks several parameters of the input formula shows that the procedure achieves the desired

bounds in the special cases of $\mathcal{Pa}(2^{\mathbb{N}}(\cdot))$ and existential $\mathcal{Pa}(\lambda x.2^{|x|})$.

Our work brings the following ideas:

- For $\mathcal{Pa}(2^{\mathbb{N}}(\cdot))$, we rewrite the formula by processing quantifier blocks inside out but do not eliminate quantifier alternation. The resulting formula is put in a nontrivial fragment of $\mathcal{Pa}$: integer octagon arithmetic ($\mathcal{Oct}$), which we observe to be decidable in PSpace.
- In eliminating problematic variables from formulae, our algorithm exploits a new substitution strategy: it tailors substitutions to individual inequalities, rather than applying them in the entire formula globally or in an individual disjunct in the DNF (à la Reddy and Loveland [22]). For both $\mathcal{Pa}(2^{\mathbb{N}}(\cdot))$ and $\exists\mathcal{Pa}(\lambda x.2^{|x|})$, this will be key to obtaining strong bounds on the number of homogeneous terms produced during the transformation, and bounds on these terms will give us bounds on the running times of the algorithms.

We believe that our procedure, in addition to providing the desired bounds, gives a good intuition for the decidability of $\mathcal{Pa}(\lambda x.2^{|x|})$ and the sources of non-elementary blow-up within it. Note that in this work we deal for simplicity with powers of 2, but the same complexity results apply to any other base $k \in \mathbb{N}$, $k > 2$. Expansion with two bases is undecidable [12].

2 Preliminaries

The symbols $\mathbb{Z}$, $\mathbb{N}$ and $\mathbb{N}_+$ denote the set of integers, natural numbers (including zero), and positive integers, respectively. We write $\#A$ for the cardinality of a finite set A. Given $n, m \in \mathbb{Z}$, we define $[n, m] \coloneqq \{n, n+1, \dots, m\}$ and, if $n \in \mathbb{N}_+$, $[n] \coloneqq [0, n-1]$. For two sets D and C, $[D \to C]$ stands for the set of all functions from D to C. We write $\lfloor\cdot\rfloor$ and $\lceil\cdot\rceil$ to denote the *floor* and *ceiling* functions, respectively, $|\cdot|$ to denote the *absolute value* function, and $\log(\cdot)$ to denote the *binary logarithm* function. All these functions take as input a real number. Note that $n \in \mathbb{N}$ can be represented in binary using $\lceil\log(n+1)\rceil$ many bits.

We sometimes apply standard set operations and predicates, such as for instance $\in$, $\subseteq$ and $\setminus$, to vectors $\boldsymbol{v} = (v_1, \dots, v_d)$. In these cases, there is an implicit conversion of $\boldsymbol{v}$ into the set $V = \{v_1, \dots, v_d\}$. As an example, $v \in \boldsymbol{v}$ and $\boldsymbol{v} \setminus A$ stand for $v \in V$ and $V \setminus A$, respectively, where A is a set (or another vector).

Presburger arithmetic with a power function. We consider the structure $\mathcal{Pa}(\lambda x.2^{|x|}) \coloneqq \langle \mathbb{Z}, 1, +, (a \cdot x)_{a\in\mathbb{Z}}, 2^{|x|}, (q \mid x)_{q\in\mathbb{N}_+}, < \rangle$, in which the classical signature of Presburger arithmetic ($\mathcal{Pa}$) is enriched with the unary *power of the absolute value* function $x \mapsto 2^{|x|}$. As usual, 1 is the constant (interpreted as) $1 \in \mathbb{Z}$, $+$ and $<$ stand for addition and strict ordering over $\mathbb{Z}$, respectively, $x \mapsto a \cdot x$ is the unary function multiplying its input by the constant $a \in \mathbb{Z}$, and $x \mapsto q \mid x$ is the unary relation that is true for integers divisible by $q \in \mathbb{N}_+$.

The *first-order formulae* $\Phi, \Psi, \varphi, \psi, \dots$ of $\mathcal{Pa}(\lambda x.2^{|x|})$ are generated from the grammar

$$\Phi, \Psi \coloneqq \alpha \mid \top \mid \bot \mid \neg\Phi \mid \Phi \wedge \Psi \mid \exists x\, \Phi \mid \forall x\, \Phi \qquad \alpha \coloneqq t_1 < t_2 \mid (q \mid t_1),$$

where x is a first-order variable from an infinite countable set $\mathbb{V}$. The elements of α are the *atomic formulae* of the logic, i.e., they are *linear inequalities* $t_1 < t_2$ between terms t_1 and t_2, or *divisibility constraints* $q \mid t_1$, where $q \in \mathbb{N}_+$. Instead of allowing arbitrary terms of the signature, we will deal with a simpler language where *terms* are expressions of the form $\sum_{i\in I} a_i \cdot 2^{|x_i|} + \sum_{j\in J} b_j \cdot x_j + c$ where $c \in \mathbb{Z}$ is the *constant* of the term, $a_i, b_j \in \mathbb{Z} \setminus \{0\}$ are the *coefficients* of the *power terms* $(2^{|x_i|})_{i\in I}$ and of the *linear* variables $(x_j)_{j\in J}$, and I, J are finite sets of indices (which might overlap). We also restrict to terms where no variable occurs linearly twice, or occurs exponentiated twice. It is easy to see that formulae of the full language can be converted to use this restricted term language, and our algorithms will

not take us out of this fragment. When we talk about equality of terms, we mean modulo associativity and commutativity of $+$. A term is said to be *homogeneous* if its constant is 0.

The Boolean connectives $\vee$, $\rightarrow$ and $\leftrightarrow$, and the standard (in)equalities between terms $\leq$, $=$, $\geq$ and $>$ are defined from $\wedge$, $\neg$ and $<$, as usual. We use the absolute value of variables occurring linearly as a shortcut: e.g., $a \cdot |x| < t$ is equivalent to the formula $(x \geq 0 \rightarrow a \cdot x < t) \wedge (x < 0 \rightarrow -a \cdot x < t)$. We write $\Phi(x_1, \ldots, x_d)$ or $\Phi(\boldsymbol{x})$ to highlight the fact that all free variables of the formula Φ are in $\boldsymbol{x}$. A formula without free variables is said to be a *sentence*. We write $\Phi \Leftrightarrow \Psi$ whenever Φ and Ψ are equivalent. A finite set of formulae $S \coloneqq \{\Phi_i : i \in I\}$ is said to be a *cover for* (or *to cover*) a formula Ψ whenever $\Psi \Leftrightarrow \bigvee_{i \in I} \Phi_i$.

The *satisfaction problem* asks whether a given sentence is true.

Term and formula normalization. To simplify the exposition, we often bring terms and formulae to convenient (normal) form, without mentioning this explicitly every time. This normalization does not change our bounds on the asymptotic running time of the algorithms, nor their correctness.

- We assume inequalities have the form $t < 0$, where t is a term. Thus, we convert inequalities of the form $t_1 < t_2$ into $t_1 - t_2 < 0$. The construction of $t_1 - t_2$ follows the convention on terms described above. We will still sometimes refer to more general inequalities $t_1 < t_2$ for brevity, but these should be taken as abbreviations for inequalities of the above form.
- We rearrange terms following associativity and commutativity of $+$. We also evaluate arithmetic expressions, including, e.g., $2^{|a|}$ and $|a|$, where $a \in \mathbb{Z}$.
- In divisibility constraints of the form $q \mid \sum_{i \in I} a_i \cdot 2^{|x_i|} + \sum_{j \in J} b_j \cdot x_j + c$, we always assume $a_i, b_j, c \in [q]$.
- Inequalities $a < b$ and divisibility constraints $q \mid a$ on integers $a, b \in \mathbb{Z}$ and $q \in \mathbb{N}_+$ are evaluated to $\top$ or $\bot$. So are divisibility constraints $1 \mid t$ or $q \mid 0$, where $q \in \mathbb{N}_+$ and t is a term (these are $\top$).
- Inequalities of the form $a \cdot x < b$ with $a, b \in \mathbb{Z}$ and $|a| \geq 2$ are rewritten into $x \leq \lfloor \frac{b-1}{a} \rfloor$ if $a > 0$, and to $x \geq \lceil \frac{b-1}{a} \rceil$ if $a < 0$. This normalization is required in the context of the quantifier elimination (q.e.) procedure for Presburger arithmetic applied to octagons (see *integer octagon arithmetic* below).
- Trivial inequalities involving power terms, where just the fact that $2^{|c|}$ is always positive suffices to evaluate the atomic formula, are also rewritten as $\top$ or $\bot$. For instance, $a \cdot 2^{|x|} < c$ when a and c have different signs or when $c = 0$; or $a \cdot 2^{|x|} < b \cdot 2^{|y|}$ where a and b have different signs.

Beyond normalization, we need the following operations and notation for terms. We write $t(\boldsymbol{x})$ if all variables appearing in the term t are in $\boldsymbol{x}$. Let α_1 be a formula (resp., a term of the form x or $2^{|x|}$). Given a second formula (resp., term) α_2, $\Phi[\alpha_2 \,/\, \alpha_1]$ stands for the formula obtained from Φ by replacing every occurrence of α_1 by α_2. Additionally, when α_1 and α_2 are two terms t_1 and t_2, and given $n \in \mathbb{N}_+$, we write $\Phi[\frac{t_2}{n} \,/\, t_1]$ for the formula obtained from Φ by replacing each inequality $a \cdot t_1 + t' < t''$ by $a \cdot t_2 + n \cdot t' < n \cdot t''$ and each divisibility constraint $q \mid a \cdot t_1 + t'$ by $n \cdot q \mid a \cdot t_2 + n \cdot t'$. This operation can be seen as scaling by n the atomic formulae where t_1 occurs linearly, relying on the equivalences $s_1 < s_2 \Leftrightarrow n \cdot s_1 < n \cdot s_2$ and $q \mid s \Leftrightarrow n \cdot q \mid n \cdot s$, followed by the substitution of each $n \cdot t_1$ by t_2. We will restrict the use of term substitutions to the following cases: $\Phi[t \,/\, x]$ and $\Phi[\frac{t}{n} \,/\, x]$, where x is a variable only occurring linearly in Φ; and $\Phi[t \,/\, 2^{|x|}]$ and $\Phi[\frac{t}{n} \,/\, 2^{|x|}]$. Note that in the last two cases, all linear occurrences of the variable x are left untouched. We extend the notion of substitution to multiple terms or formulae: $\Phi[\beta_i \,/\, \alpha_i : i \in [1, k]] \coloneqq (\ldots(\Phi[\beta_1 \,/\, \alpha_1])[\beta_2 \,/\, \alpha_2]\ldots)[\beta_k \,/\, \alpha_k]$.

Parameters of formulae. As often done for $\mathcal{P}\boldsymbol{a}$, the complexity analysis of our procedure requires the introduction of several parameters for a formula. We define functions $\mathit{lin}(\cdot)$, $\mathit{hom}(\cdot)$, $\mathit{heft}(\cdot)$, $\mathit{mod}(\cdot)$, $\mathcal{B}(\cdot)$, and $\mathit{alt}(\cdot)$, to track various features of a formula Φ from $\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$:

- $\mathit{lin}(\Phi)$ is the set containing the terms 0 and 2 as well as all the terms t that appear in linear inequalities $t < 0$ of Φ (implicitly converting $t_1 < t_2$ into $t_1 - t_2 < 0$);
- $\mathit{hom}(\Phi)$ is the set of *homogeneous linear terms* obtained from the linear terms in $\mathit{lin}(\Phi)$ by eliminating their constant term c (alternatively, updating c to 0);
- $\mathit{heft}(\Phi)$ is the maximum number of variables in a term of Φ;
- $\mathit{mod}(\Phi)$ is the least common multiple of all $q \in \mathbb{N}_+$ appearing in constraints $q \mid t$ of Φ (if the formula Φ has no divisibility constraints, then we postulate $\mathit{mod}(\Phi) = 1$);
- $\mathcal{B}(\Phi)$ denotes the number of occurrences of negations $\neg$ and conjunctions $\wedge$ in Φ (note that the syntax permits binary conjunction only);
- $\mathit{alt}(\Phi)$ is the *quantifier alternation rank* (number of quantifier blocks) of a formula Φ in prenex normal form.

Throughout the paper, we assume an encoding of terms where constants and coefficients are given in binary representation. By $\mathrm{len}(\Phi)$ we denote the *length* of the formula Φ: the number of bits required to write it down. For simplicity, we assume it is always at least 2. We extend the notion of infinity norm to terms. The *infinity norm* $\|t\|$ of a linear term t is the maximum absolute value of a coefficient or constant appearing in t. For a finite set of terms T, we define $\|T\| \coloneqq \max\{\|t\| : t \in T\}$. The 1-*norm* of t, denoted $\|t\|_1$, is the sum of absolute values of all its coefficients and of its constant; this is always non-negative.

3 Summary of main results

This paper focuses on two fragments of $\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$:

- The first-order theory of $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot)) \coloneqq \langle \mathbb{Z}, 1, +, (a \cdot x)_{a\in\mathbb{Z}}, 2^{\mathbb{N}}(x), (q \mid x)_{q\in\mathbb{N}_+}, < \rangle$, that is, the structure which enriches Presburger arithmetic with the unary relation $x \mapsto 2^{\mathbb{N}}(x)$ that is true for the powers of 2, i.e., $2^{\mathbb{N}}(x) = \top$ iff $x \in \{1, 2, 4, \ldots\}$. Note that the relation $2^{\mathbb{N}}(x)$ can be expressed in $\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$, with the formula $\exists y.\, x = 2^{|y|}$.
- The existential fragment of $\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$, denoted by $\exists\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$. Formulae of this fragment are of the form $\exists \boldsymbol{x}.\Phi$, where Φ is quantifier-free (q.f., in short).

The main results of this paper are summarized below:

▶ **Theorem 1.** *The satisfaction problem for* $\exists\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$ *is in* NExpTime.

▶ **Theorem 2.** *The satisfaction problem for* $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot))$ *is in* 3ExpTime.

Theorems 1 and 2 are based on a common core procedure for $\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$ that we introduce in Section 4. The procedure manipulates the subformulae of an input formula so that they (eventually) enter the following fragments of $\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$:

- The *power comparisons fragment*, denoted by $\mathcal{P}\boldsymbol{owCmp}$. In this fragment, inequalities are restricted to the form $a \cdot 2^{|x|} < b \cdot 2^{|y|}$ or $a \cdot 2^{|x|} < b$, where $a, b \in \mathbb{Z}$, and divisibility constraints are of the form $q \mid 2^{|x|} - r$, where $q \in \mathbb{N}_+$ and $r \in [q]$.
- *Integer octagon arithmetic*, denoted by $\mathcal{O}\boldsymbol{ct}$ (see e.g. [13, 16]), that is, the fragment of $\mathcal{P}\boldsymbol{a}$ in which inequalities are restricted to the forms $\pm x \pm y < c$ and $\pm x < c$, where $c \in \mathbb{Z}$, and divisibility constraints are of the form $q \mid x - r$, where $q \in \mathbb{N}_+$ and $r \in [q]$.
- The fragment $\mathcal{S}\boldsymbol{em}$ (short for *Semenov*, as this fragment is related to the one used in [23]). In formulae Φ of this fragment, each variable appears either always linearly or always in a power, and every *bound* variable x appears only in atomic formulae from $\mathcal{P}\boldsymbol{owCmp}$

(hence, x is always in a power). Moreover, divisibility constraints in Φ are *simple*, i.e., they are of the form $q \mid 2^{|x|} - r$ or of the form $q \mid x - r$, where $q \in \mathbb{N}_+$ and $r \in [q]$. Notice that a sentence in this fragment must be in $\boldsymbol{\mathcal{P}owC mp}$.

- The quantifier-free fragment of $\boldsymbol{\mathcal{P}a}(\lambda x.2^{|x|})$, denoted $\boldsymbol{\mathcal{QF}}$, consisting of all q.f. formulae.

4 The core procedure

Overall organization. Our final decision procedures, which will be presented in Section 5, rely on a core procedure (Algorithm 1) that interleaves calls to what are essentially quantifier elimination subroutines à la Presburger [20] and Semenov [23], respectively, to be explained further below. The input of Algorithm 1 is a formula Φ of $\boldsymbol{\mathcal{P}a}(\lambda x.2^{|x|})$ in prenex normal form. The procedure can be run in two modes, taking an additional parameter $\boldsymbol{\mathcal{F}}$ accordingly. This parameter specifies the "target" fragment of the logic:

- For Φ obtained as a translation of a $\boldsymbol{\mathcal{P}a}(2^{\mathbb{N}}(\cdot))$ formula into $\boldsymbol{\mathcal{P}a}(\lambda x.2^{|x|})$, set $\boldsymbol{\mathcal{F}} = \boldsymbol{\mathcal{S}em}$.
- For general formulae of $\boldsymbol{\mathcal{P}a}(\lambda x.2^{|x|})$, and for the handling of existential $\boldsymbol{\mathcal{P}a}(\lambda x.2^{|x|})$ in non-deterministic exponential time, set $\boldsymbol{\mathcal{F}} = \boldsymbol{\mathcal{QF}}$.

The output of the algorithm is a simplified formula: more specifically, it is a formula of the form $\exists \boldsymbol{x}.\varphi$ or $\neg\exists \boldsymbol{x}.\varphi$, where φ is in $\boldsymbol{\mathcal{F}}$: "*alternation-free modulo* $\boldsymbol{\mathcal{F}}$" below. If the input is a sentence, then the output has no leading quantifiers and is thus a sentence of $\boldsymbol{\mathcal{F}}$.

The procedure processes blocks of quantifiers at a time, eliminating them one by one. Each block corresponds to one iteration of the outer **while** loop. In line 2 we split the quantifier prefix at the innermost existential block that takes us out of the fragment $\boldsymbol{\mathcal{F}}$. There may be a choice as to whether $\neg$ appears at the beginning of Π, but this introduces no ambiguity to the choice of $\boldsymbol{u}$, because $\forall v.\Psi$ is in $\boldsymbol{\mathcal{F}}$ iff $\exists v.\Psi$ is in $\boldsymbol{\mathcal{F}}$. This follows because both fragments $\boldsymbol{\mathcal{F}} = \boldsymbol{\mathcal{S}em}$ and $\boldsymbol{\mathcal{F}} = \boldsymbol{\mathcal{QF}}$ are closed under negation.

The organization of the procedure maintains a DNF-like structure. The set Q acts as a worklist containing the formulae; intuitively, they are the conjunctions (although not necessarily of atomic formulae). The PresQE and SemCover subroutines embed Reddy and Loveland's optimization for $\boldsymbol{\mathcal{P}a}$ [22]: whenever a pair $(\boldsymbol{x}, \varphi_1 \vee \varphi_2)$ could be produced, it is split into two pairs $(\boldsymbol{x}, \varphi_1)$ and $(\boldsymbol{x}, \varphi_2)$ evolving independently for as long as possible. Thus, the DNF-like structure is maintained within each iteration of the outer **while** loop of the Master procedure:

$$\Phi \Leftrightarrow \Pi.\Pi'.\left[\left(\bigvee_{(\boldsymbol{x},\varphi)\in Q} \exists \boldsymbol{x}.\varphi\right) \vee \bigvee_{\varphi\in D} \varphi\right].$$

For each $\varphi \in D \cup \{\varphi : (\boldsymbol{x}, \varphi) \in Q \text{ for some } \boldsymbol{x}\}$, we have $\varphi \in \boldsymbol{\mathcal{F}}$. Pairs from Q are processed in the inner **while** loop one at a time. Formulae from D are "done" and will only be picked up again after leaving the current block: the algorithm will no longer process them within the current block. Thanks to the DNF-like structure, our analysis of the parameter growth for an individual pair $(\boldsymbol{x}, \varphi)$ can ignore the complexity of the big disjunction (i.e., other pairs in Q and D).

Above we have presented Algorithm 1 deterministically: any deterministic choice can be made in line 5 when popping an element from Q, and in lines 7–9 when choosing an appropriate $x \in \boldsymbol{x}$. This implementation will be employed to obtain the claimed triply-exponential bound for $\boldsymbol{\mathcal{P}a}(2^{\mathbb{N}}(\cdot))$, but not the NExpTime bound for the existential fragment of $\boldsymbol{\mathcal{P}a}(\lambda x.2^{|x|})$. In the latter case, we will only perform the outer loop once. The prefix Π will always be empty, and thus the formula we are processing can always be considered

Algorithm 1 Master procedure.

Input: fragment $\mathcal{F} \in \{\mathcal{QF}, \mathcal{Sem}\}$;
formula $\Phi(\boldsymbol{y})$ in $\mathcal{Pa}(\lambda x.2^{|x|})$ in prenex normal form with quantifier-free part from $\mathcal{F}$ in which all divisibility constraints are simple
Output: an equivalent formula $\Phi'(\boldsymbol{y})$, alternation-free modulo $\mathcal{F}$;
if Φ is a sentence, Φ' is a sentence of $\mathcal{F}$

1: **while** true **do**
2: $\quad\Pi \leftarrow$ the shortest quantifier prefix of Φ, possibly with $\neg$ in front, such that $\Phi = \Pi.\exists \boldsymbol{u}.\Psi$ where Ψ is in $\mathcal{F}$ (if necessary, rewrite $\forall \boldsymbol{u}$ as $\neg\exists \boldsymbol{u}.\neg$)
3: $\quad Q \leftarrow \{(\boldsymbol{u}, \Psi)\}$; $D \leftarrow \varnothing$
4: $\quad\Pi' \leftarrow$ empty string of quantifiers ▷ Π' is a **global** variable
5: $\quad$**while** $(\boldsymbol{x}, \varphi) \leftarrow \mathrm{pop}(Q)$ **do**
6: $\quad\quad$**if** $\boldsymbol{x}$ is empty **then** add φ to D
7: $\quad\quad$**else if** some $x \in \boldsymbol{x}$ does not appear in φ **then** add pair $(\boldsymbol{x} \setminus \{x\}, \varphi)$ to Q
8: $\quad\quad$**else if** $\exists x.\varphi$ is in $\mathcal{F}$ for some $x \in \boldsymbol{x}$ **then** add pair $(\boldsymbol{x} \setminus \{x\}, \exists x.\varphi)$ to Q
9: $\quad\quad$**else if** some $x \in \boldsymbol{x}$ appears only linearly in φ **then** add $\mathrm{PresQE}(x, \boldsymbol{x}, \varphi)$ to Q
10: $\quad\quad$**else** add $\mathrm{Linearize}(\mathrm{SemCover}(\boldsymbol{x}, \varphi))$ to Q
11: $\quad\Phi \leftarrow \Pi.\Pi'.\ \bigvee_{\varphi \in D} \varphi$
12: $\quad$**if** Π contains no quantifiers **then return** Φ

Algorithm 2 Function Linearize.

Input: a set S of pairs $(\boldsymbol{x}, \theta)$, with $\boldsymbol{x}$ a vector of variables and θ a formula
Output: if $\mathcal{F} = \mathcal{QF}$: for each $(\boldsymbol{x}, \theta)$, a pair $(\boldsymbol{x}, \theta')$ where $\theta \Leftrightarrow \theta'$ and, for every $x \in \boldsymbol{x}$, if $2^{|x|}$ only occurs in constraints from $\mathcal{PowCmp}$ in θ, then x only occurs linearly in θ'

1: **if** $\mathcal{F} = \mathcal{Sem}$ **then** return S ▷ do nothing unless $\mathcal{F} = \mathcal{QF}$
2: **for** $(\boldsymbol{x}, \theta) \in S$ **do**
3: $\quad\boldsymbol{x}' \leftarrow$ vector of all $x \in \boldsymbol{x}$ s.t. $2^{|x|}$ only occurs in constraints from $\mathcal{PowCmp}$ in θ
4: $\quad$**for** $x \in \boldsymbol{x}'$ **do**
5: $\quad\quad$update θ by applying all of the following replacements:
6: $\quad\quad a \cdot 2^{|x|} < b \ \mapsto \begin{cases} |x| < \lceil \log_2(b/a) \rceil & \text{if } a > 0 \text{ and } b > 0 \\ |x| > \lfloor \log_2(b/a) \rfloor & \text{if } a < 0 \text{ and } b < 0 \end{cases}$
7: $\quad\quad a \cdot 2^{|x|} < b \cdot 2^{|y|} \ \mapsto \begin{cases} |x| < |y| + \lceil \log_2(b/a) \rceil & \text{if } a > 0 \text{ and } b > 0 \\ |x| > |y| + \lfloor \log_2(b/a) \rfloor & \text{if } a < 0 \text{ and } b < 0 \end{cases}$
8: $\quad\quad q \mid 2^{|x|} - r \ \mapsto \begin{cases} q' \mid |x| - r' & \text{if } r' = \min\{s \geq 0 : q \mid 2^s - r\}, \\ & \quad q' = \min\{t > 0 : q \mid r \cdot (2^t - 1)\} \\ |x| = r' & \text{if } r' = \min\{s \geq 0 : q \mid 2^s - r\}, \\ & \quad \{t > 0 : q \mid r \cdot (2^s - 1)\} = \varnothing \\ \bot & \text{otherwise, i.e., } \{s \geq 0 : q \mid 2^s - r\} = \varnothing \end{cases}$
▷ in the replacements in line 8, search for $s, t \leq q - 1$ only
9: $\quad$**return** S

Algorithm 3 Function PresQE.

Input: variable x; vector of variables $\boldsymbol{x}$, where $x \in \boldsymbol{x}$;
formula $\varphi(x, \boldsymbol{y})$ of $\mathscr{F}$ where $\boldsymbol{x} \setminus \{x\} \subseteq \boldsymbol{y}$ and x appears only linearly in atomic formulae
Output: a set of pairs $(\boldsymbol{x}, \psi(\boldsymbol{y}))$ where $\psi \in \mathscr{F}$ and the set of all ψ is a cover for $\exists x.\varphi$

$T \leftarrow \{(a, -t(\boldsymbol{y})) : a > 0,\ a \cdot x + t \in \mathit{hom}(\varphi)\} \cup \{(-a, t(\boldsymbol{y})) : a < 0,\ a \cdot x + t \in \mathit{hom}(\varphi)\}$
$g \leftarrow \Pi\{a : (a, t) \in T \text{ for some } t\}$ ▷ product of all elements of non-empty set
$\Gamma \leftarrow \{\varphi[\frac{t+k}{a} / x] \wedge (a \mid t+k) \ :\ (a, t) \in T, k \in [-r, r] \text{ where } r \coloneqq a \cdot (2 \cdot \|\mathit{lin}(\varphi)\| + g \cdot \mathit{mod}(\varphi))\}$
return $\{(\boldsymbol{x}, \psi) : \psi \in \mathrm{SimplifyDiv}(\gamma), \gamma \in \Gamma\}$

Algorithm 4 Function SemCover.

Input: vector $\boldsymbol{x}$ of variables; formula $\varphi(\boldsymbol{x}, \boldsymbol{z})$ of $\mathscr{F}$, containing $2^{|x|}$ for each $x \in \boldsymbol{x}$
Output: a set of pairs $(\boldsymbol{x}, \psi(\boldsymbol{x}, \boldsymbol{z}))$, where $\psi \in \mathscr{F}$ and the set of all $\Pi'.\exists \boldsymbol{x}.\psi$ covers $\Pi'.\exists \boldsymbol{x}.\varphi$; in every ψ some $2^{|x|}$ $(x \in \boldsymbol{x})$ only occurs in constraints from $\boldsymbol{\mathcal{P}ow\mathcal{C}mp}$
Side effect: update global variable Π' (string of quantifiers)

for $x \in \boldsymbol{x}$ **do**
  $I \leftarrow$ set of inequalities in φ outside $\boldsymbol{\mathcal{P}ow\mathcal{C}mp}$ in which x appears as a power
  $H \leftarrow \{(\eta, \sigma) : \eta(\boldsymbol{x}) + \sigma(\boldsymbol{z}) + c < 0 \text{ in } I;\ \eta \text{ and } \sigma \text{ homogeneous}\}$
  $\Gamma_x \leftarrow \{\varphi\}$
  for $(\eta, \sigma) \in H$ **do**
    $A \leftarrow$ subset of I with these η and σ (only c varies)
    $2^g \leftarrow 2^7 \cdot \big(\lambda(\|\eta\|_1 + \max\{|c| : (\eta + \sigma + c < 0) \in A\})\big)^2$
      ▷ factors up to 2^g are considered "small"
    $a \leftarrow$ coefficient at $2^{|x|}$ in η
    $V \leftarrow$ variables in η except x
    $\beta \leftarrow 2^{|x|} > 2^g \wedge (\bigwedge_{u \in V} 2^{|x|} > 2^g \cdot 2^{|u|})$
    $\Gamma_x \leftarrow \big\{2^{|x|} = 2^j \wedge \gamma[\alpha[2^j \,/\, 2^{|x|}] \,/\, \alpha : \alpha \in A]\,,$
      $2^{|x|} > 2^g \wedge 2^{|x|} = 2^j \cdot 2^{|v|} \wedge \gamma[\alpha[2^j \cdot 2^{|v|} \,/\, 2^{|x|}] \,/\, \alpha : \alpha \in A]\,,$
      $\beta \wedge \lambda(a) \cdot 2^{|x|} < \lambda(\sigma) \wedge \sigma < 0 \wedge \gamma[\top \,/\, \alpha : \alpha \in A]\,,$
      $\beta \wedge \lambda(a) \cdot 2^{|x|} < \lambda(\sigma) \wedge \sigma \geq 0 \wedge \gamma[\bot \,/\, \alpha : \alpha \in A]\,,$
      $\beta \wedge \lambda(a) \cdot 2^{|x|} = \lambda(\sigma) \wedge \gamma[\alpha[\frac{\lambda(\sigma)}{\lambda(a)} \,/\, 2^{|x|}] \,/\, \alpha : \alpha \in A]\,,$
      $\beta \wedge \lambda(a) \cdot 2^{|x|} = 2 \cdot \lambda(\sigma) \wedge \gamma[\alpha[\frac{2 \cdot \lambda(\sigma)}{\lambda(a)} \,/\, 2^{|x|}] \,/\, \alpha : \alpha \in A]\,,$
      $\beta \wedge \lambda(a) \cdot 2^{|x|} > 2 \cdot \lambda(\sigma) \wedge a < 0 \wedge \gamma[\top \,/\, \alpha : \alpha \in A]\,,$
      $\beta \wedge \lambda(a) \cdot 2^{|x|} > 2 \cdot \lambda(\sigma) \wedge a > 0 \wedge \gamma[\bot \,/\, \alpha : \alpha \in A]$
      $:\ \ \gamma \in \Gamma_x,\ 0 \leq j \leq g,\ v \in V\big\}$
$\Gamma \leftarrow \bigcup_{x \in \boldsymbol{x}} \{(\bigwedge_{y \in \boldsymbol{x}} 2^{|x|} \geq 2^{|y|}) \wedge \gamma : \gamma \in \Gamma_x\}$ ▷ we next remove all occurrences of λ
$\Sigma \leftarrow \{\sigma : \lambda(\sigma) \text{ is a subterm of some } \gamma \in \Gamma\} \setminus \{0\}$
for $\sigma \in \Sigma$ **do**
  if $\forall w_\sigma$ is not in Π' **then**
    $w_\sigma \leftarrow$ fresh variable; add $\forall w_\sigma$ to Π' ▷ update **global** Π'
$\Theta \leftarrow \{(\sigma \neq 0 \wedge \neg(2^{|w_\sigma|} \leq |\sigma| < 2 \cdot 2^{|w_\sigma|})) : \sigma \in \Sigma\}$
for each $\Sigma' \subseteq \Sigma$ and each $\gamma \in \Gamma$ **do**
  add to Θ the following formula:
  $(\bigwedge_{\sigma \in \Sigma'} 2^{|w_\sigma|} \leq |\sigma| < 2 \cdot 2^{|w_\sigma|}) \wedge (\bigwedge_{\sigma \in \Sigma \setminus \Sigma'} \sigma = 0) \wedge \gamma[2^{|w_\sigma|} \,/\, \lambda(\sigma) : \sigma \in \Sigma'][0 \,/\, \lambda(\sigma) : \sigma \in \Sigma \setminus \Sigma']$
return $\{(\boldsymbol{x}, \theta) : \theta \in \Theta\}$

Algorithm 5 Function SimplifyDiv.

Input: formula φ *almost* in $\mathscr{F}$: may contain non-simple divisibility constraints
Output: a cover for φ of formulae from $\mathscr{F}$, in which all divisibility constraints are simple

1: $G \leftarrow$ set of non-simple divisibilities in φ
2: $d \leftarrow$ least common multiple of all divisors in G
3: $\boldsymbol{t} \leftarrow$ all variables x and powers $2^{|y|}$ appearing in G
4: $\Gamma \leftarrow \varnothing$
5: **for** $r \in [\boldsymbol{t} \to [d]]$ **do**
6: add $\big((\bigwedge_{t \in \boldsymbol{t}} d \mid t - r(t)) \wedge \varphi[r(\alpha) \,/\, \alpha : \alpha \in G]\big)$ to Γ
7: **where** $r(q \mid \sum_{i=1}^{n} a_i \cdot t_i + c) \coloneqq q \mid \sum_{i=1}^{n} a_i \cdot r(t_i) + c$ ▷ simplifies to $\top$ or $\bot$
8: **return** Γ

an existentially quantified DNF, or equivalently a disjunction of existentials. It suffices to guess one disjunct, corresponding to one element of Q that is satisfiable. Thus, we will replace a deterministic inner loop that maintains a set of pairs in Q with a non-deterministic algorithm that maintains a single pair from Q. In the deterministic interpretation, calls to the subroutines in lines 9 and 10 replace a single element of Q with a set of pairs. In the non-deterministic interpretation, we guess one pair in the output of the subroutine as the new element of Q.

Subroutines. We turn from the Master procedure to its subroutines. The core of the subroutine PresQE (Algorithm 3) corresponds to Weispfenning's quantifier elimination for $\mathcal{P}\boldsymbol{a}$ [25], while Linearize given in Algorithm 2 is a simple procedure taking $\mathcal{P}\boldsymbol{owC}\boldsymbol{mp}$ atomic formulae like $2^{|x|} < 2^{|y|}$ and transforming them to Presburger formulae $x < y$ by "taking logs". We remark that all three types of divisibility replacements in line 8 of Linearize are possible: e.g., $(7 \mid 2^{|x|} - 4) \mapsto (3 \mid |x| - 2)$, and $(20 \mid 2^{|x|} - 2) \mapsto (|x| = 1)$, and $(6 \mid 2^{|x|} - 3) \mapsto \bot$.

The SemCover subroutine (Algorithm 4) is a variation of procedures dating back to Semenov's [23]. This will be less familiar to most readers, and so we discuss it in detail here.

The purpose of subroutine SemCover is to ensure that, in each of the pairs $(\boldsymbol{x}, \psi)$ in its output, for some variable $x \in \boldsymbol{x}$ every occurrence is either linear or in an atomic formula from $\mathcal{P}\boldsymbol{owC}\boldsymbol{mp}$. Across all outputs, the identity of the variable x may differ. Thus, the subroutine is essentially "$\mathcal{P}\boldsymbol{owC}\boldsymbol{mp}$-ifying" the formula. The significance of converting atomic formulae to $\mathcal{P}\boldsymbol{owC}\boldsymbol{mp}$ is that powers can then be eliminated by just "taking logarithms", i.e., by invoking Linearize. And once a quantified variable is so heavily processed that it occurs only linearly (outside powers), then by applying standard Presburger arithmetic quantifier elimination, we can eliminate the variable completely using PresQE.

To be more precise about how SemCover assists the Master procedure, consider what happens when $(\boldsymbol{x}, \psi)$ from the output of SemCover gets popped from Q in the Master procedure. Our actions depend on the chosen fragment (unless x is eliminated from ψ entirely, in which case line 7 takes care of it).

If $\mathscr{F} = \mathcal{S}em$: for some $x \in \boldsymbol{x}$, we can move $\exists x$ into ψ while still staying in the fragment, since x occurs only in power comparisons (line 8).

If $\mathscr{F} = \mathcal{QF}$: all occurrences of x became linear after the execution of Linearize on the output of SemCover, so the variable x can be eliminated by PresQE (line 9).

A look inside subroutine SemCover. Intuitively, the overall workflow of the Master procedure is repeated processing of atomic formulae lying within the scope of a particular block of quantifiers. The constraints we process will be those containing "problematic quantified variables": those that appear in atomic formulae involving powers, but are outside the fragment $\mathcal{PowCmp}$. We exhibit the idea using the following subformula:

$$\exists x.\exists y. \quad 3 \cdot 2^{|x|} - 5 \cdot 2^{|y|} - z < 0. \tag{1}$$

Here both x and y are problematic within the sole atomic subformula of the quantified formula. A major component of all prior procedures is to replace such a formula with a quantified DNF corresponding to a case analysis on the relative values of the problematic variables. These cases correspond to lines 11 to 19 of Algorithm 4 and are a cover for the formula under analysis, hence the name "Semenov cover" given to the algorithm. Each case is defined by a $\mathcal{PowCmp}$ "guard" and, under the assumption specified in a given case, we will be able to eliminate one problematic variable within a constraint, without introducing new problematic existentially-quantified variables. Thus, by applying the procedure repeatedly, we can expunge all problematic quantified variables.

The case analysis includes a guess as to which existentially quantified variable is the largest. In the example, one such guess is that $2^{|x|}$ is the largest. In all the subcases for this guess, we will make x unproblematic. The Semenov cover breaks up this guess into several subcases. One subcase is where $2^{|x|}$ is not much bigger than one of the other power terms, say $2^{|x|} = 4 \cdot 2^{|y|}$. In such cases we can substitute $2^{|x|}$ by a constant multiple of the other term, where the constant is itself a power of 2. Returning to the subcase mentioned just above, where $2^{|x|} = 4 \cdot 2^{|y|}$, we can replace $2^{|x|}$ by $4 \cdot 2^{|y|}$. The remaining case is where $2^{|x|}$ is significantly bigger than all other power terms like $2^{|y|}$; the threshold for "significantly" is set by line 7 of Algorithm 4. In this case we further analyze the most significant digit of the binary expansion for each term.

▶ **Definition.** For any integer N, let $\lambda(N)$ denote the *highest power of* 2 *below* $|N|$ [1]; we have $\lambda(0) = 0$ and $\lambda(N) \leq |N| < 2\lambda(N)$.

Algorithm 4 will make use of intermediate terms that contain λ's – for example, $\lambda(\sigma)$ for σ an ordinary $\mathcal{Pa}(\lambda x.2^{|x|})$ term. The semantics of such terms is the obvious one, which could be formalized by translation into $\mathcal{Pa}(\lambda x.2^{|x|})$, where the function λ is definable.

Returning to the example, our "significantly bigger" hypothesis implies that

$$\lambda(3 \cdot 2^{|x|} - 5 \cdot 2^{|y|}) = \lambda(3 \cdot 2^{|x|}) = 2^{x+1}.$$

This equality in turn implies that, when $\lambda(3 \cdot 2^{|x|})$ is strictly below $\lambda(z)$, the corresponding inequality in Equation (1) is true: $\lambda(3 \cdot 2^{|x|} - 5 \cdot 2^{|y|})$ is strictly below $\lambda(z)$, and while each term can differ from the corresponding λ, the difference cannot be large enough to make the inequality go the other way. By a similar argument, in the subcase where $\lambda(3 \cdot 2^{|x|})$ is at least four times greater than $\lambda(z)$, the inequality must be false. Here we reason that if $\lambda(3 \cdot 2^{|x|} - 5 \cdot 2^{|y|})$ is at least four times greater than $\lambda(z)$, then the offset of each term from its λ value cannot change the inequality from true to false.

This leaves some subcases where $\lambda(3 \cdot 2^{|x|})$ is close to $\lambda(z)$, and in these cases we can substitute away $2^{|x|}$ as well. For example, in the subcase where $\lambda(3 \cdot 2^{|x|}) = \lambda(z)$, we note that $\lambda(3 \cdot 2^{|x|}) = 2 \cdot 2^{|x|}$, and thus we could replace $2^{|x|}$ with $\lambda(z)/2$. By multiplying through the inequality by 2, we can eliminate the division by 2.

[1] We will be mostly concerned with this function on positive integers, but using absolute values gives us the convenience of avoiding partial functions.

Using the output of SemCover. The procedure above removed x, but there are several caveats. Firstly, each case was associated with a condition, where the problematic variable x still appears! However, these conditions are in $\boldsymbol{\mathcal{P}owC}\boldsymbol{mp}$, and therefore all occurrences of x are now unproblematic. Secondly, in some of our substitutions to eliminate x, we introduced λ terms, which appear both in the condition describing the case and in the formula obtained by substituting (assuming the condition). One solution to this problem, applied in earlier procedures such as Point's [19], is to extend the signature with several functions such as λ, and declare that such conditions are acceptable. In this way one can obtain quantifier elimination in the extended signature. In our SemCover subroutine, we proceed slightly differently, eliminating λ terms in favor of new variables that are bound by *definitional quantifiers*. That is, the new variables are associated with additional conditions which define them from the free variables. For example, $\lambda(z)$ can be replaced by 2^w, with additional conditions $2^w \leq |z| < 2 \cdot 2^w$. There is a unique such w for a given z, so the quantification over w can be thought of simultaneously as an existential conjoined with this condition and as a universal relativized to this condition. Such quantifications take us out of $\boldsymbol{\mathcal{P}owC}\boldsymbol{mp}$. But when considered as leading universal quantifiers, they will not increase the quantifier alternation of the global formula – they will add on variables to the next quantified block considered in the Master procedure. And since Algorithm 1 will process from inner quantifier blocks outward, the fattening of outer quantifier blocks does not jeopardize termination of our procedure. Note that at the end of processing quantifier blocks outward with Algorithm 1, we will have only an outermost block of definitional quantifiers; if there are no free variables in the top-level input formula Φ, the quantified variables will depend only on constants, and thus can be replaced by numbers, leading to a quantifier-free sentence.

Analysis of the core procedure. We analyze the procedure, showing in particular that each of Algorithms 1–5 correctly implements its specification. In the sequel we will also need the following facts.

▶ **Lemma 3.** *All divisibility constraints in $D \cup \{\varphi : (\boldsymbol{x}, \varphi) \in Q$ for some $\boldsymbol{x}\}$ are simple.*

▶ **Lemma 4.** *The Master procedure always terminates and, on a formula $\Phi(\boldsymbol{y})$, returns an equivalent formula $\Phi'(\boldsymbol{y})$ such that:*

- *$\Phi'(\boldsymbol{y})$ is equal to either $\exists \boldsymbol{w}.\varphi'(\boldsymbol{w}, \boldsymbol{y})$ or $\neg\exists \boldsymbol{w}.\varphi'(\boldsymbol{w}, \boldsymbol{y})$, where $\varphi' \in \boldsymbol{\mathcal{F}}$,*
- *if Φ is a sentence, then $\Phi' \in \boldsymbol{\mathcal{F}}$ (in other words, if $\boldsymbol{y}$ is empty, then $\boldsymbol{w}$ is empty).*

  In fact, Φ' starts with $\neg$ iff the outermost quantifier block of Φ is existential.

▶ **Lemma 5.** *Consider a prenex formula $\Pi.\Phi$, with Φ from $\boldsymbol{\mathcal{F}}$, in which all variables from the quantifier prefix Π appear only linearly. When running the Master procedure on Φ,* SemCover *is never invoked. Moreover, if no variable in Φ occurs in a power term (i.e., it is a formula from $\boldsymbol{\mathcal{P}a}$), then the quantifier-free formula returned by the procedure is in $\boldsymbol{\mathcal{P}a}$.*

5 Decision procedures and their complexity

In this section, we provide our top-level decision procedures, which make use of the algorithms presented in Section 4. We then provide a complexity analysis that establishes Theorems 1 and 2. To simplify the exposition, the growth of the formulae returned by the procedure is described with the help of "parameter tables" having the following shape:

	$\mathrm{p}_1(\cdot)$	$\mathrm{p}_2(\cdot)$	$\cdots$	$\mathrm{p}_n(\cdot)$
φ	a_1	a_2	$\cdots$	a_n
ψ_1	$f_{1,1}(a_1,\ldots,a_n)$	$f_{1,2}(a_1,\ldots,a_n)$	$\cdots$	$f_{1,n}(a_1,\ldots,a_n)$
$\ldots$	$\ldots$	$\ldots$	$\ldots$	$\ldots$
ψ_m	$f_{m,1}(a_1,\ldots,a_n)$	$f_{m,2}(a_1,\ldots,a_n)$	$\cdots$	$f_{m,n}(a_1,\ldots,a_n)$

In this table, φ,ψ_1,…,ψ_m are formulae, $\mathrm{p}_1(\cdot)$,…,$\mathrm{p}_n(\cdot)$ are parameter functions from formulae to $\mathbb{N}$, $a_1,\ldots,a_n \in \mathbb{N}_+$, and all $f_{j,k}$ are functions from $\mathbb{N}^n$ to $\mathbb{N}$. The table states that

if $\mathrm{p}_i(\varphi) \leq a_i$ for all $i \in [1,n]$, then $\mathrm{p}_k(\psi_j) \leq f_{j,k}(a_1,\ldots,a_n)$ for all $j \in [1,m]$ and $k \in [1,n]$.

We sometimes assume lower bounds on the values $a_1,\ldots,a_n$ (e.g., $h \geq 2$ and $a \geq 2$ in the table of Lemma 6) in order to simplify the definition of the functions $f_{j,k}$. Note that this does not change the semantics of the table. We sometimes write the ditto mark 〃 inside a cell of the table. In that case, the ditto mark represents the value of the cell directly above it (e.g., the rightmost 〃 appearing in the table of Lemma 6 is short for $b+2\cdot v+1$).

Theorem 1: NExpTime upper bound for existential $\mathscr{P}\boldsymbol{a}(\lambda x.2^{|x|})$

Before arguing for a NExpTime decision procedure for $\exists\mathscr{P}\boldsymbol{a}(\lambda x.2^{|x|})$, we analyze the growth of formulae resulting from calls to PresQE, SemCover and Linearize.

Our analysis of PresQE simply merges the analysis of Weispfenning's quantifier elimination for Presburger arithmetic from [25] (implemented in lines 1 to 3 of PresQE) with an analysis of SimplifyDiv. Here are the resulting bounds:

▶ **Lemma 6.** *On input $(x,\boldsymbol{x},\varphi(\boldsymbol{x},\boldsymbol{z}))$ where x only occurs linearly in φ,* PresQE *returns a set $\{(\boldsymbol{x},\psi_1),\ldots,(\boldsymbol{x},\psi_k)\}$ whose formulae satisfy the parameter table below ($i \in [1,k]$):*

	$\#hom$	$heft$	$\|hom(\cdot)\|$	$\|lin(\cdot)\|$	mod	$\mathcal{B}$
φ	$h \geq 2$	v	$a \geq 2$	c	m	b
ψ_i	h	$2\cdot v$	$2\cdot a^2$	$a^{h+2}(c+m)$	$a\cdot m$	$b+2\cdot v+1$
$\bigvee_{j=1}^{k}\psi_j$	h^2	〃	〃	〃	$a^h m$	$k(\,〃+1)$

and $k \leq h\cdot c\cdot m^{2v+1}\cdot a^{2v+h+4}$. The running time is in $(len(\varphi)\cdot c\cdot m)^{\mathrm{poly}(h,v)}$.

A simple analysis of SemCover yields the following bounds.

▶ **Lemma 7.** *Let $\Theta = \{(\boldsymbol{x},\theta_1),\ldots,(\boldsymbol{x},\theta_k)\}$ be the output of* SemCover$(\boldsymbol{x},\varphi(\boldsymbol{x},\boldsymbol{z}))$*, where $\boldsymbol{x}=(x_1,\ldots,x_n)$ with $n\geq 1$. Then, the following parameter table holds, where $i\in[1,k]$:*

	$\#hom$	$heft$	$\|lin(\cdot)\|$	mod	$\mathcal{B}$
φ	h	$v \geq 2$	$c \geq 2$	m	b
θ_i	$h\cdot(v+10)+n$	v	$2^{11}\cdot v^2\cdot c^4$	m	$b+h\cdot(v+11)+n$
$\bigvee_{j=1}^{k}\theta_j$	$h\cdot 2^8\cdot v^3\log(c)+n^2$	〃	〃	〃	$k\cdot(\,〃+1)$

where $k \leq (v+1)^{8h}\cdot\log(c)^h\cdot n$. Moreover, (i) at most h universal quantifiers are added to the global variable Π'; (ii) the running time is in $(len(\varphi)\cdot n)^{\mathrm{poly}(h)}$; and (iii) for every $i\in[1,k]$ there are at most h terms $t\in hom(\theta_i)$ that contain some variable from $\boldsymbol{x}$ and satisfy $(t+c'<0)\in lin(\theta_i)$ with $t+c'<0$ not in $\mathscr{P}\boldsymbol{owCmp}$, for some $c'\in\mathbb{Z}$.

Note that an estimate of $\|hom(\theta_i)\|$ is missing from Lemma 7. For SemCover, this parameter grows similarly to $\|lin(\theta_i)\|$, which by definition always bounds $\|hom(\theta_i)\|$. We also note that Lemma 7 gives an upper bound on the number of global variables added to Π'. This bound is later required to analyze $\mathscr{Pa}(2^{\mathbb{N}}(\cdot))$, but is not needed in the context of deciding sentences from $\exists\mathscr{Pa}(\lambda x.2^{|x|})$. Indeed, from Lemma 4, in this latter case Π' is empty.

In computing the upper bounds on $\|hom(\theta_i)\|$ and $\|hom(\bigvee_{j=1}^{k}\theta_j)\|$ keep in mind that in lines 11 to 18 of SemCover we perform "tailored substitutions": we only replace $2^{|x|}$ in linear terms $\alpha \in A$ with either a constant, a unique (given α) expression $\lambda(\sigma)$, or a multiple of a power $2^{|y|}$, where y appears in α. Our analysis tracks the impact of iterating these types of replacements on the number of homogeneous terms.

We continue by analyzing Linearize. Here the bounds are quite simple, but one observation is in order: line 8 might require iterating through the $q-1$ residue classes of q in order to find suitable q' and r'. Since q is encoded in binary, this yields an exponential running time for Linearize (see m below), as shown in the following lemma.

▶ **Lemma 8.** *Consider a set $S = \{(\boldsymbol{x},\theta_1),\dots,(\boldsymbol{x},\theta_k)\}$ where $\boldsymbol{x} = (x_1,\dots,x_n)$, and let r be the maximum number of variables appearing in some θ_i. On input S,* Linearize *returns a set $\{(\boldsymbol{x},\theta'_1),\dots,(\boldsymbol{x},\theta'_k)\}$ with bounds as in the following table, for all $j \in [1,k]$:*

	$\#hom$	$heft$	$\|hom(\cdot)\|$	$\|lin(\cdot)\|$	mod	$\mathcal{B}$
θ_j	h	v	a	$c \geq 2$	$m \geq 2$	b
θ'_j	$h + (6\cdot r+2)\cdot n$	v	a	c	m^2	$22\cdot b$

The running time is in $\mathrm{poly}(\max_{i=1}^{k} len(\theta_i), m, n, \#S)$.

We now complete the description of the non-deterministic algorithm deciding $\exists\mathscr{Pa}(\lambda x.2^{|x|})$ in NExpTime, completing the informal comments in Section 4. As a preliminary step, the algorithm runs SimplifyDiv on the matrix of the input existential sentence Φ, guessing a residue class for each variable and power, and obtaining an existential sentence where all the divisibilities are simple. The algorithm puts that sentence in prenex form. Afterwards, the algorithm follows Algorithm 1 (with $\mathscr{F} = \mathcal{Q}\mathscr{F}$), but replaces $\mathrm{pop}(Q)$ in line 5, as well as other forms of iteration inside PresQE and SemCover, with non-deterministic guesses. More precisely, when SemCover is called, it guesses a variable $x \in \boldsymbol{x}$ in line 1, iterates (deterministically) over every $(\eta,\sigma) \in H$ in line 5, and guesses only one of the cases in lines 11 to 18. As a result, in the non-deterministic version of SemCover, the variable Γ in line 20 contains a single formula γ. Since Φ is an existential sentence, the various terms σ considered by SemCover are always 0. Hence, $\lambda(\sigma)$ is 0 and lines 21 to 28 have no effect on the subroutine, which simply returns a singleton set containing the pair $(\boldsymbol{x},\gamma)$. For PresQE, non-deterministic guesses replace the iterations done in line 3, as well as the ones performed in line 5 of SimplifyDiv (as done in the aforementioned preliminary step of the algorithm).

The non-deterministic versions of PresQE and SemCover described above always return singleton sets containing a pair of the form $(\boldsymbol{x},\theta)$. Then, by the correctness of PresQE and SemCover, we conclude that on an input sentence Φ containing n quantified variables, the non-deterministic version of Algorithm 1 never calls each of the subroutines PresQE, SemCover and Linearize more than n times. By looking at the bounds on ψ_i, θ_i and θ'_j from Lemmas 6–8 we conclude that these $3n$ subroutine calls (non-deterministically) return a formula that never requires more than exponential space to be represented. Since Φ is a sentence and $\mathscr{F} = \mathcal{Q}\mathscr{F}$, the non-deterministic algorithm will eventually obtain a formula Ψ with no variables, only constants, which can be evaluated in exponential time. As usual, the algorithm returns true if one such (non-deterministically derived) formula Ψ is valid.

Theorem 2: 3ExpTime upper bound for $\mathcal{Pa}(2^{\mathbb{N}}(\cdot))$

We now move to $\mathcal{Pa}(2^{\mathbb{N}}(\cdot))$. Let Φ be obtained by translating a sentence of $\mathcal{Pa}(2^{\mathbb{N}}(\cdot))$ into a prenex sentence of $\mathcal{Pa}(\lambda x.2^{|x|})$ without divisibility constraints (i.e., replace each $2^{\mathbb{N}}(x)$ with $\exists y.\, x = 2^{|y|}$, each $q \mid t$ with $\exists z.\, t = q \cdot z$, and bring the resulting sentence in prenex form). Note that this translation is in polynomial time, and that each variable in Φ appears either always linearly or always in a power. The algorithm to decide Φ is described below:

1: $\Psi_1 \leftarrow$ run Algorithm 1 with $\mathcal{F} = \mathcal{Sem}$, on Φ ▷ as Φ is a sentence, $\Psi_1 \in \mathcal{PowCmp}$.
2: $\Pi.\Psi_2(\boldsymbol{x}) \leftarrow$ prenex form of Ψ_1 ▷ Ψ_2 q.f.; $\boldsymbol{x}$ are the variables appearing in Π
3: $\{(\boldsymbol{x}, \Psi_3)\} \leftarrow$ Linearize($\{(\boldsymbol{x}, \Psi_2)\}$) ▷ $\Psi_3(\boldsymbol{x})$ belongs to $\mathcal{Oct}$
4: $\Omega \leftarrow$ run Algorithm 1 with $\mathcal{F} = \mathcal{QF}$, on $\Pi.\Psi_3$ ▷ Ω does not contain variables
5: evaluate truth of Ω

Above we highlight the fact that, after the first invocation to Algorithm 1, we obtain a formula from $\mathcal{PowCmp}$ which is then manipulated by Linearize into a formula from integer octagon arithmetic ($\mathcal{Oct}$). Then, in order to estimate the running time of this algorithm, we need to study the running time of Algorithm 1 on inputs that either come from $\mathcal{Pa}(2^{\mathbb{N}}(\cdot))$ or are from $\mathcal{Oct}$. Let us discuss the latter case first.

Since $\mathcal{Oct}$ is a fragment of Presburger arithmetic, line 4 above fundamentally runs Weispfenning's quantifier elimination procedure for Presburger arithmetic (see Lemma 5), plus calls to SimplifyDiv. It turns out that on formulae from $\mathcal{Oct}$, this procedure only runs in exponential time, as summarized in the following proposition.

▶ **Proposition 9.** *Let $\mathcal{F} = \mathcal{QF}$. Consider a formula $\Phi(\boldsymbol{z})$ from integer octagon arithmetic ($\mathcal{Oct}$) in prenex form and having $alt(\varphi) = \ell \geq 1$ quantifier blocks, each with $n \geq 1$ many variables. On input Φ, Algorithm 1 returns a formula Ψ with bounds:*

	$\#hom$	$heft$	$\|hom(\cdot)\|$	$\|lin(\cdot)\|$	mod	$\mathcal{B}$
Φ	$h \geq 2$	2	1	$c \geq 2$	$m \geq 2$	b
Ψ	$4 \cdot \#\boldsymbol{z}^2$	2	1	$4^{\ell \cdot n}(c + 2 \cdot m)$	m	$k(b + \ell \cdot n + 1)$

and $k \leq 2^{2^5 \ell^2 n^2}(\#\boldsymbol{z}^2 \cdot c \cdot m)^{\ell \cdot n}$. The running time of the procedure is in $(len(\Phi) \cdot c \cdot m)^{\mathrm{poly}(\ell, n)}$.

The proof of this proposition is by induction on $alt(\varphi)$, and essentially follows the standard arguments to bound the running time of the quantifier elimination procedure for Presburger arithmetic. The key ingredient that leads to the bounds above is that, for $\mathcal{Oct}$, the natural numbers a in line 3 and g in line 2 of PresQE are always 1. This has two effects. Firstly, it shows that $\mathcal{Oct}$ admits quantifier elimination, i.e., while running the procedure no atomic formulae outside $\mathcal{Oct}$ can arise. This is best witnessed by looking at line 3 in PresQE. There, the divisibility constraints $a \mid t + k$ are trivially satisfied, and we are replacing x with a term of the form $\pm y + c$ for some $c \in \mathbb{Z}$. From these substitutions, only constraints from $\mathcal{Oct}$ or constraints of the form $\pm 2 \cdot y < b$ can arise, and the latter are normalized to $y \leq \lfloor \frac{b-1}{2} \rfloor$ or $y \geq \lceil \frac{1-b}{2} \rceil$ as explained in Section 2. The second effect is on the growth of the constants. The variable r in line 3 only depends on $mod(\Phi)$, which now does not grow during the procedure, and on $\|lin(\Phi)\|$, which grows only exponentially in the number of variables in Φ.

We now move to the running time of Algorithm 1 on inputs that come from $\mathcal{Pa}(2^{\mathbb{N}}(\cdot))$. The properties of this procedure are summarized in the next proposition.

▶ **Proposition 10.** *Let $\mathcal{F} = \mathcal{Sem}$. Let $\Phi(\boldsymbol{y})$ be a formula from $\mathcal{Pa}(\lambda x.2^{|x|})$ in prenex normal form, with no divisibility constraints, and in which each quantified variable appears either only linearly or only in powers. Suppose Φ has $alt(\Phi) = B$ quantifier blocks, each with at most $L \geq 1$ variables occurring linearly and each block having at most $E \geq 1$ variables occurring in powers. On input Φ, Algorithm 1 returns a formula Ψ with bounds as in the following table:*

	$\#hom$	*heft*	$\|lin(\cdot)\|$	*mod*	$\mathcal{B}$
Φ	$h \geq 2$	$v \geq 2$	$c \geq 4$	$m \geq 4$	b
Ψ	$H \coloneqq (E \cdot h \cdot \log(c \cdot m))^{(2 \cdot v)^{2^5 \cdot L \cdot B^3}}$	$2^{B \cdot L} v$	2^H	2^H	$b \cdot 2^H$

and the number of quantifiers added to Π' is at most H. The running time of the procedure is in $len(\Phi) \uparrow (E \cdot h \cdot \log(c \cdot m)) \uparrow v \uparrow \mathrm{poly}(L, B)$.

In the above proposition, $a \uparrow b \coloneqq a^b$ is the exponentiation function and, following Knuth's up-arrow notation, it is right-associative. In view of our bounds for one iteration of SemCover given in Lemma 7, the bound on $\#hom(\Psi)$ should seem somewhat surprising. We know from the correctness of SemCover that, after a call to SemCover, one of the variables appearing in powers will only occur in constraints from $\mathcal{PowCmp}$. Since all these variables need to have this property before moving to the next quantifier block, SemCover must be chained at least E times within a block, E being the number of variables occurring in powers in the block. Then, from the bound $\#hom(\theta_j) \leq h \cdot (v + 10) + n$ in Lemma 7, one might expect $\#hom(\Psi)$ to be roughly $h \cdot v^E$, thus exponential in E even for a single block of quantifiers. Proposition 10, however, proves otherwise: $\#hom(\Psi)$ is only polynomial in E. For this, we need to sharpen the correctness statement for SemCover.

We already know that in each output formula some variable x is made unproblematic, and no new problematic occurrences of variables are created. We prove a stronger statement: namely, that every *rewriting* of a homogeneous term (by a substitution in lines 11–18) makes the number of problematic variables in that term decrease. This is possible thanks to the tailoring of these substitutions to individual inequalities, which allows us to track the evolution of each term independently of the rest of the formula. As a result:

- a formula that is placed into D at the end of processing a single quantifier block can be a result of E chained calls to SemCover, but
- the number of calls to SemCover that rewrite an individual term during its evolution is bounded by the heft.

Therefore, we can iterate the above-mentioned bound $\#hom(\theta_j) \leq h \cdot (v + 10) + n$ just $2^L \cdot v$ times instead of E times. Thus $\#hom(\Psi)$ in Proposition 10 is found to be exponential in v and only polynomial in E. We remark that if $\#hom(\Psi)$ were instead found to be exponential in E, then the algorithm would not have any hope of running in elementary time. This is because, after a block of quantifiers is considered, E increases by the number of variables introduced in SemCover, which from Lemma 7 is roughly the number of homogeneous terms.

To prove Theorem 2 it suffices to chain the bounds and running times of Proposition 10, Lemma 8 and Proposition 9, according to the algorithm given at the beginning of the section.

Avoiding quadruply exponential numbers. It may not be immediately evident from the bounds in the various tables why we do not perform quantifier elimination eagerly and instead run Algorithm 1 without fully eliminating quantifiers first (in mode $\mathcal{Sem}$), then call Linearize, and only afterwards eliminate the remaining quantifiers by running Algorithm 1 again (now in mode $\mathcal{QF}$). In fact, this sequence is fundamental for obtaining a 3ExpTime procedure.

Consider the formula $\Psi \coloneqq q \mid 2^{|x|} - r \wedge y \geq 2^{|x|}$. For specific values of q and r, the smallest $|x|$ satisfying Ψ might be $q-1$. If Ψ is a subformula obtained during quantifier elimination, then, according to Proposition 10, q might have a triply exponential magnitude relative to the input size. This means that the smallest y satisfying Ψ might have a quadruply exponential magnitude. Eliminating x and y in this case would lead to a quadruply exponential blow-up in the number of disjuncts to be considered during quantifier elimination. Our strategy avoids this problem by delaying (if necessary) the elimination of x and y until we obtain a formula in $\mathcal{PowCmp}$. Calling Linearize reduces the reasoning to the exponents, which are triply exponential at worst.

An observation on $\mathcal{Oct}$. The bounds for integer octagon arithmetic presented in Proposition 9 reveal not only that this logic admits an exponential-time quantifier elimination procedure, but also that the satisfaction problem for this theory can be solved in PSpace. Indeed, observe that the bound on $\|lin(\Psi)\|$ given in Proposition 9 implies that all constants and coefficients appearing in the output formula Ψ have polynomial bit-length. Then, one can apply the standard quantifier relativization algorithm from $\mathcal{Pa}$ to obtain a PSpace procedure for $\mathcal{Oct}$. Briefly, the quantifier relativization procedure for $\mathcal{Pa}$ first replaces every quantifier $\exists x.\varphi$ in the input formula with a *bounded quantifier* $\exists x \in [-f(\varphi), f(\varphi)].\, \varphi$, where $f\colon \mathcal{Pa} \to \mathbb{N}$, and then iterates through all (finitely many) values the quantified variable can take, searching for a solution to the formula. The bound on $\|lin(\Psi)\|$ obtained for $\mathcal{Oct}$ implies that $f(\Psi)$ has bit-length that is at most polynomial in $\mathrm{len}(\Psi)$. See [22] for more information on quantifier relativization.

On the non-elementary bound for $\mathcal{Pa}(\lambda x.2^{|x|})$. To conclude, we provide some insights on why our procedure runs in non-elementary time on formulae from the Tower-complete logic $\mathcal{Pa}(\lambda x.2^{|x|})$. One of the ingredients that guarantee that our procedure for $\mathcal{Pa}(2^{\mathbb{N}}(\cdot))$ runs in 3ExpTime is that we are able to postpone calls to Linearize to after Algorithm 1. In $\mathcal{Pa}(\lambda x.2^{|x|})$ this is not possible: since each variable can appear both linearly and in powers, Linearize must be invoked after each call to SemCover, in order to "linearize" a variable, and then eliminate it with PresQE. However, SemCover adds, in the worst case, a number of additional variables that is roughly the number h of homogeneous terms in the formula (see Lemma 7). When the next quantifier block is considered, these variables must all be linearized and eliminated with PresQE. As indicated in the table of Lemma 6 (leftmost column of the last row), in doing this, the number of homogeneous terms of the resulting formula becomes exponential in h. This "h^h" dependency makes the algorithm run in non-elementary time (in fact Tower).

6 Conclusion

We have proven new elementary upper bounds for $\mathcal{Pa}(2^{\mathbb{N}}(\cdot))$, and for the existential fragment of $\mathcal{Pa}(\lambda x.2^{|x|})$. We believe this is a step towards understanding which decidable arithmetic theories have elementary bounds, and moreover that our method extends to provide elementary bounds for any prefix class of $\mathcal{Pa}(\lambda x.2^{|x|})$, but we leave this for future work. Our results open several research directions, which we now summarize.

Tighter bounds for $\mathcal{Pa}(2^{\mathbb{N}}(\cdot))$. It is well-known that, using the bounds on the formulae returned by quantifier elimination procedures for $\mathcal{Pa}$, one can derive a 2AExpTime(poly) quantifier relativization procedure for $\mathcal{Pa}$ [25]. Here 2AExpTime(poly) is the class of

all problems that can be decided with an alternating Turing machine running in doubly exponential time and performing a polynomial number of alternations. In fact, $\mathcal{P}\boldsymbol{a}$ is complete for this class under polynomial-time reductions [1]. Our 3ExpTime procedure for $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot))$ shows that, in terms of deterministic time complexity, this theory is not harder to decide than $\mathcal{P}\boldsymbol{a}$. However, at this stage obtaining a 2AExpTime(poly) quantifier relativization algorithm from the bounds of our procedure seems not easy.

Automata-based decision procedures. As $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot))$ is a fragment of Büchi arithmetic, it also admits a representation by finite automata. It appears plausible that the automata-based procedure for $\mathcal{P}\boldsymbol{a}$ [14, 7] could be adapted to $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot))$. However, having the procedure run in 3ExpTime might be very challenging. This is due to the fact that, as observed above, $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot))$ formulae may require numbers of quadruply exponential magnitude; instead of triply exponential as in the case of $\mathcal{P}\boldsymbol{a}$.

Geometric decision procedures. A class of regular expressions corresponding to $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot))$ was already defined by Semenov [23, Theorem 5]. These expressions can be seen as an extension of semilinear sets [18, 9], so it is conceivable that there is an elementary decision procedure for $\mathcal{P}\boldsymbol{a}(2^{\mathbb{N}}(\cdot))$ which is based on geometry and manipulates these objects directly. However, similarly to the automata-based approach, making such a procedure run in 3ExpTime, as the recent one for $\mathcal{P}\boldsymbol{a}$ [5] does, appears challenging.

Tighter bounds for $\exists\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$. An obvious question is whether our upper bound for the existential fragment can be improved. For comparison, the existential fragment of Büchi arithmetic is known to be in NP [11]. While the same may be true for $\exists\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$, it would be very surprising if such a result were to be proved with a technique similar to the one in our paper. In our NExpTime algorithm for $\exists\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$, the main source of blow-up is the use of Weispfenning's quantifier elimination procedure to eliminate linearly occurring variables. Quantifier elimination is known to be often non-optimal when it comes to deciding existential fragments of logics, and this is the case for $\exists\mathcal{P}\boldsymbol{a}$, the existential fragment of Presburger arithmetic. A possible avenue to improve the NExpTime upper bound would be to look at geometric procedures, which in the context of $\exists\mathcal{P}\boldsymbol{a}$ perform much better.

Improving the NP lower bound is also challenging. There are several extensions of $\exists\mathcal{P}\boldsymbol{a}$ that currently fall between NP and NExpTime. These include $\exists\mathcal{P}\boldsymbol{a}$ with pre-quadratic constraints [10, 21] and $\exists\mathcal{P}\boldsymbol{a}$ with divisibility constraints [15]. One idea is to exploit the ability of $\exists\mathcal{P}\boldsymbol{a}(\lambda x.2^{|x|})$ to express a pairing function, that is, an injection from $\mathbb{N}\times\mathbb{N}$ to $\mathbb{N}$, with, e.g., the formula $z = 2^{|2x|} + 2^{|2y+1|}$ [6, p. 55]. Pairing functions are known to lead to non-elementary lower bounds in the presence of quantifier alternation, and an interesting direction would be to study their effect on existential theories.

A Dichotomy for Succinct Representations of Homomorphisms

Christoph Berkholz

Harry Vinall-Smeeth
Humboldt-Universität zu Berlin, Germany

Abstract

The task of computing homomorphisms between two finite relational structures $\mathcal{A}$ and $\mathcal{B}$ is a well-studied question with numerous applications. Since the set $\mathrm{Hom}(\mathcal{A}, \mathcal{B})$ of all homomorphisms may be very large having a method of representing it in a succinct way, especially one which enables us to perform efficient enumeration and counting, could be extremely useful.

One simple yet powerful way of doing so is to decompose $\mathrm{Hom}(\mathcal{A}, \mathcal{B})$ using union and Cartesian product. Such data structures, called d-representations, have been introduced by Olteanu and Závodný [32] in the context of database theory. Their results also imply that if the treewidth of the left-hand side structure $\mathcal{A}$ is bounded, then a d-representation of polynomial size can be found in polynomial time. We show that for structures of bounded arity this is optimal: if the treewidth is unbounded then there are instances where the size of any d-representation is superpolynomial. Along the way we develop tools for proving lower bounds on the size of d-representations, in particular we define a notion of reduction suitable for this context and prove an almost tight lower bound on the size of d-representations of all k-cliques in a graph.

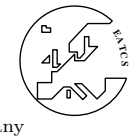
1 Introduction

The task of computing homomorphisms between two finite relational structures has a long history and numerous applications. Most notably, as pointed out by Feder and Vardi [17], it is the right abstraction for the constraint satisfaction problem (CSP) – a framework for search problems that generalised Boolean satisfiability. Moreover, evaluating conjunctive queries on a relational database is equivalent to computing homomorphisms from the query structure to the database. While deciding the existence of a homomorphism from a structure $\mathcal{A}$ to a structure $\mathcal{B}$ is a classical NP-complete problem, several restrictions of the input instance have been considered in order to understand the landscape of tractability. One line of research investigates *right-hand-side* restrictions, where it is asked for which classes of structures $\mathcal{B}$ the CSP becomes tractable and when it remains hard. This culminated in



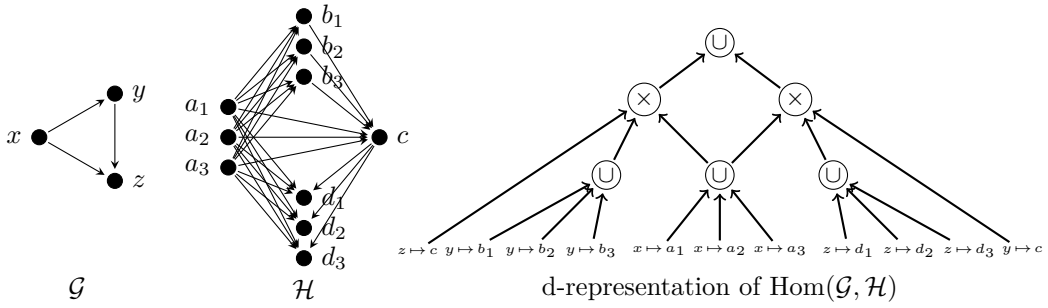


Figure 1 A deterministic d-representation of all homomorphisms from $\mathcal{G}$ to $\mathcal{H}$.

the solution [9, 38] of the CSP-dichotomy conjecture [17] that characterises those $\mathcal{B}$ where finding a homomorphism from a given structure $\mathcal{A}$ can be done in polynomial time (assuming P≠NP).

Another line of research, to which we contribute in this paper, focuses on *left-hand-side* restrictions: for which classes of structures $\mathcal{A}$ can we efficiently find a homomorphism from $\mathcal{A}$ to a given $\mathcal{B}$? In this scenario, a dichotomy is only known when all relations have bounded arity, as is the case for graphs, digraphs, or k-uniform hypergraphs. Grohe [20] showed that, modulo complexity theoretic assumptions, for any class of structures $\mathfrak{A}$ of bounded arity the decision problem, "Given a structure $\mathcal{A} \in \mathfrak{A}$ and a structure $\mathcal{B}$, is there a homomorphism from $\mathcal{A}$ to $\mathcal{B}$?" is in polynomial time if and only if the homomorphic core of every structure in $\mathfrak{A}$ has bounded treewidth. For classes of unbounded arity, polynomial time tractability has been shown for fractional hypertreewidth [5, 21], but a full characterisation of tractability has only been obtained in the parameterised setting using submodular width [29]. Besides deciding the existence of a homomorphism, the complexity of counting all homomorphism has also been characterised in the right-hand-side regime [8] and for bounded-arity classes of left-hand-side structures [14]. A third task, that is less well understood, is to *enumerate* all homomorphisms; here only partial results on the complexity are known (e. g. [10, 13, 37, 19]).

In this work we consider the task of *representing* the set Hom($\mathcal{A}, \mathcal{B}$) of all homomorphisms in a succinct and accessible way. In particular, we want to store all, potentially exponentially many, homomorphisms, in a data structure of polynomial size that enables us to, e. g. generate a stream of all homomorphisms. The data structures we are interested in – so-called d-representations – were first introduced to represent homomorphisms in the context of join evaluation under the name *factorised databases* [32]. They are conceptually very simple: the set of homomorphisms is represented by a circuit, where the "inputs" are mappings of single vertices and larger sets of mappings are generated by combining local mappings using Cartesian product $\times$ and union $\cup$. In the circuit previously computed sets of local homomorphisms are represented by gates and can be used several times, see Figure 1 for an example. Such a representation is called *deterministic* if every $\cup$-gate is guaranteed to combine disjoint sets. Deterministic representations have the advantage that the number of homomorphisms can be efficiently counted by adding the sizes of the local homomorphism sets on every $\cup$-gate and multiplying them on every $\times$-gate. Moreover, all homomorphisms can be efficiently enumerated where the delay between two outputs is only linear in the size of every produced homomorphism (= size of the universe of $\mathcal{A}$) [2]. It is known that if the treewidth of the left-hand side structure is bounded, then a deterministic d-representation of polynomial size can be found in polynomial time [32]. Our main theorem shows that for structures of bounded arity this is optimal: if the treewidth is unbounded, then there are instances where the size of any (not necessarily deterministic) representation is superpolynomial.

▶ **Theorem 1.** *Let $r \in \mathbb{N}$, σ a signature of arity $\leq r$ and $\mathfrak{A}$ a class of σ-structures. Then the following are equivalent:*

1. *There is a $w \in \mathbb{N}$ such that every structure in $\mathfrak{A}$ has treewidth at most w.*
2. *A deterministic d-representation of $\mathrm{Hom}(\mathcal{A}, \mathcal{B})$ can be computed in polynomial time, for any $\mathcal{A} \in \mathfrak{A}$ and any $\mathcal{B}$.*
3. *There is a $c \in \mathbb{N}$ such that for any $\mathcal{A} \in \mathfrak{A}$ and any $\mathcal{B}$ there exists a (not necessarily deterministic) d-representation of $\mathrm{Hom}(\mathcal{A}, \mathcal{B})$ of size $O\big((\|\mathcal{A}\| + \|\mathcal{B}\|)^c\big)$.*

Related work. The research on succinct data structures for homomorphism problems has emerged from the two different perspectives. When fixing the right-hand-side structure $\mathcal{B}$, then data structures like multi-valued decision diagrams (MDD) [4], AND/OR multi-valued decision diagrams (AOMDD) [30], and multi-valued decomposable decision graphs (MDDG) [25] have been proposed, which arose from representations for Boolean functions that are studied in *knowledge compilation* (see, e. g., [15]). The (deterministic) d-representations studied in this paper can be interpreted as (deterministic) DNNF circuits with zero-suppressed semantics [2, Lemma 7.4], where a $\cup$-gate corresponds to a (deterministic) $\vee$-gate and a $\times$-gate corresponds to a *decomposable* $\wedge$-gate.

In the left-hand-side regime, representations have been introduced in the context of enumerating query results. Most notably, Olteanu and Závodnỳ [32] introduced the notion of *factorised databases* that are used to decompose the result relation of a conjunctive query using Cartesian product and union. Their findings imply the upper bound part of our dichotomy theorem: if $\mathcal{A}$ has bounded treewidth, its tree decomposition defines a so-called *d-tree*, which structures the polynomial size d-representation. They have also shown a limited lower bound for *structured* representations ("d-representations respecting a d-tree"). However, this lower bound considers only a small subclass of all possible d-representations. In a similar vein, in knowledge compilation there exist several restrictions of DNNFs e. g. requiring $\vee$-gates to be decision or deterministic [15], or enforcing structuredness [33]. In this light, the significance of our lower bound comes from the fact that it holds for the most general notion of representations (d-representations), which correspond to unrestricted DNNFs.

The proof of our lower bound has some connections to the conditional lower bound for the counting complexity of homomorphisms [14], which in turn builds upon the construction of Grohe [20]. The essence of these proofs is to rely on an assumption about the hardness of the parametrised clique problem and reduce this to all structures of unbounded treewidth. We take a similar route: in Section 5 we prove an unconditional lower bound for representing cliques and obtain our main lower bound using a sequence of reductions in Section 6.

The circuit notion for representing the set of homomorphisms between two given structures (or, equivalently, the result relation of a multiway join query) in a succinct data structure might be confused with previous work on the (Boolean or arithmetic) circuit complexity for deciding or counting homomorphisms or subgraphs. In this research branch, a structure $\mathcal{B}$ over a universe of size n is given as input to a circuit $C_{\mathcal{A},n}$, which decides the existence of or counts the number of homomorphisms (or subgraph-embeddings) from $\mathcal{A}$ to $\mathcal{B}$. Examples include monotone circuits for finding cliques [1, 36], bounded-depth circuits for finding cliques and other small subgraphs [35, 26] as well as graph polynomials and monotone arithmetic circuits [16, 7, 24] for counting homomorphisms. In particular, the recent work of Komarath, Pandey and Rahul [24] studies monotone arithmetic circuits that have, for each pattern $\mathcal{G}$ and each n, an input indicator variable $x_{\{u,v\}}$ for each potential edge $\{u, v\} \in [n]^2$ in the second graph $\mathcal{H}$. For every input (i.e. setting indicator variables according to a graph $\mathcal{H}$

on n vertices), the arithmetic circuit has to compute the number of homomorphisms from $\mathcal{G}$ to $\mathcal{H}$. Interestingly, Komorath et al. prove a tight bound and show that such arithmetic circuits need size $n^{\mathrm{tw}(\mathcal{G})+1}$. Unfortunately, this and related results from circuit complexity (such as lower bounds for the clique problem) do not translate to the knowledge compilation approach. Part of the reason is that we crucially have a different representation *for each pair* $\mathcal{G}$, $\mathcal{H}$ and having, e. g. an arithmetic circuit computing the constant number $|\mathrm{Hom}(\mathcal{G},\mathcal{H})|$ is trivial. Moreover, due to monotonicity, the worst-case right-hand-side instances $\mathcal{H}$ in [24] are complete graphs, whereas d-representations lack this form of monotonicity: adding edges to $\mathcal{H}$ can make factorisation simpler and in particular occurences of patterns in complete graphs can be succinctly factorised.

Despite this, some techniques on a more general level (e. g. arguing about the transversal of a circuit or using random graphs as bad examples) are useful in circuit complexity as well as for proving lower bounds on representations.

2 Preliminaries

We write $\mathbb{N}$ for the set of non-negative integers and define $[n] := \{1, \ldots, n\}$ for any positive integer n. Given a set S we write 2^S to denote the power set of S. Whenever writing a to denote a k-tuple, we write a_i to denote the tuple's i-th component; i. e., $a = (a_1, \ldots, a_k)$. For a function $f\colon X \to Y$ and $X' \subset X$ we write $\pi_{X'} f$ to denote the projection of f to X'. Given a set of functions, each of which has a domain containing X', we write $\pi_{X'} F := \{\pi_{X'} f \mid f \in F\}$.

Graphs, Minors, Structures, Tree Decompositions. Whenever $\mathcal{G}$ is a graph or a hypergraph we write $V(\mathcal{G})$ and $E(\mathcal{G})$ for the set of nodes and the set of edges, respectively, of $\mathcal{G}$. We let $\mathcal{K}_k$ be the complete graph on k vertices, $\mathcal{C}_k$ the k-cycle graph, and $\mathcal{G}_k$ the $k \times k$-grid graph. Given a graph $\mathcal{G}$ and $\{u, v\} \in E(\mathcal{G})$, we can form a new graph by *edge contraction*: replacing u and v be a new vertex w adjacent to all neighbours of u and v. A graph $\mathcal{H}$ is a *minor* of $\mathcal{G}$ if $\mathcal{H}$ can be obtained from $\mathcal{G}$ by repeatedly deleting vertices, deleting edges and contracting edges.

A *tree decomposition* of a graph $\mathcal{G}$ is a pair (T, β) where T is a tree and $\beta\colon V(T) \to 2^{V(\mathcal{G})}$ associates to every node $t \in V(T)$ a bag $\beta(t)$ such that the following is satisfied: (1) For every $v \in V(\mathcal{G})$ the set $\{t \in V(T) \mid v \in \beta(t)\}$ is non-empty and forms a connected set in T. (2) For every $\{u, v\} \in E(\mathcal{G})$ there is some $t \in V(T)$ such that $\{u, v\} \subseteq \beta(t)$. The width of a tree decomposition is $\max_{t \in V(T)} |\beta(t)| - 1$ and the *treewidth of* $\mathcal{G}$ is the minimum width of any tree decomposition of $\mathcal{G}$.

A (relational) signature σ is a set of relation symbols R, each of which is equipped with an arity $r = r(R)$. A (finite, relational) σ-structure $\mathcal{A}$ consists of a finite universe A and relations $R^{\mathcal{A}} \subseteq A^r$ for every r-ary relation symbol $R \in \sigma$. We will write $\|\mathcal{A}\| := \sum_{R \in \sigma} |R^{\mathcal{A}}|$. The *Gaifman graph* of $\mathcal{A}$ is the graph with vertex set A and edges $\{u, v\}$ for any distinct u, v that occur together in a tuple of a relation in $\mathcal{A}$. The *treewidth* of a structure is the treewidth of its Gaifman graph. We say $\mathcal{A}$ is *connected* if its Gaifman graph is connected and we will henceforth assume, without loss of generality, that all structures in this paper are connected.

Enumeration. An enumeration algorithm for $\mathrm{Hom}(\mathcal{A}, \mathcal{B})$ proceeds in two stages. In the *preprocessing* stage the algorithm does some preprocessing on $\mathcal{A}$ and $\mathcal{B}$. In the *enumeration phase* the algorithm enumerates, without repetition, all homomorphisms in $\mathrm{Hom}(\mathcal{A}, \mathcal{B})$, followed by the end of enumeration message. The *delay* is the maximum of three times: the time between the start of the enumeration phase and the first output homomorphism, the

maximum time between the output of two consecutive homomorphisms and between the last tuple and the end of enumeration message. The *preprocessing time* is the time the algorithm spends in the preprocessing stage, which may be 0. Similarly given a d-representation C for $\mathrm{Hom}(\mathcal{A}, \mathcal{B})$, an enumeration algorithm for C has a preprocessing stage, where it can do some preprocessing on C, and an enumeration phase defined as above.

3 Homomorphisms and the complexity of constraint satisfaction

A *homomorphism* $h\colon \mathcal{A} \to \mathcal{B}$ between two σ-structures $\mathcal{A}$ and $\mathcal{B}$ is a mapping from A to B that preserves all relations, i. e., for every r-ary $R \in \sigma$ and $(a_1, \ldots, a_r) \in A^r$ it holds that if $(a_1, \ldots, a_r) \in R^{\mathcal{A}}$, then $(h(a_1), \ldots, h(a_r)) \in R^{\mathcal{B}}$. We let $\mathrm{Hom}(\mathcal{A}, \mathcal{B})$ be the set of all homomorphisms from $\mathcal{A}$ to $\mathcal{B}$. A (homomorphic) core of a structure $\mathcal{A}$ is an inclusion-wise minimal substructure $\mathcal{A}' \subseteq \mathcal{A}$ such that there is a homomorphism from $\mathcal{A}$ to $\mathcal{A}'$. It is well known that all cores of a structure are isomorphic, hence we will also speak of *the* core of a structure.

Following common notation we fix a (potentially infinite) signature σ and define for classes of σ-structures $\mathfrak{A}$ and $\mathfrak{B}$ the (promise) decision problem $\mathrm{CSP}(\mathfrak{A}, \mathfrak{B})$ to be: "Given two σ-structures $\mathcal{A} \in \mathfrak{A}$ and $\mathcal{B} \in \mathfrak{B}$, is there a homomorphism from $\mathcal{A}$ to $\mathcal{B}$?" Similarly, the counting problem $\#\mathrm{CSP}(\mathfrak{A}, \mathfrak{B})$ asks: "Given two σ-structures $\mathcal{A} \in \mathfrak{A}$ and $\mathcal{B} \in \mathfrak{B}$, what is the number of homomorphisms from $\mathcal{A}$ to $\mathcal{B}$?" A lot of work has been devoted towards classifying the classes of structures for which the problems are solvable in polynomial time. Normally either the left-hand-side $\mathfrak{A}$ or the right-hand-side $\mathfrak{B}$ is restricted and the other part ($\mathfrak{B}$ or $\mathfrak{A}$) is the class _ of all structures. A related problem is Enum-$\mathrm{CSP}(\mathfrak{A}, \mathfrak{B})$ [10], which is the following task: "Given two σ-structures $\mathcal{A} \in \mathfrak{A}$ and $\mathcal{B} \in \mathfrak{B}$, enumerate all homomorphisms from $\mathcal{A}$ to $\mathcal{B}$". One way of defining tractability for enumeration algorithms is *polynomial delay enumeration*, where the preprocessing time and the delay is polynomial in $\mathcal{A}$ and $\mathcal{B}$.

In this paper we focus on "left-hand-side" restrictions, where $\mathfrak{B}$ is the class of all structures. Moreover, we assume that the arity of each symbol in σ is bounded by some constant r. In this setting the complexity of $\mathrm{CSP}(\mathfrak{A}, \_)$ and $\#\mathrm{CSP}(\mathfrak{A}, \_)$ is fairly well understood: the decision problem is polynomial time tractable iff the core of every structure in $\mathfrak{A}$ has bounded treewidth, while the counting problem is tractable if every structure from $\mathfrak{A}$ itself has bounded treewidth. This is made precise by the following two theorems.

▶ **Theorem 2** ([20]). *Let $r \in \mathbb{N}$, σ be a signature of arity $\leq r$ and $\mathfrak{A}$ a class of σ-structures. Under the assumption that there is no $c \in \mathbb{N}$ such that for every $k \in \mathbb{N}$ there is an algorithm that finds a k-clique in an n-vertex graph in time $O(n^c)$ the following two statements are equivalent.*

1. *There is a $w \in \mathbb{N}$ such that the core of every structure in $\mathfrak{A}$ has treewidth at most w.*
2. $\mathrm{CSP}(\mathfrak{A}, \_)$ *is solvable in polynomial time.*

▶ **Theorem 3** ([14]). *Let $r \in \mathbb{N}$, σ be a signature of arity $\leq r$ and $\mathfrak{A}$ a class of σ-structures. Under the assumption that there is no $c \in \mathbb{N}$ such that for every $k \in \mathbb{N}$ there is an algorithm that counts the number of k-cliques in an n-vertex graph in time $O(n^c)$ the following two statements are equivalent.*

1. *There is a $w \in \mathbb{N}$ such that every structure in $\mathfrak{A}$ has treewidth at most w.*
2. $\#\mathrm{CSP}(\mathfrak{A}, \_)$ *is solvable in polynomial time.*

To understand the difference between these characterisations, consider the class $\mathfrak{A}$ of all structures $\mathcal{A}_k$ that are complete graphs on k vertices with an additional vertex with a self-loop. The homomorphic core of such structures is just the self-loop and finding one

homomorphism from $\mathcal{A}_k$ to $\mathcal{B}$ is equivalent to finding a self-loop in $\mathcal{B}$. However, counting homomorphisms from $\mathcal{A}_k$ to $\mathcal{B}$ is as hard as counting k-cliques: if $\mathcal{B}$ is a simple graph $\mathcal{G}$ with one additional vertex with a self-loop, then the number of homomorphisms from $\mathcal{A}_k$ to $\mathcal{B}$ is the number of k-cliques in $\mathcal{G}$ plus one.

The complexity of the corresponding enumeration problem Enum-CSP($\mathfrak{A}$, _) is still open. It has been shown that polynomial delay enumeration is possible if $\mathfrak{A}$ has bounded treewidth [10]. On the other hand, polynomial delay enumeration implies solvability of the decision problem in polynomial time (because either the first solution or an end-of-enumeration message has to appear after polynomial time). Hence it follows from Theorem 2, under the same complexity assumption, that there is no polynomial delay enumeration algorithm if the cores of the structures in $\mathfrak{A}$ have unbounded treewidth. For further discussion on this topic we refer the reader to [10].

Our main result (Theorem 1) can be viewed as an unconditional dichotomy for enumeration and counting in a restricted class of algorithms: when the algorithm relies on local decompositions into union and product, then the tractable instances are exactly those that have bounded treewidth. Interestingly, this matches the conditional dichotomy for the counting case (Theorem 3).

4 Factorised Representations

In this section we formally introduce the factorisation formats for CSPs. These formats agree with the factorised representations of relations introduced by Olteanu and Závodný [32] in the context of evaluating conjunctive queries on relational databases. While we stick to the naming conventions introduced there we provide a slightly different circuit-based definition that is very much inspired by [2] and the notion of *set circuits* introduced in [3].

A *factorisation circuit* C for two sets A and B is an acyclic directed graph with node labels and a unique sink. Each node without incoming edges is called an *input gate* and labelled by $\{a \mapsto b\}$ for some $a \in A$ and $b \in B$. Every other node is labelled by either $\cup$ or $\times$ and called a $\cup$-*gate* or $\times$-*gate*, respectively. For each gate g in the circuit we inductively define its *domain* $\mathrm{dom}(g) \subseteq A$ by $\mathrm{dom}(g) = \{a\}$ if g is an input gate with label $\{a \mapsto b\}$ and $\mathrm{dom}(g) = \bigcup_{i=1}^{r} \mathrm{dom}(g_i)$ if g is a non-input gate with child gates $g_1, \dots, g_r$.

A factorisation circuit is *well-defined* if for every gate g with child gates $g_1, \dots, g_r$ it holds that $\mathrm{dom}(g) = \mathrm{dom}(g_1) = \cdots = \mathrm{dom}(g_r)$ if g is a $\cup$-gate and $\mathrm{dom}(g_i) \cap \mathrm{dom}(g_j) = \emptyset$ for all $i \neq j$ if g is a $\times$-gate. For every gate g in a well-defined factorisation circuit we let S_g be a set of mappings $h\colon \mathrm{dom}(g) \to B$ defined by

$$S_g := \begin{cases} \{\{a \mapsto b\}\} & \text{if } g \text{ is an input labelled by } \{a \mapsto b\} \\ S_{g_1} \cup \cdots \cup S_{g_r} & \text{if } g \text{ is a } \cup\text{-gate with children } g_1, \dots, g_r, \\ \{\, h_1 \cup \cdots \cup h_r \mid h_i \in S_{g_i},\, i \in [r] \,\} & \text{if } g \text{ is a } \times\text{-gate with children } g_1, \dots, g_r. \end{cases} \quad (1)$$

We define $S_C := S_s$ for the sink s of C. For each gate g we let C_g be the sub-circuit with sink g. By $\|C\|$ we denote the size of a factorisation circuit C, which is defined to be the number of gates plus the number of wires. The number of gates in C is denoted by $|C|$.

Before defining factorised representations for CSP-instances, we introduce two special types of circuits. A factorisation circuit is *treelike* if the underlying graph is a tree, i. e., every non-sink gate has exactly one parent. Moreover, a well-defined factorisation circuit is *deterministic* if for every $\cup$-gate g the set S_g is a *disjoint* union of its child sets $S_{g_1}, \dots, S_{g_r}$. Note that while treelikeness is a syntactic property of the circuit structure, being deterministic is a semantic property that depends on the valuations of the gates. Now we are ready to state a circuit-based definition of the factorised representations defined in [32].

▶ **Definition 4.** *Let $\mathcal{A}$ and $\mathcal{B}$ be two σ-structures.*

1. *A (deterministic)* d-representation *for $\mathcal{A}$ and $\mathcal{B}$ is a well-defined (deterministic) factorisation circuit over $V(\mathcal{A})$ and $V(\mathcal{B})$ where $S_C = \mathrm{Hom}(\mathcal{A}, \mathcal{B})$.*
2. *A (deterministic)* f-representation *is a (deterministic) d-representation with the additional restriction that the circuit is treelike.*

For brevity we will sometimes refer to d/f-representations as d/f-reps. Note that a d-rep can be more succinct than a f-rep and we will mostly deal with d-reps in this paper. However, in the proofs it will sometimes be convenient to expand out the circuit in order to make it treelike. More formally, the *transversal* $\mathrm{Trans}(C)$ of a d-rep C is the f-rep obtained from C as follows: using a top-down transversal starting at the output gate, we replace each gate g with parents $p_1, \ldots, p_d$ by d copies $g_1, \ldots, g_d$ such that the in-edges of each g_i are exactly the children of g and g_i has exactly one out-edge going to p_i. This procedure produces a treelike circuit that is well-defined/deterministic if C was well-defined/deterministic. Finally it can easily be verified that $S_{\mathrm{Trans}(C)} = S_C$.

We will often want to construct new factorised circuits from old ones. The following lemma introduces two constructions that will be particularly useful, the proof of correctness can be found in the full version of this paper.

▶ **Lemma 5.** *Let $\mathcal{A}, \mathcal{B}$ be σ-structures and C be a d-rep of $\mathrm{Hom}(\mathcal{A}, \mathcal{B})$. Let $X = \{x_1, \ldots, x_\ell\} \subseteq A$, $Y_1, \ldots, Y_\ell \subseteq B$, $\ell \geq 1$. Then one can construct the following factorised circuits in time $O(\|C\|)$.*

1. *C', such that $S_{C'} = \pi_X \mathrm{Hom}(\mathcal{A}, \mathcal{B})$ and $\|C'\| \leq \|C\|$.*
2. *C'', such that $S_{C''} = \{h \in \mathrm{Hom}(\mathcal{A}, \mathcal{B}) \mid h(x_i) \in Y_i, i \in [\ell]\}$ and $\|C''\| \leq \|C\|$.*

A special f-rep is the *flat representation*: a depth-2 circuit with a single $\cup$-gate at the top followed by a layer of $\times$-gates. Note that for any pair $\mathcal{A}$, $\mathcal{B}$, of σ-structures the flat representation has size $1 + |\mathrm{Hom}(\mathcal{A}, \mathcal{B})| \cdot (2|A| + 2)$. Intuitively, this representation corresponds to listing all homomorphisms and provides a trivial upper bound on representation size.

Deterministic d-representations have two desirable properties: they allow us to compute $|\mathrm{Hom}(\mathcal{A}, \mathcal{B})|$ in time $O(\|C\|)$ and to enumerate all homomorphisms with $O(|A|)$ delay after $O(\|C\|)$ preprocessing. Efficient counting is possible by computing bottom-up the number $|S_g|$ for each gate using multiplication on every $\times$-gate and summation on every (deterministic) $\cup$-gate. If, additionally, C is normal – i. e., no parent of a $\cup$-gate is a $\cup$-gate and the in-degree of every $\cup$- and $\times$-gate is at least 2 – Olteanu and Závodný [32, Theorem 4.11] show enumeration with $O(|A|)$ delay and *no* preprocessing is possible by sequentially enumerating the sets S_{g_i} of every child of a (deterministic) $\cup$-gate and by a nested loop to generate all combinations of child elements at $\times$-gates. The case where C is not normal is shown in [2, Theorem 7.5] and is more involved. Note that the delay is optimal in the sense that every homomorphism that is enumerated is of size $O(|A|)$.

In the other direction this means that constructing a deterministic d-rep is at least as hard as counting the number of homomorphisms. Our main theorem implies that, modulo the same assumptions as Theorem 3, the opposite is also true: for a class $\mathfrak{A}$ of structures of bounded arity there is a polynomial time algorithm that constructs a d-representation of polynomial size for two given structures $\mathcal{A} \in \mathfrak{A}$ and $\mathcal{B}$ if and only if, there is a polynomial-time algorithm that counts the number of homomorphisms between $\mathcal{A} \in \mathfrak{A}$ and $\mathcal{B}$.

Upper bounds on representation size. We have already argued that there is always a flat representation of size $O(|A| \cdot |\mathrm{Hom}(\mathcal{A}, \mathcal{B})|)$. Thus, as a corollary of [5] we get an upper bound of $O(|A| \cdot \|\mathcal{B}\|^{\rho^*(\mathcal{A})})$, where $\rho^*(\mathcal{A})$ is the *fractional edge cover number of* $\mathcal{A}$. Note that, however, the fractional edge cover number for structures of bounded arity is quite large. More precisely, if all relations in $\mathcal{A}$ have arity at most r, then $\rho^*(\mathcal{A}) \geq \frac{1}{r}|A|$.

Luckily in many cases we can do better: the results by Olteanu and Závodný in [32] imply that given a tree-decomposition of $\mathcal{A}$ of width $w-1$ we can construct a d-rep of $\mathrm{Hom}(\mathcal{A},\mathcal{B})$ of size $O(\|\mathcal{A}\|^2\|\mathcal{B}\|^w)$ in time $O(\mathrm{poly}(\|\mathcal{A}\|)\|\mathcal{B}\|^w\log(\|\mathcal{B}\|))$. Moreover the d-reps produced are normal and deterministic, meaning they allow us to perform efficient enumeration and counting. Therefore if $\mathfrak{A}$ is a class of bounded treewidth this gives us one method for solving $\#\mathrm{CSP}(\mathfrak{A},\_)$ in polynomial time. In fact, the same holds true if w is the more general *fractional hypertreewidth*, although for the case of bounded arity structures the two measure differ only by a constant. We discuss the unbounded arity case in the conclusion and, in more detail, in the full version of this paper.

5 A near-optimal bound for cliques

The goal of this section is to prove the following two theorems:

▶ **Theorem 6.** *For any $k\in\mathbb{N}$ there exist arbitrary large graphs $\mathcal{G}$ with m edges such that any f-rep of $\mathrm{Hom}(\mathcal{K}_k,\mathcal{G})$ has size $\Omega(m^{k/2}/\log^k(m))$.*

▶ **Theorem 7.** *For any $k\in\mathbb{N}$ there exist arbitrary large graphs $\mathcal{G}$ with m edges such that any d-rep of $\mathrm{Hom}(\mathcal{K}_k,\mathcal{G})$ has size $\Omega(m^{k/2}/\log^{3k-1}(m))$.*

These bounds are almost tight since the number of k-cliques in a graph with m edges is bounded by $m^{k/2}$. Moreover Theorem 7 is a crucial ingredient for proving our main theorem in Section 6. We will first prove Theorem 6 and then show how this implies the bound for d-reps.

The main idea is to exploit a correspondence between the structure of a (simple) graph $\mathcal{G}$ and f-reps of $\mathrm{Hom}(\mathcal{K}_k,\mathcal{G})$. To illustrate this consider the case $k=2$, where $V(\mathcal{K}_2)=\{x_1,x_2\}$ and each $h\in\mathrm{Hom}(\mathcal{K}_2,\mathcal{G})$ corresponds to an edge of $\mathcal{G}$. Let C be a f-rep of $\mathrm{Hom}(\mathcal{K}_2,\mathcal{G})$, with $\times$-gates $g_1,\dots,g_\alpha$. Each g_i has two children g_i^1, g_i^2 with $\mathrm{dom}(g_i^1)=x_1$ and $\mathrm{dom}(g_i^2)=x_2$. Since no $\times$-gates can occur in $C_{g_i^1}$ or $C_{g_i^2}$, $S^1_{g_i}=\{\{x_1\mapsto a\}\mid a\in A_i\}$ and $S_{g_i^2}=\{\{x_2\mapsto b\}\mid b\in B_i\}$ for some disjoint $A_i,B_i\subseteq V(\mathcal{G})$. Therefore $A_i\times B_i$ is a complete bipartite subgraph of $\mathcal{G}$. Since the ancestors of each $\times$-gate can only be $\cup$-gates, each f-rep of $\mathrm{Hom}(\mathcal{K}_2,\mathcal{G})$ corresponds to a set of complete bipartite subgraphs that cover every edge of $\mathcal{G}$. Finding such sets and investigating their properties has been studied in various contexts, for example see [12, 18, 22, 31].

Moreover, the number of input gates appearing in C is $\sum_{i=1}^{\alpha}|A_i|+|B_i|$ and so finding a f-rep of $\mathrm{Hom}(\mathcal{K}_2,\mathcal{G})$ of minimum size corresponds to minimising the sum of the sizes of the partitions in our complete bipartite covering of $\mathcal{G}$, call this the cost of the covering. Proving Theorem 6 for the case $k=2$, corresponds to finding graphs where every covering of the edges by complete bipartite subgraphs has high cost. This is a problem investigated by Chung et al. in [12], where one key idea is that if a graph contains no large complete bipartite subgraphs and a large number of edges then the cost of any cover must be high. We deploy this idea in our more general context. This motivates the following lemma, which follows from a simple probabilistic argument.

▶ **Lemma 8.** *For every $k\in\mathbb{N}$ there exists some $c_k\in\mathbb{R}^+$ such that for every sufficiently large integer n there is a graph $\mathcal{G}$ with n vertices, such that*

1. *$\mathcal{G}$ has $m\geq\frac{1}{8}n^2$ edges,*
2. *$\mathcal{G}$ contains no complete bipartite subgraph $\mathcal{K}_{a,a}$ for $a\geq 3\log(n)$, and*
3. *the number of k-cliques in $\mathcal{G}$ is at least c_kn^k.*

Proof. We first prove the following claim.

▷ Claim 9. Let $\mathcal{G}_n$ be a random graph on n vertices with edge probability $\frac{1}{2}$. Let $\epsilon > 0$. Then for any $a = a(n) \geq (2+\epsilon)\log(n)$,

$$P_a := \mathbb{P}(\mathcal{G}_n \text{ has } \mathcal{K}_{a,a} \text{ as a subgraph}) \to 0 \text{ as } n \to \infty.$$

Proof of Claim. By the union bound and the bound on a we get

$$P_a \leq \binom{n}{a}^2 2^{-a^2} \leq n^{2a} 2^{-a^2} = 2^{2a\log(n) - a^2} \leq 2^{-(\epsilon^2+2\epsilon)\log^2 n}.$$ ◁

Now let $\mathcal{G}_n$ be as above, $s = s(k) := \binom{k}{2} + 1$ and p be the probability that such a graph has at least $\binom{n}{k}2^{-s}$ k-cliques. The expected number of k-cliques in $\mathcal{G}_n$ is $\binom{n}{k}2^{-\binom{k}{2}}$. Therefore,

$$\binom{n}{k}2^{-\binom{k}{2}} \leq \binom{n}{k}2^{-s}(1-p) + \binom{n}{k}p$$

and so $p \geq 1/(2^s - 1)$. Moreover, by the Chernoff bound, (1) from the statement of the Lemma fails only with exponentially small probability. By Claim 9 there must exist a $\mathcal{G}$ satisfying (1), (2), and (3) for sufficiently large n. ◀

Equipped with Lemma 8 we are already in a position to prove Theorem 6.

Proof of Theorem 6. Let $\mathcal{G}$ be an n-vertex graph provided by Lemma 8 and suppose that C is a f-rep for $\mathcal{K}_k$ and $\mathcal{G}$. If $\max_{x \in \mathrm{dom}(g)} |\{a \mid h(x) = a, h \in S_g\}| \leq 3\log(n)$ for a gate g we say that g is *small*. Otherwise we say g is *big*. Note that a $\times$-gate cannot have two big children g_1 and g_2 because otherwise there would be $x_1 \in \mathrm{dom}(g_1)$ and $x_2 \in \mathrm{dom}(g_2)$ such that

$$\{a \mid h(x_1) = a, h \in S_{g_1}\} \times \{a \mid h(x_2) = a, h \in S_{g_2}\}$$

forms a complete bipartite subgraph with partitions bigger than $3\log n$ in $\mathcal{G}$, contradicting (2) from Lemma 8.

If g is small, then C_g represents $|S_g| \leq 3^{|\mathrm{dom}(g)|}\log^{|\mathrm{dom}(g)|}(n)$ homomorphisms. We claim that for any gate g of C, $|S_g| \leq |C_g| \cdot 3^{|\mathrm{dom}(g)|}\log^{|\mathrm{dom}(g)|}(n)$. Clearly this holds for input gates. We can therefore induct bottom up on C. Suppose our claim holds for all children $g_1, \ldots, g_r$ of some gate g. If g is a $\times$-gate then we know at most one of the g_i is big, say g_1. Define $b := \sum_{i=2}^{r} |\mathrm{dom}(g_i)|$. Then,

$$|S_g| = \prod_{i=1}^{r} |S_{g_i}| \leq |C_{g_1}| \cdot 3^{|\mathrm{dom}(g_1)|}\log^{|\mathrm{dom}(g_1)|}(n) \cdot 3^b \log^b(n) \leq |C_g| \cdot 3^{|\mathrm{dom}(g)|}\log^{|\mathrm{dom}(g)|}(n),$$

The $\cup$-gate case follows immediately from the induction hypothesis because the circuit is treelike so if g has children $g_1, \ldots, g_r$ then $|C_g| = 1 + \sum_{i=1}^{r} |C_{g_i}|$.

From the claim we infer in particular that $|\mathrm{Hom}(\mathcal{K}_k, \mathcal{G})| = |S_s| \leq |C| \cdot 3^k \log^k(n)$ for the sink s of C. By (3) from Lemma 8 it follows that $|C| \geq c_k n^k/(3^k \log^k(n))$ which, combined with (1) from Lemma 8, implies the claimed result. ◀

We now transfer this bound to d-reps, by showing that, for the same graphs used above, any d-rep cannot be much smaller than the smallest f-rep.

Proof of Theorem 7. Let $\mathcal{G}$ be an n-vertex graph provided by Lemma 8 as above and C a d-rep of $\mathrm{Hom}(\mathcal{K}_k, \mathcal{G})$ with sink s. If a gate has out-degree of more than one we call it a *definition*. As in the proof of Theorem 6, if $\max_{x \in \mathrm{dom}(g)} |\{a \mid h(x) = a, h \in S_g\}| \leq 3\log(n)$ for a gate g we say that g is *small*. Otherwise we say g is *big*.

Our strategy is to convert C into an equivalent f-rep that is not much bigger than C. For ease of analysis and exposition we will do this by first eliminating all small definitions and then all big definitions. First if s is small replace the whole circuit with its equivalent flat representation. Otherwise, we mark all small gates g that have a big parent and compute the equivalent flat representation F_g of C_g. Since every unmarked small gate is a descendant of some marked gate, we can now safely delete all unmarked small gates. Afterwards we consider every wire between a marked gate g and one of its big parents p and replace it by a copy of F_g as input to p. We obtain an equivalent circuit $\hat{C}$ where every small gate has only one parent. The size (number of gates plus number of wires) increases only by a factor determined by the maximum size of a flat representation:

▷ Claim 10. $\|\hat{C}\| \leq \|C\| \cdot (2k+3)3^k \log^k(n)$.

When we try and eliminate big definitions one challenge is that if g is big, then $\|\hat{C}_g\|$ can be large and so making lots of copies of it could blow up the size of our circuit. To overcome this we introduce the notion of an *active parent*. We then show that non-active parents are effectively redundant and that there can't be too many active ones, which allows us to construct an equivalent treelike circuit of the appropriate size.

So let g be a definition with parents $p_1, \ldots, p_\alpha$, $\alpha > 1$, and suppose there is a unique path from p_i to the sink s for every i. Then for every gate v on the unique path from g to s which passes through p_i, we inductively define a set of (partial) homomorphisms $A_i^v = A_i^v(g)$ as follows, where $\hat{v}$ refers to the child of v also lying on this path.

- $A_i^g := S_g$,
- if v is a $\cup$-gate $A_i^v := A_i^{\hat{v}}$,
- otherwise v is a $\times$-gate with children $u_1, \ldots, u_{r-1}, \hat{v}$ and $A_i^v := \{h_1 \cup \ldots \cup h_r \mid h_i \in S_{u_i},\, i \in [r-1],\, h_r \in A_i^{\hat{v}}\}$.

Write $A_i := A_i^s$, intuitively this is the set of homomorphisms that the wire from g to p_i contributes to. We say that a parent p_i of g is *active* if $A_i \not\subseteq \cup_{j \neq i} A_j$. Now using a top-down traversal starting at the output gate of $\hat{C}$, we replace each gate with active parents $p_1, \ldots, p_\beta$, by β copies $g_1, \ldots, g_\beta$ such that the children of each g_i are exactly the children of g and g_i has exactly one out-edge going to p_i. At each stage we also clean-up the circuit by iteratively deleting all gates which have no incoming wires, as well as all the wires originating from such gates. We can think of this process as constructing a slimmed down version of the traversal, where at each stage we only keep wires going to active parents. Call the resulting circuit C'.

We first note that this process is well-defined, as there is a unique path from the sink to itself and since whenever we visit a gate we have already visited all of its parents. Moreover, by construction this results in a treelike circuit. In the next claim we bound the size of C' and show it is indeed an equivalent circuit. The idea is that firstly a gate cannot have too many active parents, as otherwise we would get a large biclique in $\mathcal{G}$ which is ruled out by Lemma 8, and secondly that since only active parents contribute new homomorphisms we really do get an equivalent circuit, see the full version of this paper for details.

▷ Claim 11. C' is a f-rep of $\mathrm{Hom}(\mathcal{K}_k, \mathcal{G})$ and $\|C'\| \leq 3^k \log^{k-1}(n)\|\hat{C}\|$.

Pulling everything together we get that

$$\|C\| \underset{\text{(Claim 10)}}{\geq} \frac{\|\hat{C}\|}{(2k+3)3^k \log^k(n)} \underset{\text{(Claim 11)}}{\geq} \frac{\|C'\|}{(2k+3)3^{2k} \log^{2k-1}(n)} = \Omega\left(\frac{m^{k/2}}{\log^{3k-1}(m)}\right),$$

where the final equality follows by Theorem 6 since C' is a f-rep of $\mathrm{Hom}(\mathcal{K}_k, \mathcal{G})$. ◀

6 The representation dichotomy for structures of bounded arity

In this section we lift the lower bound for cliques to all classes of graphs with unbounded treewidth. We first introduce a notion of reductions between representations and show that having lower bounds for all graphs of unbounded treewidth immediately implies our main dichotomy theorem for bounded-arity structures.

Afterwards, we introduce minor and almost-minor reductions and use them to obtain a lower bound for representing homomorphisms from large grids and from graphs having large grids as a minor. The superpolynomial representation lower bound for all graph classes with unbounded treewidth then follows from the excluded grid theorem.

6.1 Reductions between representations

In order to define reductions between representations we fix some notation. For two structures $\mathcal{A}$ and $\mathcal{B}$ we let $\mathsf{D}(\mathcal{A},\mathcal{B})$ be the set of all d-representations of $\mathrm{Hom}(\mathcal{A},\mathcal{B})$ and $\mathsf{d}(\mathcal{A},\mathcal{B}) = \min_{C\in\mathsf{D}(\mathcal{A},\mathcal{B})} \|C\|$ be the size of the smallest such representation.

For a class $\mathfrak{C}$ of structures the function $\mathsf{d}_{\mathcal{A},\mathfrak{C}}\colon \mathbb{N}\to\mathbb{N}$ expresses the required size of a d-representation of homomorphisms between $\mathcal{A}$ and $\mathcal{C}\in\mathfrak{C}$ in terms of the size m of $\mathcal{C}$, i. e., $\mathsf{d}_{\mathcal{A},\mathfrak{C}}(m) = \max_{\{\mathcal{C}\in\mathfrak{C}\,:\,\|\mathcal{C}\|\le m\}} \mathsf{d}(\mathcal{A},\mathcal{C})$. We write $\mathsf{d}_{\mathcal{A}}$ as an abbreviation for $\mathsf{d}_{\mathcal{A},\mathfrak{C}}$ when $\mathfrak{C}$ is the class of all structures. Translated to this notation, [32] showed that $\mathsf{d}_{\mathcal{A}} = O(m^{\mathrm{tw}(\mathcal{A})+1})$, whereas Theorem 7 states the lower bound $\mathsf{d}_{K_k} = \Omega(m^{k/2}/\log^{3k-1}(m))$. We also write, for a signature σ, $\mathfrak{C}_\sigma$ to denote the class of all σ-structures.

The main goal of this section is to prove, for some increasing function f, a lower bound of the form $\mathsf{d}_{\mathcal{A}} = \Omega(m^{f(\mathrm{tw}(\mathcal{A}))/\,\mathrm{ar}(\mathcal{A})})$ for every structure $\mathcal{A}$, which immediately implies our main theorem. To achieve this we use reductions with our k-clique lower bound as a starting point. Suppose we already have a lower bound on $\mathsf{d}_{\mathcal{A},\mathfrak{C}}$ for a class $\mathfrak{C}$ of arbitrarily large hard instances (implying a lower bound on $\mathsf{d}_{\mathcal{A}}$), then we can use the following reduction *from* $\mathcal{A}$ *to* $\mathcal{B}$ *via* $\mathfrak{C}$ to obtain a lower bound on $\mathsf{d}_{\mathcal{B}}$.

▶ **Definition 12.** *Let $\mathcal{A}$ be a σ-structure and let $\mathfrak{C}$ be a class of σ-structures. Let $\mathcal{B}$ be a σ'-structure and $c\colon\mathbb{R}^+\to\mathbb{R}^+$ be a strictly increasing function. Then a* c-reduction *from $\mathcal{A}$ to $\mathcal{B}$ via $\mathfrak{C}$ is a pair $(\phi,(\psi_{\mathcal{C}})_{\mathcal{C}\in\mathfrak{C}})$, where $\phi\colon\mathfrak{C}\to\mathfrak{C}_{\sigma'}$ and $\psi_{\mathcal{C}}\colon\mathsf{D}(\mathcal{B},\phi(\mathcal{C}))\to\mathsf{D}(\mathcal{A},\mathcal{C})$ such that:*

1. *for every $n\in\mathbb{N}$ there is a $\mathcal{C}\in\mathfrak{C}$ such that $\|\phi(\mathcal{C})\|\ge n$,*
2. *$\|\phi(\mathcal{C})\|\le c(\|\mathcal{C}\|)$ for all $\mathcal{C}\in\mathfrak{C}$, and*
3. *$\|\psi_{\mathcal{C}}(C)\|\le\|C\|$ for every structure $\mathcal{C}\in\mathfrak{C}$ and circuit $C\in\mathsf{D}(\mathcal{B},\phi(\mathcal{C}))$.*

If $c(m)=\alpha m$ for some $\alpha\in\mathbb{R}^+$, we say we have a linear reduction.

▶ **Lemma 13.** *Suppose there is a c-reduction $(\phi,(\psi_{\mathcal{C}})_{\mathcal{C}\in\mathfrak{C}})$ from $\mathcal{A}$ to $\mathcal{B}$ via $\mathfrak{C}$, let $\mathfrak{D}=\{\phi(\mathcal{C})\mid\mathcal{C}\in\mathfrak{C}\}$ be the image of ϕ. Then $\mathsf{d}_{\mathcal{B},\mathfrak{D}} = \Omega(\mathsf{d}_{\mathcal{A},\mathfrak{C}}\circ\lfloor c^{-1}\rfloor)$.*

Proof. Fix $m\in\mathbb{N}$, where $m\ge\min_{\{\mathcal{C}\in\mathfrak{C}\}}\|\mathcal{C}\|$. Let $\mathcal{C}\in\mathfrak{C}$ with $\|\mathcal{C}\|\le m$. Then $\psi_{\mathcal{C}}$ witnesses that $\mathsf{d}(\mathcal{A},\mathcal{C})\le\mathsf{d}(\mathcal{B},\phi(\mathcal{C}))$. Also $\|\phi(\mathcal{C})\|\le c(m)$, since c is an increasing function. So $\mathsf{d}_{\mathcal{B},\mathfrak{D}}(c(m)) = \max_{\{\mathcal{C}\,:\,\|\phi(\mathcal{C})\|\le c(m)\}}\mathsf{d}(\mathcal{B},\phi(\mathcal{C}))\ge\max_{\{\mathcal{C}\,:\,\|\mathcal{C}\|\le m\}}\mathsf{d}(\mathcal{A},\mathcal{C}) = \mathsf{d}_{\mathcal{A},\mathfrak{C}}(m)$. Since $\mathfrak{C}$ and $\mathfrak{D}$ contain arbitrarily large structures, the asymptotic bound from the lemma follows. ◀

We start illustrating the power of these reductions by making two simplifications. First, we reduce the general problem of representing homomorphisms to representing homomorphisms that respect a partition. Second, we further reduce to graph homomorphisms that respect a partition. All proofs from this subsection can be found in the full version of the paper.

For the first reduction we need the notion of the *individualisation* of a σ-structure $\mathcal{A}$, which is obtained from $\mathcal{A}$ by giving every element of the universe a distinct color. More precisely, we extend the vocabulary σ with unary relations (= colours) $\sigma_A = \{P_a \colon a \in A\}$ and let $\mathcal{A}^{\mathrm{id}}$ be the $\sigma \cup \sigma_A$-expansion of $\mathcal{A}$ by adding $P_a^{\mathcal{A}^{\mathrm{id}}} = \{a\}$.

▶ **Lemma 14.** *Let $\mathcal{A}$ be a σ-structure and let $\mathfrak{C}$ be the class of all $\sigma \cup \sigma_A$-structures where $\{P_a^{\mathcal{C}} \mid a \in A\}$ is a partition of the universe. Then $\mathsf{d}_{\mathcal{A}} = \Omega(\mathsf{d}_{\mathcal{A}^{id},\mathfrak{C}})$.*

We call structures and (vertex-coloured) graphs *individualised* if every vertex has a distinct colour. In the next lemma we reduce from individualised structures to individualised graphs. Recall the definition of the Gaifman graph $\mathcal{G}_{\mathcal{A}}$ from the preliminaries.

▶ **Lemma 15.** *Let $\mathcal{A}$ be an individualised structure and $\mathcal{G}_{\mathcal{A}}^{id}$ the individualisation of its Gaifman graph. Let $\mathfrak{C}$ be the class of all structures $\mathcal{C}$ where $\{P_a^{\mathcal{C}} \mid a \in A\}$ is a partition of its universe and $\mathfrak{H}$ be the class of all vertex-coloured graphs $\mathcal{H}$ where $\{P_a^{\mathcal{H}} \mid a \in A\}$ is a partition of its vertex set. Then $\mathsf{d}_{\mathcal{A},\mathfrak{C}}(m) = \Omega\big((\mathsf{d}_{\mathcal{G}_{\mathcal{A}}^{id},\mathfrak{H}}(m))^{2/\operatorname{ar}(\mathcal{A})} \big)$.*

Taking both lemmas into account, we can now focus on individualised graphs $\mathcal{G}$ on the left-hand side and on graphs $\mathcal{H}$ with the corresponding colouring $\{P_a^{\mathcal{H}} \mid a \in V(\mathcal{G})\}$ that partitions its vertex set on the right-hand side. We call such graphs *$V(\mathcal{G})$-partitioned graphs*. However we would also like to deploy our lower bound from Section 5; the next lemma allows to transfer this lower bound to individualised structures.

▶ **Lemma 16.** *Let $\mathcal{G}$ be a graph and $\mathfrak{C}$ be the class of all $V(\mathcal{G})$-partitioned graphs. Then $\mathsf{d}_{\mathcal{G}^{id},\mathfrak{C}} = \Omega(\mathsf{d}_{\mathcal{G}})$.*

6.2 Minor reductions

In this subsection we show that we can reduce $\mathcal{G}'$ to $\mathcal{G}$ if $\mathcal{G}$ is a minor of $\mathcal{G}'$. We start by illustrating how to handle edge contractions via an example.

▶ **Example 17** (Reduction from 4-cycle to 3-cycle)**.** Consider the 3-cycle $\mathcal{K}_3$ on vertices x_1, x_2, x_3, which is a minor of the 4-cycle $\mathcal{C}_4$ on vertices x_1, x_2, x_3, x_4 by contracting one edge $\{x_4, x_1\}$. We show that we can lift the lower bound for $\mathcal{K}_3^{\mathrm{id}}$ (Theorem 7 + Lemma 16) to $\mathcal{C}_4^{\mathrm{id}}$ (and hence $\mathcal{C}_4$ by Lemma 14) by a simple linear reduction from $\mathcal{K}_3^{\mathrm{id}}$ to $\mathcal{C}_4^{\mathrm{id}}$ via the class of all $\{x_1, x_2, x_3\}$-partitioned graphs. Let $\mathcal{H}$ be a $\{x_1, x_2, x_3\}$-partitioned graph. We define the $\{x_1, x_2, x_3, x_4\}$-partitioned graph $\mathcal{H}' = \phi(\mathcal{H})$ by $P_x^{\mathcal{H}'} := P_x^{\mathcal{H}}$ for $x \in \{x_1, x_2, x_3\}$, $P_{x_4}^{\mathcal{H}'} := \{\widehat{v} \mid v \in P_{x_1}^{\mathcal{H}}\}$ and $E(\mathcal{H}') =$

$$
\begin{aligned}
&\big\{\{v, \widehat{v}\} \mid v \in P_{x_1}^{\mathcal{H}}\big\} \\
\cup &\big\{\{v, w\} \mid v \in P_{x_1}^{\mathcal{H}},\, w \in P_{x_2}^{\mathcal{H}},\, \{v, w\} \in E(\mathcal{H})\big\} \\
\cup &\big\{\{v, w\} \mid v \in P_{x_2}^{\mathcal{H}},\, w \in P_{x_3}^{\mathcal{H}},\, \{v, w\} \in E(\mathcal{H})\big\} \\
\cup &\big\{\{v, \widehat{w}\} \mid v \in P_{x_3}^{\mathcal{H}},\, w \in P_{x_1}^{\mathcal{H}},\, \{v, w\} \in E(\mathcal{H})\big\}.
\end{aligned}
$$

Note that the size of $\mathcal{H}'$ is linear in the size of $\mathcal{H}$. The construction ensures that any mapping $h' \colon \{x_1, \dots, x_4\} \to V(\mathcal{H}')$ is a homomorphism from $\mathcal{C}_4^{\mathrm{id}}$ to $\mathcal{H}'$ if, and only if, $h'(x_4) = \widehat{h'(x_1)}$ and $h(x_i) := h'(x_i)$, for $i \in [3]$, is a homomorphism from $\mathcal{K}_3^{\mathrm{id}}$ to $\mathcal{H}$. Therefore, $\operatorname{Hom}(\mathcal{K}_3^{\mathrm{id}}, \mathcal{H}) = \pi_{\{x_1,x_2,x_3\}} \operatorname{Hom}(\mathcal{C}_4^{\mathrm{id}}, \mathcal{H}')$ and a representation C' of $\operatorname{Hom}(\mathcal{K}_3^{\mathrm{id}}, \mathcal{H})$ can be obtained from a representation C of $\operatorname{Hom}(\mathcal{C}_4^{\mathrm{id}}, \mathcal{H}')$ by Lemma 5 which, moreover, guarantees that $\|C'\| \leq \|C\|$. Therefore we do have a linear reduction from $\mathcal{C}_4^{\mathrm{id}}$ to $\mathcal{K}_3^{\mathrm{id}}$. It follows that $\mathsf{d}_{\mathcal{C}_4}(m) = \Omega(\mathsf{d}_{\mathcal{C}_4^{\mathrm{id}},\mathfrak{C}}(m)) = \Omega(\mathsf{d}_{\mathcal{K}_3^{\mathrm{id}},\mathfrak{H}}(m)) = \Omega(\mathsf{d}_{\mathcal{K}_3}(m)) = \Omega(m^{3/2}/\log^7(m))$,

where $\mathfrak{C}$ is the class of $V(\mathcal{C}_4^{\mathrm{id}})$-partitioned graphs and $\mathfrak{H}$ is the class of $V(\mathcal{K}_3^{\mathrm{id}})$-partitioned graphs. The first equality follows by Lemma 14, the second by Lemma 13, the third by Lemma 16 and the last by Theorem 7.

So to handle edge contractions we take the partitioned hard right-hand side instance and "re-introduce" the edge $\{x, y\}$ contracted to x by copying P_x to P_y and adding a perfect matching between the two partitions P_x and P_y. Handling edge deletions is even simpler: suppose that $\{x, y\}$ is deleted from $\mathcal{G}'$ to $\mathcal{G}$ and we want to reduce $\mathcal{G}'$ to $\mathcal{G}$. Then we take a partitioned hard instance for $\mathcal{G}$ and just introduce the complete bipartite graph between the partitions P_x and P_y; this may square the size of the graph. Since the sets of (partition-respecting) homomorphisms are the same for both instances, we do not even have to modify the representations in the reduction. The next lemma summarises these findings. Its proof is omitted as it is subsumed by Lemma 22.

▶ **Lemma 18.** *Let $\mathcal{G}_X, \mathcal{G}_Y$ be graphs with vertex sets X and Y respectively such that $\mathcal{G}_X$ is a minor of $\mathcal{G}_Y$. Let $\mathfrak{H}$ be the class of all $V(\mathcal{G}_X)$-partitioned graphs and $\mathfrak{H}'$ the class of all $V(\mathcal{G}_Y)$-partitioned graphs. Then there is a c-reduction $(\phi, (\psi_{\mathcal{H}})_{\mathcal{H}\in\mathfrak{H}})$ from $\mathcal{G}_Y^{id}$ to $\mathcal{G}_X^{id}$ via $\mathfrak{H}$ with $\phi(\mathfrak{H}) \subseteq \mathfrak{H}'$ and $c(m) = O(m^2)$.*

This yields together with Lemmas 13, 14 and 16 along with Theorem 7 the following corollary.

▶ **Corollary 19.** *If $\mathcal{G}$ has $\mathcal{K}_k$ as a minor, then $\mathsf{d}_{\mathcal{G}} = \Omega(m^{k/4}/\log^{(3k-1)/2}(m))$.*

6.3 Relaxation of the minor condition

Every graph having $\mathcal{K}_k$ as a minor has treewidth at least $k-1$, so Corollary 19 provides the desired lower bound of Theorem 1 for certain large-treewidth graphs. However, there are graphs of large treewidth that do not have a large clique as a minor. Instead, the excluded grid theorem [34] and its more efficient version [11] tells us that graphs of large treewidth always have a large $k \times k$-grid as a minor.

▶ **Theorem 20** ([11])**.** *There is a polynomial function $w : \mathbb{N} \to \mathbb{N}$ such that for every k the $(k \times k)$-grid is a minor of every graph of treewidth at least $w(k)$.*

Thus, in order to prove Theorem 1 it suffices to combine Lemma 18 with a lower bound for grid graphs. We cannot reduce immediately to our k-clique lower bound, as the grid does not have a $\mathcal{K}_k$ minor for $k \geq 5$. However, the complete graph $\mathcal{K}_k$ is "almost a minor" of $\mathcal{G}_{2k-2}$ for the following notion of *almost minor* that is good enough to prove a variant of Lemma 18.

▶ **Definition 21.** *For two graphs $\mathcal{G}_X$, $\mathcal{G}_Y$ with vertex sets $X = V(\mathcal{G}_X)$ and $Y = V(\mathcal{G}_Y)$ we say that a map $M\colon Y \to 2^X$ is* almost minor *if the following conditions hold:*

1. *for every $y \in Y$, $|M(y)| \in \{1, 2\}$;*
2. *for every $x \in X$ there is a $y \in Y$ s.t. $M(y) = \{x\}$ and for every x, x' adjacent in $\mathcal{G}_X$ there exists y, y' adjacent in $\mathcal{G}_Y$ such that $M(y) = \{x\}$ and $M(y') = \{x'\}$;*
3. *for each $x \in X$, $\{y\colon x \in M(y)\}$ is connected in $\mathcal{G}_Y$ and*
4. *if $M(y) = \{x, x'\}$ with $x \neq x'$ and y' is adjacent to y in $\mathcal{G}_Y$, then $M(y') = \{x\}$ or $M(y') = \{x'\}$.*

If such a map exists we say $\mathcal{G}_X$ is an almost minor of $\mathcal{G}_Y$.

For the special case when $|M(y)| = 1$ for all y, M is a *minor map* and G_X is a minor of G_Y. The motivation for this definition is that whilst grids are planar, large cliques are not and so we introduce "junctions", i.e. nodes y such that $M(y) = \{x_1, x_2\}$ which allows

$\{v \mid x_i \in M(v)\}$, $i \in \{1,2\}$ to intersect in a controlled way, see Figure 2. We should also observe here that this notion is related to Marx's notion of an *embedding* [27].[1] Now we can state our reduction lemma for almost minors, which extends Lemma 18.

▶ **Lemma 22.** *Let $\mathcal{G}_X$, $\mathcal{G}_Y$ be the graphs with vertex sets X and Y, respectively, such that $\mathcal{G}_X$ is an almost minor of $\mathcal{G}_Y$. Let $\mathfrak{H}$ be the class of all X-partitioned graphs and $\mathfrak{H}'$ be the class of all Y-partitioned graphs, then there is a c-reduction $(\phi, (\psi_{\mathcal{H}})_{\mathcal{H}\in\mathfrak{H}})$ from $\mathcal{G}_Y^{id}$ to $\mathcal{G}_X^{id}$ via $\mathfrak{H}$ with $\phi(\mathfrak{H}) \subseteq \mathfrak{H}'$ and $c = O(m^2)$.*

Proof. We start by defining the Y-partitioned graph $\mathcal{H}^* = \phi(\mathcal{H})$ for an arbitrary X-partitioned graph $\mathcal{H}$. To define the partitions, we consider two cases: if $M(y) = \{x\}$, we let $P_y^{\mathcal{H}^*} := \{v_a^y \mid a \in P_x^{\mathcal{H}}\}$ and if $M(y) = \{x, x'\}$, then $P_y^{\mathcal{H}^*} := \{v_{\{a,b\}}^y \mid a \in P_x^{\mathcal{H}}, b \in P_{x'}^{\mathcal{H}}\}$. For every edge $\{y, y'\} \in E(\mathcal{G}_Y)$ we define the edge set $E_{\{y,y'\}}$ between the partitions $P_y^{\mathcal{H}^*}$ and $P_{y'}^{\mathcal{H}^*}$ by the following exhaustive cases:

1. if $M(y) = M(y') = \{x\}$: $E_{\{y,y'\}} := \left\{\{v_a^y, v_a^{y'}\} \mid a \in P_x^{\mathcal{H}}\right\}$
2. if $M(y) = \{x\}$, $M(y') = \{x'\}$, and $\{x, x'\} \in E(\mathcal{G}_X)$:
   $E_{\{y,y'\}} := \left\{\{v_a^y, v_b^{y'}\} \mid a \in P_x^{\mathcal{H}}, b \in P_{x'}^{\mathcal{H}}, \{a, b\} \in E(\mathcal{H})\right\}$
3. if $M(y) = \{x\}$, $M(y') = \{x'\}$, $x \neq x'$, and $\{x, x'\} \notin E(\mathcal{G}_X)$:
   $E_{\{y,y'\}} := \left\{\{v_a^y, v_b^{y'}\} \mid a \in P_x^{\mathcal{H}}, b \in P_{x'}^{\mathcal{H}}\right\}$
4. if $M(y) = \{x\}$ and $M(y') = \{x, x'\}$: $E_{\{y,y'\}} := \left\{\{v_a^y, v_{\{a,b\}}^{y'}\} \mid a \in P_x^{\mathcal{H}}, b \in P_{x'}^{\mathcal{H}}\right\}$

Finally, we set $E(\mathcal{H}^*) := \bigcup_{e \in E(\mathcal{G}_Y)} E_e$ and note that $\|\mathcal{H}^*\| = O(\|\mathcal{H}\|^2)$. For every homomorphism h from $\mathcal{G}_X^{\mathrm{id}}$ to $\mathcal{H}$ we define the mapping $h^*\colon Y \to V(\mathcal{H}^*)$ by

$$h^*(y) := \begin{cases} v^y_{h(x)}, & \text{if } M(y) = \{x\} \\ v^y_{\{h(x),h(x')\}}, & \text{if } M(y) = \{x, x'\} \end{cases}$$

The next claim provides the key property of our construction: h^* is a homomorphism from $\mathcal{G}_Y^{\mathrm{id}}$ to $\mathcal{H}^*$ and every homomorphism from $\mathcal{G}_Y^{\mathrm{id}}$ to $\mathcal{H}^*$ has this form, see the full version of this paper for a proof.

▷ Claim 23. $\mathrm{Hom}(\mathcal{G}_Y^{\mathrm{id}}, \mathcal{H}^*) = \{h^* \colon h \in \mathrm{Hom}(\mathcal{G}_X^{\mathrm{id}}, \mathcal{H})\}$

We finish the lemma by defining the mapping $\psi_{\mathcal{H}}$ that transforms any d-representation for $\mathrm{Hom}(\mathcal{G}_X^{\mathrm{id}}, \mathcal{H})$ into a d-representation for $\mathrm{Hom}(\mathcal{G}_Y^{\mathrm{id}}, \mathcal{H}^*)$. For each $x \in X$ we fix one $y_x \in Y$ such that $M(y_x) = \{x\}$ (those vertices exist by the definition of an almost minor map). Then we apply Lemma 5 and obtain a d-representation of $\pi_{\{y_x \colon x \in X\}} \mathrm{Hom}(\mathcal{G}_Y^{\mathrm{id}}, \mathcal{H}^*)$. After renaming every y_x to x and every v_a^y to a in the input labels of this circuit, we get a d-representation of $\mathrm{Hom}(\mathcal{G}_X^{\mathrm{id}}, \mathcal{H})$. ◀

With the following lemma we have everything in hand to proof our main theorem.

▶ **Lemma 24.** *For every k, $\mathcal{K}_k$ is an almost minor of $\mathcal{G}_{2k-2}$.*

[1] In particular the definition of a *depth-2 embedding* can be obtained from our definition of an almost minor by the following modifications. First remove clause (4). Second replace (2) with the following condition: for every $x \in X$ there is a $y \in Y$ s.t. $x \in M(y)$ and for every x, x' adjacent in $\mathcal{G}_X$ there exists *either* y, y' adjacent in $\mathcal{G}_Y$ such that $x \in M(y)$ and $x' \in M(y')$ *or* there exists y such that $\{x, x'\} \subseteq M(y)$. If we also remove clause (1) we get the general definition of an embedding.

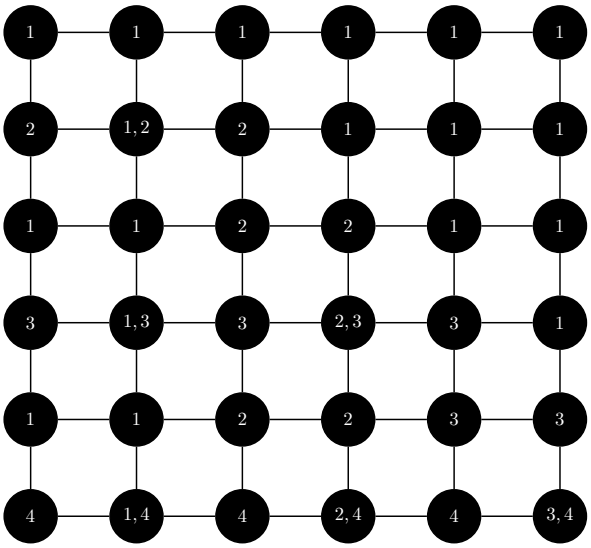

Figure 2 Construction from Lemma 24 for the case $k = 4$. The node in the ith row and jth column is labelled by the $\{a \mid u_a \in M(v_{i,j})\}$.

Proof of Lemma 24. Set

$$X := V(\mathcal{K}_k) = \{u_i \mid i \in [k]\},$$
$$Y := V(\mathcal{G}_{2k-2}) = \{v_{i,j} \mid i, j \in [2k-2]\},$$

where $v_{i,j}$ is the vertex in the ith row and jth column of the grid. Define $M \colon Y \to 2^X$ as follows:

1. if $j - 1 > i$, $M(v_{i,j}) = \{u_1\}$,
2. otherwise if $i \geq j - 1$ then:
   a. if i and j are both odd, $M(v_{i,j}) = \{u_{(j+1)/2}\}$,
   b. if i is odd and is j even, $M(v_{i,j}) = \{u_{j/2}\}$,
   c. if i is even and j is odd, $M(v_{i,j}) = \{u_{(i+2)/2}\}$,
   d. if i and j are both even, $M(v_{i,j}) = \{u_{(i+2)/2}, u_{j/2}\}$.

See Figure 2 for the case $k = 4$. It is easy to see that this map is almost minor, see the full version of this paper for a proof. ◀

Proof of Theorem 1. Let $\mathfrak{A}$ have unbounded treewidth. Then for every k there exists $\mathcal{B}_k \in \mathfrak{A}$ of treewidth at least $w(k)$. Then the Gaifman graph of $\mathcal{B}_k$, $\mathcal{G}_{\mathcal{B}_k}$ also has treewidth at least $w(k)$. By Theorem 20, $\mathcal{G}_{\mathcal{B}_k}$ has $\mathcal{G}_k$ as a minor. Since by Lemma 24, $\mathcal{K}_{(k+2/2)}$ is an almost minor of $\mathcal{G}_k$ we have:

$$\begin{aligned}
\mathsf{d}_{\mathcal{B}_k}(m) &\underset{\text{(Lemma 14)}}{=} \Omega\left(\mathsf{d}_{\mathcal{B}_k^{\mathrm{id}},\mathfrak{C}}(m)\right) \\
&\underset{\text{(Lemma 15)}}{=} \Omega\left((\mathsf{d}_{\mathcal{G}^{\mathrm{id}}_{\mathcal{B}_k},\mathfrak{H}}(m))^{2/\operatorname{ar}(\mathcal{B}_k)}\right) \\
&\underset{\text{(Lemma 18)}}{=} \Omega\left((\mathsf{d}_{\mathcal{G}^{\mathrm{id}}_{k},\mathfrak{H}'}(m))^{1/\operatorname{ar}(\mathcal{B}_k)}\right) \\
&\underset{\text{(Lemma 22)}}{=} \Omega\left((\mathsf{d}_{\mathcal{K}^{\mathrm{id}}_{(k+2)/2},\mathfrak{D}}(m))^{1/2\operatorname{ar}(\mathcal{B}_k)}\right)
\end{aligned}$$

$$\underset{\text{(Lemma 16)}}{=} \Omega\left(((\mathsf{d}_{\mathcal{K}_{(k+2)/2}}(m))^{1/2\,\mathrm{ar}(\mathcal{B}_k)}\right)$$
$$\underset{\text{(Theorem 7)}}{=} \Omega\left(m^{(k+2)/4r}/\log^{(3k+2)/2r}(m)\right)$$

Where $\mathfrak{C}$ is the class of $\sigma \cup \sigma_{B_k}$ structures $\mathcal{C}$ such that $\{P_a^{\mathcal{C}} \mid a \in B_k\}$ is a partition of the universe, $\mathfrak{H}$ the class of $V(\mathcal{G}^{\mathrm{id}}_{\mathcal{B}_k})$-partitioned graphs, $\mathfrak{H}'$ the class of $V(\mathcal{G}^{\mathrm{id}}_{k})$-partitioned graphs and $\mathfrak{D}$ the class of $V(\mathcal{K}^{\mathrm{id}}_{(k+2)/2})$-partitioned graphs. From the above we can conclude that (3) implies (1) in the statement of the theorem. Moreover, as discussed in Section 4, (1) implies (2) follows from [32] and (2) implies (3) trivially. ◀

7 Conclusion

Our main result characterises those bounded-arity classes of structures $\mathfrak{A}$ where the set of homomorphisms from $\mathcal{A} \in \mathfrak{A}$ to $\mathcal{B}$ can be succinctly represented. More precisely, the known upper bound of $O(\|\mathcal{A}\|^2\|\mathcal{B}\|^{\mathrm{tw}(\mathcal{A})+1})$ is matched by a corresponding lower bound of $\Omega(\|\mathcal{B}\|^{\mathrm{tw}(\mathcal{A})^\varepsilon})$, where $\mathrm{tw}(\mathcal{A})$ is the tree-width of $\mathcal{A}$ and $\varepsilon > 0$ is a constant depending on the excluded grid theorem and the arity of the signature. A future task would be to further close the gap between upper and lower bounds.

Another open question is to understand the representation complexity for all classes of structures $\mathfrak{A}$ (of unbounded arity). As mentioned in Section 4, a polynomial $O(\|\mathcal{A}\|^2 \cdot \|\mathcal{B}\|^{\mathrm{fhtw}(\mathcal{A})})$ upper bound was shown where $\mathrm{fhtw}(\mathcal{A})$ is the fractional hypertreewidth of $\mathcal{A}$ [32] and one might wonder whether this is tight. At least this is not the case in a parametrised setting, where a $f(\|\mathcal{A}\|)\|\mathcal{B}\|^w$ sized representation for some (not necessarily polynomial-time) computable f, is considered *tractable*. It is known that for structures $\mathcal{A}$ of *bounded submodular width* the homomorphism problem can be decomposed into a (not necessarily disjoint) union of $f(\|\mathcal{A}\|)$ instances of bounded fractional hypertreewidth [29, 6], leading to a d-representation of size $f(\|\mathcal{A}\|)\|\mathcal{B}\|^{\mathrm{subw}(\mathcal{A})}$ where $\mathrm{subw}(\mathcal{A})$ denotes the submodular width of $\mathcal{A}$, see Appendix A in the full version of this paper for details. Note that submodular width can be strictly smaller than fractional hypertreewidth [28]. For a more concrete example in this direction, the fractional hypertreewidth of $\mathcal{C}_4$ is 2, but one can show that $\mathrm{Hom}(\mathcal{C}_4, \mathcal{H})$ has deterministic d-representations of size $O(\|\mathcal{H}\|^{3/2})$ – almost matching the $O(\|\mathcal{H}\|^{3/2}/\log^7(\|\mathcal{H}\|))$ lower bound in Example 17. Note that while submodular width characterises the FPT-fragment of deciding the existence of homomorphisms on structures of unbounded arity [29], a tight characterisation for the parameterised counting problem is, despite some recent progress [23], still missing. In particular, it is not clear whether bounded submodular width implies tractable counting. We may face similar difficulties when studying the complexity of *deterministic* d-representations that allow efficient counting.

In the course of proving our main result we have developed tools and techniques for proving lower bounds on the size of d-representations, in particular using our k-clique lower bound as a starting point, defining an appropriate notion of reduction and showing that one can always get such a reduction if the "almost minor" relation holds. Whilst the proof of the clique lower bound in Section 5 exploits the specific nature of d-representations, we observe that much of the content of Section 6 can easily be used for other forms of representations. Since we now have understood the limitations of unrestricted d-representations, it would be good to know whether there are even more succinct representation formats that still allow efficient enumeration.

Abstract

We propose a novel topological perspective on data languages recognizable by orbit-finite nominal monoids. For this purpose, we introduce pro-orbit-finite nominal topological spaces. Assuming globally bounded support sizes, they coincide with nominal Stone spaces and are shown to be dually equivalent to a subcategory of nominal boolean algebras. Recognizable data languages are characterized as topologically clopen sets of pro-orbit-finite words. In addition, we explore the expressive power of pro-orbit-finite equations by establishing a nominal version of Reiterman's pseudovariety theorem.

1 Introduction

While automata theory is largely concerned with formal languages over finite alphabets, the extension to *infinite alphabets* has been identified as a natural approach to modelling structures involving *data*, such as nonces [26], channel names [23], object identities [22], process identifiers [11], URLs [5], or values in XML documents [31]. For example, if $\mathbb{A}$ is a (countably infinite) set of data values, typical languages to consider might be

$$L_0 = \{\, vaaw \mid a \in \mathbb{A},\, v, w \in \mathbb{A}^* \,\} \qquad \text{(“some data value occurs twice in a row”), or}$$
$$L_1 = \{\, avaw \mid a \in \mathbb{A},\, v, w \in \mathbb{A}^* \,\} \qquad \text{(“the first data value occurs again”).}$$

Automata for data languages enrich finite automata with register mechanisms that allow to store data and test data values for equality (or more complex relations, e.g. order) [24, 31]. In a modern perspective first advocated by Bojańczyk, Klin, and Lasota [9], a convenient abstract framework for studying data languages is provided by the theory of *nominal sets* [36].

Despite extensive research in the past three decades, no universally acknowledged notion of *regular* data language has emerged so far. One reason is that automata models with data notoriously lack robustness, in that any alteration of their modus operandi (e.g. deterministic vs. nondeterministic, one-way vs. two-way) usually affects their expressive power. Moreover, machine-independent descriptions of classes of data languages in terms of algebra or model theory are hard to come by. However, there is one remarkable class of data languages that closely mirrors classical regular languages: data languages recognizable by orbit-finite

nominal monoids [7]. Originally introduced from a purely algebraic angle, recognizable data languages have subsequently been characterized in terms of *rigidly guarded MSO*$^\sim$, a fragment of monadic second-order logic with equality tests [13], *single-use register automata* [10] (both one-way and two-way), and *orbit-finite regular list functions* [10]. In addition, several landmark results from the algebraic theory of regular languages, namely the McNaughton-Papert-Schützenberger theorem [29, 40], the Krohn-Rhodes theorem [25], and Eilenberg's variety theorem [14] have been extended to recognizable data languages [7, 10, 13, 44].

In the present paper, we investigate recognizable data languages through the lens of *topology*, thereby providing a further bridge to classical regular languages. The topological approach to the latter is closely tied to the algebraic one, which regards regular languages as the languages recognizable by finite monoids. Its starting point is the construction of the topological space $\widehat{\Sigma^*}$ of *profinite words*. Informally, this space casts all information represented by regular languages over Σ and their recognizing monoids into a single mathematical object. Regular languages can then be characterized by purely topological means: they may be interpreted as precisely the clopen subsets of $\widehat{\Sigma^*}$, in such way that algebraic recognition by finite monoids becomes a continuous process. Properties of regular languages are often most conveniently classified in terms of the topological concept of *profinite equations*, that is, equations between profinite words; see [3, 4, 33] for a survey of profinite methods in automata theory. Moreover, since $\widehat{\Sigma^*}$ forms a Stone space, the power of *Stone duality* – the dual equivalence between Stone spaces and boolean algebras – becomes available. This allows for the use of duality-theoretic methods for the study of regular languages and their connection to logic and model theory, which in part even extend to *non-regular* languages [18–21, 35].

On a conceptual level, the topological view of regular languages rests on a single category-theoretic fact: Stone spaces admit a universal property. In fact, they arise from the category of finite sets as the free completion under codirected limits, a.k.a. its *Pro-completion*:

$$\mathbf{Stone} \simeq \mathrm{Pro}(\mathbf{Set}_\mathrm{f}). \tag{1.1}$$

In the world of data languages, the role of finite sets is taken over by orbit-finite nominal sets. This strongly suggests to base a topological approach on their free completion $\mathrm{Pro}(\mathbf{Nom}_\mathrm{of})$. However, this turns out to be infeasible: the category $\mathrm{Pro}(\mathbf{Nom}_\mathrm{of})$ is not concrete over nominal sets (Proposition 3.6), hence it cannot be described via any kind of nominal topological spaces. This is ultimately unsurprising given that the description (1.1) of Stone spaces as a free completion depends on the axiom of choice, which is well-known to fail in the topos of nominal sets. As a remedy, we impose *global bounds* on the support sizes of nominal sets, that is, we consider the categories $\mathbf{Nom}_k$ and $\mathbf{Nom}_{\mathrm{of},k}$ of (orbit-finite) nominal sets where every element has a support of size k, for some fixed natural number k. This restriction is natural from an automata-theoretic perspective, as it corresponds to imposing a bound k on the number of registers of automata, and it fixes exactly the issue making unrestricted nominal sets non-amenable (Lemma 3.9). Let us emphasize, however, that the category $\mathbf{Nom}_k$ is not proposed as a new foundation for names and variable binding; for instance, it generally fails to be a topos.

The first main contribution of our paper is a generalization of (1.1) to k-bounded nominal sets. For this purpose we introduce *nominal Stone spaces*, a suitable nominalization of the classical concept, and prove that k-bounded nominal Stone spaces form the Pro-completion of the category of k-bounded orbit-finite sets. We also derive a nominal version of Stone duality, which relates k-bounded nominal Stone spaces to *locally k-atomic orbit-finitely complete nominal boolean algebras*. Hence we establish the following equivalences of categories:

$$\mathbf{nC}_\mathrm{of}\mathbf{A}_{\mathrm{l}k}\mathbf{BA} \simeq^\mathrm{op} \mathbf{nStone}_k \simeq \mathrm{Pro}(\mathbf{Nom}_{\mathrm{of},k}).$$

The above equivalences are somewhat remarkable since even the category of k-bounded nominal sets does not feature choice. They hold because the presence of bounds allows us to reduce topological properties of nominal Stone spaces, most notably compactness, to their classical counterparts.

Building on the above topological foundations, which we regard to be of independent interest, we subsequently develop first steps of a topological theory of data languages. Specifically, we introduce nominal Stone spaces of (bounded) *pro-orbit-finite words* and prove their clopen subsets to correspond to data languages recognizable by bounded equivariant monoid morphisms, generalizing the topological characterization of classical regular languages (Theorem 5.14). Moreover, we investigate the expressivity of *pro-orbit-finite equations* and show that they model precisely classes of orbit-finite monoids closed under finite products, submonoids, and *multiplicatively support-reflecting quotients* (Theorem 6.8). This provides a nominal version of Reiterman's celebrated pseudovariety theorem [37] for finite monoids.

Related work. The perspective taken in our paper draws much of its inspiration from the recent categorical approach to algebraic recognition based on monads [8, 38, 42]. The importance of Pro-completions in algebraic language theory has been isolated in the work of Chen et al. [12] and Urbat et al. [42]. In the latter work the authors introduce *profinite monads* and present a general version of Eilenberg's variety theorem parametric in a given Stone-type duality. The theory developed there applies to algebraic base categories, but not to the category of nominal sets.

Our version of nominal Stone duality builds on the orbit-finite restriction of the duality between nominal sets and complete atomic nominal boolean algebras due to Petrişan [17]. It is fundamentally different from the nominal Stone duality proposed by Gabbay, Litak, and Petrişan [16], which relates *nominal Stone spaces with* И to *nominal boolean algebras with* И. The latter duality is not amenable for the theory of data languages; see Remark 3.17.

Reiterman's pseudovariety theorem has recently been generalized to the level of finite algebras for a monad [1, 12] and, in a more abstract disguise, finite objects in a category [30]. For nominal sets, varieties of algebras over binding signatures have been studied by Gabbay [16] and by Kurz and Petrişan [27], resulting in nominal Birkhoff-type theorems [6]. Urbat and Milius [44] characterize classes of orbit-finite monoids called *weak* pseudovarieties by sequences of nominal word equations. This gives a nominal generalization of the classical Eilenberg-Schützenberger theorem [15], which in fact is a special case of the general HSP theorem in [30]. Nominal pro-orbit-finite equations as introduced in the present paper are strictly more expressive than sequences of nominal word equations (Example 6.11), hence our nominal Reiterman theorem is not equivalent to the nominal Eilenberg-Schützenberger theorem. Moreover, we note that the nominal Reiterman theorem does not appear to be an instance of any of the abstract categorical frameworks mentioned above.

2 Preliminaries

We assume that readers are familiar with basic notions from category theory, e.g. functors, natural transformations, and (co)limits, and from point-set topology, e.g. metric and topological spaces, continuous maps, and compactness. In the following we recall some facts about Pro-completions, the key categorical concept underlying our topological approach to data languages. Moreover, we give a brief introduction to the theory of nominal sets [36].

Pro-completions. A small category I is *cofiltered* if (i) I is non-empty, (ii) for every pair of objects $i, j \in I$ there exists a span $i \leftarrow k \rightarrow j$, and (iii) for every pair of parallel arrows $f, g\colon j \to k$, there exists a morphism $h\colon i \to j$ such that $f \cdot h = g \cdot h$. Cofiltered preorders are

called *codirected*; thus a preorder I is codirected if $I \neq \emptyset$ and every pair $i, j \in I$ has a lower bound $k \leq i, j$. For instance, every meet-semilattice with bottom is codirected. A diagram $D\colon I \to \mathbf{C}$ in a category $\mathbf{C}$ is *cofiltered* if its index category I is cofiltered. A *cofiltered limit* is a limit of a cofiltered diagram. *Codirected limits* are defined analogously. The two concepts are closely related: a category has cofiltered limits iff it has codirected limits, and a functor preserves cofiltered limits iff it preserves codirected limits [2, Cor. 1.5]. The dual concept is that of a *filtered colimit* or a *directed colimit*, respectively.

▶ **Example 2.1.**

1. In the category **Set** of sets and functions, every filtered diagram $D\colon I \to \mathbf{Set}$ has a colimit cocone $c_i\colon D_i \to \operatorname{colim} D$ $(i \in I)$ given by $\operatorname{colim} D = \big(\coprod_{i\in I} D_i\big)/{\sim}$ and $c_i(x) = [x]_\sim$, where the equivalence relation $\sim$ on the coproduct (i.e. disjoint union) $\coprod_{i\in I} D_i$ relates $x \in D_i$ and $y \in D_j$ iff there exist morphisms $f\colon i \to k$ and $g\colon j \to k$ in I such that $Df(x) = Dg(y)$.
2. Every cofiltered diagram $D\colon I \to \mathbf{Set}$ has a limit whose cone $p_i\colon \lim D \to D_i$ $(i \in I)$ is given by the *compatible families* of D and projection maps:

$$\lim D = \{(x_i)_{i\in I} \mid x_i \in D_i \text{ and } Df(x_i) = x_j \text{ for all } f\colon i \to j \text{ in } I\} \quad \text{and} \quad p_j((x_i)_{i\in I}) = x_j.$$

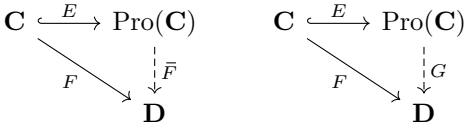
3. In the category **Top** of topological spaces and continuous maps, the limit cone of a cofiltered diagram $D\colon I \to \mathbf{Top}$ is formed by taking the limit in **Set** and equipping $\lim D$ with the *initial topology*, viz. the topology generated by the basic open sets $p_i^{-1}[U_i]$ for $i \in I$ and $U_i \subseteq D_i$ open.

An object C of a category $\mathbf{C}$ is *finitely copresentable* if the contravariant hom-functor $\mathbf{C}(-, C)\colon \mathbf{C}^{\mathrm{op}} \to \mathbf{Set}$ preserves directed colimits. In more elementary terms, this means that for every codirected diagram $D\colon I \to \mathbf{C}$ with limit cone $p_i\colon L \to D_i$ $(i \in I)$,

1. every morphism $f\colon L \to C$ factorizes as $f = g \circ p_i$ for some $i \in I$ and $g\colon D_i \to C$, and
2. the factorization is essentially unique: given another factorization $f = h \cdot p_i$, there exists $j \leq i$ such that $g \cdot D_{j,i} = h \cdot D_{j,i}$.

A *Pro-completion* of a small category $\mathbf{C}$ is a free completion under codirected (equivalently cofiltered) limits. It is given by a category $\mathrm{Pro}(\mathbf{C})$ with codirected limits together with a full embedding $E\colon \mathbf{C} \hookrightarrow \mathrm{Pro}(\mathbf{C})$ satisfying the following universal property:

1. every functor $F\colon \mathbf{C} \to \mathbf{D}$, where the category $\mathbf{D}$ has codirected limits, extends to a functor $\bar{F}\colon \mathrm{Pro}(\mathbf{C}) \to \mathbf{D}$ that preserves codirected limits and satisfies $F = \bar{F} \circ E$;
2. $\bar{F}$ is essentially unique: For every functor G that preserves codirected limits and satisfies $F = G \circ E$, there exists a natural isomorphism $\alpha\colon \bar{F} \cong G$ such that $\alpha E = \mathrm{id}_F$.



The universal property determines $\mathrm{Pro}(\mathbf{C})$ uniquely up to equivalence of categories. We note that every object EC $(C \in \mathbf{C})$ is finitely copresentable in $\mathrm{Pro}(\mathbf{C})$, see e.g. [1, Thm A.4]. The dual of Pro-completions are *Ind-completions*: free completions under *directed colimits*.

▶ **Example 2.2.** The Pro-completion $\mathrm{Pro}(\mathbf{Set}_{\mathrm{f}})$ of the category of finite sets is the full subcategory of **Top** given by *profinite spaces* (topological spaces that are codirected limits of finite discrete spaces). Profinite spaces are also known as *Stone spaces* or *boolean spaces* and can be characterized by topological properties: they are precisely compact Hausdorff spaces with a basis of clopen sets. This equivalent characterization depends on the axiom of

choice (or rather the ultrafilter theorem, a weak form of choice), as does *Stone duality*, the dual equivalence between the categories of Stone spaces and boolean algebras. The duality maps a Stone space to its boolean algebra of clopen sets, equipped with the set-theoretic boolean operations. Its inverse maps a boolean algebra the set of ultrafilters (equivalently, prime filters) on it, equipped with a suitable profinite topology.

Profinite words. The topological approach to classical regular languages is based on the space $\widehat{\Sigma^*}$ of *profinite words* over the alphabet Σ. This space is constructed as the codirected limit of all finite quotient monoids of Σ^*, the free monoid of finite words generated by Σ. Formally, let $\Sigma^*{\downarrow}\mathbf{Mon}_\mathrm{f}$ be the codirected poset of all surjective monoid morphisms $e\colon \Sigma^* \twoheadrightarrow M$, where M is a finite monoid; the order on $\Sigma^*{\downarrow}\mathbf{Mon}_\mathrm{f}$ is defined by $e \leq e'$ if $e' = e \cdot h$ for some h. Then $\widehat{\Sigma^*}$ is the limit of the diagram $D\colon \Sigma^*{\downarrow}\mathbf{Mon}_\mathrm{f} \to \mathrm{Pro}(\mathbf{Set}_\mathrm{f})$ sending $e\colon \Sigma^* \twoheadrightarrow M$ to the underlying set of M, regarded as a finite discrete topological space. The space $\widehat{\Sigma^*}$ is completely metrizable; in fact, it is the Cauchy completion of the metric space (Σ^*, d) where $d(v,w) = \sup\{\, 2^{-|M|} \mid M \text{ is a finite monoid separating } v, w \,\}$. Here a monoid M *separates* $v, w \in \Sigma^*$ if there exists a morphism $h\colon \Sigma^* \to M$ such that $h(v) \neq h(w)$. Regular languages over Σ correspond to clopen subsets of $\widehat{\Sigma^*}$, or equivalently to continuous maps $L\colon \widehat{\Sigma^*} \to 2$ into the discrete two-element space.

Nominal Sets. Fix a countable set $\mathbb{A}$ of *names*, and denote by $\mathrm{Perm}\,\mathbb{A}$ the group of finite permutations, i.e. bijections $\pi\colon \mathbb{A} \to \mathbb{A}$ fixing all but finitely many names. Given $S \subseteq \mathbb{A}$ write

$$\mathrm{Perm}_S\,\mathbb{A} = \{\pi \in \mathrm{Perm}\,\mathbb{A} \mid \pi(a) = a \text{ for all } a \in S\}$$

for the the subgroup of permutations fixing S. A $\mathrm{Perm}\,\mathbb{A}$*-set* is a set X with a group action, that is, an operation $\cdot\colon \mathrm{Perm}\,\mathbb{A} \times X \to X$ such that $\mathrm{id} \cdot x = x$ and $\pi \cdot (\sigma \cdot x) = (\pi \circ \sigma) \cdot x$ for every $x \in X$ and $\pi, \sigma \in \mathrm{Perm}\,\mathbb{A}$. The *trivial* group action on X is given by $\pi \cdot x = x$ for all $x \in X$ and $\pi \in \mathrm{Perm}\,\mathbb{A}$.

A subset $S \subseteq \mathbb{A}$ is a *support* of $x \in X$ if every permutation $\pi \in \mathrm{Perm}_S\,\mathbb{A}$ acts trivially on x, that is, $\pi \cdot x = x$. The idea is that x is some syntactic object (e.g. a word, a tree, or a λ-term) whose free variables are contained in S. A $\mathrm{Perm}\,\mathbb{A}$-set X is a *nominal set* if every element $x \in X$ has a finite support. This implies that every $x \in X$ has a *least* finite support, denoted by $\mathrm{supp}\,x \subseteq \mathbb{A}$.

For a nominal set X its *nominal powerset* $\mathcal{P}_\mathrm{fs}X \subseteq \mathcal{P}X$ consists of all subsets of $U \subseteq X$ which are finitely supported under the action $\pi \cdot U := \{\pi \cdot x \mid x \in U\}$. For example, for the nominal set $\mathbb{A}$ of names with the action $\pi \cdot a = \pi(a)$, its nominal powerset $\mathcal{P}_\mathrm{fs}\mathbb{A}$ consists of all finite and cofinite subsets of $\mathbb{A}$. A subset $U \subseteq X$ is *equivariant* if it has empty support. If there exists a finite subset $S \subseteq \mathbb{A}$ supporting every $x \in U$ then U is *uniformly finitely supported*, and S also supports U. Given a finite set $S \subseteq \mathbb{A}$ of names and a subset $U \subseteq X$, we define the S*-hull* of U by $\mathrm{hull}_S\,U = \{\pi \cdot x \mid x \in U, \pi \in \mathrm{Perm}_S\,\mathbb{A}\}$. This is the smallest S-supported subset of X containing U.

For finite $S \subseteq \mathbb{A}$ the S*-orbit* of an element $x \in X$ is the set $\mathrm{orb}_S\,x = \{\pi \cdot x \mid \pi \in \mathrm{Perm}_S\,\mathbb{A}\}$. The $\emptyset$-orbit of x is called its *orbit*, denoted $\mathrm{orb}\,x$. We write $\mathrm{orb}_S\,X = \{\mathrm{orb}_S\,x \mid x \in X\}$ for the set of all S-orbits of X, and $\mathrm{orb}\,X$ for the set of all orbits. The S-orbits form a partition of X. A finitely supported subset $Y \subseteq X$ is *orbit-finite* if it intersects only finitely many orbits of X. In particular, the nominal set X is *orbit-finite* if $\mathrm{orb}\,X$ is a finite set. This implies that for every finite subset $S \subseteq \mathbb{A}$ the set $\mathrm{orb}_S\,X$ is finite. Moreover, X contains only finitely many elements with support S.

▶ **Example 2.3.** The set $\mathbb{A}^*$ of finite words over $\mathbb{A}$ forms a nominal set with the group action $\pi \cdot (a_1 \cdots a_n) = \pi(a_1) \cdots \pi(a_n)$. The languages $L_0, L_1 \subseteq \mathbb{A}^*$ from the Introduction are equivariant subsets. Given a fixed name $a \in \mathbb{A}$, the subset $L_2 = \{awa \mid w \in \mathbb{A}^*\}$ is finitely supported with $\operatorname{supp} L_2 = \{a\}$. All the above sets have an infinite number of orbits. An example of an orbit-finite set is given by $\mathbb{A}^2 = \mathbb{A} \times \mathbb{A} \subseteq \mathbb{A}^*$; its two orbits are $\{aa \mid a \in \mathbb{A}\}$ and $\{ab \mid a \neq b \in \mathbb{A}\}$.

A map $f\colon X \to Y$ between nominal sets is *finitely supported* if there exists a finite set $S \subseteq \mathbb{A}$ such that $f(\pi \cdot x) = \pi \cdot f(x)$ for all $x \in X$ and $\pi \in \operatorname{Perm}_S \mathbb{A}$, and *equivariant* if it is supported by $S = \emptyset$. Equivariant maps satisfy $\operatorname{supp} f(x) \subseteq \operatorname{supp} x$ for all $x \in X$. Nominal sets and equivariant maps form a category **Nom**, with the full subcategory $\mathbf{Nom}_{\mathrm{of}}$ of orbit-finite nominal sets. The category **Nom** is complete and cocomplete. Colimits and finite limits are formed like in **Set**; general limits are formed by taking the limit in **Set** and restricting to finitely supported elements. The category $\mathbf{Nom}_{\mathrm{of}}$ is closed under finite limits and finite colimits in **Nom**. *Quotients* and *subobjects* in **Nom** are represented by surjective and injective equivariant maps. Every equivariant map f has an image factorization $f = m \cdot e$ with m injective and e surjective; we call e the *coimage* of f.

A nominal set is *strong* if for all $x \in X$ and $\pi \in \operatorname{Perm} \mathbb{A}$ one has $\pi \cdot x = x$ iff $\pi \in \operatorname{Perm}_S \mathbb{A}$, where $S = \operatorname{supp} x$. (Note that the "if" direction holds in every nominal set.) For example, the nominal set $\mathbb{A}^{\#n} = \{f\colon n \to \mathbb{A} \mid f \text{ injective}\}$ with pointwise action is strong and has a single orbit. Up to isomorphism, (orbit-finite) strong nominal sets are precisely (finite) coproducts of such sets.

3 Nominal Stone Spaces

In this section, we establish the topological foundations for our pro-orbit-finite approach to data languages. We start by recalling the basic definitions of nominal topology [17, 32].

▶ **Definition 3.1.**

1. *A* nominal topology *on a nominal set X is an equivariant subset $\mathcal{O}_X \subseteq \mathcal{P}_{fs}X$ closed under finitely supported union (that is, if $\mathcal{U} \subseteq \mathcal{O}_X$ is finitely supported then $\bigcup \mathcal{U} \in \mathcal{O}_X$) and finite intersection. Sets $U \in \mathcal{O}_X$ are called* open *and their complements* closed*; sets that are both open and closed are* clopen*. A nominal set X together with a nominal topology $\mathcal{O}_X$ is a* nominal topological space*. An equivariant map $f\colon X \to Y$ between nominal topological spaces is* continuous *if for every open set U of Y its preimage $f^{-1}[U]$ is an open set of X. Nominal topological spaces and continuous maps form the category* **nTop**.
2. *A* subbasis *of a nominal topological space $(X, \mathcal{O}_X)$ is an equivariant subset $\mathcal{B} \subseteq \mathcal{O}_X$ such that every open set of X is a finitely supported union of finite intersections of sets in $\mathcal{B}$. If additionally every finite intersection of sets in $\mathcal{B}$ is a finitely supported union of sets in $\mathcal{B}$, then $\mathcal{B}$ is called a* basis*. In this case, every open set of X is a finitely supported union of elements of $\mathcal{B}$.*

▶ **Example 3.2.**

1. A topological space may be viewed as a nominal topological space equipped with the trivial group action. Then every (open) subset has empty support and every union is finitely supported, so we recover the axioms of classical topology.
2. Every nominal set X equipped with the *discrete topology*, where all finitely supported subsets are open, is a nominal topological space. It has a basis given by all singleton sets.

3. A *nominal (pseudo-)metric space* is given by a nominal set X with a (pseudo-)metric[1] $d\colon X \times X \to \mathbb{R}$ which is equivariant as a function into the set $\mathbb{R}$, regarded as a nominal set with the trivial group action. As usual, the open ball around $x \in X$ with radius $r > 0$ is given by $B_r x = \{y \in X \mid d(x,y) < r\}$. Since $\pi \cdot B_r(x) = B_r(\pi \cdot x)$ for all $\pi \in \operatorname{Perm}\mathbb{A}$ and $x \in X$, every nominal (pseudo-)metric space carries a nominal topology whose basic opens are the open balls.

▶ Remark 3.3. Every nominal topological space induces two families of ordinary topological spaces, one by taking only opens with a certain support and the other by forming orbits. In more detail, let $S \subseteq \mathbb{A}$ be a finite set of names and let X be a nominal topological space with topology $\mathcal{O}$.

1. The underlying set of the nominal space X carries a classical topology $\mathcal{O}_S$ consisting of all S-supported open sets of $\mathcal{O}$. We denote the resulting topological space by $|X|_S$.
2. The set $\operatorname{orb}_S X$ of S-orbits can be equipped with the quotient topology $\mathcal{O}_{\operatorname{orb}_S}$ induced by the projection $X \twoheadrightarrow \operatorname{orb}_S X$ mapping each $x \in X$ to its S-orbit $\operatorname{orb}_S x$. In this topology, a set $O \subseteq \operatorname{orb}_S X$ of S-orbits is open iff its union $\bigcup O$ is open in X.

These constructions give rise to functors $|-|_S, \operatorname{orb}_S\colon \mathbf{nTop} \to \mathbf{Top}$. They allow us to switch between nominal and classical topology.

As noted in Example 2.2, the Pro-completion of the category $\mathbf{Set}_\mathrm{f}$ is the category of profinite spaces. One may expect that the Pro-completion of $\mathbf{Nom}_\mathrm{of}$ analogously consists of all *pro-orbit-finite* spaces, that is, nominal topological spaces that are codirected limits of orbit-finite discrete spaces. However, this fails due to a simple fact: while codirected limits of non-empty finite sets are always non-empty (which is a consequence of Tychonoff's theorem, thus the axiom of choice), codirected limits of non-empty orbit-finite nominal sets may be empty.

▶ Remark 3.4. Similar to **Top**, codirected limits in **nTop** are formed by taking the limit in **Nom** equipping it with the initial topology.

▶ **Example 3.5.** Consider the ω^{op}-chain $1 \leftarrow \mathbb{A} \leftarrow \mathbb{A}^{\#2} \leftarrow \mathbb{A}^{\#3} \leftarrow \cdots$ in $\mathbf{Nom}_\mathrm{of}$ with connecting maps omitting the last component. Its limit in **Set** (see Example 2.1) is given by $\mathbb{A}^{\#\omega}$, the set of all injective functions from ω to $\mathbb{A}$. Clearly no such function has finite support, thus the limit in **Nom** (and therefore also in **nTop**) is empty.

This entails that it is in fact impossible to characterize $\operatorname{Pro}(\mathbf{Nom}_\mathrm{of})$ by any sort of spaces. By definition of the free completion $\operatorname{Pro}(\mathbf{Nom}_\mathrm{of})$, the inclusion functor $I\colon \mathbf{Nom}_\mathrm{of} \hookrightarrow \mathbf{Nom}$ extends uniquely to a functor $\bar{I}\colon \operatorname{Pro}(\mathbf{Nom}_\mathrm{of}) \to \mathbf{Nom}$ preserving codirected limits. The analogous functor $\bar{I}\colon \operatorname{Pro}(\mathbf{Set}_\mathrm{f}) \to \mathbf{Set}$ is the forgetful functor of the category of profinite spaces. In contrast, we have

▶ **Proposition 3.6.** *The category* $\operatorname{Pro}(\mathbf{Nom}_\mathrm{of})$ *is* not *concrete: the functor* $\bar{I}$ *is not faithful.*

Proof. Consider the chain $1 \leftarrow \mathbb{A} \leftarrow \mathbb{A}^{\#2} \leftarrow \cdots$ of Example 3.5. Let $D\colon \omega^{\mathrm{op}} \to \mathbf{Nom}_\mathrm{of}$ denote the corresponding diagram, and let $E\colon \mathbf{Nom}_\mathrm{of} \hookrightarrow \operatorname{Pro}(\mathbf{Nom}_\mathrm{of})$ be the embedding. To prove that $\bar{I}$ is not faithful, let 2 be the two element nominal set. We show that $|\operatorname{Pro}(\mathbf{Nom}_\mathrm{of})(\lim ED, E2)| > |\mathbf{Nom}(\bar{I}(\lim ED), \bar{I}E2)|$. Indeed, we have

$$\begin{aligned}
\operatorname{Pro}(\mathbf{Nom}_\mathrm{of})(\lim_{n<\omega} ED_n, E2) &\cong \operatorname*{colim}_{n<\omega} \operatorname{Pro}(\mathbf{Nom}_\mathrm{of})(ED_n, E2) && E2 \text{ finitely copresentable}\\
&\cong \operatorname*{colim}_{n<\omega} \mathbf{Nom}_\mathrm{of}(D_n, 2) && E \text{ full embedding}\\
&\cong 2
\end{aligned}$$

[1] Recall that a pseudometric differs from a metric by not requiring $d(x,y) \neq 0$ for $x \neq y$.

because $\mathbf{Nom}_{\mathrm{of}}(D_0, 2) \cong 2$ and the two elements are not merged by the colimit injection. However,

$$\begin{aligned}
\mathbf{Nom}(\bar{I}(\lim_{n<\omega} ED_n), \bar{I}E2) &\cong \mathbf{Nom}(\lim_{n<\omega} \bar{I}ED_n, \bar{I}E2) && \bar{I} \text{ preserves codirected limits} \\
&\cong \mathbf{Nom}(\lim_{n<\omega} ID_n, 2) && I = \bar{I}E \\
&\cong \mathbf{Nom}(\emptyset, 2) && \text{Example 3.5} \\
&\cong 1. &&
\end{aligned}$$

◀

We thus restrict our focus to well-behaved subcategories of $\mathbf{Nom}_{\mathrm{of}}$. We choose these subcategories in such way that situations like in Example 3.5, where unrestricted accumulation of supports results in empty codirected limits, are avoided.

▶ **Definition 3.7.** *A nominal set X is* k-bounded*, for $k \in \mathbb{N}$, if $|\mathrm{supp}\, x| \leq k$ for every $x \in X$.*

For concrete categories $\mathbf{C}$ over $\mathbf{Nom}$ (or $\mathbf{Nom}_{\mathrm{of}}$) we denote by $\mathbf{C}_k$ the full subcategory of $\mathbf{C}$ whose underlying objects are k-bounded. For instance, $\mathbf{Nom}_k$ is the category of k-bounded nominal sets, and $\mathbf{nTop}_k$ is the category of k-bounded nominal topological spaces.

▶ Remark 3.8.

1. The full subcategories $\mathbf{Nom}_k \hookrightarrow \mathbf{Nom}$ and $\mathbf{Nom}_{\mathrm{of},k} \hookrightarrow \mathbf{Nom}_{\mathrm{of}}$ are coreflective [28, Section IV.3]: the coreflector (viz. the right adjoint of the inclusion functor) sends a nominal set X to its subset $X_k = \{x \in X \mid |\mathrm{supp}\, x| \leq k\}$. Hence $\mathbf{Nom}_k$ is complete: limits are formed by taking the limit in $\mathbf{Nom}$ and applying the coreflector. Analogously, $\mathbf{Nom}_{\mathrm{of},k}$ is finitely complete.
2. In contrast to $\mathbf{Nom}$, the category $\mathbf{Nom}_k$ generally fails to be a topos because it is not cartesian closed. For instance, the functor $\mathbb{A}^{\#2} \times (-)$ on $\mathbf{Nom}_2$ does not preserve coequalizers, hence it is not a left adjoint.
3. The category $\mathbf{Nom}$ is known to be equivalent to the category of pullback-preserving presheaves $\mathbb{I} \to \mathbf{Set}$, where $\mathbb{I}$ is the category of finite sets and injective functions [36, Theorem 6.8]. By inspecting the proof it is easy to see that this restricts to an equivalence between $\mathbf{Nom}_k$ and the category of *k-generated* pullback-preserving presheaves $\mathbb{I} \to \mathbf{Set}$. Here a presheaf $F \colon \mathbb{I} \to \mathbf{Set}$ is k-generated if for every finite set S and every $x \in FS$ there exists a set S' of cardinality at most k and an injective map $f \colon S' \to S$ such that $x \in Ff[FS']$.

With regard to codirected limits, the restriction to bounded nominal sets fixes the issue arising in Example 3.5:

▶ **Lemma 3.9.** *Codirected limits in $\mathbf{Nom}_k$ are formed at the level of $\mathbf{Set}$.*

We proceed to give a topological characterization of $\mathrm{Pro}(\mathbf{Nom}_{\mathrm{of},k})$ in terms of nominal Stone spaces, generalizing the corresponding result (1.1) for $\mathrm{Pro}(\mathbf{Set}_{\mathrm{f}})$. To this end, we introduce suitable nominalizations of the three characteristic properties of Stone spaces: compactness, Hausdorffness, and existence of a basis of clopens. The nominal version of compactness comes natural and is compatible with the functors $|-|_S$ and orb_S of Remark 3.3.

▶ **Definition 3.10.** *An* open cover *of a nominal topological space $(X, \mathcal{O})$ is a finitely supported set $\mathcal{C} \subseteq \mathcal{O}$ that covers X, i.e. $\bigcup \mathcal{C} = X$. A* subcover *of $\mathcal{C}$ is a finitely supported subset of $\mathcal{C}$ that also covers X. A nominal topological space X is* compact *if every open cover $\mathcal{C}$ of X has an orbit-finite subcover: there exist $U_1, \ldots, U_n \in \mathcal{C}$ such that $X = \bigcup_{i=1}^{n} \bigcup \mathrm{orb}\, U_i$.*

▶ **Lemma 3.11.** *For every nominal topological space X the following conditions are equivalent:*

1. *The space X is compact.*
2. *Every uniformly finitely supported open cover of X has a finite subcover.*
3. *For every finite set $S \subseteq \mathbb{A}$ the topological space $|X|_S$ is compact.*
4. *For every finite set $S \subseteq \mathbb{A}$ the topological space $\mathrm{orb}_S X$ is compact.*

The Hausdorff property is more subtle: rather than just separation of points, we require separation of S-orbits ("thick points") by disjoint S-supported open neighbourhoods.

▶ **Definition 3.12.** *A nominal topological space X is* (nominal) Hausdorff *if for every finite set $S \subseteq \mathbb{A}$ and every pair $x_1, x_2 \in X$ of points lying in different S-orbits, there exist disjoint S-supported open sets $U_1, U_2 \subseteq X$ such that $x_i \in U_i$ for $i = 1, 2$.*

Note that the nominal Hausdorff condition is clearly equivalent to being able to separate disjoint *S-orbits*: If $\mathrm{orb}_S\, x_1 \neq \mathrm{orb}_S\, x_2$, then any two disjoint open S-supported neighbourhoods U_1, U_2 of x_1, x_2 satisfy $\mathrm{orb}_S\, x_i \subseteq U_i$ for $i = 1, 2$. Note also that $\mathrm{orb}_S\, x = \{x\}$ whenever $\mathrm{supp}\, x \subseteq S$, hence the nominal Hausdorff condition implies the ordinary one. For bounded nominal compact Hausdorff spaces, we have a codirected Tychonoff theorem:

▶ **Proposition 3.13.** *For every codirected diagram of non-empty k-bounded nominal compact Hausdorff spaces, the limit in* **nTop** *is a non-empty k-bounded nominal compact Hausdorff space.*

Finally, having a basis of clopen sets is not sufficient in our setting. To see this, note that in an ordinary topological space X every clopen subset $C \subseteq X$ can be represented as $C = f^{-1}[A]$ for some continuous map $f\colon X \to Y$ into a finite discrete space Y and some subset $A \subseteq Y$. (In fact, one may always take $Y = 2$ and $A = \{1\}$.) This is no longer true in the nominal setting, see Remark 3.15 below. Therefore, in lieu of clopens we work with *representable* subsets:

▶ **Definition 3.14.** *A subset $R \subseteq X$ of a nominal space X is* representable *if there exists a continuous map $f\colon X \to Y$ into an orbit-finite discrete space Y such that $R = f^{-1}[A]$ for some $A \in \mathcal{P}_{fs} Y$.*

▶ Remark 3.15.

1. Every representable set is clopen, but the converse generally fails. To see this, consider the discrete space $X = \coprod_{n<\omega} \mathbb{A}^{\#n}$. We show that for fixed $a \in \mathbb{A}$ the (clopen) subset $R = \{x \mid a \in \mathrm{supp}\, x\} \subseteq X$ is not representable. Towards a contradiction suppose that R is represented by $f\colon X \to Y$ as $R = f^{-1}[A]$ for some $A \in \mathcal{P}_{\mathrm{fs}} Y$. Since Y is orbit-finite, we can choose m large enough such that there exists some $x \in \mathbb{A}^{\#m} \setminus R \subseteq X$ for which $\mathrm{supp}\, f(x) \subsetneq \mathrm{supp}\, x$. Choose a name $b \in \mathrm{supp}\, x \setminus \mathrm{supp}\, f(x)$. Then $a, b \notin \mathrm{supp}\, f(x)$, and so we have
$$f((a\ b) \cdot x) = (a\ b) \cdot f(x) = f(x).$$
Since $(a\ b) \cdot x \in R$, this shows $f(x) \in A$ and thus $x \in R$. This contradicts the above choice of x.
2. If a nominal space X has a basis of representable sets, then we may assume without loss of generality that the basic open sets are of the form $f^{-1}[y]$ for some $f\colon X \to Y$ and $y \in Y$, where Y is orbit-finite and discrete. Indeed, if $R = f^{-1}[A]$ for $A \in \mathcal{P}_{\mathrm{fs}} Y$, then $R = \bigcup_{y \in A} f^{-1}[y]$. Moreover, given representable sets $R_i = f_i^{-1}[y_i]$, $i = 1, 2$, the set $R_1 \cap R_2$ is equal to $\langle f_1, f_2 \rangle^{-1}[y_1, y_2]$ and therefore representable as well. Hence, to show that representable subsets form a basis it suffices to check whether every open set is a finitely supported union of subsets of the form $f^{-1}[y]$.

▶ **Definition 3.16.** *A* nominal Stone space *is a nominal compact Hausdorff space with a basis of representables. We let* **nStone** *denote the full subcategory of* **nTop** *given by nominal Stone spaces.*

▶ Remark 3.17. Nominal Stone spaces as per Definition 3.16 are conceptually very different from *nominal Stone spaces with* M, introduced by Gabbay et al. [17] as the dual of *nominal boolean algebras with* M. The latter are equipped with a *restriction operator* $\mathbf{n}$ tightly related to the freshness quantifier M of nominal sets, which enables a nominal version of the ultrafilter theorem and thus a represention of boolean algebras with M via spaces of ultrafilters. In nominal Stone spaces with M, the Hausdorff property is implicit (but would be analogous to that in standard topology), the basis is given by clopen rather than representable sets, and the notion of compactness (called $\mathbf{n}$-*compactness*) considers open covers closed under the operator $\mathbf{n}$, which are required to have a *finite* subcover. By this definition, the orbit-finite discrete space $\mathbb{A}$ fails to be compact (the $\mathbf{n}$-cover $\{\{a\} \mid a \in \mathbb{A}\} \cup \{\emptyset\}$ has no finite subcover). Hence, given that algebraic recognition is based on orbit-finite sets, nominal Stone spaces with M are not suitable for a topological interpretion of data languages.

▶ **Example 3.18.** Every orbit-finite nominal set can be viewed as a nominal Stone space equipped with the discrete topology. We thus regard $\mathbf{Nom}_{\mathrm{of}}$ as a full subcategory of **nStone**. Nontrivial examples of nominal Stone spaces are given by the spaces of pro-orbit-finite words introduced later.

Within the class of nominal Stone spaces, representable and clopen subsets coincide:

▶ **Lemma 3.19.** *If X is a nominal Stone space, then every clopen set $C \subseteq X$ is representable.*

The following theorem is the key result leading to our topological approach to data languages.

▶ **Theorem 3.20.** *For each $k \in \mathbb{N}$, the category of k-bounded nominal Stone spaces is the Pro-completion of the category of k-bounded orbit-finite nominal sets:*

$$\mathrm{Pro}(\mathbf{Nom}_{\mathrm{of},k}) = \mathbf{nStone}_k.$$

Moreover, k-bounded nominal Stone spaces are precisely the nominal topological spaces arising as codirected limits of k-bounded orbit-finite discrete spaces.

For $k = 0$, we recover the corresponding characterization of classical Stone spaces.

4 Nominal Stone Duality

Next, we give a dual characterization of (bounded) nominal Stone spaces. It builds on the known duality between nominal sets and complete atomic nominal boolean algebras due to Petrişan [32].

▶ **Definition 4.1.** *A* nominal boolean algebra *is a nominal set equipped with the structure of a boolean algebra such that all operations are equivariant. It is* (orbit-finitely) complete *if every (orbit-finite) finitely supported subset has a supremum. A* subalgebra *of an (orbit-finitely) complete nominal boolean algebra is an equivariant subset closed under boolean operations and the respective suprema. Let* $\mathbf{nC}_{\mathrm{of}}\mathbf{BA}$ *and* **nCBA** *denote the categories of (orbit-finitely) complete nominal boolean algebras; their morphisms are equivariant homomorphisms preserving (orbit-finite) suprema.*

▶ **Definition 4.2.** *An element $x \in B$ of a nominal boolean algebra is an* atom *if $x \neq \bot$ and $y < x$ implies $y = \bot$. The (equivariant) set of atoms of B is denoted* $\mathrm{At}\, B$. *The algebra B is* atomic *if every element is the supremum of all atoms below it; if additionally* $\mathrm{At}\, B \in \mathbf{Nom}_{\mathrm{of},k}$ *we call it* k-atomic. *If $A \subseteq B$ is a k-atomic subalgebra we write $A \leq_{\mathrm{of},k} B$. An algebra $B \in \mathbf{nCBA}$ is called* locally k-atomic *if every element of B is contained in some $A \leq_{\mathrm{of},k} B$. We denote by $\mathbf{nCA}_k\mathbf{BA} \subseteq \mathbf{nCBA}$ the full subcategory of all k-atomic complete nominal boolean algebras, and $\mathbf{nC}_{\mathrm{of}}\mathbf{A}_{\mathrm{l}k}\mathbf{BA} \subseteq \mathbf{nC}_{\mathrm{of}}\mathbf{BA}$ denotes the full subcategory of all locally k-atomic orbit-finitely complete nominal boolean algebras.*

▶ Remark 4.3.

1. Orbit-finite completeness is equivalent to the weaker condition that suprema of S-orbits exist for all finite subsets $S \subseteq \mathbb{A}$. In fact, every S-supported orbit-finite subset $X \subseteq B$ is a finite union $X = \bigcup_{i=1}^{n} \mathrm{orb}_S\, x_i$ of S-orbits, whence $\bigvee X = \bigvee_{i=1}^{n} \bigvee \mathrm{orb}_S\, x_i$.
2. Every k-atomic orbit-finitely complete nominal boolean algebra is complete: For every finitely supported subset $X \subseteq B$ we have $\bigvee X = \bigvee\{b \in \mathrm{At}(B) \mid \exists (x \in X).\ b \leq x\}$, which is a supremum of an orbit-finite subset.

▶ **Theorem 4.4.** *For each $k \in \mathbb{N}$, the category of locally k-atomic orbit-finitely complete nominal boolean algebras is the Ind-completion of the category of k-atomic complete nominal boolean algebras:*

$$\mathbf{nC}_{\mathrm{of}}\mathbf{A}_{\mathrm{l}k}\mathbf{BA} \simeq \mathrm{Ind}(\mathbf{nCA}_k\mathbf{BA}).$$

▶ **Theorem 4.5** (Nominal Stone Duality)**.** *For each $k \in \mathbb{N}$, the category of locally k-atomic orbit-finitely complete nominal boolean algebras is dual to the category of k-bounded nominal Stone spaces:*

$$\mathbf{nC}_{\mathrm{of}}\mathbf{A}_{\mathrm{l}k}\mathbf{BA} \simeq^{\mathrm{op}} \mathbf{nStone}_k.$$

Proof. The category **Nom** of nominal sets is dually equivalent to the category **nCABA** of complete atomic nominal boolean algebras [32]. The duality sends a nominal set X to the boolean algebra $\mathcal{P}_{\mathrm{fs}}X$, equippped with the set-theoretic boolean structure. Conversely, a complete atomic nominal boolean algebra B is mapped to the nominal set $\mathrm{At}(B)$ of its atoms, and an **nCABA**-morphism $h\colon C \to B$ to the equivariant map $\mathrm{At}(B) \to \mathrm{At}(C)$ sending $b \in \mathrm{At}(B)$ to the unique $c \in \mathrm{At}(C)$ such that $c \leq h(b)$. For every $k \in \mathbb{N}$ the duality clearly restricts to one between k-bounded orbit-finite nominal sets and k-atomic complete nominal boolean algebras. Thus Theorem 4.4 and Theorem 3.20 yield

$$\mathbf{nC}_{\mathrm{of}}\mathbf{A}_{\mathrm{l}k}\mathbf{BA} \simeq \mathrm{Ind}(\mathbf{nCA}_k\mathbf{BA}) \simeq^{\mathrm{op}} \mathrm{Pro}(\mathbf{nCA}_k\mathbf{BA}^{\mathrm{op}}) \simeq \mathrm{Pro}(\mathbf{Nom}_{\mathrm{of},k}) \simeq \mathbf{nStone}_k. \quad \blacktriangleleft$$

▶ Remark 4.6. We give an explicit description of the dual equivalence of Theorem 4.5.

1. In the direction $\mathbf{nStone}_k \to \mathbf{nC}_{\mathrm{of}}\mathbf{A}_{\mathrm{l}k}\mathbf{BA}$ it maps a k-bounded nominal Stone space X to the nominal boolean algebra $\mathrm{Clo}(X)$ of clopens (or representables, see Lemma 3.19). A continuous map $f\colon X \to Y$ is mapped to the homomorphism $f^{-1}\colon \mathrm{Clo}(Y) \to \mathrm{Clo}(X)$ taking preimages.
2. The direction $\mathbf{nC}_{\mathrm{of}}\mathbf{A}_{\mathrm{l}k}\mathbf{BA} \to \mathbf{nStone}_k$ requires some terminology. A finitely supported subset $F \subseteq B$ of an algebra $B \in \mathbf{nC}_{\mathrm{of}}\mathbf{A}_{\mathrm{l}k}\mathbf{BA}$ is a *nominal orbit-finitely complete prime filter* if (i) $F \neq \emptyset$, (ii) F is upwards closed ($x \in F \wedge x \leq y \Rightarrow y \in F$), (iii) F is downwards directed ($x, y \in F \Rightarrow x \wedge y \in F$), and (iv) for every finitely supported k-bounded orbit-finite subset $X \subseteq B$ such that $\bigvee X \in F$, one has $X \cap F \neq \emptyset$. The equivalence now maps $B \in \mathbf{nC}_{\mathrm{of}}\mathbf{A}_{\mathrm{l}k}\mathbf{BA}$ to the space $\mathcal{F}_{\mathrm{np}}(B)$ of nominal orbit-finitely complete prime

filters of B, whose topology is generated by the basic open sets $\{F \in \mathcal{F}_{\mathrm{np}}(B) \mid b \in F\}$ for $b \in B$. A morphism $h\colon B \to C$ of $\mathbf{nC}_{\mathrm{of}}\mathbf{A}_{\mathrm{l}k}\mathbf{BA}$ is mapped to the continuous map $h^{-1}\colon \mathcal{F}_{\mathrm{np}}(C) \to \mathcal{F}_{\mathrm{np}}(B)$ taking preimages.

In Theorem 4.5 we made the support bound k explicit, but we can also leave it implicit. A nominal Stone space is *bounded* if it lies in $\mathbf{nStone}_k$ for some natural number k; similarly, a *locally bounded atomic orbit-finitely complete nominal boolean algebras* is an element of $\mathbf{nC}_{\mathrm{of}}\mathbf{A}_{\mathrm{l}k}\mathbf{BA}$ for some k.

▶ **Corollary 4.7.** *The category of locally bounded atomic orbit-finitely complete nominal boolean algebras is dual to the category of bounded nominal Stone spaces.*

▶ Remark 4.8. For $k = 0$ we recover the classical Stone duality between boolean algebras and Stone spaces. Indeed, 0-bounded nominal Stone spaces are precisely Stone spaces, and locally 0-atomic orbit-finitely complete nominal boolean algebras are precisely boolean algebras.

5 Pro-Orbit-Finite Words

In this section, we generalize the topological characterization of regular languages to data languages recognizable by orbit-finite nominal monoids [7, 10, 13].

▶ **Definition 5.1.** *A* nominal monoid M *is a monoid object in* $\mathbf{Nom}$*, that is, it is given by nominal set M equipped with an equivariant associative multiplication $M \times M \to M$ and an equivariant unit $1 \in M$. Nominal monoids and equivariant monoid homomorphisms form a category* $\mathbf{nMon}$*.*

As for ordinary monoids, the *free monoid* generated by $\Sigma \in \mathbf{Nom}$ is the nominal set Σ^* of finite words (with pointwise group action); its multipliation is concatenation and its unit the empty word.

▶ Remark 5.2. We emphasize the difference between k-bounded nominal monoids – nominal monoids whose carrier is k-bounded – and monoid objects in $\mathbf{Nom}_k$, which are partial nominal monoids where the product $x \cdot y$ is defined iff $|\operatorname{supp} x \cup \operatorname{supp} y| \leq k$.

▶ **Definition 5.3.** *A* data language *over $\Sigma \in \mathbf{Nom}_{\mathrm{of}}$ is a finitely supported subset $L \subseteq \Sigma^*$. It is* recognizable *if there exists an equivariant monoid morphism $h\colon \Sigma^* \to M$ with M orbit-finite and a finitely supported subset $P \subseteq M$ such that $L = h^{-1}[P]$. In this case, we say that the morphism h* recognizes *L.*

For example, the equivariant language L_0 from the Introduction is recognizable, while the language L_1 is not recognizable.

▶ Remark 5.4.

1. The morphism h can be taken to be surjective; otherwise, take its coimage.
2. Via characteristic functions, data languages correspond precisely to finitely supported maps $L\colon \Sigma^* \to 2$, where 2 is the two-element nominal set. Recognizablity then states that L factorizes through some equivariant monoid morphism with orbit-finite codomain.

Recall from Section 2 that the Stone space $\widehat{\Sigma^*}$ of profinite words over a finite alphabet Σ is constructed as the limit in $\mathbf{Stone} \simeq \mathrm{Pro}(\mathbf{Set}_{\mathrm{f}})$ of all finite quotient monoids of Σ^*. The obvious generalization to a *nominal* alphabet $\Sigma \in \mathbf{Nom}_{\mathrm{of}}$, which constructs the limit of all orbit-finite quotient monoids in $\mathrm{Pro}(\mathbf{Nom}_{\mathrm{of}})$, is unlikely to yield a useful object since this category is not concrete (Proposition 3.6); in fact, it is futile from a language-theoretic

perspective, cf. Remark 5.15. Instead, our results of Section 3 suggest to restrict the diagram scheme to $\Sigma^*{\downarrow}\mathbf{nMon}_{\mathrm{of},k}$, the poset of k-bounded orbit-finite quotient monoids (where $e \leq e'$ iff e' factorizes through e), and take the limit in $\mathrm{Pro}(\mathbf{Nom}_{\mathrm{of},k}) = \mathbf{nStone}_k$. However, this diagram is not codirected, so its limit may not be a nominal Stone space. We again focus on well-behaved (i.e., codirected), subcategories by introducing *support bounds*.

▶ **Definition 5.5.** *A* support bound *is a map $s\colon \Sigma^* \to \mathcal{P}\mathbb{A}$ such that $s[\Sigma^*] \subseteq \mathcal{P}_k\mathbb{A}$ for some $k \in \mathbb{N}$, where $\mathcal{P}_k\mathbb{A} = \{S \subseteq \mathbb{A} \mid |S| \leq k\}$. We usually identify s with its codomain restrictions to $\mathcal{P}_k\mathbb{A}$ for sufficiently large k. A morphism $h\colon \Sigma^* \to M$ of nominal monoids is* s-bounded *if $\operatorname{supp} h(w) \subseteq s(w)$ for all $w \in \Sigma^*$; we write $h\colon \Sigma^* \to_s M$. We denote by $\Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k}$ the subposet of $\Sigma^*{\downarrow}\mathbf{nMon}_{\mathrm{of},k}$ given by s-bounded quotient monoids.*

▶ **Lemma 5.6.** *For every support bound s, the poset $\Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k}$ is codirected.*

Proof. Let $h\colon \Sigma^* \to_s M_h$ and $h'\colon \Sigma^* \to_s M_{h'}$ be two s-bounded quotients in $\Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k}$. Form the coimage $k\colon \Sigma^* \twoheadrightarrow M$ of their pairing $\langle h, h'\rangle\colon \Sigma^* \to M_h \times M_{h'}$. Then for all $w \in \Sigma^*$

$$\operatorname{supp} k(w) = \operatorname{supp}(h(w), h'(w)) = \operatorname{supp} h(w) \cup \operatorname{supp} h'(w) \subseteq s(w).$$

Hence, k is a lower bound for h, h' in the poset $\Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k}$. ◀

▶ **Definition 5.7.** *For an orbit-finite nominal set Σ and a support bound $s\colon \Sigma^* \to \mathcal{P}_k\mathbb{A}$ we define the nominal Stone space $\widehat{\Sigma^*_s}$ to be the limit of the codirected diagram*

$$D\colon \Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k} \to \mathbf{nStone}_k, \qquad (e\colon \Sigma^* \twoheadrightarrow_s M) \mapsto |M|,$$

where $|M|$ is the nominal set underlying M, regarded as a discrete nominal topological space. The elements of $\widehat{\Sigma^*_s}$ are called the (s-bounded) pro-orbit-finite words over Σ. *We denote by $\hat{e}\colon \widehat{\Sigma^*_s} \to M$ the limit projection associated to $e\colon \Sigma^* \twoheadrightarrow_s M$ in $\Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k}$.*

▶ Remark 5.8.

1. One may equivalently define $\widehat{\Sigma^*_s}$ as the limit of the larger cofiltered diagram D' given by

   $$D'\colon \Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k} \to \mathbf{nStone}_k, \qquad (e\colon \Sigma^* \to_s M) \mapsto |M|,$$

   where $\Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k}$ is the category of all equivariant s-bounded monoid morphisms $h\colon \Sigma^* \to_s M$ with k-bounded orbit-finite codomain; a morphism from h to $h'\colon \Sigma^* \to_s M'$ is an equivariant monoid morphism $k\colon M \to M'$ such that $h' = k \cdot h$. In fact, the inclusion $\Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k} \hookrightarrow \Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k}$ is an initial functor, hence the limits of D and D' coincide. Since the limit of D' is formed as in **Set** (Lemma 3.9), the space $\widehat{\Sigma^*_s}$ is carried by the nominal set of compatible families $(x_h)_h$ of D', and the limit projection $\hat{h}$ associated to $h\colon \Sigma^* \to_s M$ is given by $(x_h)_h \mapsto x_h$.
2. The forgetful functor $V\colon \mathbf{nStone}_k \to \mathbf{Nom}_k$ and the inclusion $I\colon \mathbf{Nom}_k \to \mathbf{Nom}$ both preserve codirected limits. The morphisms $\Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k}$ viewed as equivariant functions form a cone for the diagram IVD', so there exists a unique equivariant map $\eta\colon \Sigma^* \to IV\widehat{\Sigma^*_s}$ such that

   $$h = \big(\Sigma^* \dashrightarrow^{\eta} IV\widehat{\Sigma^*_s} \xrightarrow{IV\hat{h}} IVM\big) \qquad \text{for all } h \in \Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k}.$$

   In more explicit terms, the map η is given by $\eta(w) = (h(w))_h$ for $w \in \Sigma^*$. For simplicity we omit I and V and write $\eta\colon \Sigma^* \to \widehat{\Sigma^*_s}$. The image of η forms a dense subset of $\widehat{\Sigma^*_s}$. We note that η is generally not injective since we restrict to a subdiagram $\Sigma^*{\downarrow}_s\mathbf{nMon}_{\mathrm{of},k}$ of the diagram $\Sigma^*{\downarrow}\mathbf{nMon}_{\mathrm{of}}$,

3. The space $\widehat{\Sigma^*_s}$ is a nominal monoid with product $\hat{h}(x \cdot y) = \hat{h}(x) \cdot \hat{h}(y)$ and unit $\eta(\varepsilon)$, with ε the empty word. Since the multiplication is readily seen to be continuous, $\widehat{\Sigma^*_s}$ can be regarded as an object of $\mathbf{Mon}(\mathbf{nStone})$, the category of nominal Stone spaces equipped with a continuous monoid structure and continuous equivariant monoid morphisms.

Now recall from Section 2 that the space $\widehat{\Sigma^*}$ can be constructed as the metric completion of Σ^*, where the metric measures the size of separating monoids. We now investigate to what extent the metric approach applies to the nominal setting, using nominal (pseudo-)metrics; see Example 3.2.

▶ **Definition 5.9.** *Let s be a support bound on Σ^*. We say that a nominal monoid M s-*separates *$v, w \in \Sigma^*$ if there exists an s-bounded equivariant monoid morphism $h\colon \Sigma^* \to_s M$ such that $h(v) \neq h(w)$. We define a nominal pseudometric d_s on Σ^* by setting*

$$d_s(v,w) = \sup\{\, 2^{-|\operatorname{orb} M|} \mid \text{the orbit-finite nominal monoid } M \text{ } s\text{-separates } v, w \,\}.$$

We let Σ^*/d_s denote the corresponding nominal metric space, obtained as a quotient space of the pseudometric space (Σ^*, d_s) by identifying v, w if $d_s(v,w) = 0$.

▶ Remark 5.10. In contrast to the classical case, d_s is generally not a metric: there may exist words $v \neq w$ which are not s-separated by any orbit-finite nominal monoids. For example, if $\Sigma = \mathbb{A}$ and $s(a_1 \cdots a_n) = a_1$ for $a_1, \ldots, a_n \in \Sigma$, then for every s-bounded h and distinct names $a, b, c \in \mathbb{A}$ we have $h(ab) = h((b\ c) \cdot ac) = (b\ c) \cdot h(ac) = h(ac)$ since $b, c \notin s(ac) \supseteq \operatorname{supp} h(ac)$. Therefore, the additional metrization process is required.

For the next lemma we need some terminology. A nominal metric space is *complete* if every finitely supported Cauchy sequence has a limit. A nominal topological space is *completely metrizable* if its topology is induced by a complete metric. A subset $D \subseteq X$ of a nominal metric space is *(topologically) dense* if every open neighbourhood of a point $x \in X$ contains an element of D.

▶ Remark 5.11. In contrast to classical metric spaces, density is not equivalent to *sequential density* (every point $x \in X$ is a limit of a finitely supported sequence in D). To see this, consider the space $\mathbb{A}^\omega$ of finitely supported infinite words with the prefix metric, that is, $d(v,w) = 2^{-n}$ if n is the length of the longest common prefix of v, w. Let $D \subseteq X$ be the equivariant subset given by

$$D = \{\, x \in \mathbb{A}^\omega \mid |\operatorname{supp} x| \geq 2 \text{ and } |\operatorname{supp} x| \geq |\operatorname{initialblock}(x)| \,\},$$

where $\operatorname{initialblock}(x)$ is the longest prefix of x of the form a^n ($a \in \mathbb{A}$). The set D is dense, but not sequentially dense: $a^\omega \in \mathbb{A}^\omega$ is not the limit of any finitely supported sequence in D.

▶ **Lemma 5.12.**

1. *The space $\widehat{\Sigma^*_s}$ is completely metrizable via the complete nominal metric*

$$\hat{d}_s(x,y) = \sup\{\, 2^{-|\operatorname{orb} M|} \mid \exists (h\colon \Sigma^* \to_s M)\colon \hat{h}(x) \neq \hat{h}(y) \,\}. \tag{5.1}$$

2. *The canonical map η (Remark 5.8) yields a dense isometry $\eta\colon (\Sigma^*, d_s) \to (\widehat{\Sigma^*_s}, \hat{d}_s)$.*

▶ Remark 5.13. In classical topology, it would now be clear that $\widehat{\Sigma^*_s}$ is the metric completion of the metric space Σ^*/d_s, i.e. it satisfies the universal property that every uniformly continuous map from Σ^*/d_s to a complete metric space has a unique uniformly continuous extension to $\widehat{\Sigma^*_s}$. However, this rests on the coincidence of topological and sequential density, which fails over nominal sets as seen in Remark 5.11. We therefore conjecture that $\widehat{\Sigma^*_s}$ is not the nominal metric completion of Σ^*/d_s.

By using support bounds, we obtain a topological perspective on recognizable data languages. Let $\mathrm{Rec}_s\,\Sigma$ denote the set of data languages recognized by s-bounded equivariant monoid morphisms.

▶ **Theorem 5.14.** *For every support bound $s\colon \Sigma^* \to \mathcal{P}_k\mathbb{A}$, the k-bounded nominal Stone space $\widehat{\Sigma^*_s}$ of s-bounded pro-orbit-finite words is dual to the locally k-atomic orbit-finitely complete boolean algebra $\mathrm{Rec}_s(\Sigma^*)$ of s-recognizable languages. In particular, we have the isomorphism*

$$\mathrm{Rec}_s(\Sigma^*) \;\cong\; \mathrm{Clo}(\widehat{\Sigma^*_s}) \qquad \textit{in} \qquad \mathbf{nC}_{\mathrm{of}}\mathbf{A}_{\mathrm{l}k}\mathbf{BA}.$$

Proof (Sketch). The isomorphism is illustrated by the two diagrams below:

$$\begin{array}{ccccccc} L & = h^{-1}[P] & \subseteq & \Sigma^* & \xrightarrow{h} & M & \supseteq\ P \\ \downarrow & & & {\scriptstyle\eta}\downarrow & \nearrow_{\hat h} & & \\ \overline{\eta[L]} & = \hat h^{-1}[P] & \subseteq & \widehat{\Sigma^*_s} & & & \end{array} \qquad \begin{array}{ccccccc} \eta^{-1}[C] & = h^{-1}[P] & \subseteq & \Sigma^* & \xrightarrow{h} & M & \supseteq\ P = p^{-1}[U] \\ \updownarrow & & & {\scriptstyle\eta}\downarrow & \nearrow_{\hat h} & \downarrow{\scriptstyle\exists p} & \\ C & = f^{-1}[U] & \subseteq & \widehat{\Sigma^*_s} & \xrightarrow{f} & Y & \supseteq\ U \end{array}$$

In more detail, if $L \subseteq \Sigma^*$ is s-recognizable, say $L = h^{-1}[P]$ for an s-bounded morphism h, then its corresponding clopen is the topological closure $\overline{\eta[L]} = \hat h^{-1}[P]$ represented by the continuous extension $\hat h$. Conversely, every clopen $C \subseteq \widehat{\Sigma^*_s}$ restricts to an s-recognizable language $\eta^{-1}[C] \subseteq \Sigma^*$. We get s-recognizability of $\eta^{-1}[C]$ by factorizing a representation $f\colon \widehat{\Sigma^*_s} \to Y$ of C through a limit projection $\hat h$ as $f = p\cdot\hat h$, using that Y is finitely copresentable. Thus h recognizes $\eta^{-1}[C]$. ◀

▶ Remark 5.15. In the proof of Theorem 5.14, finite copresentability of orbit-finite sets is crucial to recover recognizable languages from representable subsets, highlighting the importance of working in the Pro-completion $\mathrm{Pro}(\mathbf{Nom}_{\mathrm{of},k}) = \mathbf{nStone}_k$. In a naive approach one might instead want to consider the limit of the diagram $D\colon \Sigma^*{\downarrow}\mathbf{nMon}_{\mathrm{of}} \to \mathbf{nTop}$ of *all* equivariant morphisms from Σ^* to orbit-finite monoids. The resulting space $\widehat{\Sigma^*}$ is still a nominal Hausdorff space with a basis of representables, but it generally fails to be compact, and its representable subsets do not correspond to recognizable data languages. To see this, consider the space $\widehat{\mathbb{A}^*}$ and the orbit-finite nominal monoids $\mathbb{A}^{\leq n}$ (words of length at most n) with multiplication cutting off after n letters. We denote by $h_n\colon \mathbb{A}^* \to \mathbb{A}^{\leq n}$ and $p_{k,n}\colon \mathbb{A}^{\leq k} \twoheadrightarrow \mathbb{A}^{\leq n}$, $n \leq k$, the equivariant monoid morphisms given by projection to the first n letters. For every compatible family $x = (x_h) \in \widehat{\mathbb{A}^*}$ its subfamily $(x_{h_n})_{n\in\mathbb{N}}$ corresponds to a (possibly infinite) word over $\mathbb{A}$ with finite support. Hence there exists a largest natural number $N = N(x)$ such that $|\operatorname{supp} x_{h_N}| = N$. The subsets $C_n = \{x \in \widehat{\mathbb{A}^*} \mid N(x) = n\}$, $n \in \mathbb{N}$, are equivariant clopens since $C_n = \hat h_n^{-1}[\mathbb{A}^{\#n}] \cap \hat h_{n+1}^{-1}[\mathbb{A}^{\leq n+1} \setminus \mathbb{A}^{\#(n+1)}]$. Thus each C_n is representable (by a continuous map into the two-element discrete space), non-empty (since $\eta(w) = (h(w))_h \in C_n$ for every word $w \in \mathbb{A}^{\#n} \subseteq \mathbb{A}^*$ of pairwise distinct letters), and pairwise disjoint. Hence they form a cover of $\widehat{\mathbb{A}^*}$ that admits no orbit-finite (equivalently, finite) subcover, showing that $\widehat{\mathbb{A}^*}$ is not compact. Moreover, the sets $C_M = \bigcup_{m\in M} C_m$, where $M \subseteq \mathbb{N}$, are equivariant clopens (hence representable) and pairwise distinct. Thus $\widehat{\mathbb{A}^*}$ has uncountably many clopens. On the other hand, there exist only countably many recognizable languages over $\mathbb{A}$ (using that, up to isomorphism, there exist only countably many orbit-finite sets [36, Thm. 5.13] and thus countably many orbit-finite nominal monoids), showing that there is no bijective correspondence between representable sets in $\widehat{\mathbb{A}^*}$ and recognizable data languages over $\mathbb{A}$.

6 A Nominal Reiterman Theorem

As an application of pro-orbit-finite methods, we present a nominal extension of Reiterman's classical pseudovariety theorem [37]. The latter characterizes classes of finite algebras presentable by profinite equations as precisely those closed under finite products, subalgebras, and homomorphic images. This result has been generalized to first-order structures [34] and, recently, to abstract categories [1, 30]. A key insight for the categorical perspective is that equations should be formed over projective objects. (Recall that an object X in a category is projective w.r.t. a class $\mathcal{E}$ of morphisms if for all cospans $X \xrightarrow{f} Y \xleftarrow{e} Z$ with $e \in \mathcal{E}$ there exists a factorization of f through e.) In **Nom**, one takes strong nominal sets, which are projective with respect to support-reflecting quotients (see Definition 6.1.2). For spaces of pro-orbit-finite words we have the support bound as an additional constraint, which makes the situation more complex: In a cospan $\widehat{\Sigma_s^*} \xrightarrow{\hat{h}} N \xleftarrow{e} M$ with e support-reflecting, no s-bounded factorization of $\hat{h}$ through e may exist. Surprisingly, there nonetheless exists a suitable type of quotients for nominal monoids, called *MSR quotients*, which is *independent* of the support bound s.

▶ **Definition 6.1.** *A surjective equivariant morphism $e\colon M \twoheadrightarrow N$ of nominal monoids is*

1. support-preserving *if* $\operatorname{supp} e(x) = \operatorname{supp} x$ *for every* $x \in X$*;*
2. support-reflecting *if for every* $y \in Y$ *there exists* $x \in e^{-1}[y]$ *such that* $\operatorname{supp} x = \operatorname{supp} y$*;*
3. multiplicatively support-reflecting *(*MSR *for short) if there exists a nominal submonoid* $M' \subseteq M$ *such that the domain restriction* $e|_{M'}\colon M' \to N$ *of* e *is surjective and support-preserving.*

▶ Remark 6.2. Note that a surjective morphism e is support-reflecting iff it restricts to a support-preserving surjection $e|_{M'}$ for some equivariant subset $M' \subseteq M$. For MSR morphisms one additionally requires that M' may be chosen to form a submonoid. So the implications

$$\text{support-preserving} \implies \text{multiplicatively support-reflecting} \implies \text{support-reflecting}$$

hold, but none of the two converses holds in general; for the first one consider the morphism $\mathbb{A}^* \twoheadrightarrow 1$ into the trivial monoid, and for the second one see Example 6.11.

▶ **Proposition 6.3.** *A surjective equivariant morphism $e\colon M \twoheadrightarrow N$ between orbit-finite nominal monoids is MSR iff all the monoids $\widehat{\Sigma_s^*}$ (where $\Sigma \in \mathbf{Nom}_{\mathrm{of}}$ is strong and $s\colon \Sigma^* \to \mathcal{P}\mathbb{A}$ is a support bound) are projective with respect to e in $\mathbf{Mon}(\mathbf{nStone})$, with M and N regarded as discrete spaces.*

▶ **Definition 6.4.** *An* MSR-pseudovariety of nominal monoids *is a class $\mathcal{V} \subseteq \mathbf{nMon}_{\mathrm{of}}$ of orbit-finite nominal monoids closed under*

1. *finite products: if $M_1, \dots, M_n \in \mathcal{V}$, $n \in \mathbb{N}$, then $M_1 \times \cdots \times M_n \in \mathcal{V}$;*
2. *submonoids: if $M \in \mathcal{V}$ and $N \subseteq M$ is a nominal submonoid, then $N \in \mathcal{V}$:*
3. *MSR quotients: if $M \in \mathcal{V}$ and $e\colon M \twoheadrightarrow N$ is an MSR quotient, then $N \in \mathcal{V}$.*

▶ **Definition 6.5.** *Let $s\colon \Sigma^* \to \mathcal{P}\mathbb{A}$ be a support bound. A* morphic pro-orbit-finite equation, *or* morphic proequation *for short, is a surjective* **nStone***-morphism $\varphi\colon \widehat{\Sigma_s^*} \twoheadrightarrow E$. An orbit-finite monoid M* satisfies *φ if for every s-bounded morphism $h\colon \Sigma^* \to M$, the limit projection $\hat{h}\colon \widehat{\Sigma_s^*} \to M$ factorizes through φ in $\mathbf{nStone}_k$, for some $k \in \mathbb{N}$ such that $M \in \mathbf{Nom}_{\mathrm{of},k}$ and s corestricts to $\mathcal{P}_k\mathbb{A}$:*

$$\hat{h} = \big(\widehat{\Sigma_s^*} \xrightarrow{\varphi} E \overset{\exists}{\dashrightarrow} M\big).$$

For a set $\mathcal{T}$ of morphic proequations, taken over possibly different $\widehat{\Sigma_s^*}$, we denote by $\mathcal{V}(\mathcal{T})$ the class of orbit-finite monoids satisfying all proequations in $\mathcal{T}$. A class $\mathcal{V}$ of orbit-finite monoids is presentable by morphic proequations *if $\mathcal{V} = \mathcal{V}(\mathcal{T})$ for some set $\mathcal{T}$ of morphic proequations.*

Note that proequations use support bounds, while the definition of an MSR-pseudovariety does not.

▶ **Theorem 6.6** (Nominal Reiterman). *A class of orbit-finite nominal monoids is an MSR-pseudovariety iff it is presentable by morphic proequations.*

The main technical observations for the proof are that (i) every orbit-finite set is k-bounded for some k, hence finitely copresentable in $\mathbf{nStone}_k$, and (ii) there are "enough" proequations in the sense that every orbit-finite nominal monoid is a quotient of some $\widehat{\Sigma_s^*}$. The quotient is not necessarily MSR, which entails that abstract pseudovariety theorems [1, 30] do not apply to our present setting.

We also give a syntactic version of our nominal Reiterman theorem, which uses explicit proequations in lieu of morphic proequations.

▶ **Definition 6.7.** *An* explicit proequation *is a pair $(x, y) \in \widehat{\Sigma_s^*} \times \widehat{\Sigma_s^*}$ for some strong $\Sigma \in \mathbf{Nom}_{\mathrm{of}}$ and some support bound s, denoted by $x = y$. An orbit-finite monoid M* satisfies *the explicit proequation $x = y$ if*

$$\hat{h}(x) = \hat{h}(y) \qquad \text{for every } s\text{-bounded equivariant monoid morphism } h\colon \Sigma^* \to M.$$

(Here choose a common support size bound k for M and s, so that $\hat{h}$ lies in $\mathbf{nStone}_k$.)

▶ **Theorem 6.8** (Explicit Nominal Reiterman). *A class of orbit-finite nominal monoids is an MSR-pseudovariety iff it is presentable by explicit proequations.*

▶ **Example 6.9.** Recall that in a finite monoid M every element m has a unique idempotent power, denoted by m^ω. This holds analogously for orbit-finite nominal monoids M [7, Theorem 5.1]: one has $m^\omega = m^{(n\cdot k!)!}$ where n is the number of orbits M and k is the maximum support size. (The number $n \cdot k!$ is an upper bound on the number of elements of M with any given finite support [36, Thm. 5.13], hence on the cardinality of the set $\{m^i : i \in \mathbb{N}\}$.) The nominal monoid M is *aperiodic* if $m^\omega \cdot m = m^\omega$ for all $m \in M$. Languages recognizable by aperiodic orbit-finite monoids are captured precisely by first-order logic on data words [7, 13]. One readily verifies that the class of aperiodic orbit-finite monoids forms an MSR-pseudovariety; in fact, it is closed under all quotients. To present it by pro-orbit-finite equations, note that for every $x \in \widehat{\Sigma_s^*}$ the family $x^\omega = (\hat{h}(x)^\omega)_h$ is again compatible, hence $x^\omega \in \widehat{\Sigma_s^*}$. If $s\colon \Sigma^* \to \mathcal{P}_k\mathbb{A}$ and $h\colon \Sigma^* \to_s M$ is an s-bounded equivariant monoid morphism such that M has at most n orbits, then $\hat{h}(x^\omega) = \hat{h}(x)^\omega = \hat{h}(x)^{(n\cdot k!)!} = \hat{h}(x^{(n\cdot k!)!})$, hence $\hat{d}_s(x^\omega, x^{(n\cdot k!)!}) < 2^{-n}$ in the metric (5.1) on $\widehat{\Sigma_s^*}$. This shows that x^ω is the limit of the sequence $(x^{(n\cdot k!)!})_{n\in\mathbb{N}}$ in $\widehat{\Sigma_s^*}$, and moreover that the pseudovariety of aperiodic orbit-finite monoids is presented by the explicit proequations $x^\omega \cdot x = x^\omega$, where $x \in \widehat{\Sigma_s^*}$ and $s\colon \Sigma^* \to \mathcal{P}_k\mathbb{A}$ ranges over all support bounds on strong orbit-finite alphabets. Restricting to $k = 0$, we recover the well-known description of aperiodic finite monoids by the (single) profinite equation $x^\omega \cdot x = x^\omega$.

▶ Remark 6.10. **1.** Pseudovarieties of finite monoids admit an alternative equational characterization based on sequences of word equations rather than profinite equations. A *word equation* is a pair $(v, w) \in \Sigma^* \times \Sigma^*$ of words over some finite alphabet Σ, denoted $v = w$; it is *satisfied* by a monoid M if $h(v) = h(w)$ for every monoid morphism $h\colon \Sigma^* \to M$.

More generally, a sequence $(v_0 = w_0, v_1 = w_1, \ldots)$ of word equations, taken over possibly different finite alphabets, is *eventually satisfied* by M if it satisfies all but finitely many of the equations. As shown by Eilenberg and Schützenberger [15], a class of finite monoids forms a pseudovariety iff it is presentable by a (single) sequence of word equations.

2. Recently, a nominal version of the Eilenberg-Schützenberger theorem by Urbat and Milius [44]. They consider nominal word equations (defined as above, where Σ is now a strong orbit-finite nominal set) and show that sequences of nominal word equations present precisely *weak pseudovarieties*, i.e. classes of orbit-finite nominal monoids closed under finite products, submonoids, and support-reflecting quotients. Clearly every MSR-pseudovariety is weak, but the converse does not hold; hence over nominal sets, sequences of word equations and pro-orbit-finite equations are of different expressivity. The example below illustrates one source of additional expressivity of pro-orbit-finite equations: The support bound s can control how the support changes during multiplication, which is not expressible by sequences of word equations.

▶ **Example 6.11.** An example of an MSR-pseudovariety that is not a weak pseudovariety is given by the class $\mathcal{V}$ of all orbit-finite nominal monoids M such that

$$\forall (m, n \in M)\colon \quad \operatorname{supp}(mn) = \emptyset \quad \Longleftrightarrow \quad \operatorname{supp}(m, n) = \emptyset. \tag{6.1}$$

(Note that $\operatorname{supp}(m, n) = \operatorname{supp} m \cup \operatorname{supp} n$ and that "$\Leftarrow$" always holds by equivariance of the monoid multiplication.) It is not difficult to prove that $\mathcal{V}$ is an MSR-pseudovariety. To show that $\mathcal{V}$ is not a weak pseudovariety, we construct a support-reflecting quotient under which $\mathcal{V}$ is not closed. The nominal set $\overline{1} + \overline{\mathbb{A}} = \{\overline{1}\} + \{\overline{a} \mid a \in \mathbb{A}\}$ forms a nominal monoid with multiplication given by projection on the first component and unit $\overline{1}$. We extend the multiplication to the nominal set $M = 1 + \mathbb{A} + \overline{1} + \overline{\mathbb{A}}$ by letting 1 be the unit and setting $x \cdot y = \overline{x} \cdot \overline{y}$ whenever $x, y \neq 1$; here overlining is idempotent ($\overline{\overline{x}} := \overline{x}$). This makes the multiplication associative and equivariant. Thus, M is a nominal monoid. Now let $N = 1 + \mathbb{A} + 0 = \{1\} + \mathbb{A} + \{0\}$ be the nominal monoid with multiplication $x \cdot y = 0$ for $x, y \neq 1$. Thus 0 is an absorbing element. Letting $\mathrm{const}_0\colon \overline{1} + \overline{\mathbb{A}} \to 0$ denote the constant map, we have the equivariant surjective map

$$e = \mathrm{id}_{1+\mathbb{A}} + \mathrm{const}_0\colon M = (1 + \mathbb{A}) + (\overline{1} + \overline{\mathbb{A}}) \twoheadrightarrow (1 + \mathbb{A}) + 0 = N.$$

Note that e is a monoid morphism: it maps 1 to 1 and if $x, y \neq 1$ then $e(x), e(y) \neq 1$ and hence $e(x \cdot y) = e(\overline{x} \cdot \overline{y}) = 0 = e(x) \cdot e(y)$. The quotient e is support-reflecting, but it is not MSR: the subset $1 + \mathbb{A} + \overline{1} \subseteq M$ of support-preserving elements does not form a submonoid of M. Finally, clearly M satisfies (6.1) while N does not.

7 Conclusion and Future Work

We have introduced topological methods to the theory of data languages, and also explored some of their subtleties and limitations. Following the spirit of Marshall Stone's slogan *"always topologize"*, the core insight of our paper may be summarized as:

Data languages topologize for bounded supports.

In fact, by restricting to support-bounded orbit-finite nominal sets and analyzing their Pro-completion, we have shown that fundamental results from profinite topology (notably Stone duality and the equivalence between profinite spaces and Stone spaces) generalize to the pro-orbit-finite world. These results are of independent interest; in particular, they are

potentially applicable to data languages recognizable by all kinds of orbit-finite structures. For the case of monoids, we derived a topological interpretation of recognizable data languages via clopen sets of pro-orbit-finite words, as well as a nominal version of Reiterman's pseudovariety theorem characterizing the expressive power of pro-orbit-finite equations.

The foundations laid in the present paper open up a number of promising directions for future research. One first goal is to develop a fully fledged duality theory for data languages along the lines of the work of Gehrke et al. [18] on classical regular languages, based on an *extended nominal Stone duality* between pro-orbit-finite monoids and nominal boolean algebras with operators.

Regarding specific applications, we aim to analyze further classes of orbit-finite monoids in terms of pro-orbit-finite equations, following the lines of Example 6.9, in order to classify the corresponding data languages. One natural candidate is the class of $\mathcal{J}$-trivial monoids, with the vision of a nominal version of Simon's theorem [41] relating $\mathcal{J}$-triviality to existential first-order logic on data words.

Finally, we aim to extend our topological theory of recognizable data languages, and the corresponding nominal Reiterman theorem, to algebraic structures beyond orbit-finite monoids. Potential instances include algebras for a signature Σ, which serve as recognizers for data tree languages, infinitary structures such as nominal ω-semigroups [45], modeling languages of infinite data words, and algebraic structures with binders, which we expect to bear interesting connections to data languages with binders and their automata models [39,43].

Population Protocols with Unordered Data

Michael Blondin
Department of Computer Science, Université de Sherbrooke, Canada

François Ladouceur
Department of Computer Science, Université de Sherbrooke, Canada

Abstract

Population protocols form a well-established model of computation of passively mobile anonymous agents with constant-size memory. It is well known that population protocols compute Presburger-definable predicates, such as absolute majority and counting predicates. In this work, we initiate the study of population protocols operating over arbitrarily large data domains. More precisely, we introduce *population protocols with unordered data* as a formalism to reason about anonymous crowd computing over unordered sequences of data. We first show that it is possible to determine whether an unordered sequence from an infinite data domain has a datum with absolute majority. We then establish the expressive power of the "immediate observation" restriction of our model, namely where, in each interaction, an agent observes another agent who is unaware of the interaction.

1 Introduction

Context. Population protocols form a well-established model of computation of passively mobile anonymous agents with constant-size memory [1]. Population protocols allow, e.g., for the formal analysis of chemical reaction networks and networks of mobile sensors (see [23] for a review article on population protocols and more generally on dynamic networks).

In a population protocol, anonymous agents hold a mutable state from a finite set. They collectively seek to evaluate a predicate on the initial global state of the population. At each discrete moment, a scheduler picks two agents who jointly update their respective states according to their current states. Such a scheduler is assumed to be "fair" (or, equivalently, to pick pairs of agents uniformly at random). Let us illustrate the model with a classical protocol for the aboslute majority predicate. Consider a population of ℓ (anonymous) agents, each initialized with either Y or N, that seek to compute whether the number of Y exceeds the number of N, i.e., to collectively evaluate the predicate $\varphi(\#Y, \#N) \coloneqq (\#Y > \#N)$. For example, a population of $\ell = 5$ agents may be initialized to $\{\!\{Y, N, Y, Y, N\}\!\}$. An update of two agents occurs according to these four rules:

strong to weak	*propagation of winning side*	*tiebreaker*
$\{\!\{Y, N\}\!\} \to \{\!\{n, n\}\!\}$	$\{\!\{Y, n\}\!\} \to \{\!\{Y, y\}\!\}$ $\{\!\{N, y\}\!\} \to \{\!\{N, n\}\!\}$	$\{\!\{y, n\}\!\} \to \{\!\{n, n\}\!\}$

A possible execution from the aforementioned population is $\{\!\{Y, N, Y, Y, N\}\!\} \to \{\!\{Y, N, Y, n, n\}\!\} \to \{\!\{Y, n, n, n, n\}\!\} \to \{\!\{Y, y, n, n, n\}\!\} \to \cdots \to \{\!\{Y, y, y, y, y\}\!\}$.

Agents in states $\{Y, y\}$ believe that the output of φ should be *true*, while agents in $\{N, n\}$ believe that it should be *false*. Thus, in the above execution, a lasting *true*-consensus has been reached by the population (although no agent is locally certain of it).

It is well known that population protocols compute precisely the predicates definable in Presburger arithmetic, namely first-order logic over the naturals with addition and order. This was first shown through convex geometry [2], and reproven using the theory of vector addition systems [15]. For example, this means that, given voting options $\{1, \ldots, k\}$, there is a population protocol that determines whether some option i has an absolute majority, i.e., whether more than $\ell/2$ of the ℓ agents initially hold a common $i \in \{1, \ldots, k\}$.

Since k must be stored in the state-space, such a majority protocol can only handle a fixed number of voting options. As rules also depend on k, this means that a whole population would need to be reconfigured in order to handle a larger k, e.g. if new voting options are made available. This is conceptually impractical in the context of flocks of anonymous mobile agents. Instead, we propose that the input of an agent can be modeled elegantly as drawn from an infinite set $\mathbb{D}$, with rules independent from $\mathbb{D}$.

Contribution. In this work, we initiate the study of population protocols operating over arbitrarily large domains. More precisely, we propose a more general model where each agent carries a read-only datum from an infinite domain $\mathbb{D}$ together with a mutable state from a finite set. In this setting, a population can, e.g., seek to determine whether there is an absolute majority datum. For example, if $\mathbb{D} \coloneqq \{1, 2, 3, \ldots\}$, then the population initialized with $\{\!\{(1, x), (1, x), (2, x), (3, x), (1, x)\}\!\}$ should reach a lasting *true*-consensus, while it should reach a lasting *false*-consensus from $\{\!\{(1, x), (1, x), (2, x), (3, x), (2, x)\}\!\}$.

As in the standard model, a fair scheduler picks a pair of agents. An interaction occurs according to a rule of the form $\{\!\{p, q\}\!\} \xrightarrow{d \sim e} \{\!\{p', q'\}\!\}$, where $d, e \in \mathbb{D}$ are the data values of the two agents, and where $\sim \in \{=, \neq\}$ compares them. As for states, we assume that arbitrarily many agents may be initialized with the same datum; and that agents can only compare data through (in)equality. So, $\mathbb{D}$ is not a set of (unique) identifiers and hence agents remain anonymous as in the standard model.

To illustrate our proposed model of computation, we first show that it can compute the absolute majority predicate. This means that a *single* protocol can handle *any* number of options in an absolute majority vote. From the perspective of distributed computing, this provides a framework to reason about anonymous crowd computing over unordered sequences of data. From the standpoint of computer-aided verification, this opens the possibility of formally analyzing single protocols (e.g. modeled as colored Petri nets) rather than resorting to parameterized verification, which is particularly difficult in the context of counter systems.

As a stepping stone towards pinpointing the expressive power of *population protocols with unordered data*, we then characterize *immediate observation* protocols. In this well-studied restriction, rules have the form $\{\!\{p, q\}\!\} \xrightarrow{d \sim e} \{\!\{p, q'\}\!\}$, i.e. an agent updates its state by observing another agent (who is unaware of it). In standard population protocols, this class is known to compute exactly predicates from $\mathbf{COUNT}_*$ [2]. The latter is the Boolean

closure of predicates of the form $\#q \geq c$, where $\#q$ counts the number of agents in state q, and $c \in \mathbb{N}$ is a constant. In our case, we show that immediate observation protocols compute exactly *interval predicates*, which are Boolean combinations of such *simple interval predicates*:

$$\exists \text{ pairwise distinct } d_1, d_2, \ldots, d_n \in \mathbb{D} : \bigwedge_{i=1}^{n} \bigwedge_{j=1}^{m} \#(d_i, q_j) \in T(i,j), \tag{1}$$

where $\#(d_i, q_j)$ counts agents in state q_j with datum d_i, and each $T(i,j) \subseteq \mathbb{N}$ is an interval.

In order to show that immediate observation protocols do not compute more than interval predicates, we exploit the fact that (finitely supported) data vectors are well-quasi-ordered. While our approach is inspired by [2], it is trickier to simultaneously deal with the several sources of unboundedness: number of data values, number of agents with a given datum, and number of agents with a given state. As a byproduct, we show that the absolute majority predicate cannot be computed by immediate observation protocols.

To show the other direction, i.e. that interval predicates are computable by immediate observation protocols, we describe a protocol for simple interval predicates. In contrast with the standard setting, we need to implement existential quantification. This is achieved by a data leader election and a global leader election. We call the latter elected agent the "controller". Its purpose is to handle the bookkeeping of data leaders choosing their role in (1). A correction mechanism is carefully implemented so that the population only reaches a *true*-consensus upon locking a correct assignment to the existential quantification.

Related work. It has been observed by the verification and concurrency communities that population protocols can be recast as Petri nets. In particular, this has enabled the automatic formal analysis of population protocols [15, 7] and the discovery of bounds on their state complexity [12, 6]. Our inspiration comes from the other direction: we introduce protocols with data by drawing from the recent attention to colored Petri nets [17, 19, 18]. Our model corresponds to unordered data Petri nets where the color and number of tokens is invariant.

Population protocols for computing majority and plurality have been extensively studied (e.g., see [14, 4, 5, 3] for recent results). To the best of our knowledge, the closest work is [16], where the authors propose space-efficient *families* of deterministic protocols for variants of the majority problem including plurality consensus. They consider the k voting options as "colors" specified by $\lceil \log k \rceil$ bits stored within the agents.

Other incomparable models of distributed systems with some sort of data include broadcast networks of register automata [13], distributed register automata [9], and distributed memory automata [10]. Such formalisms, inspired by register automata [20], allow identities, control structures and alternative communication mechanisms; none allowed in population protocols.

Paper organization. Section 2 provides basic definitions and introduces our model. In Section 3, we present a protocol that computes the absolute majority predicate. Section 4 establishes the expressive power of immediate observation protocols. We conclude in Section 5. Note that most proofs appear in the appendix of the full version.

2 Preliminaries

We write $\mathbb{N}$ and $[a..b]$ to respectively denote sets $\{0, 1, 2, \ldots\}$ and $\{a, a+1, \ldots, b\}$. The *support* of a multiset $\boldsymbol{m}$ over E is $\text{act}(\boldsymbol{m}) \coloneqq \{e \in E : \boldsymbol{m}(e) > 0\}$ (We use the notation $\text{act}(\boldsymbol{m})$ rather than $\text{supp}(\boldsymbol{m})$ as we will later refer to "active states".) We write $\mathbb{N}^E$ to denote the set of multisets over E with finite support. The empty multiset, denoted $\mathbf{0}$, is such that

$\mathbf{0}(e) = 0$ for all $e \in E$. Let $\boldsymbol{m}, \boldsymbol{m}' \in \mathbb{N}^E$. We write $\boldsymbol{m} \leq \boldsymbol{m}'$ iff $\boldsymbol{m}(e) \leq \boldsymbol{m}'(e)$ for all $e \in E$. We define $\boldsymbol{m} + \boldsymbol{m}'$ as the multiset such that $(\boldsymbol{m} + \boldsymbol{m}')(e) \coloneqq \boldsymbol{m}(e) + \boldsymbol{m}'(e)$ for all $e \in E$. The difference, denoted $\boldsymbol{m} - \boldsymbol{m}'$, is defined similarly provided that $\boldsymbol{m} \geq \boldsymbol{m}'$.

2.1 Population protocols with unordered data

A *population protocol with unordered data*, over an infinite domain $\mathbb{D}$ equipped with equality, is a tuple (Q, δ, I, O) where

- Q is a finite set of elements called *states*,
- $\delta \subseteq Q^2 \times \{=, \neq\} \times Q^2$ is the set of *transitions*,
- $I \subseteq Q$ is the set of *initial states*, and
- $O \colon Q \to \{\mathit{false}, \mathit{true}\}$ is the *output* function.

We refer to an element of $\mathbb{D}$ as a *datum* or as a *color*. We will implicitly assume throughout the paper that δ contains $((p, q), \sim, (p, q))$ for all $p, q \in Q$ and $\sim \in \{=, \neq\}$.

A *form* $\boldsymbol{f}$ is an element from $\mathbb{N}^Q$. We denote the set of all forms by $\mathbb{F}$. Given $Q' \subseteq Q$, let $\boldsymbol{f}(Q') \coloneqq \sum_{q \in Q'} \boldsymbol{f}(q)$. A *configuration* is a mapping $\mathbf{C}$ from $\mathbb{D}$ to $\mathbb{F}$ such that $\mathrm{supp}(\mathbf{C}) \coloneqq \{d \in \mathbb{D} : \mathbf{C}(d) \neq \mathbf{0}\}$ is finite, and $\sum_{d \in \mathbb{D}, q \in Q} \mathbf{C}(d)(q) \geq 2$. We often write $\mathbf{C}(d)(q)$ as $\mathbf{C}(d, q)$. Informally, the latter denotes the number of agents with datum d in state q. We extend this notation to subsets of states: $\mathbf{C}(d, Q') \coloneqq \mathbf{C}(d)(Q')$. We naturally extend $+$, $-$ and $\leq$ to $\mathbb{D} \to \mathbb{F}$, e.g. $\mathbf{C} + \mathbf{C}'$ is such that $(\mathbf{C} + \mathbf{C}')(d) \coloneqq \mathbf{C}(d) + \mathbf{C}'(d)$ for all $d \in \mathbb{D}$.

Let $\mathbf{C}$ be a configuration. We define the *active states* as the set $\mathrm{act}(\mathbf{C}) \coloneqq \{q \in Q : \mathbf{C}(d, q) > 0 \text{ for some } d \in \mathbb{D}\}$. We say that $\mathbf{C}$ is *initial* if $\mathrm{act}(\mathbf{C}) \subseteq I$. Given $Q' \subseteq Q$, let $|\mathbf{C}|_{Q'} \coloneqq \sum_{d \in \mathbb{D}} \mathbf{C}(d, Q')$ and $|\mathbf{C}| \coloneqq |\mathbf{C}|_Q$. The *output* of $\mathbf{C}$ is defined by $O(\mathbf{C}) \coloneqq b$ if $O(q) = b$ for every $q \in \mathrm{act}(\mathbf{C})$; and by $O(\mathbf{C}) = \bot$ otherwise. Informally, $O(\mathbf{C})$ indicates whether all agents agree on some output b.

▶ **Example 1.** Let $\mathbb{D} \coloneqq \{\bullet, \blacksquare, \blacklozenge, \ldots\}$ and $Q \coloneqq \{p, q\}$. Let $\boldsymbol{f} \coloneqq \{\!\{p, p, q\}\!\}$ and $\boldsymbol{f}' \coloneqq \{\!\{q\}\!\}$. Let $\mathbf{C} \coloneqq \{\bullet \mapsto \boldsymbol{f}, \blacksquare \mapsto \boldsymbol{f}', \blacklozenge \mapsto \mathbf{0}, \ldots\}$. We have $\mathbf{C}(\bullet, p) = 2$, $\mathbf{C}(\bullet, q) = \mathbf{C}(\blacksquare, q) = 1$, $\mathbf{C}(\blacksquare, p) = \mathbf{C}(\blacklozenge, p) = \mathbf{C}(\blacklozenge, q) = 0$ and $|\mathbf{C}|_{\{q\}} = 2$. Configuration $\mathbf{C}$ represents a population of four agents carrying an immutable datum and a mutable state: $\{\!\{(\bullet, p), (\bullet, p), (\bullet, q), (\blacksquare, q)\}\!\}$. ◀

For the sake of brevity, given a form $\boldsymbol{f}$, let $\boldsymbol{f}_d \colon \mathbb{D} \to \mathbb{F}$ be defined by $\boldsymbol{f}_d(d) \coloneqq \boldsymbol{f}$ and $\boldsymbol{f}_d(d') \coloneqq \mathbf{0}$ for every $d' \neq d$. Furthermore, given a state q, let $\boldsymbol{q}_d \colon \mathbb{D} \to \mathbb{F}$ be defined by $\boldsymbol{q}_d(d)(q) \coloneqq 1$ and $\boldsymbol{q}_d(d')(q') \coloneqq 0$ for every $(d', q') \neq (d, q)$.

Let $\mathbf{C}$ be a configuration and let $t = ((p, q), \sim, (p', q')) \in \delta$. We say that transition t is *enabled* in $\mathbf{C}$ if there exist $d, e \in \mathbb{D}$ such that $d \sim e$, $\mathbf{C} \geq \boldsymbol{p}_d + \boldsymbol{q}_e$. If the latter holds, then t can be used to obtain the configuration $\mathbf{C}' \coloneqq \mathbf{C} - (\boldsymbol{p}_d + \boldsymbol{q}_e) + (\boldsymbol{p}'_d + \boldsymbol{q}'_e)$, which we denote $\mathbf{C} \xrightarrow{t} \mathbf{C}'$. We write $\mathbf{C} \to \mathbf{C}'$ to denote that $\mathbf{C} \xrightarrow{t} \mathbf{C}'$ holds for some $t \in \delta$. We further define $\xrightarrow{*}$ as the reflexive-transitive closure of $\to$.

▶ **Example 2.** Let $O(p) \coloneqq \mathit{false}$, $O(q) \coloneqq \mathit{true}$ and $t \coloneqq ((p, q), =, (q, q))$. Using the notation of Example 1 to represent configurations, we have:

$$\{\!\{(\bullet, p), (\bullet, p), (\bullet, q), (\blacksquare, q)\}\!\} \xrightarrow{t} \{\!\{(\bullet, p), (\bullet, q), (\bullet, q), (\blacksquare, q)\}\!\} \xrightarrow{t} \{\!\{(\bullet, q), (\bullet, q), (\bullet, q), (\blacksquare, q)\}\!\}.$$

Let $\mathbf{C}$, $\mathbf{C}'$ and $\mathbf{C}''$ denote the three configurations above. We have $O(\mathbf{C}) = O(\mathbf{C}') = \bot$ and $O(\mathbf{C}'') = \mathit{true}$. Moreover, transition t is not enabled in $\mathbf{C}''$ as no datum $d \in \mathbb{D}$ satisfies $\mathbf{C}''(d, p) \geq 1$ and $\mathbf{C}''(d, q) \geq 1$. So, the agents have "converged to a *true*-consensus". ◀

An *execution* is an infinite sequence of configurations $\mathbf{C}_0\mathbf{C}_1\cdots$ such that $\mathbf{C}_0 \to \mathbf{C}_1 \to \cdots$. We say that such an execution *converges* to output $b \in \{false, true\}$ if there exists $\tau \in \mathbb{N}$ such that $O(\mathbf{C}_\tau) = O(\mathbf{C}_{\tau+1}) = \cdots = b$. An execution $\mathbf{C}_0\mathbf{C}_1\cdots$ is *fair* if, for every configuration $\mathbf{C}'$, it is the case that $|\{i \in \mathbb{N} : \mathbf{C}_i \xrightarrow{*} \mathbf{C}'\}| = \infty$ implies $|\{i \in \mathbb{N} : \mathbf{C}_i = \mathbf{C}'\}| = \infty$. In words, fairness states that if $\mathbf{C}'$ is reachable infinitely often, then it appears infinitely often along the execution. Informally, this means that some "progress" cannot be avoided forever.

Let Σ be a nonempty finite set. An *input* is some $\mathbf{M} \in \mathbb{N}^{\mathbb{D}\times\Sigma}$ with $\sum_{d\in\mathbb{D},\sigma\in\Sigma} \mathbf{M}(d,\sigma) \geq 2$. An input $\mathbf{M}$ is translated, via a bijective *input mapping* $\iota\colon \Sigma \to I$, into the initial configuration $\iota(\mathbf{M}) \coloneqq \sum_{d\in\mathbb{D},\sigma\in\Sigma} \sum_{j=1}^{\mathbf{M}(d,\sigma)} \boldsymbol{\iota(\sigma)}_d$. We say that a protocol *computes* a predicate φ if, for every input $\mathbf{M}$, every fair execution starting in $\iota(\mathbf{M})$ converges to output $\varphi(\mathbf{M})$. By abuse of notation, we sometimes write $\varphi(\mathbf{C}_0)$ for $\varphi(\iota^{-1}(\mathbf{C}_0))$.

▶ **Example 3.** Let $\mathbb{D} \coloneqq \{\bullet, \blacksquare, \blacklozenge, \ldots\}$, $\Sigma \coloneqq \{x_1, \ldots, x_4\}$, $I \coloneqq \{q_1, \ldots, q_4\}$ and $\iota(x_i) \coloneqq q_i$. The input $\mathbf{M} \coloneqq \{\!\{(\bullet, x_1), (\bullet, x_1), (\bullet, x_2), (\bullet, x_2), (\bullet, x_2), (\bullet, x_4), (\blacksquare, x_1), (\blacksquare, x_3)\}\!\}$ yields the initial configuration $\iota(\mathbf{M}) = \{\bullet \mapsto \{\!\{q_1, q_1, q_2, q_2, q_2, q_4\}\!\}, \blacksquare \mapsto \{\!\{q_1, q_3\}\!\}, \blacklozenge \mapsto \mathbf{0}, \ldots\}$.

Observe that, as for standard protocols, the set of predicates computed by population protocols with unordered data is closed under Boolean operations. Given a protocol that computes φ, we obtain a protocol that computes $\neg\varphi$ by changing the value of $O(q)$ to $\neg O(q)$ for all $q \in Q$. Given predicates ψ_1 and ψ_2, respectively computed by protocols $(Q_1, \delta_1, I_1, O_1)$ and $(Q_2, \delta_2, I_2, O_2)$, it is easy to obtain a protocol computing $\psi = \psi_1 \wedge \psi_2$ by having both protocols run in parallel. This is achieved by defining $(Q \coloneqq Q_1 \times Q_2, \delta, I \coloneqq I_1 \times I_2, O)$ where

- δ contains $(((p_1, p_2), (q_1, q_2)), \sim, ((p'_1, p_2), (q'_1, q_2)))$ for every $((p_1, q_1), \sim, (p'_1, q'_1)) \in \delta_1$;
- δ contains $(((p_1, p_2), (q_1, q_2)), \sim, ((p_1, p'_2), (q_1, q'_2)))$ for every $((p_2, q_2), \sim, (p'_2, q'_2)) \in \delta_2$;
- $O(q_1, q_2) = O_1(q_1) \wedge O_2(q_2)$.

3 A protocol for the majority predicate

Let $\Sigma \coloneqq \{x\}$. In this section, we present a protocol for the absolute majority predicate defined as $\varphi_{\text{maj}}(\mathbf{M}) \coloneqq \exists d \in \mathbb{D} : \mathbf{M}(d, x) > \sum_{d'\neq d} \mathbf{M}(d', x)$. Since each input pair has the form (d, x) with $d \in \mathbb{D}$, we omit the "dummy element" x in the informal presentation of the protocol. Note that for the sake of brevity, we use the term majority instead of absolute majority for the remainder of this paper.

Our protocol is not unlike the classical (sequential) Boyer–Moore algorithm [11]: we seek to elect a color as the majority candidate, and then check whether it indeed has the majority. It is intended to work in stages. In the *pairing stage*, each unpaired agent seeks to form a pair with an unpaired agent of a distinct color. For example, if the initial population is $\{\!\{\bullet, \bullet, \bullet, \bullet, \blacksquare, \blacksquare, \blacklozenge\}\!\}$, then we (non-deterministically) end up with either of these two pairings:

paired agents	*agents left unpaired*
$\{\!\{\bullet\!-\!\blacksquare, \bullet\!-\!\blacksquare, \bullet\!-\!\blacklozenge\}\!\}$	$\{\!\{\bullet\}\!\}$
$\{\!\{\bullet\!-\!\blacksquare, \blacksquare\!-\!\blacklozenge\}\!\}$	$\{\!\{\bullet, \bullet, \bullet\}\!\}$

The agents left unpaired must all have the same color d, e.g. "$\bullet$" in the above example. Moreover, if the population has a majority color, then it must be d.

Since the agents are anonymous and have a finite memory, they cannot actually remember with whom they have been paired. Thus, once a candidate color has been elected, e.g. "$\bullet$" in the above example, there is a *grouping stage*. In the latter, unpaired agents indicate to agents of their color that they are part of the candidate majority group. This is done by internally storing the value "Y", which stands for "Yes". Similarly, unpaired agents indicate to agents of a distinct color that they are part of the candidate minority group using "N". Once this is over, the *majority stage* takes place using the classical protocol from the introduction.

Two issues arise from this idealized description. First, the protocol is intended to work in stages, but they may occur concurrently due to their distributed nature. For this reason, we add a correction mechanism:

- If an unpaired agent of the candidate majority color d finds a paired agent of color d (resp. $d' \neq d$) with "N" (resp. "Y"), then it flips it to "Y" (resp. "N");
- If an unpaired agent of the candidate majority color d finds a paired agent of color d (resp. $d' \neq d$) with either "n" or "y", then it flips it to "$\overline{Y}$" (resp. "$\overline{N}$").

The intermediate value $\overline{Y}$ (resp. $\overline{N}$) must be reverted to Y (resp. N) by finding an agent that has initially played role Y (resp. N) and is then reset to its original value.

The second issue has to do with the fact that, in even-size populations, all agents may get paired. In that case, no unpaired agent is left to group the agents. To address this, each agent carries an "even bit" to indicate its belief on whether some unpaired agent remains.

3.1 States

The set of states is defined as $Q \coloneqq \{\mathit{false}, \mathit{true}\}^3 \times \{Y, N, \overline{Y}, \overline{N}, y, n\}$. To ease the reader's understanding, we manipulate states with four "macros". Each macro has a set of possible values; each state is a combination of values for the different macros.

name	*values for $q \in Q$*	*value for $q \in I$*
$\mathrm{pair}(q)$	$\{\mathit{false}, \mathit{true}\}$	*false*
$\mathrm{grp}(q)$	$\{\mathit{false}, \mathit{true}\}$	*true*

name	*values for $q \in Q$*	*value for $q \in I$*
$\mathrm{even}(q)$	$\{\mathit{false}, \mathit{true}\}$	*false*
$\mathrm{maj}(q)$	$\{Y, N, \overline{Y}, \overline{N}, y, n\}$	Y

The input mapping is defined by $\iota(x) \coloneqq q_I$, where q_I is the unique state of I. Informally, $\mathrm{pair}(q)$ indicates whether the agent has been paired; $\mathrm{grp}(q)$ indicates whether the agent belongs to the candidate majority group; $\mathrm{maj}(q)$ is the current value of the majority computation; and $\mathrm{even}(q)$ is the even bit.

3.2 Transitions and stages

We describe the protocol by introducing rules corresponding to each stage. Note that a rule is a structure on which transitions can be based; therefore, a single rule can yield multiple transitions of the same nature. For convenience, some lemmas are stated before they can actually be proven, as they require the full set of transitions to be defined first. Proofs in the appendix take into account the complete list of transitions.

As the set of transitions for the protocol is lengthy, we present it using a "precondition-update" notation where for any two agents in state $p, q \in Q$, respectively with colors $d_1, d_2 \in \mathbb{D}$, a single transition whose preconditions on p, q and d_1, d_2 are met is used. The result of such an interaction is the agent initially in state p updating its state to p', where p' is identical to p except for the specified macros; and likewise for q. To help the readability, the precondition and update of states p and q are on distinct lines in the forthcoming tables.

3.2.1 Pairing stage

The first rule is used for the pairing stage whose main goal is to match as many agents as possible with agents of a different color:

rule	*state precondition*	*color precondition*	*state update*
(1)	$\neg\mathrm{pair}(p)$ $\neg\mathrm{pair}(q)$	$d_1 \neq d_2$	$\mathrm{pair}(p') \wedge \mathrm{even}(p')$ $\mathrm{pair}(q') \wedge \mathrm{even}(q')$

This rule gives rise to the following lemmas concerning the end of the pairing stage and the nature of unpaired agents, if they exist. For the remainder of the section, let us fix a fair execution $\mathbf{C}_0\mathbf{C}_1\cdots$ where $\mathbf{C}_0$ is initial. Moreover, let $P \coloneqq \{q \in Q : \text{pair}(q)\}$ and $U \coloneqq Q \setminus P$.

▶ **Lemma 4.** *There exists $\tau \in \mathbb{N}$ such that $|\mathbf{C}_\tau|_U = |\mathbf{C}_{\tau+1}|_U = \cdots$. Furthermore, for every $i \geq \tau$, all unpaired agents of $\mathbf{C}_i$ share the same color, i.e. the set $\{d \in \mathbb{D} : \mathbf{C}_i(d, U) > 0\}$ is either empty or a singleton.*

Let α denote the minimal threshold τ given by Lemma 4, which is informally the "end of the pairing stage".

▶ **Lemma 5.** *Let $i \in \mathbb{N}$. If $\varphi_{maj}(\mathbf{C}_0)$ and d is the majority color, then $\mathbf{C}_i(d, U) > 0$.*

3.2.2 Grouping stage

The next set of transitions seeks to correctly set each agent's group, representing its status in the computation of the majority. An agent is either part of the candidate majority group (*true*), or part of the candidate minority group (*false*). Note that this group (and its related majority computing value) are irrelevant if there are no unpaired agents in $\mathbf{C}_\alpha$; this special case is handled using the even bit, which is ignored for now.

rule	*state precondition*	*color precondition*	*state update*
(2)	$\neg\text{pair}(p)$ $\text{pair}(q) \wedge \quad \text{grp}(q) \wedge \text{maj}(q) = Y$	$d_1 \neq d_2$	*none* $\neg\text{grp}(q') \wedge \text{maj}(q') = N$
(3)	$\neg\text{pair}(p)$ $\text{pair}(q) \wedge \neg\text{grp}(q) \wedge \text{maj}(q) = N$	$d_1 = d_2$	*none* $\text{grp}(q') \wedge \text{maj}(q') = Y$
(4)	$\neg\text{pair}(p)$ $\text{pair}(q) \wedge \quad \text{grp}(q) \wedge \text{maj}(q) \in \{y, n\}$	$d_1 \neq d_2$	*none* $\text{maj}(q') = \overline{N}$
(5)	$\neg\text{pair}(p)$ $\text{pair}(q) \wedge \neg\text{grp}(q) \wedge \text{maj}(q) \in \{y, n\}$	$d_1 = d_2$	*none* $\text{maj}(q') = \overline{Y}$

The forthcoming rules below are part of a two-rule combination whose aim is to rectify an error in grouping assignments. It allows agents who engaged in the computation within the candidate minority group (resp. majority group) who encountered a currently valid majority candidate of their color (resp. a different color) to reset their value to Y (resp. N) and their group to *true* (resp. *false*) by finding another agent, also engaged, to do the same. This, along with the rules described in the next subsection, ensures that the invariant below holds.

Let $Q_a \coloneqq \{q \in Q : \text{maj}(q) = a\}$, $Q_M \coloneqq \{q \in Q : \text{grp}(q)\}$ and $Q_m \coloneqq Q \setminus Q_M$.

▶ **Lemma 6.** *For every $i \in \mathbb{N}$, it is the case that $|\mathbf{C}_i|_{Q_Y} - |\mathbf{C}_i|_{Q_N} = |\mathbf{C}_i|_{Q_M} - |\mathbf{C}_i|_{Q_m}$.*

rule	*state precondition*	*color precondition*	*state update*
(6)	$\text{grp}(p) \wedge \text{maj}(p) = \overline{N}$ $\neg\text{grp}(q) \wedge \text{maj}(q) \in \{y, n\}$	*none*	$\neg\text{grp}(p') \wedge \text{maj}(p') = N$ $\text{maj}(q') = N$
(7)	$\neg\text{grp}(p) \wedge \text{maj}(p) = \overline{Y}$ $\text{grp}(q) \wedge \text{maj}(q) \in \{y, n\}$	*none*	$\text{grp}(p') \wedge \text{maj}(p') = Y$ $\text{maj}(q') = Y$
(8)	$\text{grp}(p) \wedge \text{maj}(p) = \overline{N}$ $\neg\text{grp}(q) \wedge \text{maj}(q) = \overline{Y}$	*none*	$\neg\text{grp}(p') \wedge \text{maj}(p') = n$ $\text{grp}(q') \wedge \text{maj}(q') = n$

We give the following example to help illustrate the necessity of the intermediate states $\overline{Y}, \overline{N}$ in the context of the suggested protocol.

▶ **Example 7.** Let us first consider a possible execution from the initial population $\{\!\{\bullet, \bullet, \blacksquare, \blacksquare, \blacklozenge\}\!\}$, for which there is no majority datum. Observe that since the number of agents is odd, in any execution, there will be a datum with an unpaired agent after the pairing stage. Assume, for the sake of our demonstration, that this datum is blue ($\blacklozenge$). Entering the grouping stage, this blue agent will eventually let the other agents know that they are not part of the majority candidate group and, at some point, rule (11) will occur, leading to all agents permanently with $\mathrm{maj}(q) \in \{N, n\}$. This is summarized in these three snapshots (where the even bit is omitted for the sake of clarity):

input	pair	grp	maj
$\bullet$	×	✓	Y
$\bullet$	×	✓	Y
$\blacksquare$	×	✓	Y
$\blacksquare$	×	✓	Y
$\blacklozenge$	×	✓	Y

$\xrightarrow{*}$

input	pair	grp	maj
$\bullet$	✓	×	N
$\bullet$	✓	×	N
$\blacksquare$	✓	×	N
$\blacksquare$	✓	×	N
$\blacklozenge$	×	✓	Y

$\rightarrow$

input	pair	grp	maj
$\bullet$	✓	×	N
$\bullet$	✓	×	n
$\blacksquare$	✓	×	N
$\blacksquare$	✓	×	N
$\blacklozenge$	×	✓	n

Now, consider a population where a majority datum does indeed exist: $\{\!\{\bullet, \bullet, \bullet, \bullet, \blacksquare, \blacksquare, \blacklozenge\}\!\}$. Note that this population is strictly greater than the previous population. Therefore, we can promptly obtain a configuration similar to the one described above, where two more agents of datum red ($\bullet$) have yet to participate in the computation. Since the computation must output *true*, the consensus on $\{N, n\}$ initiated by the blue agent has to be reverted.

In this case, after the final pairing is done via an interaction between the blue agent ($\blacklozenge$) and one of the newly introduced red agents ($\bullet$), the error handling first works through rule (4) or (5): the unpaired red agent ($\bullet$) notifies the blue agent ($\blacklozenge$) that its group is incorrect by setting its computation value to $\overline{N}$ and similarly, it notifies all red agents ($\bullet$) who had previously participated in the (now incorrect) majority stage to switch their computation value to $\overline{Y}$. This is summarized in these three snapshots:

input	pair	grp	maj
$\bullet$	✓	×	N
$\bullet$	✓	×	n
$\blacksquare$	✓	×	N
$\blacksquare$	✓	×	N
$\blacklozenge$	✓	✓	n
$\bullet$	✓	✓	Y
$\bullet$	×	✓	Y

$\ldots \xrightarrow{*}$

input	pair	grp	maj
$\bullet$	✓	✓	Y
$\bullet$	✓	×	$\overline{Y}$
$\blacksquare$	✓	×	N
$\blacksquare$	✓	×	N
$\blacklozenge$	✓	✓	$\overline{N}$
$\bullet$	✓	✓	Y
$\bullet$	×	✓	Y

$\rightarrow$

input	pair	grp	maj
$\bullet$	✓	✓	Y
$\bullet$	✓	✓	n
$\blacksquare$	✓	×	N
$\blacksquare$	✓	×	N
$\blacklozenge$	✓	×	n
$\bullet$	✓	✓	Y
$\bullet$	×	✓	Y

This inevitably leads each incorrectly grouped agent to rectify its group bit as well as its computation value, accordingly, through rules (6), (7) or (8). We then have a configuration for which the grouping stage is over and where either the majority stage is not yet initiated, or it has been correctly initiated with the right majority candidate. ◀

The following lemmas show that the grouping stage eventually ends if there are unpaired agents in $\mathbf{C}_\alpha$. Moreover, they show that the majority candidate color d eventually propagates the majority group to agents of color d, and the minority group to agents of color $d' \neq d$.

▶ **Lemma 8.** *Let E be the set of states engaged in the majority computation, i.e. $E \coloneqq \{q \in Q : \mathrm{maj}(q) \in \{y, n, \overline{Y}, \overline{N}\}\}$. Let $E_M \coloneqq E \cap Q_M$ and $E_m \coloneqq E \cap Q_m$. For every $i \in \mathbb{N}$, the following holds: $|\mathbf{C}_i|_{E_M} = |\mathbf{C}_i|_{E_m}$.*

▶ **Lemma 9.** *Let $d \in \mathbb{D}$. If $\mathbf{C}_\alpha(d, U) > 0$, then there exists some $\tau \geq \alpha$ such that, for all $i \geq \tau$, $d' \in \mathbb{D}$ and $q \in \mathrm{act}(\mathbf{C}_i(d'))$, the following holds: $\mathrm{grp}(q) = (d' = d)$.*

3.2.3 Majority stage

The last set of transitions emulates a standard population protocol for the majority predicate. Populations of even size without a majority give rise to a case requiring careful handling. Indeed, for such a population the pairing stage may leave no unmatched agent. Therefore, we give the following rules to fix this specific issue.

rule	*state precondition*	*color precondition*	*state update*
(9)	$\neg\mathrm{pair}(p)$ $\mathrm{even}(q)$	*none*	*none* $\neg\mathrm{even}(q')$
(10)	$\mathrm{pair}(p) \wedge \mathrm{even}(p)$ $\mathrm{pair}(q) \wedge \neg\mathrm{even}(q)$	*none*	*none* $\mathrm{even}(q')$

▶ **Lemma 10.** *There exists $\tau \geq \alpha$ such that for every $i \geq \tau$ and $q \in \mathrm{act}(\mathbf{C}_i)$, it is the case that $\mathrm{even}(q)$ holds iff $|\mathbf{C}_i|_U = 0$.*

For other populations, a unique candidate color for the majority exists following the pairing stage. For the predicate to be *true*, this candidate must have more agents than all of the other colors combined. This is validated (or invalidated) through the following rules.

rule	*state pre.*	*col. pre.*	*state update*
(11)	$\mathrm{maj}(p) = Y$ $\mathrm{maj}(q) = N$	*none*	$\mathrm{maj}(p') = n$ $\mathrm{maj}(q') = n$
(12)	$\mathrm{maj}(p) = Y$ $\mathrm{maj}(q) = n$	*none*	*none* $\mathrm{maj}(q') = y$

rule	*state pre.*	*col. pre.*	*state update*
(13)	$\mathrm{maj}(p) = N$ $\mathrm{maj}(q) = y$	*none*	*none* $\mathrm{maj}(q') = n$
(14)	$\mathrm{maj}(p) = n$ $\mathrm{maj}(q) = y$	*none*	*none* $\mathrm{maj}(q') = n$

▶ **Lemma 11.** *If $\varphi_{maj}(\mathbf{C}_0)$ holds, then there exists $\tau \geq \alpha$ such that for every $i \geq \tau$ and $q \in \mathrm{act}(\mathbf{C}_i)$, it is the case that $\mathrm{maj}(q) \in \{Y, y\}$ and $\neg\mathrm{even}(q)$ hold.*

▶ **Lemma 12.** *If $\neg\varphi_{maj}(\mathbf{C}_0)$ holds, then there exists $\tau \geq \alpha$ such that either:*

- *$\mathrm{even}(q)$ holds for every $i \geq \tau$ and $q \in \mathrm{act}(\mathbf{C}_i)$; or*
- *$\mathrm{maj}(q) \in \{N, n\}$ holds for every $i \geq \tau$ and $q \in \mathrm{act}(\mathbf{C}_i)$.*

We define the output of a given state $q \in Q$ as $O(q) \coloneqq (\mathrm{maj}(q) \in \{Y, y\} \wedge \neg\mathrm{even}(q))$. The correctness of the protocol follows immediately from Lemmas 11 and 12:

▶ **Corollary 13.** *There exists $\tau \in \mathbb{N}$ such that $O(\mathbf{C}_\tau) = O(\mathbf{C}_{\tau+1}) = \cdots = \varphi_{maj}(\mathbf{C}_0)$.*

4 Immediate observation protocols

We say that a population protocol is *immediate observation (IO)* if each of its transitions has the form $((p, q), \sim, (p, q'))$, i.e. only one agent can update its state by "observing" the other agent. There is no restriction on $\sim$, but one can also imagine the datum to be observed.

In this section, we characterize the expressive power of immediate observation protocols. First, we establish properties of IO protocols regarding truncations, thereby allowing us to prove that the majority predicate is not computable. Then, we show that IO protocols do not compute more than interval predicates. Finally, we show that every interval predicate can be computed by an IO protocol. Before proceeding, let us define interval predicates.

Let $\dot{\exists} d_1, d_2, \ldots, d_n$ denote a disjoint existential quantification, i.e. it indicates that $d_i \neq d_j$ for all $i, j \in [1..n]$ such that $i \neq j$. A *simple interval predicate*, interpreted over inputs from $\mathbb{N}^{\mathbb{D}\times\Sigma}$, where $\Sigma = \{x_1, \ldots, x_m\}$, is a predicate of the form

$$\psi(\mathbf{M}) = \dot{\exists} d_1, d_2, \ldots, d_n \in \mathbb{D} : \bigwedge_{i=1}^{n} \bigwedge_{j=1}^{m} \mathbf{M}(d_i, x_j) \in T(i, j), \tag{2}$$

where $m, n \in \mathbb{N}_{>0}$, each $T(i, j) \subseteq \mathbb{N}$ is a nonempty interval, and for every $i \in [1..n]$, there exists $j \in [1..m]$ such that $0 \notin T(i, j)$. An *interval predicate* is a Boolean combination of simple interval predicates.

4.1 State and form truncations

Given configurations $\mathbf{C}, \mathbf{C}'$, we write $\mathbf{C} \sqsubseteq \mathbf{C}'$ if there exists an injection $\rho\colon \mathbb{D} \to \mathbb{D}$ such that $\mathbf{C}(d) \leq \mathbf{C}'(\rho(d))$ for every $d \in \mathbb{D}$. We write $\mathbf{C} \equiv \mathbf{C}'$ if $\mathbf{C} \sqsubseteq \mathbf{C}'$ and $\mathbf{C}' \sqsubseteq \mathbf{C}$. We say that a subset of configurations X is *upward closed* if $\mathbf{C} \in X$ and $\mathbf{C} \sqsubseteq \mathbf{C}'$ implies $\mathbf{C}' \in X$. We say that a set B is a *basis* of an upward closed set X if $X = \{\mathbf{C}' : \mathbf{C} \sqsubseteq \mathbf{C}' \text{ for some } \mathbf{C} \in B\}$.

A configuration $\mathbf{C}$ is said *unstable* if either $O(\mathbf{C}) = \bot$ or there exists $\mathbf{C}'$ such that $\mathbf{C} \xrightarrow{*} \mathbf{C}'$ with $O(\mathbf{C}) \neq O(\mathbf{C}')$. Let $\mathcal{U}$ denote the set of unstable configurations, and let $\mathcal{S}_b \coloneqq \{\mathbf{C} : \mathbf{C} \notin \mathcal{U}, O(\mathbf{C}) = b\}$ denote the set of stable configurations with output b. As in the case of standard protocols (without data) [1], it is simple to see that $\mathcal{U}$ is upward closed. Moreover, since $\sqsubseteq$ is a well-quasi-order, it follows that $\mathcal{U}$ has a finite basis.

This allows us to extend the notion of truncations from [1]. A *state truncation* to $k \geq 1$ of some form $\boldsymbol{f}$, denoted by $\tau_k(\boldsymbol{f})$, is the form such that $\tau_k(\boldsymbol{f})(q) \coloneqq \min(\boldsymbol{f}(q), k)$ for all $q \in Q$. The concept of state truncations is also extended to configurations: $\tau_k(\mathbf{C})$ is the configuration such that $\tau_k(\mathbf{C})(d) \coloneqq \tau_k(\mathbf{C}(d))$ for all $d \in \mathbb{D}$. From a sufficiently large threshold, the stability and output of a configuration remain unchanged under state truncations:

▶ **Lemma 14.** *Let ψ be a predicate computed by a population protocol with unordered data. Let S_b be the set of stable configurations with output b of the protocol. There exists $k \geq 1$ such that, for all $b \in \{0, 1\}$, we have $\mathbf{C} \in \mathcal{S}_b$ iff $\tau_k(\mathbf{C}) \in \mathcal{S}_b$.*

Given a configuration $\mathbf{C}$ and a form $\boldsymbol{f}$, let $\#_{\boldsymbol{f}}(\mathbf{C}) \coloneqq |\{d \in \mathbb{D} : \mathbf{C}(d) = \boldsymbol{f}\}|$. Due to the nature of immediate observation protocols, it is always possible to take a form $\boldsymbol{f}$ of color d present in an configuration $\mathbf{C}$, duplicate $\boldsymbol{f}$ with a fresh color d', and have the latter mimic the behaviour of the former.

▶ **Lemma 15.** *Let $\mathbf{C}$ and $\mathbf{C}'$ be configurations such that $\mathbf{C} \xrightarrow{*} \mathbf{C}'$. For every $d \in \operatorname{supp}(\mathbf{C})$ and $d' \in \mathbb{D} \setminus \operatorname{supp}(\mathbf{C})$, it is the case that $\mathbf{C} + (\mathbf{C}(d))_{d'} \xrightarrow{*} \mathbf{C}' + (\mathbf{C}'(d))_{d'}$.*

Combined with the fact that $\mathcal{U}$ has a finite basis, this allows to show that from some threshold, duplicating forms with fresh colors does not change the output of the population.

▶ **Lemma 16.** *Let ψ be a predicate computed by a population protocol with unordered data. Let $\boldsymbol{f}$ be a form with $\mathrm{act}(\boldsymbol{f}) \subseteq I$. There exists $h(\boldsymbol{f}) \in \mathbb{N}$ such that, for all initial configuration $\mathbf{C}_0$ and $d \in \mathbb{D} \setminus \mathrm{supp}(\mathbf{C}_0)$ with $\#_{\boldsymbol{f}}(\mathbf{C}_0) \geq h(\boldsymbol{f})$, it is the case that $\psi(\mathbf{C}_0 + \boldsymbol{f}_d) = \psi(\mathbf{C}_0)$.*

The *form truncation* of a configuration $\mathbf{C}$, denoted $\sigma(\mathbf{C})$, is an (arbitrary) configuration such that $\sigma(\mathbf{C}) \sqsubseteq \mathbf{C}$ and $\#_{\boldsymbol{f}}(\sigma(\mathbf{C})) = \min(\#_{\boldsymbol{f}}(\mathbf{C}), h(\boldsymbol{f}))$ for every form $\boldsymbol{f}$, where $h(\boldsymbol{f})$ is given by Lemma 16. By Lemma 16, $\psi(\mathbf{C}_0)$ holds iff $\psi(\sigma(\mathbf{C}_0))$ holds. Moreover, Lemma 16 allows us to show that IO protocols are less expressive than the general model.

▶ **Proposition 17.** *No IO population protocol computes the majority predicate φ_{maj}.*

Proof. For the sake of contradiction, suppose that some IO protocol computes φ_{maj}. Let q_I be the unique initial state and let $\boldsymbol{f} \coloneqq \{\!\{q_I\}\!\}$. Let $h(\boldsymbol{f})$ be given by Lemma 16. Let $\mathbf{C}_0$ be an initial configuration such that

- $\mathbf{C}_0(d) = \sum_{i=1}^{h(\boldsymbol{f})+1} \boldsymbol{f}$ holds for a unique datum $d \in \mathbb{D}$, and
- $\mathbf{C}_0(d') = \boldsymbol{f}$ holds for exactly $h(\boldsymbol{f})$ other data $d' \in \{d_1, d_2, \ldots, d_{h(\boldsymbol{f})}\}$.

We have $\varphi_{\mathrm{maj}}(\mathbf{C}_0) = \mathit{true}$, since d has $h(\boldsymbol{f})+1$ agents in a population of $2 \cdot h(\boldsymbol{f})+1$ agents. Let $\mathbf{C}_0'$ be the initial configuration obtained from $\mathbf{C}_0$ by adding a datum $d^* \notin \mathrm{supp}(\mathbf{C}_0)$ such that $\mathbf{C}_0'(d^*) = \boldsymbol{f}$. By Lemma 16, $\varphi_{\mathrm{maj}}(\mathbf{C}_0') = \varphi_{\mathrm{maj}}(\mathbf{C}_0) = \mathit{true}$. However, datum d no longer has a majority in $\mathbf{C}_0'$, which is a contradiction. ◀

4.2 Predicates computed by IO protocols are interval predicates

▶ **Theorem 18.** *Let (Q, δ, I, O) be an immediate observation protocol with unordered data that computes a predicate ψ. The predicate ψ can be expressed as an interval predicate.*

Proof. We will express ψ as a finite Boolean combination of simple interval predicates.

Let h be the mapping given by Lemma 16. Let $\mathbb{T} \coloneqq \{\mathbf{C} : \psi(\mathbf{C}) = \mathit{true}\}$ and $\mathbb{T}_1 \coloneqq \{\mathbf{C} \in \mathbb{T} : \mathbf{C}(d, q) \leq k \text{ for all } d \in \mathbb{D}, q \in Q\}$. From Lemma 14, we learn that state truncations do not change the stability of a configuration. So, $\psi(\mathbf{C})$ holds iff $\bigvee_{\mathbf{C}' \in \mathbb{T}_1} \tau_k(\mathbf{C}) = \mathbf{C}'$ holds. Let $\mathbb{T}_2 \coloneqq \{\mathbf{C} \in \mathbb{T}_1 : \#_{\boldsymbol{f}}(\mathbf{C}) \leq h(\boldsymbol{f}) \text{ for all } \boldsymbol{f} \in \mathbb{F}\}$. It follows from Lemma 16 that $\psi(\mathbf{C})$ holds iff $\bigvee_{\mathbf{C}' \in \mathbb{T}_2} \sigma(\tau_k(\mathbf{C})) = \mathbf{C}'$ holds.

The latter is an infinite disjunction. Let us make it finite. Observe that if $\mathbf{C} \xrightarrow{*} \mathbf{C}'$ and $\overline{\mathbf{C}} \equiv \mathbf{C}$ hold, then there exists $\overline{\mathbf{C}'} \equiv \mathbf{C}'$ such that $\overline{\mathbf{C}} \xrightarrow{*} \overline{\mathbf{C}'}$. Moreover, note that equivalent configurations have the same output as they share the same active states. Indeed, $\mathbf{C} \equiv \overline{\mathbf{C}}$ iff $\bigwedge_{\boldsymbol{f} \in \mathbb{F}} \#_{\boldsymbol{f}}(\mathbf{C}) = \#_{\boldsymbol{f}}(\overline{\mathbf{C}})$. Hence, for every initial configuration $\mathbf{C} \equiv \overline{\mathbf{C}}$, we have $\psi(\mathbf{C}) = \psi(\overline{\mathbf{C}})$. Let $\mathbb{T}_2/\!\equiv$ be the set of all equivalence classes of $\equiv$ on $\mathbb{T}_2$, and let $\mathbb{T}_3$ be a set that contains one representative configuration per equivalence class of $\mathbb{T}_2/\!\equiv$. It is readily seen that $\psi(\mathbf{C})$ holds iff $\bigvee_{\mathbf{C}' \in \mathbb{T}_3} \sigma(\tau_k(\mathbf{C})) \equiv \mathbf{C}'$ holds.

Let us argue that $\mathbb{T}_3$ is finite. Let $\mathbb{F}_k \coloneqq \{\boldsymbol{f} \neq \mathbf{0} : \boldsymbol{f}(q) \leq k \text{ for all } q \in Q\}$. For every configuration $\mathbf{C} \in \mathbb{T}_1$, each form $\boldsymbol{f}$ with $\#_{\boldsymbol{f}}(\mathbf{C}) > 0$ belongs to $\mathbb{F}_k$. As $\mathbb{T}_2 \subseteq \mathbb{T}_1$, this also holds for configurations of $\mathbb{T}_2$. Given $\mathbf{C} \in \mathbb{T}_2$, we have $\#_{\boldsymbol{f}}(\mathbf{C}) \leq h(\boldsymbol{f})$ for all $\boldsymbol{f} \in \mathbb{F}_k$, and $\#_{\boldsymbol{f}}(\mathbf{C}) = 0$ for all $\boldsymbol{f} \notin \mathbb{F}_k$. Thus, as $\mathbb{F}_k$ is finite, we conclude that $\mathbb{T}_3$ is finite.

Let us now exploit our observations to express ψ as an interval predicate. Let us fix some $\mathbf{C}' \in \mathbb{T}_3$. It suffices to explain how to express "$\sigma(\tau_k(\mathbf{C})) \equiv \mathbf{C}'$". Indeed, as $\mathbb{T}_3$ is finite, we can conclude by taking the finite disjunction $\bigvee_{\mathbf{C}' \in \mathbb{T}_3} \sigma(\tau_k(\mathbf{C})) \equiv \mathbf{C}'$.

For every form $\boldsymbol{f} \in \mathbb{F}_k$, let $\mathrm{lt}(\boldsymbol{f}) \coloneqq \{q \in Q : \boldsymbol{f}(q) < k\}$, $\mathrm{eq}(\boldsymbol{f}) \coloneqq \{q \in Q : \boldsymbol{f}(q) = k\}$ and

$$\varphi_{\boldsymbol{f},d}(\mathbf{C}) \coloneqq \bigwedge_{q \in \mathrm{lt}(\boldsymbol{f})} (\mathbf{C}(d, q) = \boldsymbol{f}(q)) \wedge \bigwedge_{q \in \mathrm{eq}(\boldsymbol{f})} (\mathbf{C}(d, q) \geq \boldsymbol{f}(q)).$$

Observe that $\varphi_{\boldsymbol{f},d}(\mathbf{C})$ holds iff $\tau_k(\mathbf{C})(d) = \boldsymbol{f}$.

For every $\boldsymbol{f} \in \mathbb{F}_k$ such that $\#_{\boldsymbol{f}}(\mathbf{C}') < h(\boldsymbol{f})$, we define this formula, where $n \coloneqq \#_{\boldsymbol{f}}(\mathbf{C}')$:

$$\psi_{\boldsymbol{f}}(\mathbf{C}) \coloneqq \dot{\exists} d_1, d_2, \ldots, d_n \in \mathbb{D} : \bigwedge_{i=1}^{n} \varphi_{\boldsymbol{f},d_i}(\mathbf{C}) \wedge \neg \dot{\exists} d_1, d_2, \ldots, d_{n+1} \in \mathbb{D} : \bigwedge_{i=1}^{n+1} \varphi_{\boldsymbol{f},d_i}(\mathbf{C}).$$

For every $\boldsymbol{f} \in \mathbb{F}_k$ such that $\#_{\boldsymbol{f}}(\mathbf{C}') = h(\boldsymbol{f})$, we define this formula, where $n \coloneqq \#_{\boldsymbol{f}}(\mathbf{C}')$:

$$\psi_{\boldsymbol{f}}(\mathbf{C}) \coloneqq \dot{\exists} d_1, d_2, \ldots, d_n \in \mathbb{D} : \bigwedge_{i=1}^{n} \varphi_{\boldsymbol{f},d_i}(\mathbf{C}).$$

Observe that $\psi_{\boldsymbol{f}}$ is either a simple interval predicate or a Boolean combination of two simple interval predicates. Note that $\psi_{\boldsymbol{f}}(\mathbf{C})$ holds iff $\#_{\boldsymbol{f}}(\sigma(\tau_k(\mathbf{C}))) = \#_{\boldsymbol{f}}(\mathbf{C}')$ holds. This means that $\bigwedge_{\boldsymbol{f} \in \mathbb{F}_k} \psi_{\boldsymbol{f}}(\mathbf{C})$ holds iff $\sigma(\tau_k(\mathbf{C})) \equiv \mathbf{C}'$ holds, and hence we are done. ◀

4.3 An IO protocol for simple interval predicates

As Boolean combinations can be implemented (see end of Section 2.1), it suffices to describe a protocol for a simple interval predicate of the form (2). We refer to each $i \in [1..n]$ as a *role*. In the forthcoming set of states Q, we associate to each $q \in Q$ an element $\mathrm{elem}(q) \in [1..m]$. Each agent's element is set through the input; e.g. an agent mapped from symbol $(\bullet, x_1)$ is initially in a state q such that $\mathrm{elem}(q) = 1$. Let $Q_j \coloneqq \{q \in Q : \mathrm{elem}(q) = j\}$. For any two configurations $\mathbf{C}_a$ and $\mathbf{C}_b$ of an execution, any datum $d \in \mathbb{D}$ and any element $j \in [1..m]$, the invariant $\mathbf{C}_a(d, Q_j) = \mathbf{C}_b(d, Q_j)$ holds. We say that $d \in \mathbb{D}$ *matches* role i in configuration $\mathbf{C}$ if $\mathbf{C}(d, Q_j) \in T(i, j)$ holds for all $j \in [1..m]$. Let $r \coloneqq \max(r_1, \ldots, r_n) + 1$, where

$$r_i \coloneqq \max(\{\min T(i,j) : j \in [1..m]\} \cup \{\max T(i,j) : j \in [1..m], \sup T(i,j) < \infty\}).$$

Agents will not need to count beyond value r to decide whether a role is matched.

As for the majority protocol, our simple interval protocol works in stages, each one being necessary to ensure properties and invariants for the subsequent stages. In the *election stage*, a unique controller for the population and a single leader per datum of the support are selected; the former seeks to distribute a set of roles to the latter.

All agents contribute to the tallying of their immutable element j through the *counting stage*. This is done using the "tower method" described in [2], whereby two agents of the same datum, element *and* value meet and allow one of the two agents to increment its value. The maximal value computed in that manner is subsequently communicated to the (unique) datum leader.

Once the leaders carry correct counts for each element of their respective datum, they undertake roles that they match in the *distribution stage*. These roles can be swapped for other roles (as long as requirements are met) through a process of interrogating the controller. The controller is constantly notified of selected roles and updates its list of tasks accordingly.

If a fully assigned task list is obtained by the controller, it spreads a *true*-output throughout the population in what we call the *output propagation stage*. If that is not possible, leaders are in a consistent state of trial-and-error for their role assignments, ultimately failing to completely fill the task list, leaving the controller free to propagate its *false*-output.

▶ **Example 19.** Consider $n = m = 2$ with $T(1,1) \coloneqq [2..\infty)$, $T(1,2) \coloneqq [0..4]$, $T(2,1) \coloneqq \mathbb{N}$, $T(2,2) \coloneqq [1..\infty)$. Let $\mathbf{M} \coloneqq \{\!\{(\bullet, x_1), (\bullet, x_1), (\bullet, x_1), (\bullet, x_2), (\blacksquare, x_1), (\blacklozenge, x_2)\}\!\}$. Note that $r = 5$. Datum "$\bullet$" could match roles 1 and 2, "$\blacksquare$" cannot match any role, and "$\blacklozenge$" could match role 2.

After executing the protocol for a while, we may end up with the configuration illustrated in the table below. The third, fourth, fifth and sixth agents contain the correct value for their datum and element: $\mathbf{M}(\bullet, x_1) = 3$ and $\mathbf{M}(\bullet, x_2) = \mathbf{M}(\blacksquare, x_1) = \mathbf{M}(\blacklozenge, x_2) = 1$. The second agent has been elected controller. The last three agents have been elected their respective datum's leader and have collected the correct counts for each element. Either the $\bullet$-leader or the $\blacklozenge$-leader (possibly both) has notified the controller that they play role 2.

input	val	lead	ctrl	role	count of $[\#x_1, \#x_2]$	task list for [role 1, role 2]
$(\bullet, x_1)$	1					
$(\bullet, x_1)$	2		✔			[✘, ✔]
$(\bullet, x_1)$	**3**					
$(\bullet, x_2)$	**1**	✔		2	[3, 1]	
$(\blacksquare, x_1)$	**1**	✔			[1, 0]	
$(\blacklozenge, x_2)$	**1**	✔		2	[0, 1]	

The $\bullet$-leader may change its mind and decide to play role 1 after noticing the controller does not have its task 1 assigned. This switches its role to -2. Once the $\bullet$-leader notifies the controller, its role is set to 0 and (in doubt) the controller considers that role 2 is not assigned anymore. The $\bullet$-leader then changes its role to 1. Eventually the $\bullet$-leader and $\blacklozenge$-leader notify the controller that roles 1 and 2 are taken. This is summarized in these three snapshots:

input ⋯	role ⋯	task
$(\bullet, x_1)$		
$(\bullet, x_1)$		[✘, ✘]
$(\bullet, x_1)$		
$(\bullet, x_2)$	-2	
$(\blacksquare, x_1)$		
$(\blacklozenge, x_2)$	2	

⋯ role ⋯	task
	[✘, ✘]
0	
2	

⋯ role ⋯	task
	[✔, ✔]
1	
2	

◀

Note that while we rely on stages to describe our protocol, the distributed nature of the model implies that some stages may interfere with others. Therefore, we present here a list of potential problems and the way our protocol fixes them.

- While leader election is straightforward, role assignment for leaders can happen at any time before the actual leader is elected. This could lead to the controller being notified of a role assignment for which no current leader is assigned. Thus, when an agent loses its leadership status, it reverts its role to a negative value, meaning it will have to inform the controller of the change before returning to a passive value.
- A leader may take a role before having the correct counts. We provide a reset mechanism through which the leader falls into a "negative role". This forces it to then contact the controller and rectify the situation.
- A leader may have previously taken a role before realizing it does not actually meet the requirements. The leader is then forced to convey its mistake to the controller. But the controller it notifies may not ultimately be the population's controller. Therefore, after losing the controller status, an agent has to go to a negative controller state, meaning it must reset the controller's tasks before reverting to a passive value.
- There may be many leaders with the same role. To prevent deadlocks, we allow a leader to self-reassign to a new role if it notices the controller does not have the task filled.

4.3.1 States

The set of states is defined as $Q \coloneqq \{\mathit{false}, \mathit{true}\}^{n+2} \times [1..m] \times [1..r]^{m+1} \times [-n..n] \times \{-1, 0, 1\}$. For the sake of readability, we specify and manipulate states with these macros:

name	*values for* $q \in Q$	*values for* $q \in I$
$\mathrm{elem}(q)$	$[1..m]$	$j \in [1..m]$
$\mathrm{val}(q)$	$[1..r]$	1
$\mathrm{out}(q)$	$\{\mathit{false}, \mathit{true}\}$	*false*
$\mathrm{lead}(q)$	$\{\mathit{false}, \mathit{true}\}$	*true*
$\mathrm{role}(q)$	$[-n..n]$	0
$\mathrm{count}_\ell(q)$	$[1..r]$	1 if $\ell = j$, 0 otherwise
$\mathrm{ctrl}(q)$	$\{-1, 0, 1\}$	1
$\mathrm{task}_i(q)$	$\{\mathit{false}, \mathit{true}\}$	*false*

The input mapping is defined by $\iota(x_j) \coloneqq p_j$, where p_j is the unique state of I with $\mathrm{elem}(p_j) = j$. Informally, $\mathrm{elem}(q) = j$ indicates that the agent holds the j-th element; $\mathrm{val}(q)$ is the current tally of element $\mathrm{elem}(q)$ for the datum of the agent; $\mathrm{lead}(q)$ and $\mathrm{ctrl}(q)$ respectively indicate whether an agent is a datum leader or a controller; $\mathrm{role}(q)$ indicates the role for a leader; $\mathrm{count}_j(q)$ allows a datum leader to maintain the highest count currently witnessed for element j; $\mathrm{task}_i(q)$ allows the controller to maintain a list of the currently matched roles; and $\mathrm{out}(q)$ is the current belief of an agent on the output of the protocol.

Note that the rules presented in this section are used to succinctly describe transitions. A single rule may induce several transitions. Furthermore, for the sake of brevity, we mark rules allowing *mirror transitions* with an asterisk ($*$) next to the rule number. Mirror transitions are transitions in which an agent may observe its own state and react accordingly. Thus, a $*$-rule generating transitions whose precondition formula is $A(p) \wedge B(q)$ also generates a transition whose precondition is $A(q) \wedge B(q)$, effectively making state p the state of any "dummy agent". Note that q is still the only state to be updated to q'.

4.3.2 Leader and controller election

The first two rules are meant to elect a unique leader per datum present in the population, and a unique global controller for the whole population. For the remainder of the section, let us fix a fair execution $\mathbf{C}_0\mathbf{C}_1\cdots$ where $\mathbf{C}_0$ is initial.

rule	*state precondition*	*color precondition*	*state update*
(1)	$\mathrm{lead}(p)$ $\mathrm{lead}(q)$	$d_1 = d_2$	$\mathrm{role}(q') = -\lvert\mathrm{role}(q)\rvert$ $\neg\mathrm{lead}(q')$
(2)	$\mathrm{ctrl}(p) = 1$ $\mathrm{ctrl}(q) = 1$	*none*	$\mathrm{ctrl}(q') = -1$

Note that rule (1) guarantees that the agent losing leadership has its role set to a non-positive value. Similarly, rule (2) pushes the non-controller into a temporary intermediate state for its controller value, i.e. -1. Let $Q_L \coloneqq \{q \in Q : \mathrm{lead}(q)\}$ and $Q_C \coloneqq \{q \in Q : \mathrm{ctrl}(q) = 1\}$. The following lemma identifies the end of both elections.

▶ **Lemma 20.** *There exists* $\tau \in \mathbb{N}$ *such that* $|\mathbf{C}_\tau|_{Q_C} = |\mathbf{C}_{\tau+1}|_{Q_C} = \cdots = 1$, *and* $|\mathbf{C}_\tau(d)|_{Q_L} = |\mathbf{C}_{\tau+1}(d)|_{Q_L} = \cdots = 1$ *for every* $d \in \mathbb{D}$.

Let α denote the minimal value τ given by Lemma 20, which we refer to as the end of the election stage.

4.3.3 Element count by datum

The next rules allow to count how many agents with a common datum hold the same element. This count is ultimately communicated to the datum leader. Given $d \in \mathbb{D}$ and $\tau \in \mathbb{N}$, we say that a state $q \in Q$ is (d, j)-*valid* if $\mathrm{elem}(q) = j$ and $\mathrm{val}(q) = \min(\mathbf{C}_\tau(d, Q_j), r)$.

rule	*state precondition*	*color precondition*	*state update*
(3)	$\mathrm{elem}(p) = \mathrm{elem}(q)$ $\mathrm{val}(q) = \mathrm{val}(p) < r$	$d_1 = d_2$	$\mathrm{val}(q') = \mathrm{val}(q) + 1$
(4)*	$\mathrm{count}_{\mathrm{elem}(p)}(q) < \mathrm{val}(p)$ $\mathrm{lead}(q)$	$d_1 = d_2$	$\mathrm{count}_{\mathrm{elem}(p)}(q') = \mathrm{val}(p)$ `if` $(\mathrm{role}(q) > 0 \wedge$ $\mathrm{val}(p) \notin T(\mathrm{role}(q), \mathrm{elem}(p)))$: $\mathrm{role}(q') = -\mathrm{role}(q)$

Observe another correction mechanism; rule (4) guarantees that a leader with an assigned role $i > 0$ verifies that it can still assume role i after updating its count. The following lemmas explain that the correct counts are eventually provided to each datum leader.

▶ **Lemma 21.** *There exists $\tau \in \mathbb{N}$ such that, for every $\tau' \geq \tau$, $d \in \mathrm{supp}(\mathbf{C}_{\tau'})$ and $j \in [1..m]$, if $\mathbf{C}_0(d, Q_j) > 0$, then $\mathbf{C}_{\tau'}(d, q) > 0$ holds for some (d, j)-valid state q.*

▶ **Lemma 22.** *There exists $\tau \geq \alpha$ such that, for every $\tau' \geq \tau$, $d \in \mathrm{supp}(\mathbf{C}_{\tau'})$, $j \in [1..m]$ and $q \in \mathrm{act}(\mathbf{C}_{\tau'}(d)) \cap Q_L$, it is the case that $\mathrm{count}_j(q) = \min(\mathbf{C}_{\tau'}(d, Q_j), r)$.*

Let τ' and τ'' denote the minimal values τ given by Lemmas 21 and 22. From now on, let $\beta \coloneqq \max(\tau', \tau'')$.

4.3.4 Role distribution and task tracking

The following rules assign roles to leaders and allow leaders to reset their roles when possible, therefore preventing deadlocks. In rule (5), variable i can take any value from $[1..n]$.

rule	*state precondition*	*color precondition*	*state update*
(5)	$\mathrm{lead}(q)$ $\mathrm{role}(q) = 0$ $\bigwedge_{j \in [1..m]} \mathrm{count}_j(q) \in T(i, j)$	*none*	$\mathrm{role}(q') = i$
(6)*	$\mathrm{ctrl}(p)$ $\mathrm{lead}(q)$ $\mathrm{role}(q) = i > 0$ $\bigvee_{i' \in [1..n] \setminus \{i\}} (\neg \mathrm{task}_{i'}(p) \wedge$ $\bigwedge_{j \in [1..m]} \mathrm{count}_j(q) \in T(i', j))$	*none*	$\mathrm{role}(q') = -i$

This induces the following result, informally meaning that if a leader has taken a role, then it currently *believes* it can fill this role.

▶ **Lemma 23.** *For every $\tau \in \mathbb{N}$, $j \in [1..m]$ and $q \in \mathrm{act}(\mathbf{C}_\tau) \cap Q_L$ such that $\mathrm{role}(q) > 0$, it is the case that $\mathrm{count}_j(q) \in T(\mathrm{role}(q), j)$.*

These rules allow to update the controller's task list and reset roles when needed:

rule	*state precondition*	*color precondition*	*state update*
(7)*	$\text{role}(p) \neq 0$ $\text{ctrl}(q) = 1$	*none*	$\text{task}_{\lvert\text{role}(p)\rvert}(q') = (\text{role}(p) > 0)$
(8)*	$\text{ctrl}(p) = 1$ $\text{role}(q) < 0$ $\neg\text{task}_{\lvert\text{role}(q)\rvert}(p)$	*none*	$\text{role}(q') = 0$

To illustrate how rules (5) through (8) operate, we give the following example.

▶ **Example 24.** Recall Example 19, introduced earlier. Consider the configuration of its first snapshot. While we initially gave intuitions on how role reassignment might happen from this specific configuration, we give here a deeper analysis of the important configurations involved in this process.

input	val	lead	ctrl	role	count of $[\#x_1, \#x_2]$	task list for [role 1, role 2]
$(\bullet, x_1)$	1					
$(\bullet, x_1)$	2		✔			[✘, ✔]
$(\bullet, x_1)$	**3**					
$(\bullet, x_2)$	**1**	✔		2	$[3, 1]$	
$(\blacksquare, x_1)$	**1**	✔			$[1, 0]$	
$(\blacklozenge, x_2)$	**1**	✔		2	$[0, 1]$	

In the above, the $\bullet$-leader currently believes (rightly so) that it can fill roles 1 and 2. Observe that the controller has task 2 assigned. However, its task 1 is still unassigned. Therefore, rule (6) allows the $\bullet$-leader to initiate its reassignment by setting its role to -2 through an interaction with the controller. This leads to the following configuration:

input	val	lead	ctrl	role	count of $[\#x_1, \#x_2]$	task list for [role 1, role 2]
$(\bullet, x_1)$	1					
$(\bullet, x_1)$	2		✔			[✘, ✔]
$(\bullet, x_1)$	**3**					
$(\bullet, x_2)$	**1**	✔		-2	$[3, 1]$	
$(\blacksquare, x_1)$	**1**	✔			$[1, 0]$	
$(\blacklozenge, x_2)$	**1**	✔		2	$[0, 1]$	

Since its role is set to -2, the $\bullet$-leader now seeks to inform the controller that it should unassign role 2 from its task list. This is achieved on their next meeting through rule (7). We then have this next configuration:

input	val	lead	ctrl	role	count of $[\#x_1, \#x_2]$	task list for [role 1, role 2]
$(\bullet, x_1)$	1					
$(\bullet, x_1)$	2		✔			[✘, ✘]
$(\bullet, x_1)$	**3**					
$(\bullet, x_2)$	**1**	✔		-2	$[3, 1]$	
$(\blacksquare, x_1)$	**1**	✔			$[1, 0]$	
$(\blacklozenge, x_2)$	**1**	✔		2	$[0, 1]$	

Note that this does not mean that no leader currently has its role set to 2; indeed, the ◆-leader still has its role set to 2. Let us now assume that, immediately after reaching this configuration, the ●-leader and the controller meet again. Since the ●-leader observes that the controller no longer has its task 2 assigned, it can assume that either it unassigned it, some other leader did, or it was never assigned. In any case, it can safely reset its role to 0 through rule (8), giving us the following configuration:

input	val	lead	ctrl	role	count of $[\#x_1, \#x_2]$	task list for [role 1, role 2]
$(●, x_1)$	1					
$(●, x_1)$	2		✔			[✘, ✘]
$(●, x_1)$	**3**					
$(●, x_2)$	**1**	✔		0	$[3, 1]$	
$(■, x_1)$	**1**	✔			$[1, 0]$	
$(◆, x_2)$	**1**	✔		2	$[0, 1]$	

Observe that the ◆-leader could have met the controller before the ●-leader, thereby reassigning role 2 in the controller's task list and undoing the ●-leader's work. This would only delay the ●-leader's role resetting; through fairness, it would not endlessly prevent it.

From this last configuration, since the ●-leader's role is set to 0, it is now free to take any role it can fill through rule (5). Let us assume, for the sake of brevity, that it takes on role 1:

input	val	lead	ctrl	role	count of $[\#x_1, \#x_2]$	task list for [role 1, role 2]
$(●, x_1)$	1					
$(●, x_1)$	2		✔			[✘, ✘]
$(●, x_1)$	**3**					
$(●, x_2)$	**1**	✔		1	$[3, 1]$	
$(■, x_1)$	**1**	✔			$[1, 0]$	
$(◆, x_2)$	**1**	✔		2	$[0, 1]$	

Suppose the ◆-leader meets the controller before the ●-leader. Then, rule (7) assigns task 2 in the controller's task list. The ●-leader can no longer reset its role through rule (6) because the controller has task 2 already assigned. Therefore, when the ●-leader eventually meets the controller again, it finally assigns task 1 to its task list via rule (7).

input	val	lead	ctrl	role	count of $[\#x_1, \#x_2]$	task list for [role 1, role 2]
$(●, x_1)$	1					
$(●, x_1)$	2		✔			[✔, ✔]
$(●, x_1)$	**3**					
$(●, x_2)$	**1**	✔		1	$[3, 1]$	
$(■, x_1)$	**1**	✔			$[1, 0]$	
$(◆, x_2)$	**1**	✔		2	$[0, 1]$	

◀

The following lemmas show that at some point in the execution, a configuration is reached where agents who are neither leaders nor controllers no longer interact with other agents.

▶ **Lemma 25.** *There exists some* $\tau \in \mathbb{N}$ *such that for every* $\tau' \geq \tau$ *and* $q \in \text{act}(\mathbf{C}_{\tau'}) \setminus Q_L$*, it is the case that* $\text{role}(q) = 0$.

rule	*state precondition*	*color precondition*	*state update*
(9)	$\mathrm{ctrl}(p) = -1$ $\mathrm{ctrl}(q) = 1$	*none*	$\bigwedge_{i\in[1..m]} \neg\mathrm{task}_i(q')$
(10)	$\mathrm{ctrl}(p) = 1$ $\mathrm{ctrl}(q) = -1$ $\bigwedge_{i\in[1..m]} \neg\mathrm{task}_i(p)$	*none*	$\mathrm{ctrl}(q') = 0$

▶ **Lemma 26.** *There exists $\tau \geq \alpha$ such that for every $\tau' \geq \tau$ and $q \in \mathrm{act}(\mathbf{C}_{\tau'})$, it is the case that $\mathrm{ctrl}(q) \in \{0, 1\}$.*

Let τ' and τ'' denote the minimal values τ given by Lemmas 25 and 26. From now on, let $\gamma \coloneqq \max(\beta, \tau', \tau'')$. Informally, this delimits the configuration where there are no negative controllers, therefore preventing recurring resets of the controller's tasks through rule (9). Finally, the following lemma argues that past $\mathbf{C}_\gamma$, a controller can only have a task set to *true* if some leader is currently assuming the corresponding role (whether positive or negative).

▶ **Lemma 27.** *For every $\tau \geq \gamma$, $i \in [1..n]$ and $q \in \mathrm{act}(\mathbf{C}_\tau) \cap Q_C$ such that $\mathrm{task}_i(q)$ holds, there exists $q' \in \mathrm{act}(\mathbf{C}_\tau)$ such that $|\mathrm{role}(q')| = i$.*

4.3.5 Output propagation

The last rule allows the controller to communicate to the other agents whether it currently has its task list completely assigned or not. Note that the output of a state q is precisely the value of $\mathrm{out}(q)$, i.e. $O(q) \coloneqq \mathrm{out}(q)$.

rule	*state precondition*	*color precondition*	*state update*
(11)*	$\mathrm{ctrl}(p)$	*none*	$\mathrm{out}(q') = \bigwedge_{i=1}^{n} \mathrm{task}_i(p)$

▶ **Lemma 28.** *It is the case that $\psi(\mathbf{C}_0)$ holds iff there exists some $\tau \geq \gamma$ such that for every $\tau' \geq \tau$, there exists $q \in \mathrm{act}(\mathbf{C}_{\tau'}) \cap Q_C$ such that $\bigwedge_{i\in[1..n]} \mathrm{task}_i(q)$ holds.*

▶ **Corollary 29.** *There exists $\tau \in \mathbb{N}$ such that $O(\mathbf{C}_\tau) = O(\mathbf{C}_{\tau+1}) = \cdots = \psi(\mathbf{C}_0)$.*

5 Conclusion

In this article, we introduced population protocols with unordered data; we presented such a protocol that computes majority over an infinite data domain; and we established the expressive power of immediate observation protocols: they compute interval predicates.

This work initiates the study of population protocols operating over arbitrarily large domains. Hence, this opens the door to numerous exciting questions, e.g. on space-efficient and time-efficient protocols. In particular, the expressive power of our model remains open.

There exist results on logics over data multisets (e.g., see [22, 24]). In particular, the author of [22] provides a decidable logic reminiscent of Presburger arithmetic. It appears plausible that population protocols with unordered data compute (perhaps precisely) this logic. While we are fairly confident that remainder and threshold predicates with respect to the data counts can be computed in our model, the existential quantification, arising in the (non-ambiguous) solved forms of [22], seems more challenging to implement than the one of simple interval predicates.

Our model further relates to logic and automata on data words: inputs of a protocol with data can be seen as data words where Q is the alphabet and $\mathbb{D}$ is the data domain. Importantly, these data words are commutative, i.e., permutations do not change acceptance. For example, the logic $\mathsf{FO}^2(+1, \sim, <)$ of [8] allows to specify non-commutative properties such as "there is a block of a's followed by a block of b's". In this respect, this logic is too "strong". It is also too "weak" as it cannot express "for each datum, the number of a's is even". For this same reason, $\mathsf{EMSO}^2(+1, \sim)$, and equivalently weak data automata [21], is too "weak". The logic $\mathsf{EMSO}^2_{\#}(+1, \sim)$, and equivalently commutative data automata [25], can express the latter, but, again, the successor relation allows to express non-commutative properties on letters. Thus, while models related to data words have been studied and could influence research on the complete characterization of the expressive power of our model, we have yet to directly connect them to our model.

Network Satisfaction Problems Solved by k-Consistency

Manuel Bodirsky

Simon Knäuer
Institut für Algebra, TU Dresden, Germany

Abstract

We show that the problem of deciding for a given finite relation algebra $\mathbf{A}$ whether the network satisfaction problem for $\mathbf{A}$ can be solved by the k-consistency procedure, for some $k \in \mathbb{N}$, is undecidable. For the important class of finite relation algebras $\mathbf{A}$ with a normal representation, however, the decidability of this problem remains open. We show that if $\mathbf{A}$ is symmetric and has a flexible atom, then the question whether NSP($\mathbf{A}$) can be solved by k-consistency, for some $k \in \mathbb{N}$, is decidable (even in polynomial time in the number of atoms of $\mathbf{A}$). This result follows from a more general sufficient condition for the correctness of the k-consistency procedure for finite symmetric relation algebras. In our proof we make use of a result of Alexandr Kazda about finite binary conservative structures.

1 Introduction

Many computational problems in qualitative temporal and spatial reasoning can be phrased as *network satisfaction problems (NSPs)* for *finite relation algebras*. Such a network consists of a finite set of nodes, and a labelling of pairs of nodes by elements of the relation algebra. In applications, such a network models some partial (and potentially inconsistent) knowledge that we have about some temporal or spatial configuration. The computational task is to replace the labels by *atoms* of the relation algebra such that the resulting network has an embedding into a representation of the relation algebra. In applications, this embedding provides a witness that the input configuration is consistent (a formal definition of relation algebras, representations, and the network satisfaction problem can be found in Section 2.1). The computational complexity of the network satisfaction problem depends on the fixed finite relation algebra, and is of central interest in the mentioned application areas. Relation algebras have been studied since the 40's with famous contributions of Tarski [41], Lyndon [34], McKenzie [37, 38], and many others, with renewed interest since the 90s [7, 11, 22, 25–27, 30].

One of the most prominent algorithms for solving NSPs in polynomial time is the so-called *path consistency procedure*. The path consistency procedure has a natural generalisation to the *k-consistency procedure*, for some fixed $k \geq 3$. Such consistency algorithms have a number of advantages: e.g., they run in polynomial time, and they are *one-sided correct*, i.e., if they reject an instance, then we can be sure that the instance is unsatisfiable. Because of these properties, consistency algorithms can be used to prune the search space in exhaustive approaches that are used if the network consistency problem is NP-complete. The question for what temporal and spatial reasoning problems the k-consistency procedure provides a necessary and sufficient condition for satisfiability is among the most important research problems in the area [9, 40]. The analogous problem for so-called *constraint satisfaction problems (CSPs)* was posed by Feder and Vardi [23] and has been solved for finite-domain CSPs by Barto and Kozik [5]. Their result also shows that for a given finite-domain template, the question whether the corresponding CSP can be solved by the k-consistency procedure can be decided in polynomial time.

In contrast, we show that there is no algorithm that decides for a given finite relation algebra $\mathbf{A}$ whether NSP($\mathbf{A}$) can be solved by the k-consistency procedure, for some $k \in \mathbb{N}$. The question is also undecidable for every fixed $k \geq 3$; in particular, there is no algorithm that decides whether NSP($\mathfrak{A}$) can be solved by the path consistency procedure. Our proof relies on results of Hirsch [29] and Hirsch and Hodkinson [25]. The proof also shows that Hirsch's *Really Big Complexity Problem (RBCP; [27])* is undecidable. The RBCP asks for a description of those finite relation algebras $\mathbf{A}$ whose NSP can be solved in polynomial time.

Many of the classic examples of relation algebras that are used in temporal and spatial reasoning, such as the point algebra, Allen's Interval Algebra, RCC5, RCC8, have so-called *normal representations*, which are representations that are particularly well-behaved from a model theory perspective [7, 9, 27]. The importance of normal representations combined with our negative results for general finite relation algebras prompts the question whether solvability of the NSP by the k-consistency procedure can at least be characterised for relation algebras $\mathbf{A}$ with a normal representation. Our main result is a sufficient condition that implies that NSP($\mathbf{A}$) can be solved by the k-consistency procedure (Theorem 30). The condition can be checked algorithmically for a given $\mathbf{A}$. Moreover, for symmetric relation algebras with a flexible atom, which form a large subclass of the class of relation algebras with a normal representation, our condition provides a necessary and sufficient criterion for solvability by k-consistency (Theorem 39). We prove that the NSP for every symmetric relation algebra with a flexible atom that cannot be solved by the k-consistency procedure is already NP-complete. Finally, for symmetric relation algebras with a flexible atom our tractability condition can even be checked in polynomial time for a given relation algebra $\mathbf{A}$ (Theorem 42).

In our proof, we exploit a connection between the NSP for relation algebras $\mathbf{A}$ with a normal representation and finite-domain constraint satisfaction problems. In a next step, this allows us to use strong results for CSPs over finite domains. There are similarities between the fact that the set of relations of a representation of $\mathbf{A}$ is closed under taking unions on the one hand, and so-called *conservative finite-domain CSPs* [3, 16–18] on the other hand; in a conservative CSP the set of allowed constraints in instances of the CSP contains all unary relations. The complexity of conservative CSPs has been classified long before the solution of the Feder-Vardi Dichotomy Conjecture [19, 23, 42, 43]. Moreover, there are particularly elegant descriptions of when a finite-domain conservative CSP can be solved by the k-consistency procedure for some $k \in \mathbb{N}$ (see, e.g., Theorem 2.17 in [17]). Our approach is to turn the

similarities into a formal correspondence so that we can use these results for finite-domain conservative CSPs to prove that k-consistency solves NSP($\mathbf{A}$). A key ingredient here is a contribution of Kazda [31] about conservative *binary* CSPs.

All the missing proofs and details can be found in an extended version of this article [13].

2 Preliminaries

A *signature* τ is a set of function or relation symbols each of which has an associated finite *arity* $k \in \mathbb{N}$. A τ-structure $\mathfrak{A}$ consists of a set A together with a function $f^{\mathfrak{A}} \colon A^k \to A$ for every function symbol $f \in \tau$ of arity k and a relation $R^{\mathfrak{A}} \subseteq A^k$ for every relation symbol $R \in \tau$ of arity k. The set A is called the *domain of* $\mathfrak{A}$. Let $\mathfrak{A}$ and $\mathfrak{B}$ be τ-structures. The *(direct) product* $\mathfrak{C} = \mathfrak{A} \times \mathfrak{B}$ is the τ-structure where

- $A \times B$ is the domain of $\mathfrak{C}$;
- for every relation symbol Q of arity $n \in \mathbb{N}$ and every tuple $((a_1, b_1), \dots, (a_n, b_n)) \in (A \times B)^n$, we have that $((a_1, b_1), \dots, (a_n, b_n)) \in Q^{\mathfrak{C}}$ if and only if $(a_1, \dots, a_n) \in Q^{\mathfrak{A}}$ and $(b_1, \dots, b_n) \in Q^{\mathfrak{B}}$;
- for every function symbol Q of arity $n \in \mathbb{N}$ and every tuple $((a_1, b_1), \dots, (a_n, b_n)) \in (A \times B)^n$, we have that

$$Q^{\mathfrak{C}}((a_1, b_1), \dots, (a_n, b_n)) := (Q^{\mathfrak{A}}(a_1, \dots, a_n), Q^{\mathfrak{B}}(b_1, \dots, b_n)).$$

We denote the (direct) product $\mathfrak{A} \times \mathfrak{A}$ by $\mathfrak{A}^2$. The k-fold product $\mathfrak{A} \times \cdots \times \mathfrak{A}$ is defined analogously and denoted by $\mathfrak{A}^k$. Structures with a signature that only contains function symbols are called *algebras* and structures with purely relational signature are called *relational structures*. Since we do not deal with signatures of mixed type in this article, we will use the term structure for relational structures only.

2.1 Relation Algebras

Relation algebras are particular algebras; in this section we recall their definition and state some of their basic properties. We introduce *proper* relation algebras, move on to abstract relation algebras, and finally define representations of relation algebras. For an introduction to relation algebras we recommend the textbook by Maddux [36]. Proper relation algebras are algebras whose domain is a set of binary relations over a common domain, and which are equipped with certain operations on binary relations.

▶ **Definition 1.** *Let D be a set and $\mathcal{R}$ a set of binary relations over D such that $(\mathcal{R}; \cup, {}^{-}, 0, 1, \mathrm{Id}, {}^{\smile}, \circ)$ is an algebra with operations defined as follows:*

1. $0 := \emptyset$,
2. $1 := \bigcup \mathcal{R}$,
3. $\mathrm{Id} := \{(x, x) \mid x \in D\}$,
4. $a \cup b := \{(x, y) \mid (x, y) \in a \vee (x, y) \in b\}$,
5. $\bar{a} := 1 \setminus a$,
6. $a^{\smile} := \{(x, y) \mid (y, x) \in a\}$,
7. $a \circ b := \{(x, z) \mid \exists y \in D : (x, y) \in a \text{ and } (y, z) \in b\}$,

for $a, b \in \mathcal{R}$. Then $(\mathcal{R}; \cup, {}^{-}, 0, 1, \mathrm{Id}, {}^{\smile}, \circ)$ is called a proper relation algebra.

The class of all proper relation algebras is denoted by PA. Abstract relation algebras are a generalisation of proper relation algebras where the domain does not need to be a set of binary relations.

▶ **Definition 2.** *An* (abstract) relation algebra $\mathbf{A}$ *is an algebra with domain* A *and signature* $\{\cup, \bar{}, 0, 1, \mathrm{Id}, \breve{}, \circ\}$ *such that*

1. *the structure* $(A; \cup, \cap, \bar{}, 0, 1)$*, with* $\cap$ *defined by* $x \cap y := \overline{(\bar{x} \cup \bar{y})}$*, is a Boolean algebra,*
2. $\circ$ *is an associative binary operation on* A*, called* composition*,*
3. *for all* $a, b, c, \in A$*:* $(a \cup b) \circ c = (a \circ c) \cup (b \circ c)$*,*
4. *for all* $a \in A$*:* $a \circ \mathrm{Id} = a$*,*
5. *for all* $a \in A$*:* $\breve{\breve{a}} = a$*,*
6. *for all* $a, b \in A$*:* $\breve{x} = \breve{a} \cup \breve{b}$ *where* $x := a \cup b$*,*
7. *for all* $a, b \in A$*:* $\breve{x} = \breve{b} \circ \breve{a}$ *where* $x := a \circ b$*,*
8. *for all* $a, b, c \in A$*:* $\bar{b} \cup (\breve{a} \circ (\overline{(a \circ b)})) = \bar{b}$*.*

We denote the class of all relation algebras by RA. Let $\mathbf{A} = (A; \cup, \bar{}, 0, 1, \mathrm{Id}, \breve{}, \circ)$ be a relation algebra. By definition, $(A; \cup, \cap, \bar{}, 0, 1)$ is a Boolean algebra and therefore induces a partial order $\leq$ on A, which is defined by $x \leq y :\Leftrightarrow x \cup y = y$. Note that for proper relation algebras this ordering coincides with the set-inclusion order. The minimal elements of this order in $A \setminus \{0\}$ are called *atoms*. The set of atoms of $\mathbf{A}$ is denoted by A_0. Note that for the finite Boolean algebra $(A; \cup, \cap, \bar{}, 0, 1)$ each element $a \in A$ can be uniquely represented as the union $\cup$ (or "join") of elements from a subset of A_0. We will often use this fact and directly denote elements of the relation algebra $\mathbf{A}$ by subsets of A_0.

By item 3. in Definition 2 the values of the composition operation $\circ$ in $\mathbf{A}$ are completely determined by the values of $\circ$ on A_0. This means that for a finite relation algebra the operation $\circ$ can be represented by a multiplication table for the atoms A_0.

An algebra with signature $\tau = \{\cup, \bar{}, 0, 1, \mathrm{Id}, \breve{}, \circ\}$ with corresponding arities 2, 1, 0, 0, 0, 1, and 2 that is isomorphic to some proper relation algebra is called *representable*. The class of representable relation algebras is denoted by RRA. Since every proper relation algebra and therefore also every representable relation algebra satisfies the axioms from the previous definition we have PA $\subseteq$ RRA $\subseteq$ RA. A classical result of Lyndon [34] states that there exist finite relation algebras $\mathbf{A} \in$ RA that are not representable; so the inclusions above are proper. If a relation algebra $\mathbf{A}$ is representable then the isomorphism to a proper relation algebra is usually called the *representation of* $\mathbf{A}$.

We will be interested in the model-theoretic behavior of sets of relations which form the domain of a proper relation algebra, and therefore consider relational structures whose relations are precisely the relations of a proper relation algebra. If the set of relations of a relational structure $\mathfrak{B}$ forms a proper relation algebra which is a representation of some abstract relation algebra $\mathbf{A}$, then it will be convenient to also call $\mathfrak{B}$ a representation of $\mathbf{A}$.

▶ **Definition 3.** *Let* $\mathbf{A} \in$ RA*. A* representation of $\mathbf{A}$ *is a relational structure* $\mathfrak{B}$ *such that*

- $\mathfrak{B}$ *is an* A*-structure, i.e., the elements of* A *are binary relation symbols of* $\mathfrak{B}$*;*
- *The map* $a \mapsto a^{\mathfrak{B}}$ *is an isomorphism between the abstract relation algebra* $\mathbf{A}$ *and the proper relation algebra* $(\mathcal{R}; \cup, \bar{}, 0, 1, \mathrm{Id}, \breve{}, \circ)$ *with domain* $\mathcal{R} := \{a^{\mathfrak{B}} \mid a \in A\}$*.*

Recall that the set of atoms of a relation algebra $\mathbf{A} = (A; \cup, \bar{}, 0, 1, \mathrm{Id}, \breve{}, \circ)$ is denoted by A_0. The following definitions are crucial for this article.

▶ **Definition 4.** *A tuple* $(x, y, z) \in (A_0)^3$ *is called an* allowed triple (of $\mathbf{A}$) *if* $z \leq x \circ y$*. Otherwise,* (x, y, z) *is called a* forbidden triple (of $\mathbf{A}$)*; in this case* $\overline{z} \cup \overline{x \circ y} = 1$*. We say that a relational* A*-structure* $\mathfrak{B}$ induces a forbidden triple (from $\mathbf{A}$) *if there exist* $b_1, b_2, b_3 \in B$ *and* $(x, y, z) \in (A_0)^3$ *such that* $x(b_1, b_2), y(b_2, b_3)$ *and* $z(b_1, b_3)$ *hold in* $\mathfrak{B}$ *and* (x, y, z) *is a forbidden triple of* $\mathbf{A}$*.*

Note that a representation of $\mathbf{A}$ by definition does not induce a forbidden triple. A relation $R \subseteq A^3$ is called *totally symmetric* if for every bijection $\pi\colon \{1,2,3\} \to \{1,2,3\}$ we have

$$(a_1, a_2, a_3) \in R \;\Rightarrow\; (a_{\pi(1)}, a_{\pi(2)}, a_{\pi(3)}) \in R.$$

The following is an immediate consequence of the definition of allowed triples.

▶ Remark 5. The set of allowed triples of a symmetric relation algebra $\mathbf{A}$ is totally symmetric.

2.2 The Network Satisfaction Problem

In this section we present computational decision problems associated with relation algebras. We first introduce the inputs to these decision problems, so-called $\mathbf{A}$-networks.

▶ **Definition 6.** *Let $\mathbf{A}$ be a relation algebra. An* $\mathbf{A}$-network $(V; f)$ *is a finite set V together with a partial function $f\colon E \subseteq V^2 \to A$, where E is the domain of f. An $\mathbf{A}$-network $(V; f)$ is* satisfiable in a representation $\mathfrak{B}$ *of $\mathbf{A}$ if there exists an assignment $s\colon V \to B$ such that for all $(x, y) \in E$ the following holds:*

$$(s(x), s(y)) \in f(x, y)^{\mathfrak{B}}.$$

An $\mathbf{A}$-network $(V; f)$ is satisfiable *if there exists a representation $\mathfrak{B}$ of $\mathbf{A}$ such that $(V; f)$ is satisfiable in $\mathfrak{B}$.*

With these notions we can define the network satisfaction problem.

▶ **Definition 7.** *The* (general) network satisfaction problem *for a finite relation algebra $\mathbf{A}$, denoted by* $\mathrm{NSP}(\mathbf{A})$*, is the problem of deciding whether a given $\mathbf{A}$-network is satisfiable.*

In the following we assume that for an $\mathbf{A}$-network $(V; f)$ it holds that $f(V^2) \subseteq A \setminus \{0\}$. Otherwise, $(V; f)$ is not satisfiable. Note that every $\mathbf{A}$-network $(V; f)$ can be viewed as an A-structure $\mathfrak{C}$ on the domain V: for all $x, y \in V$ in the domain of f and $a \in A$ the relation $a^{\mathfrak{C}}(x, y)$ holds if and only if $f(x, y) = a$.

It is well-known that for relation algebras $\mathbf{A}_1$ and $\mathbf{A}_2$ the direct product $\mathbf{A}_1 \times \mathbf{A}_2$ is also a relation algebra (see, e.g., [30]). We will see in Lemma 9 that the direct product of representable relation algebras is also a representable relation algebra.

▶ **Definition 8.** *Let $\mathbf{A}_1$ and $\mathbf{A}_2$ be representable relation algebras. Let $\mathfrak{B}_1$ and $\mathfrak{B}_2$ be representations of $\mathbf{A}_1$ and $\mathbf{A}_2$ with disjoint domains. Then the* union representation *of the direct product $\mathbf{A}_1 \times \mathbf{A}_2$ is the $(A_1 \times A_2)$-structure $\mathfrak{B}_1 \uplus \mathfrak{B}_2$ on the domain $B_1 \uplus B_2$ with the following definition for all $(a_1, a_2) \in A_1 \times A_2$:*

$$(a_1, a_2)^{\mathfrak{B}_1 \uplus \mathfrak{B}_2} := a_1^{\mathfrak{B}_1} \cup a_2^{\mathfrak{B}_2}.$$

The following well-known lemma establishes a connection between products of relation algebras and union representations (see, e.g., Lemma 7 in [21] or Lemma 3.7 in [30]); it states that union representations are indeed representations. A proof of the lemma can be found, for example, in the extended version of this article [13].

▶ **Lemma 9.** *Let $\mathbf{A}_1$ and $\mathbf{A}_2$ be relation algebras. Then the following holds:*

1. *If $\mathfrak{B}_1$ and $\mathfrak{B}_2$ are representations of $\mathbf{A}_1$ and $\mathbf{A}_2$ with disjoint domains, then $\mathfrak{B}_1 \uplus \mathfrak{B}_2$ is a representation of $\mathbf{A}_1 \times \mathbf{A}_2$.*
2. *If $\mathfrak{B}$ is a representation of $\mathbf{A}_1 \times \mathbf{A}_2$, then there exist representations $\mathfrak{B}_1$ and $\mathfrak{B}_2$ of $\mathbf{A}_1$ and $\mathbf{A}_2$ such that $\mathfrak{B}$ is isomorphic to $\mathfrak{B}_1 \uplus \mathfrak{B}_2$.*

The following result uses Lemma 9 to obtain reductions between different network satisfaction problems. A similar statement can be found in Lemma 7 from [21], however there the assumption on representability of the relation algebras $\mathbf{A}$ and $\mathbf{B}$ is missing. Note that without this assumption the statement is not longer true. Consider relation algebras $\mathbf{A}$ and $\mathbf{B}$ such that NSP($\mathbf{A}$) is undecidable and $\mathbf{B}$ does not have a representation. Then $\mathbf{A} \times \mathbf{B}$ does also not have a representation (see Lemma 9) and hence NSP($\mathbf{A} \times \mathbf{B}$) is trivial. We observe that the undecidable problem NSP($\mathbf{A}$) cannot have a polynomial-time reduction to the trivial problem NSP($\mathbf{A} \times \mathbf{B}$).

▶ **Lemma 10.** *Let* $\mathbf{A}, \mathbf{B} \in$ RRA *be finite. Then there exists a polynomial-time reduction from* NSP($\mathbf{A}$) *to* NSP($\mathbf{A} \times \mathbf{B}$).

Proof. Consider the following polynomial-time reduction from NSP($\mathbf{A}$) to NSP($\mathbf{A} \times \mathbf{B}$). We map a given $\mathbf{A}$-network $(V; f)$ to the $(\mathbf{A} \times \mathbf{B})$-network $(V; f')$ where f' is defined by $f'(x, y) := (f(x, y), 0)$. This reduction can be computed in polynomial time.

▷ Claim 1. If $(V; f)$ is satisfiable then $(V; f')$ is also satisfiable. Let $\mathfrak{A}$ be a representation of $\mathbf{A}$ in which $(V; f)$ is satisfiable and let $\mathfrak{B}$ be an arbitrary representation of $\mathbf{B}$. By Lemma 9, the structure $\mathfrak{A} \uplus \mathfrak{B}$ is a representation of $\mathbf{A} \times \mathbf{B}$. Moreover, the definition of union representations (Definition 8) yields that the $(\mathbf{A} \times \mathbf{B})$-network $(V; f')$ is satisfiable in $\mathfrak{A} \uplus \mathfrak{B}$.

▷ Claim 2. If $(V; f')$ is satisfiable then $(V; f)$ is satisfiable. Assume that $(V; f')$ is satisfiable in some representation $\mathfrak{C}$ of $\mathbf{A} \times \mathbf{B}$. By item 2 in Lemma 9 we get that $\mathfrak{C}$ is isomorphic to $\mathfrak{A} \uplus \mathfrak{B}$, where $\mathfrak{A}$ and $\mathfrak{B}$ are representations of $\mathbf{A}$ and $\mathbf{B}$. It again follows from the definition of union representations that $(V; f)$ is satisfiable in the representation $\mathfrak{A}$ of $\mathbf{A}$.

This shows the correctness of the polynomial-time reduction from NSP($\mathbf{A}$) to NSP($\mathbf{A} \times \mathbf{B}$) and finishes the proof. ◀

2.3 Normal Representations and Constraint Satisfaction Problems

We consider a subclass of RRA introduced by Hirsch in 1996. For relation algebras $\mathbf{A}$ from this class, NSP($\mathbf{A}$) corresponds naturally to a constraint satisfaction problem. In the following let $\mathbf{A}$ be in RRA. We call an $\mathbf{A}$-network $(V; f)$ *closed* (transitively closed in the work by Hirsch [28]) if f is total and for all $x, y, z \in V$ it holds that

- $f(x, x) \leq \mathrm{Id}$,
- $f(x, y) = \breve{a}$ for $a = f(y, x)$,
- $f(x, z) \leq f(x, y) \circ f(y, z)$.

It is called *atomic* if the range of f only contains atoms from $\mathbf{A}$.

▶ **Definition 11** (from [27]). *Let* $\mathfrak{B}$ *be a representation of* $\mathbf{A}$*. Then* $\mathfrak{B}$ *is called*

- fully universal*, if every atomic closed* $\mathbf{A}$*-network is satisfiable in* $\mathfrak{B}$*;*
- square*, if* $1^{\mathfrak{B}} = B^2$*;*
- homogeneous*, if for every isomorphism between finite substructures of* $\mathfrak{B}$ *there exists an automorphism of* $\mathfrak{B}$ *that extends this isomorphism;*
- normal*, if it is fully universal, square and homogeneous.*

We now investigate the connection between NSP($\mathbf{A}$) for a finite relation algebra with a normal representation $\mathfrak{B}$ and constraint satisfaction problems. Let τ be a finite relational signature and let $\mathfrak{B}$ be a (finite or infinite) τ-structure. Then the *constraint satisfaction problem for* $\mathfrak{B}$, denoted by CSP($\mathfrak{B}$), is the computational problem of deciding whether a finite input structure $\mathfrak{A}$ has a homomorphism to $\mathfrak{B}$. The structure $\mathfrak{B}$ is called the template of CSP($\mathfrak{B}$).

$\circ$	Id	$<$	$>$
Id	Id	$<$	$>$
$<$	$<$	$<$	1
$>$	$>$	1	$>$

Figure 1 Multiplication table of the point algebra $\mathbf{P}$.

Consider the following translation which associates to each $\mathbf{A}$-network $(V; f)$ an A-structure $\mathfrak{C}$ as follows: the set V is the domain of $\mathfrak{C}$ and $(x, y) \in C^2$ is in a relation $a^{\mathfrak{C}}$ if and only if (x, y) is in the domain of f and $f(x, y) = a$ holds. For the other direction let $\mathfrak{C}$ be an A-structure with domain C and consider the $\mathbf{A}$-network $(C; f)$ with the following definition: for every $x, y \in C$, if (x, y) does not appear in any relation of $\mathfrak{C}$ we leave $f(x, y)$ undefined, otherwise let $a_1(x, y), \ldots, a_n(x, y)$ be all atomic formulas that hold in $\mathfrak{C}$. We compute in $\mathbf{A}$ the element $a := a_1 \cap \cdots \cap a_n$ and define $f(x, y) := a$.

The following theorem is based on the natural 1-to-1 correspondence between $\mathbf{A}$-networks and A-structures; it subsumes the connection between network satisfaction problems and constraint satisfaction problems.

▶ **Proposition 12** (Proposition 1.3.16 in [6], see also [7, 9]). *Let $\mathbf{A} \in$ RRA be finite. Then the following holds:*

1. *$\mathbf{A}$ has a representation $\mathfrak{B}$ such that* NSP($\mathbf{A}$) *and* CSP($\mathfrak{B}$) *are the same problem up to the translation between $\mathbf{A}$-networks and A-structures.*
2. *If $\mathbf{A}$ has a normal representation $\mathfrak{B}$ the problems* NSP($\mathbf{A}$) *and* CSP($\mathfrak{B}$) *are the same up to the translation between $\mathbf{A}$-networks and A-structures.*

Usually, normal representations of relation algebras are infinite relational structures. This means that the transfer from NSPs to CSPs from Proposition 12 results in CSPs over infinite templates, as in the following example.

▶ **Example 13.** Consider the *point algebra* $\mathbf{P}$. The set of atoms of $\mathbf{P}$ is $P_0 = \{\mathrm{Id}, <, >\}$. The composition operation $\circ$ on the atoms is given by the multiplication table in Figure 1. The table completely determines the composition operation $\circ$ on all elements of $\mathbf{P}$. Note that the structure $\mathfrak{P} := (\mathbb{Q};\ \emptyset, <, >, =, \leq, \geq, \neq, \mathbb{Q}^2)$ is the normal representation of $\mathbf{P}$ and therefore NSP($\mathbf{P}$) and CSP($\mathfrak{P}$) are the same problems up to the translation between networks and structures.

2.4 The Universal-Algebraic Approach

In this section we give a brief introduction to the the universal-algebraic approach to CSPs.

2.4.1 Polymorphisms

Let τ be a finite relational signature. A *polymorphism* of a τ-structure $\mathfrak{B}$ is a homomorphism f from $\mathfrak{B}^k$ to $\mathfrak{B}$, for some $k \in \mathbb{N}$ called the *arity of* f. We write Pol($\mathfrak{B}$) for the set of all polymorphisms of $\mathfrak{B}$. The set of polymorphisms is closed under composition, i.e., for all n-ary $f \in$ Pol($\mathfrak{B}$) and s-ary $g_1, \ldots, g_n \in$ Pol($\mathfrak{B}$) it holds that $f(g_1, \ldots, g_n) \in$ Pol($\mathfrak{B}$), where $f(g_1, \ldots, g_n)$ is a homomorphism from $\mathfrak{B}^s$ to $\mathfrak{B}$ defined as follows

$$f(g_1, \ldots, g_n)(x_1, \ldots, x_s) := f(g_1(x_1, \ldots, x_s), \ldots, g_n(x_1, \ldots, x_s)).$$

If $r_1, \dots, r_n \in B^k$ and $f\colon B^n \to B$ an n-ary operation, then we write $f(r_1, \dots, r_n)$ for the k-tuple obtained by applying f component-wise to the tuples $r_1, \dots, r_n$. We say that $f\colon B^n \to B$ *preserves* a k-ary relation $R \subseteq B^k$ if for all $r_1, \dots, r_n \in R$ it holds that $f(r_1, \dots, r_n) \in R$. We want to remark that the polymorphisms of $\mathfrak{B}$ are precisely those operations that preserve all relations from $\mathfrak{B}$.

A first-order τ-formula $\varphi(x_1, \dots, x_n)$ is called *primitive positive (pp)* if it has the form

$$\exists x_{n+1}, \dots, x_m(\varphi_1 \wedge \cdots \wedge \varphi_s)$$

where $\varphi_1, \dots, \varphi_s$ are atomic τ-formulas, i.e., formulas of the form $R(y_1, \dots, y_l)$ for $R \in \tau$ and $y_i \in \{x_1, \dots, x_m\}$, of the form $y = y'$ for $y, y' \in \{x_1, \dots, x_m\}$, or of the form $\bot$. We say that a relation R is *primitively positively definable over* $\mathfrak{A}$ if there exists a primitive positive τ-formula $\varphi(x_1, \dots, x_n)$ such that R is definable over $\mathfrak{A}$ by $\varphi(x_1, \dots, x_n)$.

▶ **Proposition 14** ([15, 24]). *Let $\mathfrak{B}$ be a τ-structure with a finite domain. Then the set of primitive positive definable relations in $\mathfrak{B}$ is exactly the set of relations preserved by* $\mathrm{Pol}(\mathfrak{B})$.

2.4.2 Atom Structures

In this section we introduce for every finite $\mathbf{A} \in \mathrm{RA}$ an associated finite structure, called the *atom structure* of $\mathbf{A}$. If $\mathbf{A}$ has a fully universal representation, then there exists a polynomial-time reduction from $\mathrm{NSP}(\mathbf{A})$ to the finite-domain constraint satisfaction problem $\mathrm{CSP}(\mathfrak{A}_0)$ (Proposition 16). Hence, this reduction provides polynomial-time algorithms to solve NSPs, whenever the CSP of the associated atom structure can be solved in polynomial-time. For a discussion of the atom structure and related objects we recommend Section 4 in [12].

▶ **Definition 15.** *The* atom structure of $\mathbf{A} \in \mathrm{RA}$ *is the finite relational structure $\mathfrak{A}_0$ with domain A_0 and the following relations:*

- *for every $x \in A$ the unary relation $x^{\mathfrak{A}_0} := \{a \in A_0 \mid a \leq x\}$,*
- *the binary relation $E^{\mathfrak{A}_0} := \{(a_1, a_2) \in A_0^2 \mid \breve{a_1} = a_2\}$,*
- *the ternary relation $R^{\mathfrak{A}_0} := \{(a_1, a_2, a_3) \in A_0^3 \mid a_3 \leq a_1 \circ a_2\}$.*

Note that $\mathfrak{A}_0$ has all subsets of A_0 as unary relations and that the relation $R^{\mathfrak{A}_0}$ consists of the allowed triples of $\mathbf{A} \in \mathrm{RRA}$. We say that an operation *preserves the allowed triples* if it preserves the relation $R^{\mathfrak{A}_0}$.

▶ **Proposition 16** ([11, 12]). *Let $\mathfrak{B}$ be a fully universal representation of a finite $\mathbf{A} \in \mathrm{RRA}$. Then there is a polynomial-time reduction from* $\mathrm{CSP}(\mathfrak{B})$ *to* $\mathrm{CSP}(\mathfrak{A}_0)$.

2.4.3 Conservative Clones

Let $\mathfrak{B}$ be a finite τ-structure. An operation $f\colon B^n \to B$ is called *conservative* if for all $x_1, \dots, x_n \in B$ it holds that $f(x_1, \dots, x_n) \in \{x_1, \dots, x_n\}$. The operation clone $\mathrm{Pol}(\mathfrak{B})$ is *conservative* if every $f \in \mathrm{Pol}(\mathfrak{B})$ is conservative. We call a relational structure $\mathfrak{B}$ *conservative* if $\mathrm{Pol}(\mathfrak{B})$ is conservative.

▶ Remark 17. Let $\mathfrak{A}_0$ be the atom structure of a finite relation algebra $\mathbf{A}$. Every $f \in \mathrm{Pol}(\mathfrak{A}_0)$ preserves all subsets of A_0, and is therefore conservative. Hence, $\mathrm{Pol}(\mathfrak{A}_0)$ is conservative.

This remark justifies our interest in the computational complexity of certain CSPs where the template has conservative polymorphisms. Their complexity can be studied via universal algebraic methods as we will see in the following. An operation $f\colon B^3 \to B$ is called

- a *majority operation* if $\forall x, y \in B. f(x, x, y) = f(x, y, x) = f(y, x, x) = x$;
- a *minority operation* if $\forall x, y \in B. f(x, x, y) = f(x, y, x) = f(y, x, x) = y$.

An operation $f\colon B^n \to B$, for $n \geq 2$, is called

- a *cyclic operation* if $\forall x_1, \ldots, x_n \in B. f(x_1, \ldots, x_n) = f(x_n, x_1, \ldots, x_{n-1})$;
- a *weak near-unanimity operation* if

$$\forall x, y \in B. f(x, \ldots, x, y) = f(x, \ldots, x, y, x) = \ldots = f(y, x, \ldots, x);$$

- a *Siggers operation* if $n = 6$ and $\forall x, y \in B. f(x, x, y, y, z, z) = f(y, z, x, z, x, y)$.

The following terminology was introduced by Bulatov and has proven to be extremely powerful, especially in the context of conservative clones.

▶ **Definition 18** ([16, 17]). *A pair $(a, b) \in B^2$ is called a* semilattice edge *if there exists $f \in \mathrm{Pol}(\mathfrak{B})$ of arity two such that $f(a, b) = b = f(b, a) = f(b, b)$ and $f(a, a) = a$. A two-element set $\{a, b\} \subseteq B$* has a semilattice edge *if (a, b) or (b, a) is a semilattice edge.*

A two-element subset $\{a, b\}$ of B is called a majority edge *if neither (a, b) nor (b, a) is a semilattice edge and there exists an $f \in \mathrm{Pol}(\mathfrak{B})$ of arity three whose restriction to $\{a, b\}$ is a majority operation.*

A two-element subset $\{a, b\}$ of B is called an affine edge *if it is not a majority edge, if neither (a, b) nor (b, a) is a semilattice edge, and there exists an $f \in \mathrm{Pol}(\mathfrak{B})$ of arity three whose restriction to $\{a, b\}$ is a minority operation.*

If $S \subseteq B$ and $(a, b) \in S^2$ is a semilattice edge then we say that (a, b) *is a semilattice edge on S*. Similarly, if $\{a, b\} \subseteq S$ is a majority edge (affine edge) then we say that $\{a, b\}$ is a *majority edge on S* (*affine edge on S*).

The main result about conservative finite structures and their CSPs is the following dichotomy, first proved by Bulatov, 14 years before the proof of the Feder-Vardi conjecture.

▶ **Theorem 19** ([16]; see also [3, 17, 18]). *Let $\mathfrak{B}$ be a finite structure with a finite relational signature such that $\mathrm{Pol}(\mathfrak{B})$ is conservative. Then precisely one of the following holds:*

1. *$\mathrm{Pol}(\mathfrak{B})$ contains a Siggers operation; in this case, $\mathrm{CSP}(\mathfrak{B})$ is in P.*
2. *There exist distinct $a, b \in B$ such that for every $f \in \mathrm{Pol}(\mathfrak{B})^{(n)}$ the restriction of f to $\{a, b\}^n$ is a projection. In this case, $\mathrm{CSP}(\mathfrak{B})$ is NP-complete.*

Note that this means that $\mathrm{Pol}(\mathfrak{B})$ contains a Siggers operation if and only if for all two elements $a, b \in B$ the set $\{a, b\}$ is a majority edge, an affine edge, or there is a semilattice edge on $\{a, b\}$.

2.5 The k-Consistency Procedure

We present in the following the k-consistency procedure. It was introduced in [2] for finite structures and extended to infinite structures in several equivalent ways, for example in terms of Datalog programs, existential pebble games, and finite variable logics [8]. Also see [39] for recent results about the power of k-consistency for infinite-domain CSPs.

Let τ be a finite relational signature and let $k, l \in \mathbb{N}$ with $k < l$ and let $\mathfrak{B}$ be a fixed τ-structures with finitely many orbits of l-tuples. We define $\mathfrak{B}'$ to be the expansion of $\mathfrak{B}$ by all orbits of n-tuples for every $n \leq l$. We denote the extended signature of $\mathfrak{B}'$ by τ'. Let $\mathfrak{A}$ be an arbitrary finite τ-structure. A *partial l-decoration of* $\mathfrak{A}$ is a set g of atomic τ'-formulas such that

1. the variables of the formulas from g are a subset of A and denoted by $\mathrm{Var}(g)$,
2. $|\mathrm{Var}(g)| \leq l$,
3. the τ-formulas in g hold in $\mathfrak{A}$, where variables are interpreted as domain elements of $\mathfrak{A}$,
4. the conjunction over all formulas in g is satisfiable in $\mathfrak{B}'$.

A partial l-decoration g of $\mathfrak{A}$ is called *maximal* if there exists no partial l-decoration h of $\mathfrak{A}$ with $\mathrm{Var}(g) = \mathrm{Var}(h)$ such that $g \subsetneq h$. We denote the set of maximal partial l-decorations of $\mathfrak{A}$ by $\mathcal{R}^l_{\mathfrak{A}}$. Note that a fixed finite set of at most l variables, there are only finitely many partial l-decorations of $\mathfrak{A}$, because $\mathfrak{B}$ has by assumption finitely many orbits of l-tuples. Since this set is constant and can be precomputed, the set $\mathcal{R}^l_{\mathfrak{A}}$ can be computed efficiently. Then the (k,l)-*consistency procedure for* $\mathfrak{B}$ is the following algorithm.

Algorithm 1 (k,l)-consistency procedure for $\mathfrak{B}$.

Input : A finite τ-structure $\mathfrak{A}$.
1 **compute** $\mathcal{H} := \mathcal{R}^l_{\mathfrak{A}}$.
2 **repeat**
3 For every $f \in \mathcal{H}$ with $\mathrm{Var}(f) \leq k$ and every $U \subseteq A$ with $|U| \leq l - k$, if there does not exist $g \in \mathcal{H}$ with $f \subseteq g$ and $U \subseteq \mathrm{Dom}(g)$, then remove f from $\mathcal{H}$.
4 **until** $\mathcal{H}$ *does not change*
5 **if** $\mathcal{H}$ *is empty* **then**
6 **return** Reject.
7 **else**
8 **return** Accept.

Since $\mathcal{R}^l_{\mathfrak{A}}$ is of polynomial size (in the size of A) and the (k,l)-consistency procedure removes in step 3. at least one element from $\mathcal{R}^l_{\mathfrak{A}}$ the algorithm has a polynomial run time. The $(k,k+1)$-consistency procedure is also called k-*consistency procedure*. The $(2,3)$-consistency procedure is called *path consistency procedure*.[1]

▶ **Definition 20.** *Let $\mathfrak{B}$ be a relation τ-structure as defined before. Then the* (k,l)-consistency procedure for $\mathfrak{B}$ solves $\mathrm{CSP}(\mathfrak{B})$ *if the satisfiable instances of* $\mathrm{CSP}(\mathfrak{B})$ *are precisely the accepted instances of the (k,l)-consistency procedure.*

▶ Remark 21. Let $\mathbf{A}$ be a relation algebra with a normal representation $\mathfrak{B}$. We will in the following say that the k-consistency procedure solves $\mathrm{NSP}(\mathbf{A})$ if it solves $\mathrm{CSP}(\mathfrak{B})$. This definition is justified by the correspondence of NSPs and CSPs from Theorem 12.

▶ **Theorem 22** ([33])**.** *Let $\mathfrak{B}$ be a finite τ-structure. Then the following are equivalent:*
1. *There exist $k \in \mathbb{N}$ such that the k-consistency procedure solves* $\mathrm{CSP}(\mathfrak{B})$.
2. *$\mathfrak{B}$ has a 3-ary weak near-unanimity polymorphism f and a 4-ary weak near-unanimity polymorphism g such that: $\forall x, y, z \in B.\ f(y,x,x) = g(y,x,x,x)$.*

Let $\mathfrak{A}_0$ be the atom structure of a relation algebra $\mathbf{A}$ with a normal representation $\mathfrak{B}$. We finish this section by connecting the solvability of $\mathrm{CSP}(\mathfrak{A}_0)$ by k-consistency (or its characterization in terms of polymorphims from the previous proposition) with the solvability of $\mathrm{CSP}(\mathfrak{B})$ by k-consistency. By Remark 21 this gives a criterion for the solvability of $\mathrm{NSP}(\mathbf{A})$ by the k-consistency procedure.

The following theorem is from [39] building on ideas from [14]. We present it here in a specific formulation that already incorporates a correspondence between polymorphisms of the atom structure and canonical operations. For more details see [11, 12].

[1] Some authors also call it the *strong path consistency algorithm*, because some forms of the definition of the path consistency procedure are only equivalent to our definition of the path consistency procedure if $\mathfrak{B}$ has a transitive automorphism group.

▶ **Theorem 23** ([39]). *Let* $\mathfrak{B}$ *be a normal representation of a finite relation algebra* $\mathbf{A}$ *and* $\mathfrak{A}_0$ *the atom structure* $\mathbf{A}$*. If* $\mathrm{Pol}(\mathfrak{A}_0)$ *contains a* 3*-ary weak near-unanimity polymorphism* f *and a* 4*-ary weak near-unanimity polymorphism* g *such that* $\forall x, y, z \in B.\ f(y, x, x) = g(y, x, x, x)$*, then* $\mathrm{NSP}(\mathbf{A})$ *is solved by the* $(4, 6)$*-consistency algorithm.*

3 The Undecidability of RBCP, CON, and PC

In order to view RBCP as a decision problem, we need the following definitions. Let FRA be the set of all relation algebras $\mathbf{A}$ with domain $\mathcal{P}(\{1, \ldots, n\})$.

▶ **Definition 24** (RBCP). *We define the following subsets of* FRA*:*

- RBCP *denotes the set such that* $\mathrm{NSP}(\mathbf{A})$ *is in P.*
- RBCP^c *denotes* $\mathrm{FRA} \setminus \mathrm{RBCP}$*.*
- CON *denotes the set such that* $\mathrm{NSP}(\mathbf{A})$ *is solved by* k*-consistency for some* $k \in \mathbb{N}$*.*
- PC *denotes the set such that* $\mathrm{NSP}(\mathbf{A})$ *is solved by path consistency.*

The following theorem is our first result. Note that this can be seen as a negative answer to Hirsch's Really Big Complexity Problem [27].

▶ **Theorem 25.** RBCP *is undecidable,* CON *is undecidable, and* PC *is undecidable.*

In our undecidability proofs we reduce from the following well-known undecidable problem for relation algebras [25].

▶ **Definition 26** (Rep). *Let* Rep *be the computational problem of deciding for a given* $\mathbf{A} \in \mathrm{FRA}$ *whether* $\mathbf{A}$ *has a representation.*

In our proof we also use the fact that there exists $\mathbf{U} \in \mathrm{FRA}$ such that $\mathrm{NSP}(\mathbf{U})$ is undecidable [29]. Note that $\mathbf{U} \in \mathrm{Rep}$ since the network satisfaction problem for non-representable relation algebras is trivial and therefore decidable.

Proof of Theorem 25. We reduce the problem Rep to RBCP^c. Consider the following reduction $f\colon \mathrm{FRA} \to \mathrm{FRA}$. For a given $\mathbf{A} \in \mathrm{FRA}$, we define $f(\mathbf{A}) := \mathbf{A} \times \mathbf{U}$.

▷ Claim 1. If $\mathbf{A} \in \mathrm{Rep}$ then $f(\mathbf{A}) \in \mathrm{RBCP}^c$. If $\mathbf{A}$ is representable, then $\mathbf{A} \times \mathbf{U}$ is representable by the first part of Lemma 9. Then there is a polynomial-time reduction from $\mathrm{NSP}(\mathbf{U})$ to $\mathrm{NSP}(\mathbf{A} \times \mathbf{U})$ by Lemma 10. This shows that $\mathrm{NSP}(\mathbf{A} \times \mathbf{U})$ is undecidable, and hence $f(\mathbf{A})$ is in RBCP^c.

▷ Claim 2. If $\mathbf{A} \in \mathrm{FRA} \setminus \mathrm{Rep}$ then $f(\mathbf{A}) \in \mathrm{RBCP}$. If $\mathbf{A}$ is not representable, then $\mathbf{A} \times \mathbf{U}$ is not representable by the second part of Lemma 9, and hence $\mathrm{NSP}(\mathbf{A} \times \mathbf{U})$ is trivial and in P, and therefore in RBCP.

Clearly, f is computable (even in polynomial time). Since Rep is undecidable [25], this shows that RBCP^c, and hence RBCP, is undecidable as well. The proof for CON and PC is analogous; all we need is the fact that $\mathrm{NSP}(\mathbf{U}) \notin \mathrm{CON}$ and $\mathrm{NSP}(\mathbf{U}) \notin \mathrm{PC}$. ◀

4 Tractability via k-Consistency

We provide in this section a criterion that ensures solvability of NSPs by the k-consistency procedure (Theorem 30). A relation algebra $\mathbf{A}$ is called *symmetric* if all its elements are symmetric, i.e., $\breve{a} = a$ for every $a \in A$. We will see in the following that the assumption on $\mathbf{A}$ to be symmetric will simplify the atom structure A_0 of $\mathbf{A}$, which has some advantages in the upcoming arguments.

▶ **Definition 27.** *Let* $\mathbf{A}$ *be a finite symmetric relation algebra with set of atoms* A_0*. We say that* $\mathbf{A}$ *admits a* Siggers behavior *if there exists an operation* $s\colon A_0^6 \to A_0$ *such that*
1. *s preserves the allowed triples of* $\mathbf{A}$*,*
2. $\forall x_1, \dots, x_6 \in A_0.\ s(x_1, \dots, x_6) \in \{x_1, \dots, x_6\}$*,*
3. *s satisfies the Siggers identity:* $\forall x, y, z \in A_0.\ s(x, x, y, y, z, z) = s(y, z, x, z, x, y)$*.*

▶ Remark 28. We mention that if $\mathbf{A}$ has a normal representation $\mathfrak{B}$, then $\mathbf{A}$ admits a Siggers behavior if and only if $\mathfrak{B}$ has a pseudo-Siggers polymorphism which is canonical with respect to $\mathrm{Aut}(\mathfrak{B})$; see [14].

We say that a finite symmetric relation algebra $\mathbf{A}$ *has all* 1*-cycles* if for every $a \in A_0$ the triple (a, a, a) is allowed. Details on the notion of cycles from the relation algebra perspective can be found in [36]. The relevance of the existence of 1-cycles for constraint satisfaction comes from the following observation.

▶ **Lemma 29.** *Let* $\mathbf{A}$ *be a finite symmetric relation algebra with a normal representation* $\mathfrak{B}$ *that has a binary injective polymorphism. Then* $\mathbf{A}$ *has all* 1*-cycles.*

Proof. Let i be a binary injective polymorphism of $\mathfrak{B}$ and let $a \in A_0$ be arbitrary. Consider $x_1, x_2, y_1, y_2 \in B$ such that $a^{\mathfrak{B}}(x_1, x_2)$ and $a^{\mathfrak{B}}(y_1, y_2)$. The application of i on the tuples (x_1, x_1, x_2) and (y_1, y_2, y_2) results in a substructure of $\mathfrak{B}$ that witnesses that (a, a, a) is an allowed triple. ◀

▶ **Theorem 30.** *Let* $\mathbf{A}$ *be a finite symmetric relation algebra with a normal representation* $\mathfrak{B}$*. Suppose that the following holds:*
1. $\mathbf{A}$ *has all* 1*-cycles.*
2. $\mathbf{A}$ *admits a Siggers behavior.*

Then the $\mathrm{NSP}(\mathbf{A})$ *can be solved by the* $(4, 6)$*-consistency procedure.*

We will outline the proof of Theorem 30 and cite some results from the literature that we will use. Assume that $\mathbf{A}$ is a finite symmetric relation algebra that satisfies the assumptions of Theorem 30. Since $\mathbf{A}$ admits a Siggers behavior there exists an operation $s\colon A_0^6 \to A_0$ that is by 1. and 2. in Definition 27 a polymorphism of the atom structure $\mathfrak{A}_0$ (see Paragraph 2.4.2). By Remark 17, $\mathrm{Pol}(\mathfrak{A}_0)$ is a conservative operation clone. Recall the notion of semilattice, majority, and affine edges for conservative clones (cf. Definition 18). Since s is by 3. a Siggers operation, Theorem 19 implies that every edge in $\mathfrak{A}_0$ is semilattice, majority, or affine.

Our goal is to show that there are no affine edges in $\mathfrak{A}_0$, since this implies that there exists $k \in \mathbb{N}$ such that $\mathrm{CSP}(\mathfrak{A}_0)$ can be solved by k-consistency [17]. We present this fact here via the characterization of (k, l)-consistency in terms of weak near-unanimity polymorphisms from Theorem 22.

▶ **Proposition 31** (cf. Corollary 3.2 in [31])**.** *Let* $\mathfrak{A}_0$ *be a finite conservative relational structure with a Siggers polymorphism and no affine edge. Then* $\mathfrak{A}_0$ *has a* 3*-ary weak near-unanimity polymorphism* f *and a* 4*-ary weak near-unanimity polymorphism* g *such that*

$$\forall x, y, z \in B.\ f(y, x, x) = g(y, x, x, x).$$

Note that the existence of the weak near-unanimity polymorphisms from Proposition 31 would finish the proof of Theorem 30, because Theorem 23 implies that in this case $\mathrm{NSP}(\mathbf{A})$ can be solved by the $(4, 6)$-consistency procedure. We therefore want to prove that there are no affine edges in $\mathfrak{A}_0$. We start by analyzing the different types of edges in the atom structure $\mathfrak{A}_0$ and obtain results about their appearance (see Section 4.1).

Fortunately, there is the following result by Alexandr Kazda about binary structures with a conservative polymophism clone. A *binary structure* is a structure where all relations have arity at most two.

▶ **Theorem 32** (Theorem 4.5 in [31]). *If $\mathfrak{A}$ is a finite binary conservative relational structure with a Siggers polymorphism, then $\mathfrak{A}$ has no affine edges.*

Notice that we cannot simply apply this theorem to the atom structure $\mathfrak{A}_0$, since the maximal arity of its relations is three. We circumvent this obstacle by defining for $\mathfrak{A}_0$ a closely related binary structure $\mathfrak{A}_0^{\mathrm{b}}$, which we call the "binarisation of $\mathfrak{A}_0$":

▶ **Definition 33.** *We denote by $\mathfrak{A}_0^{\mathrm{b}}$ the structure with domain A_0 and the following relations:*
- *a unary relation U_S for each subset S of A_0;*
- *for every $a \in A_0$ the binary relation $R_a := \{(x, y) \in A_0^2 \mid (a, x, y) \in R\}$;*
- *a relation for every union of relations of the form R_a.*

In the next step we investigate how $\mathrm{Pol}(\mathfrak{A}_0)$ and $\mathrm{Pol}(\mathfrak{A}_0^{\mathrm{b}})$ relate to each other. It follows from these observations that $\mathfrak{A}_0^{\mathrm{b}}$ does not have an affine edge. In other words, it only has semilattice and majority edges. The crucial step in our proof is to transfer a witness of this fact to $\mathfrak{A}_0$ and conclude that also $\mathfrak{A}_0$ has no affine edge. The detailed proofs can be found in the extended version of the article [13] and in the PhD thesis of the second author [32].

4.1 Results about the Atom Structure

In this section we present some of our findings about the atom structure. We obtain conditions on the atom structure (namely the ternary relation R) that imply the (non-)existence of semilatice edges in the atom structure. As we explained in the previous section, these results are the starting point for our proof of Theorem 30.

For the sake of notation, we make some global assumptions for this section. Let $\mathbf{A}$ be a finite relation algebra that satisfies the assumptions from Theorem 30. We denote by $\mathfrak{A}_0$ the atom structure of $\mathbf{A}$ (Definition 15). Since $\mathbf{A}$ is a symmetric relation algebra, the relation $R^{\mathfrak{A}_0}$ is totally symmetric. Furthermore, we can drop the binary relation $E^{\mathfrak{A}_0}$, since it consists only of loops and does not change the set of polymorphisms. Let $s \in \mathrm{Pol}(\mathfrak{A}_0)$ be the Siggers operation that exists by the assumptions in Theorem 30. This implies by Theorem 19 for every $a, b \in A_0$ that the set $\{a, b\}$ is a majority edge or an affine edge, or that there is a semilattice edge on $\{a, b\}$. The different types of edges are witnessed by certain operations that we get from Proposition 3.1.in [17]: there exist a binary operation $f \in \mathrm{Pol}(\mathfrak{A}_0)$ and ternary operations $g, h \in \mathrm{Pol}(\mathfrak{A}_0)$ such that for every two element subset C of A_0,
- $f|_C$ is a semilattice operation if C has a semilattice edge, and $f|_C(x, y) = x$ otherwise;
- $g|_C$ is a majority operation if C is a majority edge, $g|_C(x, y, z) = x$ if C is affine and $g|_C(x, y, z) = f|_C(f|_C(x, y), z)$ if C has a semilattice edge;
- $h|_C$ is a minority operation if C is an affine edge, $h|_C(x, y, z) = x$ if C is majority and $h|_B(x, y, z) = f|_C(f|_C(x, y), z)$ if C has a semilattice edge.

We will fix these operations and introduce the following terminology. A tuple $(a, b) \in A_0$ is called *f-sl* if $f(a, b) = b = f(b, a)$ holds. Next, we prove several important properties of the relation R: that it must contain certain triples (Lemma 34), that it must not contain certain other triples (Lemma 35), and that it is affected by the presence of semilattice edges in $\mathbf{A}_0$ (Lemma 36 and Lemma 37).

▶ **Lemma 34.** *The relation R of the atom structure $\mathfrak{A}_0$ has the following properties:*
- *for all $a \in A_0$ we have $(a, a, a) \in R$.*
- *for all $a, b \in A_0$ we have $(a, a, b) \in R$ or $(a, b, b) \in R$;*

Proof. The first item follows from the assumption that $\mathbf{A}$ has all 1-cycles.

For the second item observe that $\{a, \mathrm{Id}\}$ cannot be a majority edge. Otherwise,

$$g((a,a,\mathrm{Id}),(\mathrm{Id},a,a),(\mathrm{Id},\mathrm{Id},\mathrm{Id})) = (\mathrm{Id},a,\mathrm{Id}) \in R$$

is a contradiction to the properties of Id. Furthermore, (a, Id) cannot be f-sl, since

$$f((a,a,\mathrm{Id}),(\mathrm{Id},a,a)) = (\mathrm{Id},a,\mathrm{Id}) \in R.$$

This is again a contradiction. Since these observations also hold for b instead of a we have the following case distinction.

1. (Id, a) is f-sl and (Id, b) is f-sl. It follows that $f((a,a,\mathrm{Id}),(\mathrm{Id},b,b)) \in \{(a,a,b),(a,b,b)\}$. Since f preserves R, $(a,a,\mathrm{Id}) \in R$, and $(\mathrm{Id},b,b) \in R$ we get that $f((a,a,\mathrm{Id}),(\mathrm{Id},b,b)) \in R$. This implies that $(a,a,b) \in R$ or $(a,b,b) \in R$.
2. (Id, a) is f-sl and $\{b, \mathrm{Id}\}$ is affine. By the definition of f we get $f((b,b,\mathrm{Id}),(\mathrm{Id},a,a)) \in \{(b,a,a),(b,b,a)\}$. By the same argument as in Case 1 we get that $(a,a,b) \in R$ or $(a,b,b) \in R$.
3. (Id, b) is f-sl and $\{a, \mathrm{Id}\}$ is affine. This case is analogous to Case 2.
4. $\{a, \mathrm{Id}\}$ is affine and $\{b, \mathrm{Id}\}$ is affine. Observe that

   $$g((a,\mathrm{Id},a),(\mathrm{Id},b,b),(\mathrm{Id},\mathrm{Id},\mathrm{Id})) \in \{(a,b,a),(a,b,b)\},$$

   since $g(a,b,\mathrm{Id}) \in \{a,b,\mathrm{Id}\}$ and the triple (a,b,Id) is forbidden. As in the cases before it follows that $(a,a,b) \in R$ or $(a,b,b) \in R$.

This concludes the proof of the second item. ◀

▶ **Lemma 35.** *Let $a,b,c \in A_0$ be such that $(a,b,c) \notin R$ and $|\{a,b,c\}| = 3$. Then there are $x,y \in \{a,b,c\}$ such that $(x,x,y) \notin R$.*

Proof. We first suppose that there is a semilattice edge on $\{a,b,c\}$. Without loss of generality we assume that (a,b) is f-sl. If $f(c,a) = c$ then $(a,a,c) \notin R$ or $(b,a,a) \notin R$ because otherwise

$$f((a,a,c),(b,a,a)) = (b,a,c) \in R$$

contradicting our assumption. If $f(c,a) = a$ then $(b,c,c) \notin R$ or $(a,a,c) \notin R$ because otherwise

$$f((b,c,c),(a,a,c)) = (b,a,c) \in R$$

which is again a contradiction. Hence, in all the cases we found $x,y \in \{a,b,c\}$ such that $(x,x,y) \notin R$ and are done. In the following we therefore assume that there is no semilattice edge on $\{a,b,c\}$.

Next we suppose that there is an affine edge on $\{a,b,c\}$. Without loss of generality we assume that $\{a,b\}$ is an affine edge. Since there are no semilattice edges on $\{a,b,c\}$ we distinguish the following two cases:

1. $\{a,c\}$ is an affine edge. In this case $(c,a,a) \notin R$ or $(a,b,a) \notin R$ because otherwise

   $$h((c,a,a),(a,a,a),(a,b,a)) = (c,b,a) \in R.$$

2. $\{a,c\}$ is a majority edge. In this case $(a,a,c) \notin R$ or $(a,b,a) \notin R$ or $(b,b,c) \notin R$, because otherwise

   $$h((a,a,c),(a,b,a),(b,b,c)) = (b,a,c) \in R.$$

In both cases we again found $x, y \in \{a, b, c\}$ such that $(x, x, y) \notin R$ and are done. We therefore suppose in the following that there are no affine edges on $\{a, b, c\}$. Hence, all edges on $\{a, b, c\}$ are majority edges. Then $(a, a, c) \notin R$ or $(a, b, a) \notin R$ or $(b, b, c) \notin R$ because otherwise

$$g((a, a, c), (a, b, a), (b, b, c)) = (a, b, c) \in R.$$

Thus, also in this case we found $x, y \in \{a, b, c\}$ such that $(x, x, y) \notin R$. ◀

The next lemma states that the edge type on $\{a, b\}$ is predetermined whenever a triple (a, a, b) is not in R.

▶ **Lemma 36.** *Let $a, b \in A_0$ be such that $(a, a, b) \notin R$. Then (a, b) is a semilattice edge in $\mathfrak{A}_0$ but (b, a) is not.*

Proof. By Lemma 34 we know that $(a, b, b) \in R$, $(a, a, a) \in R$, and $(b, b, b) \in R$. Assume for contradiction that $\{a, b\}$ is a majority edge. Then

$$g((a, a, a), (a, b, b), (b, b, a)) = (a, b, a)$$

which contradicts the fact that g preserves R. Assume next that $\{a, b\}$ is an affine edge. Then

$$h((a, b, b), (b, a, b), (b, b, b)) = (a, a, b)$$

which again contradicts that h preserves R. Finally, if (b, a) is a semilattice edge then

$$f((a, b, b), (b, a, b)) = (a, a, b)$$

which contradicts the assumption that f preserves R. If follows that (a, b) is the only semilattice edge on $\{a, b\}$ and therefore $f(a, b) = b = f(b, a)$ holds. ◀

▶ **Lemma 37.** *Let $a, a', b, c \in A_0$ be such that $(a, b, c) \notin R$, $(a, a, b) \notin R$, and $(a', b, c) \in R$. Then (a', a) is not a semilattice edge.*

Proof. Assume for contradiction (a', a) is a semilattice edge, i.e., there exists $p \in \mathrm{Pol}(\mathfrak{A}_0)$ with $p(a, a') = a = p(a', a)$. Note that by Lemma 34 it follows that $(a, a, a) \in R$ and $(a, b, b) \in R$.

▷ Claim 1. $p(b, a) = a$ implies $p(a, b) = b$. This follows immediately, since otherwise $p((a, b, b), (b, a, b)) = (a, a, b) \in R$ is a contradiction.

▷ Claim 2. $(a, a, c) \notin R$. We assume the opposite and consider the only two possible cases for $p(b, a)$.

1. $p(b, a) = b$: We get a contradiction by $p((a', b, c), (a, a, c)) = (a, b, c) \in R$.
2. $p(b, a) = a$: By Claim 1 we know that $p(a, b) = b$ follows. Then $p((a, a, c), (a', b, c)) = (a, b, c) \in R$ contrary to our assumptions.

▷ Claim 3. $p(c, a) = a$ implies $p(a, c) = c$. Lemma 34 together with Claim 2 implies that $(a, c, c) \in R$. Now Claim 3 follows immediately, since otherwise $p((a, c, c), (c, a, c)) = (a, a, c) \in R$, which contradicts Claim 2.

We finally make a case distinction for all possible values of p on (b, a) and (c, a).

1. $p(b, a) = b$ and $p(c, a) = c$: We get a contradiction by $p((a', b, c), (a, a, a)) = (a, b, c) \in R$.
2. $p(b, a) = b$ and $p(c, a) = a$: We get a contradiction by $p((a', b, c), (a, a, a)) = (a, b, a) \in R$.
3. $p(b, a) = a$ and $p(c, a) = c$: $p((a', b, c), (a, a, a)) = (a, a, c) \in R$ contradicts Claim 2.
4. $p(b, a) = a$ and $p(c, a) = a$: By Claim 1 we get $p(a, b) = b$ and by Claim 3 we get $p(a, c) = c$. This yields a contradiction by $p((a, a, a), (a', b, c)) = (a, b, c) \in R$. ◀

5 k-Consistency and Symmetric Flexible-Atom Algebras

We apply our result from Section 4 to the class of finite symmetric relation algebras with a flexible atom and obtain a k-consistency versus NP-complete complexity dichotomy.

A finite relation algebra $\mathbf{A}$ is called *integral* if the element Id is an atom of $\mathbf{A}$, i.e., $\mathrm{Id} \in A_0$. We define flexible atoms for integral relation algebras only. For a discussion about integrality and flexible atoms consider Section 3 in [12].

▶ **Definition 38.** *Let* $\mathbf{A} \in \mathrm{RA}$ *be finite and integral. An atom* $s \in A_0$ *is called* flexible *if for all* $a, b \in A \setminus \{\mathrm{Id}\}$ *it holds that* $s \leq a \circ b$.

Relation algebras with a flexible atom have been studied intensively in the context of the *flexible atoms conjecture* [1, 35]. It can be shown easily that finite relation algebras with a flexible atom have a normal representation [11, 12]. In [12] the authors obtained a P versus NP-complete complexity dichotomy for NSPs of finite symmetric relation algebras with a flexible atom (assuming $\mathrm{P} \neq \mathrm{NP}$). In the following we strengthen this result and prove that every problem in this class can be solved by k-consistency for some $k \in \mathbb{N}$ or is NP-complete (without any complexity-theoretic assumptions).

We combine Theorem 30 with the main result of [12] to obtain the following characterization for NSPs of finite symmetric relation algebras with a flexible atom that are solved by the $(4, 6)$-consistency procedure. Note that the difference of Theorem 39 and the related result in [12] is the algorithm that solves the problems in P.

▶ **Theorem 39.** *Let* $\mathbf{A}$ *be a finite symmetric integral relation algebra with a flexible atom. Then the following are equivalent:*

- $\mathbf{A}$ *admits a Siggers behavior.*
- $\mathrm{NSP}(\mathbf{A})$ *can be solved by the* $(4, 6)$*-consistency procedure.*

Proof. Every finite symmetric relation algebra $\mathbf{A}$ with a flexible atom has a normal representation $\mathfrak{B}$ by Proposition 3.5 in [12].

If the first item holds it follows from Proposition 6.1. in [12] that $\mathfrak{B}$ has a binary injective polymorphism. By Lemma 29 the relation algebra $\mathbf{A}$ has all 1-cycles. We apply Theorem 30 and get that the second item in Theorem 39 holds.

We prove the converse implication by showing the contraposition. Assume that the first item is not satisfied. Then Theorem 9.1 in [12] implies that there exists a polynomial-time reduction from $\mathrm{CSP}(K_3)$ to $\mathrm{NSP}(\mathbf{A})$ which preserves solvability by the (k, l)-consistency procedure. The problem $\mathrm{CSP}(K_3)$ is the 3-colorability problem which is known (e.g., by [4]) to be not solvable by the (k, l)-consistency procedure for every $k, l \in \mathbb{N}$. Hence $\mathrm{NSP}(\mathbf{A})$ cannot be solved by the $(4, 6)$-consistency procedure. ◀

As a consequence of Theorem 39 we obtain the following strengthening of the complexity dichotomy NSPs of finite symmetric integral relation algebra with a flexible atom [12].

▶ **Corollary 40** (Complexity Dichotomy)**.** *Let* $\mathbf{A}$ *be a finite symmetric integral relation algebra with a flexible atom. Then* $\mathrm{NSP}(\mathbf{A})$ *can be solved by the* $(4, 6)$*-consistency procedure, or it is NP-complete.*

Proof. Suppose that the first condition in Theorem 39 holds. Then Theorem 39 implies that $\mathrm{NSP}(\mathbf{A})$ can be solved by the $(4, 6)$-consistency procedure. If the first condition in Theorem 39 is not satisfied it follows from Theorem 9.1. in [12] that $\mathrm{NSP}(\mathbf{A})$ is NP-complete. ◀

6 The Complexity of the Meta Problem

In this section we study the computational complexity of deciding for a given finite symmetric relation algebra $\mathbf{A}$ with a flexible atom whether the k-consistency algorithm solves $\mathrm{NSP}(\mathbf{A})$. We show that this problem is decidable in polynomial time even if $\mathbf{A}$ is given by the restriction of its composition table to the atoms of $\mathbf{A}$: note that this determines a symmetric relation algebra uniquely, and that this is an (exponentially) more succinct representation of $\mathbf{A}$ compared to explicitly storing the full composition table.

▶ **Definition 41** (Meta Problem). *We define* Meta *to be the following computational problem.*
Input: *the composition table of a finite symmetric relation algebra* $\mathbf{A}$ *restricted to* A_0.
Question: *is there a* $k \in \mathbb{N}$ *such that* k*-consistency solves* $\mathrm{NSP}(\mathbf{A})$*?*

Our proof of Theorem 25 shows that Meta is undecidable as well.

▶ **Theorem 42.** Meta *can be decided in polynomial time if the input is restricted to finite symmetric integral relation algebras* $\mathbf{A}$ *with a flexible atom.*

Proof. By Theorem 39 it suffices to test the existence of an operation $f\colon A_0^6 \to A_0$ which satisfies conditions 1.-3. in this theorem. The three conditions can clearly be checked in polynomial time, so we already know that Meta is in NP.

Note that the search for f may be phrased as an instance of $\mathrm{CSP}(\mathfrak{A}_0)$ with $|A|^6$ variables. Using the fact that the k-consistency procedure is one-sided correct even in the case that $\mathrm{CSP}(\mathfrak{A}_0)$ is NP-hard (i.e., if the procedure rejects a given instance of $\mathrm{CSP}(\mathfrak{A}_0)$, then the instance is always unsatisfiable), we may use a standard self-reducibility argument (see, e.g., [20]) to obtain a polynomial-time algorithm for finding f. ◀

7 Conclusion and Open Questions

The question whether the network satisfaction problem for a given finite relation algebra can be solved by the famous k-consistency procedure is undecidable. Our proof of this fact heavily relies on prior work of Hirsch [29] and of Hirsch and Hodkinson [25] and shows that almost any question about the network satisfaction problem for finite relation algebras is undecidable.

However, if we further restrict the class of finite relation algebras, one may obtain strong classification results. We have demonstrated this for the class of finite symmetric integral relation algebras with a flexible atom (Theorem 40); the complexity of deciding whether the conditions in our classification result hold drops from undecidable to P (Theorem 42). One of the remaining open problems is a characterisation of the power of k-consistency for the larger class of all finite relation algebras with a normal representation.

Our main result (Theorem 30) is a sufficient condition for the applicability of the k-consistency procedure; the condition does not require the existence of a flexible atom but applies more generally to finite symmetric relation algebras $\mathbf{A}$ with a normal representation. Our condition consists of two parts: the first is the existence of all 1-cycles in $\mathbf{A}$, the second is that $\mathbf{A}$ admits a Siggers behavior. We conjecture that dropping the first part of the condition leads to a necessary and sufficient condition for solvability by the k-consistency procedure.

▶ **Conjecture 43.** *A finite symmetric relation algebra* $\mathbf{A}$ *with a normal representation admits a Siggers behavior if and only if* $\mathrm{NSP}(\mathbf{A})$ *can be solved by the* k*-consistency procedure for some* $k \in \mathbb{N}$.

$\circ$	Id	E	N
Id	Id	E	N
E	E	Id	N
N	N	N	1

Figure 2 Multiplication table of the relation algebra $\mathbf{C}$.

Note that this conjecture generalises Theorem 39. Both directions of the conjecture are open. However, the forward direction of the conjecture is true if $\mathbf{A}$ has a normal representation with a primitive automorphism group: in this case, it is known that a Siggers behavior implies the existence of all 1-cycles [10], and hence the claim follows from our main result (Theorem 39). The following example shows a finite symmetric relation algebra $\mathbf{A}$ which does not have all 1-cycles and an imprimitive normal representation, but still NSP($\mathbf{A}$) can be solved by the k-consistency procedure for some $k \in \mathbb{N}$.

▶ **Example 44.** Theorem 30 is a sufficient condition for the NSP of a relation algebra $\mathbf{A}$ to be solved by the k-consistency procedure for some $k \in \mathbb{N}$. However, there exists a finite symmetric relation algebra $\mathbf{C}$ such that NSP($\mathbf{C}$) is solved by the 2-consistency procedure, but we cannot prove this by the methods used to obtain Theorem 30. Consider the relation algebra $\mathbf{C}$ with atoms $\{\mathrm{Id}, E, N\}$ and the multiplication table in Figure 2. This relation algebra has a normal representation, namely the expansion of the infinite disjoint union of the clique K_2 by all first-order definable binary relations. We denote this structure by $\overline{\omega K_2}$. One can observe that CSP($\overline{\omega K_2}$) and therefore also the NSP of the relation algebra can be solved by the $(2,3)$-consistency algorithm (for details see [32]).

The relation algebra $\mathbf{C}$ does not have all 1-cycles and therefore does not fall into the scope of Theorem 30. In fact, our proof of Theorem does not work for $\mathbf{C}$, because the CSP of the atom structure $\mathfrak{C}_0$ of $\mathbf{C}$ cannot be solved by the k-consistency procedure for some $k \in \mathbb{N}$. Hence, the reduction of NSP($\mathbf{C}$) to CSP($\mathfrak{C}_0$) (incorporated in Theorem 23) does not imply that NSP($\mathbf{C}$) can be solved by k-consistency procedure for some $k \in \mathbb{N}$.

The following problems are still open and are relevant for resolving Conjecture 43.

- Show Conjecture 43 if the normal representation of $\mathbf{A}$ has a primitive automorphism group.
- Characterise the power of the k-consistency procedure for the NSP of finite relation algebras with a normal representation whose automorphism group is imprimitive. In this case, there is a non-trivial definable equivalence relation. It is already known that if this equivalence relation has finitely many classes, then the NSP is NP-complete and the k-consistency procedure does not solve the NSP [10]. Similarly, the NSP is NP-complete if there are equivalence classes of finite size larger than two. It therefore remains to study the case of infinitely many two-element classes, and with infinitely many infinite classes. In both cases we wish to reduce the classification to the situation with a primitive automorphism group.

Finally, we ask whether it is true that if $\mathbf{A}$ is a finite symmetric relation algebra with a flexible atom and NSP($\mathbf{A}$) can be solved by the k-consistency procedure for some k, then it can also be solved by the $(2,3)$-consistency procedure? In other words, can we improve $(4,6)$ in Corollary 40 to $(2,3)$?

Abstract

We consider regular string-to-string functions, i.e. functions that are recognized by copyless streaming string transducers, or any of their equivalent models, such as deterministic two-way automata. We give yet another characterization, which is very succinct: finiteness-preserving functors from the category of semigroups to itself, together with a certain output function that is a natural transformation.

1 Introduction

This paper is about the regular string-to-string functions (see e.g. [17]). This is a fundamental class of functions; it is one of the standard generalizations of regular languages to produce string outputs (instead of merely accepting or rejecting inputs), covering examples such as

string reversal: $123 \mapsto 321$ duplication: $123 \mapsto 123123$

It has many equivalent descriptions, including deterministic two-way automata [22, Note 4], copyless streaming string transducers (SST) [1, Section 3] (or the earlier and very similar single-use restricted macro tree transducers [14, Section 5]), MSO transductions [13, Theorem 13], combinators [4, Section 2], a functional programming language [8, Section 6], λ-calculus with linear types [15, Theorem 3] (see also [19, Claim 6.2] and [18, Theorem 1.2.3]), decompositions *à la* Krohn–Rhodes [10, Theorem 18, item 4], etc.

The number of equivalent characterizations clearly indicates that the class of regular functions is important and worth studying. However, from a mathematical point of view, a disappointing phenomenon is that each of the known descriptions uses syntax that is more complicated than one could wish for.[1] These complications are perhaps minor annoyances, and the corresponding models are undeniably useful. Nevertheless, it would be desirable to have a model with a short and abstract definition, similar to the definition of recognizability of regular languages by finite semigroups.

[1] For example, the definition of a two-way automaton requires a discussion of endmarkers and what happens when the automaton loops. In an MSO transduction, an unwiedly copying mechanism is necessary. In an SST, one needs to be careful about bounding the copies among registers. The calculi of [4, 8] both have a long list of primitives. Similar remarks apply to the other formalisms.

This paper proposes such an abstract model. We prove that the regular string-to-string functions are exactly those that can be obtained by composing two functions

$$\Sigma^* \xrightarrow{\text{some semigroup homomorphism}} \mathsf{F}(\Gamma^*) \xrightarrow{\text{out}_{\Gamma^*}} \Gamma^*$$

where F is a *functor* from the category of semigroups to itself that maps finite semigroups to finite semigroups, and the output function out_{Γ^*} – not necessarily a homomorphism – is part of a family $\text{out}_A \colon \mathsf{F}A \to A$ that is natural in the semigroup A.

We use the name transducer semigroup for the model implicit in this description, i.e. a semigroup-to-semigroup functor F together with a natural transformation for producing outputs. One of the surprising features of this model is the fact that linear growth of the output size, which is one of the salient properties of the regular string-to-string functions, does not seem to be a trivial consequence of the definition.

2 Transducer semigroups and warm-up theorems

In this section, we define the model that is introduced in this paper, namely transducer semigroups. The purpose of this model is to recognize *string-to-string* functions, which are defined to be functions of type $\Sigma^* \to \Gamma^*$, for some finite alphabets Σ and Γ. Some results will work in the slightly more general case where the domain or codomain is a more general semigroup, but we focus on the string-to-string case for the sake of concreteness.

The model is defined using terminology based on category theory. However, we do not assume that the reader has a background in category theory, beyond the two most basic notions of category and functor. Recall that a *category* consists of objects with morphisms between them, such that the morphisms can be composed and each object has an identity morphism to itself. In this paper, we will be working mainly with two categories:

Sets. The objects are sets, the morphisms are functions between them.

Semigroups. The objects are semigroups, the morphisms are semigroup homomorphisms.

To transform categories, we use functors. Recall that a *functor* between two categories consists of two maps: one that assigns to each object A in the source category an object in the target category, and another one that assigns to each morphism $f \colon A \to B$ a morphism $\mathsf{F}f \colon \mathsf{F}A \to \mathsf{F}B$. These maps need to be consistent with composition of morphisms, and the identity must go to the identity.

▶ **Example 2.1.** The *forgetful functor* from the category of semigroups to the category of sets maps a semigroup to its underlying set, and a semigroup homomorphism to the corresponding function on sets. It is an example of a semigroup-to-set functor.

▶ **Example 2.2.** These constructions can be seen as semigroup-to-semigroup functors:

Tuples. This functor maps a semigroup A to its square $A \times A$, with the semigroup operation defined coordinate-wise. The functor extends to morphisms in the expected way. This functor also makes sense for higher powers, including infinite powers, such as A^ω.

Opposite. This functor maps a semigroup A to the semigroup where the underlying set is the same, but multiplication is reversed, i.e. the product of a and b in the new semigroup is the product b and a in the old semigroup. Morphisms are not changed by the functor: they retain the homomorphism property despite the change in the multiplication operation.

Lists. This functor maps a semigroup A to the free monoid A^* that consists of lists of elements of A equipped with concatenation. (When A is finite, it can be regarded as an alphabet, in which case we shall also call these lists "strings" or "words".) On morphisms, the functor is defined element-wise (or letter-wise). A similar construction would make sense as a set-to-semigroup functor.

Non-empty lists. A variant of the previous example, which sends a semigroup A to the free semigroup A^+ that consists of non-empty lists of elements in A.

Powerset. This (covariant) powerset functor maps a semigroup A to the powerset semigroup $\mathsf{P}A$, whose underlying set is the family of all subsets of A, endowed with the operation

$$(A_1, A_2) \quad \mapsto \quad \{a_1 a_2 \mid a_1 \in A_1 \text{ and } a_2 \in A_2\}.$$

We now present the central definition of this paper.

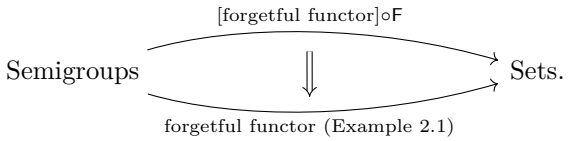
▶ **Definition 2.3** (Transducer semigroup). *A* transducer semigroup *consists of*

- *a semigroup-to-semigroup functor* F*,*
- *together with an* output mechanism *which associates to each semigroup* A *a function of type* $\mathsf{F}A \to A$ *called the* output function for A*,*

such that for every homomorphism $h\colon A \to B$*, the diagram below commutes:*

$$\begin{array}{ccc} \mathsf{F}A & \xrightarrow{\mathsf{F}h} & \mathsf{F}B \\ \downarrow{\scriptstyle \text{output function for } A} & & \downarrow{\scriptstyle \text{output function for } B} \\ A & \xrightarrow[h]{} & B \end{array}$$

In the language of category theory, a *natural transformation* between two semigroup-to-set functors G and K is a family of functions $f_A\colon \mathsf{G}A \to \mathsf{K}A$ such that $f_B \circ \mathsf{G}h = \mathsf{K}h \circ f_A$ for every semigroup homomorphism $h\colon A \to B$. So in Definition 2.3, the diagram says that the output mechanism is a natural transformation of type



Note that in a transducer semigroup, the output functions *are not necessarily homomorphisms*, which is why the forgetful semigroup-to-set functor appears above. This is important in view of the purpose of transducer semigroups, which is to define functions between semigroups, as explained in the following definition; asking out_B to be a homomorphism would severly restrict the functions that can be recognized.

▶ **Definition 2.4.** *We say that a function* $f\colon A \to B$ *between semigroups, not necessarily a homomorphism, is* recognized *by a transducer semigroup* (F, out) *if it can be decomposed as*

$$A \xrightarrow{h} \mathsf{F}B \xrightarrow{\text{out}_B} B \qquad \text{for some semigroup homomorphism } h.$$

The definition discusses functions between arbitrary semigroups, with no assumption on F, but we will mainly care about the special case – treated in Section 3 – where:

- the function is string-to-string[2] ($f\colon \Sigma^* \to \Gamma^*$), i.e. both the input and output semigroups are finitely generated free monoids;
- the functor F is *finiteness-preserving*, i.e. it maps finite semigroups to finite semigroups.

This special case will correspond to the regular string functions. Some minor results that do not assume F is finiteness-preserving are presented in Section 2.2: we characterize all functions (Theorem 2.10) and "recognizability reflecting" string-to-string functions (Theorem 2.13).

[2] Although this case involves monoids, which are a special case of semigroups, the use of a semigroup homomorphism that is not necessarily a monoid homomorphism is required to recognize functions such that $f(\varepsilon) \neq \varepsilon$. Furthermore, it will be useful in the proofs to work in the category of semigroups, rather than the category of monoids.

2.1 Examples and intuitions

▶ **Example 2.5.** Consider the transducer semigroup in which the functor is the identity, and the output mechanism is also the identity. The functions of type $A \to B$ that are recognized by this transducer semigroup are exactly the semigroup homomorphisms from A to B.

▶ **Example 2.6.** Consider the transducer semigroup in which

- the functor is the "opposite semigroup" functor from Example 2.2;
- the output function maps $a \in \mathsf{F}A$, seen as an element in A, to $aa \in A$.

The functions of type $A \to B$ that are recognized by this transducer semigroup are exactly those of the form $a \mapsto h(a)h(a)$ where $h\colon A \to B$ is some "anti-homomorphism", i.e. satisfies $h(a_1a_2) = h(a_2)h(a_1)$ for all $a_1, a_2 \in A$. In particular, if h is the string reversal function $\texttt{rev}$ on the free monoid Σ^*, which is also a semigroup, then we get the "reverse then duplicate" function that maps a string w over the alphabet Σ to $\texttt{rev}(w) \cdot \texttt{rev}(w)$.

▶ **Example 2.7.** We present here a transducer semigroup that recognizes the squaring function $w \in \Sigma^* \mapsto w^{|w|} \in \Sigma^*$ (illustrated by $\texttt{123} \mapsto \texttt{123123123}$) for any alphabet Σ.

The functor maps A to $A \times \mathbb{N}$, with the semigroup structure defined componentwise ($\mathbb{N} = \{0, 1, \dots\}$ is equipped with addition), and making the morphisms act on the left component. The output mechanism $A \times \mathbb{N} \to A$ is defined below:

$$\text{for } n \geq 1,\ (a, n) \mapsto a^n \qquad \underbrace{(a, 0) \mapsto a}_{\text{we handle this case separately because } a^0 \text{ does not make sense in an arbitrary semigroup}}$$

▶ **Example 2.8.** Our last example function is

$$w \in \{a, b, c\}^* \quad \mapsto \quad (\text{longest } c\text{-free suffix of } w) \cdot (\text{longest } c\text{-free prefix of } w) \in \{a, b\}^*$$

This can be recognized using the functor $\mathsf{F}A = A + A^2$, equipped with a suitable semigroup operation that makes the following map $h\colon \{a, b, c\}^* \to \mathsf{F}(\{a, b\}^*)$ a homomorphism:

$$h(w) = w \text{ for } w \in \{a, b\}^* \qquad h(uc \dots cv) = (u, v) \text{ for } u, v \in \{a, b\}^*$$

The output mechanism of the transducer semigroup sends any element $a \in A$ – seen as belonging to the left summand of $A + A^2$ – to aa, and (b, c) to cb.

▶ Remark 2.9. Consider a transducer semigroup with functor F. For a semigroup S, we may often think of an element of $\mathsf{F}S$ as a data structure that contains elements of S (such as a pair or a list, cf. Example 2.2). Then naturality of the output mechanism expresses that, being defined "uniformly in S", it cannot "look inside"[3] those elements of S (but it can combine them using the semigroup operation). In other words, the control flow may depend only on the part that is "independent of S" – and the condition that F is finiteness preserving (satisfied by all our examples except Example 2.7) somehow means that this part is finite.

2.2 Two simple characterizations

All functions. Our first theorem concerns transducer semigroups without any restrictions.

▶ **Theorem 2.10.** *Every function between semigroups is recognized by a transducer semigroup.*

[3] This is similar to the "generic" or "polymorphic" function definitions supported by many statically typed programming languages. The corresponding notion in type theory is *parametric polymorphism*, and it is closely related to naturality, see the introduction to [16].

Proof. We prove a slightly stronger result: for any semigroup A, there exists a transducer semigroup that recognizes all functions from A to other semigroups. The functor is

$$\mathsf{F}B = A \times (\text{set of all functions of type } A \to B, \text{ not necessarily recognizable}).$$

The semigroup operation in $\mathsf{F}B$ is defined as follows: on the first coordinate, we inherit the semigroup operation from A, while on the second coordinate, we use the trivial *left zero* semigroup structure, in which the product of two functions is simply the first one (this is a trivial way of equipping every set with a semigroup structure). The functor is defined on morphisms as in the tuple construction from Example 2.2: the first coordinate, corresponding to A, is not changed, and the second coordinate, corresponding to the set of functions, is transformed coordinate-wise, when viewed as a tuple indexed by A. This is easily seen to be a functor. The output mechanism, which is easily seen to be natural, is function application i.e. $(a, f) \mapsto f(a)$. Every function $f\colon A \to B$ is recognized by this transducer semigroup, with the appropriate homomorphism is $a \in A \mapsto (a, f)$. ◀

Recognizability reflecting functions. We now characterize functions with the property that inverse images of recognizable languages are also recognizable. We use a slightly more general setup, where instead of languages we use functions into arbitrary sets (languages can be seen as the case of functions into $\{\text{yes}, \text{no}\}$).

▶ **Definition 2.11.** *We say that a function from a semigroup A to some set X is* recognizable *if it factors through some semigroup homomorphism from A to a* finite *semigroup.*

In the rest of the paper, we shall sometimes speak of recognizable functions with infinite codomain, but note that the range of a recognizable function is always finite.

A function $f\colon B \to A$ between semigroups is called *recognizability reflecting* if for every recognizable function $g\colon A \to X$, the composition $g \circ f$ is recognizable.

▶ **Example 2.12.** Consider the semigroup $(\mathbb{N}, +)$ of natural numbers with addition, which is isomorphic to the free monoid a^*. In this semigroup, the recognizable functions are ultimately periodic colourings of numbers. A corollary is that every recognizable function gives the same answer to all factorials $\{1!, 2!, \ldots\}$, with finitely many exceptions. Take any function $f\colon \mathbb{N} \to \mathbb{N}$ such that (a) every output number arises from at most finitely many input numbers; (b) every output number is a factorial. The composition of f with any recognizable function will give the same answer to all numbers with finitely many exceptions, thus being also recognizable.

In the above example, a function with conditions (a) and (b) can be chosen in uncountably many ways, even if we require that it has linear growth. Therefore, there are too many recognizability reflecting functions (even just from $\{a\}^*$ to itself) to allow a machine model, or some other effective syntax. The following result gives a non-effective syntax.

▶ **Theorem 2.13.** *The following conditions are equivalent for a string-to-string function:*

1. *it is recognizability reflecting.*
2. *it is recognized by a transducer semigroup such that for every finite semigroup A, the corresponding output function of type $\mathsf{F}A \to A$ is recognizable.*

▶ **Example 2.14.** For any finite semigroup A, the map $(a, n) \in A \times (\mathbb{N} \setminus \{0\}) \mapsto a^n \in A$ is recognizable. This is because, since $a^{|A|!}$ is idempotent for every $a \in A$, this map factors through a homomorphism into the semigroup $A \times ((\mathbb{N} \setminus \{0\})/\sim)$ where

$$n \sim m \quad \iff \quad n = m \quad \vee \quad \big(n, m \geq |A|! \ \wedge \ n \equiv m \bmod |A|!\big)$$

is a congruence of finite index. Extending this slightly to handle the case $(a, 0) \mapsto a$, one can show that the output mechanism out_A of Example 2.7 is recognizable whenever A is finite. Therefore, the squaring function is recognizability reflecting.

3 The regular functions

The two straightforward constructions in Theorems 2.10 and 2.13 amount to little more than symbol pushing. In this section, we present a more substantial characterization, which is the main result of this paper. This characterization concerns finiteness-preserving functors. This is a strengthening of the condition from Theorem 2.13: if the functor F in a transducer semigroup is finiteness-preserving, then for every finite semigroup A, the output function $\mathsf{F}A \to A$ will be recognizable, since all functions from a finite semigroup are trivially recognizable. However, the condition is strictly stronger, as witnessed by Example 2.7, which is recognizability reflecting (cf. Example 2.14) but not finiteness preserving. As we will see, the stronger condition will characterize exactly the regular string-to-string functions.

The following counterexample illustrates the non-trivial interaction between naturality of the output mechanism and the requirement that the functor is finiteness preserving.

▶ **Example 3.1.** Consider the powerset functor P from Example 2.2. It is finiteness preserving, since the powerset of a finite semigroup is also finite. One could imagine that using powersets, one could construct a transducer semigroup that recognizes functions that are not regular, e.g. because they have exponential growth (unlike regular functions, which have linear growth). It turns out that this is impossible, because there is no possible output mechanism, i.e. no natural transformation of type $\mathsf{P}A \to A$, as we explain below.

The issue is that the naturality condition disallows choosing elements from a subset. To see why, consider a semigroup A with two elements, with the trivial left zero semigroup structure. For this semigroup, the output mechanism of type $\mathsf{P}A \to A$ would need to choose some element $a \in A$ when given as input the full set $A \in \mathsf{P}A$. However, none of the two choices is right, because swapping the two elements of A is an automorphism of the semigroup A, which maps the full set to itself, but does not map any element to itself.

We now state the main theorem of this paper.

▶ **Theorem 3.2.** *The following conditions are equivalent for every string-to-string function:*

1. *it is a regular string-to-string function;*
2. *it is recognized by a transducer semigroup in which the functor is finiteness preserving;*
3. *it is recognized by a transducer semigroup in which the functor* F maps the singleton semigroup 1 to a finite semigroup*:* $|\mathsf{F}1| < \infty$.

(Note that (2) ⇒ (3) is immediate.) Here is the plan for the rest of this section:
Section 3.1 gives a formal definition of regular functions
Section 3.2 proves the easy implication in the theorem, namely (1) ⇒ (2)
Section 3.3 proves the hard implication in the theorem, namely (3) ⇒ (1)

Before continuing, we remark on one advantage of the characterization in item (2), namely a straightforward proof of closure under composition. In contrast, for some (but not all) existing models defining regular string-to-string functions, composition requires a non-trivial construction – examples include two-way transducers [11, Theorem 2] or copyless streaming string transducers [2, Theorem 1].

▶ **Proposition 3.3.** *Functions recognized by finiteness-preserving transducer semigroups are closed under composition.*

Proof. This is because finiteness-preserving functors are closed under composition, natural families of output functions are also closed under composition, and naturality means by definition that the output functions "commute" in a suitable sense with functors.

More precisely, consider the following diagram:

$$\begin{array}{ccccc} \Sigma^* & \xrightarrow{h} & \mathsf{F}(\Gamma^*) & \xrightarrow{\mathrm{out}_{\Gamma^*}} & \Gamma^* \\ & & \downarrow{\scriptstyle \mathsf{F}h'} & & \downarrow{\scriptstyle h'} \\ & & \mathsf{FF}'(\Pi^*) & \xrightarrow{\mathrm{out}_{\mathsf{F}'(\Pi^*)}} & \mathsf{F}'(\Pi^*) \xrightarrow{\mathrm{out}'_{(\Pi^*)}} \Pi^* \end{array}$$

where the square commutes because the output mechanism is natural. The upper path describes the composition of two functions recognized by the transducer semigroups $(\mathsf{F}, \mathrm{out})$ and $(\mathsf{F}', \mathrm{out}')$, while the lower path describes a function recognized by $(\mathsf{FF}', \mathrm{out}_{\mathsf{F}'(-)} \circ \mathrm{out}')$. ◀

3.1 Defininition of streaming string transducers

In this section, we formally describe the regular functions, using a model based on streaming string transducers (SST). This model, like our proof of Theorem 3.2, covers a slightly more general case, namely string-to-semigroup functions instead of only string-to-string functions. These are functions of type $\Sigma^* \to A$ where Σ is a finite alphabet and A is an arbitrary semigroup. The purpose of this generalization is to make notation more transparent, since the fact that the output semigroup consists of strings will not play any role in our proof.

The model uses *registers* to store elements of the output semigroup. We begin by describing notation for registers and their updates. Suppose that R is a finite set of register names, and A is a semigroup called the *output semigroup*. We consider two sets

$$\textit{register valuations}\colon (R \to A) \qquad \textit{register updates}\colon (R \to (A + R)^+)$$

Below we show two examples of register updates, presented as assignments, using two registers X, Y and the semigroup $A = a^*$. (The right-hand sides are the values in $(A + R)^+$.)

$$\underbrace{\begin{array}{lcl} X & := & aYaXaaa \\ Y & := & XaaXaa \end{array}}_{\text{copyful}} \qquad \underbrace{\begin{array}{lcl} X & := & aaYaaXaaa \\ Y & := & aaa \end{array}}_{\text{copyless}}$$

The crucial property is being *copyless* – a register update is called copyless if every register name appears in at most one right-hand side of the update, and in that right-hand side it appears at most once. The main operation on these sets is *application*: a register update u can be applied to a register valuation v, giving a new register valuation vu.

In our model of streaming string tranducers, the registers will be updated by a stream of register updates that is produced by a rational function, defined as follows. Intuitively speaking, a rational function corresponds to an automaton that produces one output letter for each input position, with the output letter depending on regular properties of the input position within the input string. More formally:

▶ **Definition 3.4.** *A* rational function *of type* $\Sigma^* \to X^*$ *– where* Σ *is a finite alphabet but* X *can be any set – is a length-preserving*[4] *function with the following property: for some family*[5]

$$f_a \colon \underbrace{\Sigma^* \times \Sigma^*}_{\text{equipped with componentwise multiplication}} \to \Gamma \quad \text{for } a \in \Sigma \text{ of recognizable functions,}$$

for every input $a_1 \dots a_n$ *and* $i \in \{1, \dots, n\}$*, the* i*-th output letter is* $f_{a_i}(a_1 \dots a_{i-1},\ a_{i+1} \dots a_n)$.

Note that the range of a rational function with codomain X^* may contain only finitely many "letters" from X, so it can always be seen as a string function over finite alphabets.

Having defined register updates and rational functions, we are ready to introduce the machine model used in this paper as the reference definition of *regular functions*.

▶ **Definition 3.5.** *The syntax of a* streaming string transducer *(SST) is given by:*

- *A finite* input alphabet Σ *and an* output semigroup A.
- *A finite set* R *of* register names. *All register valuations and updates below use* R *and* A.
- *A designated* initial register valuation, *and a* final output pattern *in* R^+ *(that does not need to be copyless, though adding this restriction would not affect the expressive power).*
- *An* update oracle, *which is a rational function of type* $\Sigma^* \to (\textit{copyless register updates})^*$.

The semantics of the SST is a function of type $\Sigma^* \to A$ defined as follows. When given an input string, the SST begins in the designated initial register valuation. Next, it applies all updates produced by the update oracle, in left-to-right order. Finally, the output of the SST is obtained by combining the last register values according to the final output pattern.

▶ **Example 3.6.** We define an SST that computes the function of Example 2.8. It has two registers X and Y, whose initial valuation is $X = Y = \varepsilon$, and the final output pattern is YX. The update associated to an input letter $\ell \in \{a, b, c\}$ at position i is:

- if the position i is part of the longest c-free prefix, then $X := X\ell$, otherwise $X := X$;
- if the position i is part of the longest c-free suffix, then $Y := Y\ell$, otherwise $Y := Y$.

This sequence of updates can be produced by a rational function generated by a family of functions $(f_\ell)_{\ell \in \{a,b,c\}}$ that are recognized by $\mathbb{B}^2$, where $\mathbb{B}$ is the monoid of booleans with conjunction (rephrase the conditions as "there is no c to the left (resp. right) of i").

In a rational function, the label of the i-th output position is allowed to depend on letters of the input string that are on both sides of the i-th input position; this corresponds to regular lookaround in a streaming string transducer. Therefore, the model described above is easily seen to be equivalent to copyless SSTs with regular lookaround, which are one of the equivalent models defining the regular string-to-string functions, see [3, Section IV.C].

3.2 From a regular function to a transducer semigroup

Having defined the transducer model, we prove the easy implication in Theorem 3.2. It is apparent from Definition 3.5 that every regular function can be decomposed as a rational function followed by a function computed by a streaming string transducer whose i-th register update depends only on the i-th input letter – let us call that a *local* SST. Thanks to closure under composition (Proposition 3.3), we only need to handle these two special cases: we show that finiteness-preserving transducer semigroups recognize

- all rational functions in Section 3.2.1;
- and all local streaming string transducers in Section 3.2.2.

[4] Often in the literature, rational functions are not required to be length-preserving, see e.g. [21, p. 525], but in this paper, we only need the length-preserving case.

[5] The family $(f_a)_{a \in \Sigma}$ is very close to what is called an *(Eilenberg) bimachine* in the literature.

3.2.1 Recognizing rational functions by transducer semigroups

Consider a rational function, generated by the family $(f_a)_{a\in\Sigma}$ of recognizable functions of type $\Sigma^* \times \Sigma^* \to \Gamma$. By definition of recognizability, each f_a decomposes into

$$\Sigma^* \times \Sigma^* \xrightarrow{h_a} B_a \xrightarrow{g_a} \Gamma \qquad \text{where } h_a \text{ is a semigroup homomorphism and } B_a \text{ is finite.}$$

One can check that every f_a then factors through a monoid morphism to the finite monoid

$$\prod_{a\in\Sigma} h_a(\Sigma^* \times \Sigma^*)$$

Thus, without loss of generality, we may assume for the rest of the proof that all of the above semigroups B_a are equal to a common finite monoid B and that each semigroup homomorphism h_a is in fact a monoid morphism.

For any semigroup A, we let[6] $\mathsf{F}A = B \times (B \to A) \times B$, endowed with the following semigroup operation:

$$(\ell_1, \varphi_1, r_1) \cdot (\ell_2, \varphi_2, r_2) = \Big(\ell_1\ell_2,\ \big(b \mapsto \varphi_1(br_2) \cdot \varphi_2(\ell_1 b)\big),\ r_1 r_2\Big).$$

The construction F is extended to morphisms by considering $B \to A$ as the set of B-indexed tuples (cf. Example 2.2) of elements of A. To get a transducer semigroup, we take the output mechanism to be $(\ell, \varphi, r) \mapsto \varphi(e)$ where $e \in B$ is the neutral element.

Our rational function is then recognized by the unique monoid homomorphism of type $\Sigma^* \to \mathsf{F}(\Gamma^*)$ (indeed, F preserves monoids) which maps $a \in \Sigma$ to $\big(h_a(a, \varepsilon), g_a, h_a(\varepsilon, a)\big)$.

3.2.2 From a local SST to a transducer semigroup

Suppose now that a string-to-semigroup function $f\colon \Sigma^* \to A$ is computed by some local streaming string transducer. In the proof below, when referring to register valuations and register updates, we refer to those that use the registers and output semigroup of the fixed transducer. We say that a register update is in *normal form* if, in every right-hand side, one cannot find two consecutive letters from the semigroup A. Any register update can be *normalized*, i.e. converted into one that is in normal form, by using the semigroup operation to merge consecutive elements of the output semigroup in the right-hand sides. Here is an example, which uses three registers X, Y, Z and the semigroup $A = (\{0, 1\}, \cdot)$:

$$\underbrace{\begin{array}{lcl} X & := & 01Y1111X111 \\ Y & := & 01011 \end{array}}_{\text{not in normal form}} \xrightarrow{\text{normalization}} \underbrace{\begin{array}{lcl} X & := & 0Y1X1 \\ Y & := & 0 \end{array}}_{\text{in normal form}}$$

The register updates before and after normalization act in the same way on register valuations. If an update is copyless and in normal form, then the combined length of all right-hand sides is at most three times the number of registers. Therefore, if a semigroup A is finite, then the set of copyless register updates in normal form, call it $\mathsf{U}A$, is also finite. (However, there are infinitely many copyful register updates even when A is finite.) This set $\mathsf{U}A$ can be equipped with a composition operation

$$u_1, u_2 \in \mathsf{U}A \quad \mapsto \quad u_1 u_2 \in \mathsf{U}A,$$

[6] A construction similar in spirit to the classical *two-sided semidirect product* [20, §6].

which is defined in the same way as applying a register update to a register valuation, except that we normalize at the end. This composition operation is associative, and compatible with applying register updates to register valuations, in the sense that $(vu_1)u_2 = v(u_1u_2)$ holds for every valuation v and all updates u_1 and u_2. Therefore, $A \mapsto \mathsf{U}A$ is a finiteness-preserving semigroup-to-semigroup functor (with the natural extension to morphisms, where the homomorphism is applied to every semigroup element in a right-hand side).

The functor U described above is almost but not quite the functor that will be used in the transducer semigroup that we will define to prove the easy implication in Theorem 3.2. That functor F will also take into account the initial register valuation:

$$\mathsf{F}A = \mathsf{U}A \times \underbrace{(R \to A)}_{\text{endowed with the trivial left zero semigroup structure}} \quad \text{with componentwise multiplication \& action on morphisms}$$

Given $(u, v) \in \mathsf{F}A$, the output mechanism in the transducer semigroup applies the register update u to the register valuation v, and then multiplies together the register values given by the resulting valuation vu according to the final output pattern. Using this, we can recognize f via the homomorphism that sends each input letter to:

- the register update that this letter determines (our SST being local) in the first component;
- the designated initial register valuation in the second component.

3.3 From a transducer semigroup to a regular function

We now turn to the difficult implication (3) $\Rightarrow$ (1) in Theorem 3.2. The proof is presented in a way which, if sometimes slightly verbose, makes it easier to see how it can be adapted to other algebraic structures instead of semigroups (such as forest algebras, cf. Section 4).

3.3.1 Polynomial functors and functorial streaming string transducers

The assumption of the implication uses an abstract model (transducer semigroups), while the conclusion uses a concrete operational model (streaming string transducers). To bridge the gap, we use an intermediate model, similar to SSTs, but a bit more abstract. The abstraction arises by using polynomial functors instead of registers, as described below.

▶ **Definition 3.7.** *By* polynomial functor*, we mean a semigroup-to-set functor of the form*

$$A \quad \mapsto \quad \coprod_{q \in Q} A^{\textit{dimension of } q},$$

where Q is some possibly infinite set, whose elements are called components*, with each component having an associated* dimension *in $\mathbb{N}$. The symbol $\coprod$ stands for disjoint union of sets. This functor does not take into account the semigroup structure of the input semigroup, since the output is seen only as a set. On morphisms, the functor works in the expected way, i.e. coordinate-wise.*

A *finite polynomial functor* is a polynomial functor with finitely many components – for example, $A \mapsto A^2 + A^2 + A$. The notion of finite polynomial functor can be seen as a mild generalization of the construction which maps a semigroup A to the set A^R of register valuations for some fixed finite set R of register names. In the generalization, we allow a variable number of registers, depending on some finite information (the component).

Having defined a more abstract notion of "register valuations", namely finite polynomial functors, we now define a more abstract notion of "register updates". The first condition for such updates is that they do not look inside the register contents; this condition is captured by naturality (as discussed in Remark 2.9).

▶ **Example 3.8.** Consider the polynomial functors (where 1 represents the singleton set A^0)

$$\mathsf{F}A = A^* = 1 + A^1 + A^2 + \cdots \qquad \mathsf{G}A = A + 1.$$

An example of a natural transformation between these two functors is the function which maps a nonempty list in A^* to the product of its elements, and which maps the empty list to the unique element of 1. A non-example is the function that maps a list $[a_1, \ldots, a_n] \in A^*$ to the leftmost element a_i that is an idempotent in the semigroup, and returns 1 if such an element does not exist. The reason why the non-example is not natural is that a semigroup homomorphism can map a non-idempotent to an idempotent.

Apart from naturality, we will want our register updates to be copyless. For the purposes of the following definition, let us call a tuple of numbers in $\mathbb{N}^k$ a "sub-unit" if it belongs to $\{0,1\}^k$ and at most one coordinate is equal to 1 – or, as an edge case, if $k = 0$. For a polynomial functor F, a sub-unit of $\mathsf{F}\mathbb{N} = \sum_q \mathbb{N}^{\dim(q)}$ is a sub-unit of any of the $\mathbb{N}^{\dim(q)}$.

▶ **Definition 3.9** (Copyless natural transformation). *A natural transformation between two polynomial functors* F *and* G *is called* copyless *if when instantiated to the semigroup*[7] $(\mathbb{N}, +)$*, the corresponding function of type* $\mathsf{F}\mathbb{N} \to \mathsf{G}\mathbb{N}$ *maps sub-units to sub-units.*

It will be convenient to speak of *natural functions* $f \colon \mathsf{F}A \to \mathsf{G}A$, where F and G are semigroup-to-set functors and A is a fixed semigroup, to refer to functions that can be extended to natural transformations $(f_B \colon \mathsf{F}B \to \mathsf{G}B)_{B \text{ semigroup}}$, with $f = f_A$. *Copyless natural functions* between instantiations of polynomial functors are defined analogously.

Having defined functions that are natural and copyless, we now describe the more abstract model of SSTs used in our proof. The main difference is that instead of register valuations and updates given by some finite set of register names, we have two abstract polynomial functors, one of them finite polynomial, together with an explicitly given application function. We also allow the computation to be initialized and finalized in a more liberal way, that may depend on a regular property of the input.

▶ **Definition 3.10.** *The syntax of a* functorial streaming string transducer *is given by:*

- *A finite* input alphabet Σ *and an* output semigroup A*.*
- *A finite polynomial functor* R*, called the* register functor*, and a (not necessarily finite) polynomial functor* U *called the* update functor*.*
- *A copyless natural function of type* $\mathsf{R}A \times \mathsf{U}A \to \mathsf{R}A$*, called* application*.*
- *An* initial function $\Sigma^* \to \mathsf{R}A$ *which is recognizable (and therefore has finite range).*
- *A polynomial* final data functor K*, a* final data function $\Sigma^* \to \mathsf{K}A$ *which is recognizable, and a* final output function *of type* $\mathsf{R}A \times \mathsf{K}A \to A$ *which is a natural function (but not necessarily copyless).*
- *An* update oracle*, which is a rational function of type* $\Sigma^* \to (\mathsf{U}A)^*$*.*

Analogously to Definition 3.5, the functorial SST computes the function $\Sigma^* \to A$ obtained by the following composition, where the first map bundles together the initial function, the update oracle and the final data function:

$$\Sigma^* \to \mathsf{R}A \times (\mathsf{U}A)^* \times \mathsf{K}A \xrightarrow{(\textit{apply} \text{ updates successively}) \times \mathrm{id}_{\mathsf{K}A}} \mathsf{R}A \times \mathsf{K}A \xrightarrow{\text{final output function}} A$$

In the appendix, we prove that this model is no more expressive than usual copyless SSTs.

[7] The choice of the semigroup $(\mathbb{N}, +)$ in the Definition 3.9 is not particularly important. For example, the same notion of copylessness would arise if instead of $(\mathbb{N}, +)$, we used the semigroup $\{0, 1, 2\}$ with addition up to threshold 2. In the appendix, we present a more syntactic characterization of copyless natural transformations as part of our proof of Lemma 3.11.

▶ **Lemma 3.11.** *Definitions 3.5 and 3.10 characterize the same string-to-semigroup functions.*

3.3.2 Coproducts and views

Apart from the more abstract transducer model from Definition 3.10, the other ingredient used in the proof of the hard implication in Theorem 3.2 will be coproducts of semigroups, and some basic operations on them, as described in this section.

The *coproduct*[8] of two semigroups A and B, denoted by $A \oplus B$, is the semigroup whose elements are nonempty words over an alphabet that is the disjoint union of A and B, restricted to words that are *alternating* in the sense that two consecutive letters cannot belong to the same semigroup. The semigroup operation is defined in the expected way. We draw elements of a coproduct using coloured boxes, with the following picture showing the product operation in the coproduct of two copies, red and blue, of the semigroup $\{a, b\}^+$:

$$(\boxed{aba} \cdot \boxed{b} \cdot \boxed{b} \cdot \boxed{aa}) \cdot (\boxed{abba} \cdot \boxed{aabb}) = \boxed{aba} \cdot \boxed{b} \cdot \boxed{b} \cdot \boxed{aaabba} \cdot \boxed{aabb}.$$

A coproduct can involve more than two semigroups; in the pictures this would correspond to more colours, subject to the condition that consecutive boxes have different colours.

▶ Remark 3.12. The copyless register updates $u : R \to (A + R)^+$ of ordinary SSTs that are in normal form (cf. Section 3.2) can be seen as maps $R \to A \oplus \bigoplus_{X \in R} \{X\}^+$.

We write 1 for the semigroup that has one element. This semigroup is unique up to isomorphism and it is a *terminal object* in the category of semigroups, which means that it admits a unique homomorphism from every other semigroup A. This unique homomorphism will be denoted by $! \colon A \to 1$. (It has no connection with the factorial function on numbers.)

Consider the semigroup-to-set functors defined by (the underlying set of) a coproduct of several copies of their argument with several copies of 1, such as $A \mapsto A \oplus A \oplus A \oplus 1 \oplus 1$. In our proof, it will be useful to see them as polynomial functors, even though strictly speaking they are not defined as sums of products. This identification is allowed by the following observation (stated for $A \oplus 1$ for convenience, but the same idea applies in general).

▶ **Proposition 3.13.** *There is a family of bijections, natural in the semigroup A, between*

$$A \oplus 1 \quad \text{and} \quad \coprod_{q \in 1 \oplus 1} A^{\text{dimension of } q},$$

where the dimension of q is the number of times that the first copy of 1 appears in q.

Idea. Given $x \in A \oplus 1$, we apply $! \colon A \to 1$ to the elements of A in x to determine the component q of the polynomial functor that contains the image of x by the left-to-right bijection. This operation, a special case of what is called the shape below, forgets those elements of A appearing in x, so we record them in a tuple living in $A^{\dim(q)}$. For example, $\boxed{aba} \cdot \boxed{1} \cdot \boxed{aa} \cdot \boxed{1}$ is sent to the tuple (aba, aa) in the component $\boxed{1} \cdot \boxed{1} \cdot \boxed{1} \cdot \boxed{1}$. ◀

The crucial property of semigroups that will be used in our proof is Lemma 3.14 below, which says that an element of a coproduct can be reconstructed based on certain partial information. This information is described using the following operations.

[8] The name *coproduct* is used because of the following universal property: if $f \colon A \to C$ and $g \colon B \to C$ are two semigroup homomorphisms, then there is a unique homomorphism $A \oplus B \to C$ that coincides with f (resp. g) on the subsemigroup consisting of words with a single letter from A (resp. B).

1. **Merging**. Consider a coproduct $A_1 \oplus \cdots \oplus A_n$, such that the same semigroup A appears on all coordinates from a subset $I \subseteq \{1, \ldots, n\}$, and possibly on other coordinates as well. Define *merging the parts from* I to be the function of type

$$A_1 \oplus \cdots \oplus A_n \to A \oplus \bigoplus_{i \notin I} A_i$$

that is defined in the expected way, and explained in the following picture. In the picture, merging is applied to a coproduct of three copies of the semigroup $\{a, b\}^+$, indicated using colours red, black and blue, and the merged coordinates are red and blue:

$$\boxed{aba} \cdot \boxed{b} \cdot \boxed{aa} \cdot \boxed{b} \cdot \boxed{aa} \cdot \boxed{abba} \cdot \boxed{b} \quad \mapsto \quad \underbrace{\boxed{abab} \cdot \boxed{aa} \cdot \boxed{baaabba}}_{\text{the merge of red and blue is drawn in violet}} \cdot \boxed{b}.$$

2. **Shape.** Define the *shape operation* to be the function of type

$$A_1 \oplus \cdots \oplus A_n \to 1 \oplus \cdots \oplus 1$$

obtained by applying ! on every coordinate. The shape says how many alternating blocks there are, and which semigroups they come from, as explained in the following picture:

$$\boxed{aba} \cdot \boxed{b} \cdot \boxed{aa} \cdot \boxed{b} \cdot \boxed{aa} \cdot \boxed{abba} \cdot \boxed{b} \quad \mapsto \quad \boxed{1} \cdot \boxed{1} \cdot \boxed{1} \cdot \boxed{1} \cdot \boxed{1} \cdot \boxed{1} \cdot \boxed{1}.$$

3. **Views.** The final operation is the i-th *view*

$$A_1 \oplus \cdots \oplus A_n \to 1 \oplus A_i.$$

This operation applies ! to all coordinates other than i, and then it merges all those coordinates. Here is a picture, in which we take the view of the blue coordinate:

$$\boxed{aba} \cdot \boxed{b} \cdot \boxed{aa} \cdot \boxed{b} \cdot \boxed{aa} \cdot \boxed{abba} \cdot \boxed{b} \quad \mapsto \quad \boxed{aba} \cdot \boxed{1} \cdot \boxed{aa} \cdot \boxed{1}.$$

The key observation is that an element of a coproduct is fully determined from its shape and views, as stated in the following lemma. It seems to contain the essential property of semigroups that makes the construction work. We expect our theorem to also be true for other algebraic structures for which the lemma is true; however, the lemma seems to fail in certain settings. Concrete examples will be discussed in the conclusion (Section 4).

▶ **Lemma 3.14.** *Let* $A_1, \ldots, A_n$ *be semigroups. The* deconstruction *function of type*

$$A_1 \oplus \cdots \oplus A_n \longrightarrow (1 \oplus A_1) \times \cdots \times (1 \oplus A_n) \times (1 \oplus \cdots \oplus 1),$$

which is obtained by combining the views for all $i \in \{1, \ldots, n\}$ *and the shape, is injective.*

We prove this by exhibiting an explicit partial left inverse: a *reconstruction* function of type

$$(1 \oplus A_1) \times \cdots \times (1 \oplus A_n) \times (1 \oplus \cdots \oplus 1) \longrightarrow (A_1 \oplus \cdots \oplus A_n) + 1$$

such that deconstruction followed by reconstruction maps every element of $A_1 \oplus \cdots \oplus A_n$ to itself. The idea is to start with the shape and replace the entries from 1 with the elements appearing in the views in the right order. Rather than a formal definition, we illustrate this on an example (in the 3 views, we omit the boxes around the 1s to avoid visual cluttering):

$$\begin{array}{ccccccccccccc} \boxed{aba} & & 1 & & & \boxed{aa} & & 1 & & & & & \\ 1 & \boxed{b} & 1 & \boxed{b} & 1 & \boxed{abba} & 1 & & & & & & \\ & 1 & & \boxed{aa} & & & 1 & & & \boxed{b} & & & \\ \boxed{1} & \boxed{1} & \boxed{1} & \boxed{1} & \boxed{1} & & \boxed{1} & & & \boxed{1} & & & \end{array} \quad \mapsto \quad \boxed{aba} \cdot \boxed{b} \cdot \boxed{aa} \cdot \boxed{b} \cdot \boxed{aa} \cdot \boxed{abba} \cdot \boxed{b}$$

Besides proving Lemma 3.14, this reconstruction function also enjoys the following property, which can be seen from the definition and Proposition 3.13.

▶ **Proposition 3.15.** *When each A_i is either A or 1, reconstruction can be seen as a copyless natural function between polynomial functors in A.*

3.3.3 Factorized output

Now, consider some transducer semigroup, with the functor being F, and fix a string-to-semigroup function $f\colon \Sigma^* \to A$ that decomposes as some homomorphism $h\colon \Sigma^* \to \mathsf{F}A$ followed by the output function of type $\mathsf{F}A \to A$.

For semigroups $A_1, \ldots, A_n$, define the *vectorial output function* to be the function of type

$$\mathsf{F}A_1 \times \cdots \times \mathsf{F}A_n \longrightarrow A_1 \oplus \cdots \oplus A_n$$

that is obtained by the composition of three functions described below (where *co-projection* is the function $A_i \to A_1 \oplus \cdots \oplus A_n$ that outputs a singleton list containing its input):

$$\begin{array}{c} \mathsf{F}A_1 \times \cdots \times \mathsf{F}A_n \\ \downarrow{\scriptstyle \mathsf{F}(\text{co-projection}) \times \cdots \times \mathsf{F}(\text{co-projection})} \\ \mathsf{F}(A_1 \oplus \cdots \oplus A_n) \times \cdots \times \mathsf{F}(A_1 \oplus \cdots \oplus A_n) \\ \downarrow{\scriptstyle \text{semigroup operation}} \\ \mathsf{F}(A_1 \oplus \cdots \oplus A_n) \\ \downarrow{\scriptstyle \text{output mechanism for } A_1 \oplus \cdots \oplus A_n} \\ A_1 \oplus \cdots \oplus A_n. \end{array}$$

To illustrate the definitions in this section, we use a *running example* with the transducer semigroup for the "reverse then duplicate" function from Example 2.6. The functor F sends a semigroup A to the opposite semigroup (cf. Example 2.2), and the output mechanism is $a \mapsto aa$. Our example function on $\{a, b\}^*$ is obtained by composing the string reversal homomorphism $\{a, b\}^* \to \mathsf{F}(\{a, b\}^*)$ with the output function. Here is an example of the vectorial output function (for now, the homomorphism plays no role):

$$(1, abbb) \in \mathsf{F}1 \times \mathsf{F}(\{a, b\}^*) \qquad \mapsto \qquad \boxed{abbb}\,\boxed{1}\,\boxed{abbb}\,\boxed{1} \in 1 \oplus \{a, b\}^*.$$

The vectorial output function is natural in all of its arguments, which means that for all semigroup homomorphisms $h_1, \ldots, h_n$, the diagram below commutes:

$$\begin{array}{ccc} \mathsf{F}A_1 \times \cdots \times \mathsf{F}A_n & \xrightarrow{\text{vectorial output function}} & A_1 \oplus \cdots \oplus A_n \\ \downarrow{\scriptstyle \mathsf{F}h_1 \times \cdots \times \mathsf{F}h_n} & & \downarrow{\scriptstyle h_1 \oplus \cdots \oplus h_n} \\ \mathsf{F}B_1 \times \cdots \times \mathsf{F}B_n & \xrightarrow{\text{vectorial output function}} & B_1 \oplus \cdots \oplus B_n \end{array}$$

This is because each of the three steps in the definition of the vectorial output function is itself a natural transformation, and natural transformations compose. Naturality of the first two steps is easy to check, while for the last step we use the assumption that the (non-vectorial) output function is natural.

Let us return to our function $f = \mathrm{out}_A \circ h$ recognized by our transducer semigroup $(\mathsf{F}, \mathrm{out})$. For strings $w_1, \ldots, w_n \in \Sigma^*$, define the corresponding *factorized output* to be the result of first applying the semigroup homomorphism $h : \Sigma^* \to \mathsf{F}A$ to all the strings, and then applying the vectorial output function; we denote it by

$$\langle w_1 | \cdots | w_n \rangle \in \underbrace{A \oplus \cdots \oplus A}_{n \text{ times}},$$

Here is the factorized output illustrated on our running example (we use colours to distinguish which of the three parts of the input is used):

$$\langle abb|\varepsilon|baaba\rangle = \boxed{abaab}\ \boxed{\varepsilon}\ \boxed{bba}\ \boxed{abaab}\ \boxed{\varepsilon}\ \boxed{bba} \in \{a,b\}^* \oplus \{a,b\}^* \oplus \{a,b\}^*.$$

As we can see above, when the output semigroup is a free monoid, the factorized output morally tells us "which part of the output string comes from which part in the input string".

▶ Remark 3.16. This is similar to the idea of *origin semantics* [5] of regular functions (see also [17, Section 5]). Indeed, our definition of factorized output is inspired by a similar tool of the same name that appears in the study of origin semantics [5, Section 2].

We also use a similar notation but with some input strings underlined, e.g. the input could be $\langle \underline{abb}|\varepsilon|baaba\rangle$ with an underline for the first red part. In the underlined case, before applying the vectorial output function, we apply h to the non-underlined strings and $(\mathsf{F}! \circ h)\colon \Sigma^* \to \mathsf{F}1$ to the underlined strings. In our running example, we have

$$\langle \underline{abb}|\varepsilon|baaba\rangle = \boxed{abaab}\ \boxed{\varepsilon}\ \boxed{1}\ \boxed{abaab}\ \boxed{\varepsilon}\ \boxed{1} \in 1 \oplus \{a,b\}^* \oplus \{a,b\}^*.$$

3.3.4 Proof of (3) ⇒ (1) in Theorem 3.2

We have now collected all necessary ingredients to prove this hard direction of the equivalence. Therefore, our goal is now to show that the function $f\colon \Sigma^* \to A$ that we have previously fixed is computed by some functorial streaming string transducer as in Definition 3.10, *assuming that* $\mathsf{F}1$ *is finite*.

The idea is that we want the functorial SST to maintain the following *invariant*:

> after processing the first i letters in an input string $a_1 \cdots a_n$,
> the register valuation is equal to the factorized output $\langle a_1 \cdots a_i | \underline{a_{i+1} \cdots a_n}\rangle$.

This way, after processing all input letters, the last valuation $\langle a_1 \cdots a_n|\underline{\varepsilon}\rangle$ is very close to the output; indeed, if we see A as a 1-ary coproduct, then $f(a_1 \dots a_n) = \langle a_1 \dots a_n\rangle \in A$.

The naive choice for the register functor is then $\mathsf{R}' : A \mapsto A \oplus 1$, since $\langle w|\underline{v}\rangle \in A \oplus 1$ for all $w, v \in \Sigma^*$ by definition. However, while R' can be seen as a polynomial semigroup-to-set functor, whose set of components is $1 \oplus 1$ (cf. Proposition 3.13), it is not *finite* polynomial (the set $1 \oplus 1$ is infinite). That said, we have by naturality of vectorial output:[9]

▷ Claim 3.17. The component for $\langle w|\underline{v}\rangle \in \mathsf{R}'A$ is $\langle \underline{w}|\underline{v}\rangle \in 1 \oplus 1$.

This index is determined by definition by the values of $(\mathsf{F}! \circ h)\colon \Sigma^* \to \mathsf{F}1$ on w and v, where $h\colon \Sigma^* \to \mathsf{F}A$ is the homomorphism used to recognize f. *Since* $\mathsf{F}1$ *is finite,* the $\langle w|\underline{v}\rangle$ for w, v

[9] Let us give some details. From Proposition 3.13, we see that the component in $1 \oplus 1$ of an element in $A \oplus 1$ is obtained by applying $! \oplus 1$. So it suffices to show that

$$\langle \underline{w}|\underline{v}\rangle = (! \oplus 1)(\langle w|\underline{v}\rangle)$$

Expanding the definitions, our goal can be rewritten as

$$\text{vectorial output of } (\mathsf{F}! \circ h(w), \mathsf{F}! \circ h(v)) = (! \oplus 1)\big(\text{vectorial output of } (h(w), \mathsf{F}! \circ h(v))\big)$$

This is a direct consequence of the naturality of the vectorial output function, that can be expressed as follows: for every semigroup homomorphism $g\colon A \to B$,

$$(\text{vectorial output for } B) \circ (\mathsf{F}g \times \mathrm{id}_1) = (g \oplus 1) \circ \text{vectorial output for } A$$

(take $g = !$ and apply both sides of the equality to $(h(w), \mathsf{F}! \circ h(v))$ to get the desired Claim 3.17).

ranging over Σ^* live in finitely many components. We take our register functor $\mathsf{R}A \subset \mathsf{R}'A$ to be the finite polynomial functor consisting of these "useful" components, plus the unique component that does not use A (it will serve as a "*null value*").

To design the register updates, the key is the following lemma. It shall be proved later using the machinery of views on coproducts that we have introduced for this very purpose.

▶ **Lemma 3.18.** *There are two copyless natural functions*

$$\delta\colon (A \oplus 1) \times (1 \oplus A \oplus 1) \to (A \oplus 1) + 1 \qquad \kappa\colon (A \oplus 1) \times (1 \oplus A) \to A + 1$$

such that, for every pair of strings $w, v \in \Sigma^*$ and every letter $a \in \Sigma$,

$$\langle wa|\underline{v}\rangle = \delta(\langle w|\underline{av}\rangle, \langle \underline{w}|a|\underline{v}\rangle) \qquad f(w) = \langle w\rangle = \kappa(\langle w|\underline{\varepsilon}\rangle, \langle \underline{w}|\varepsilon\rangle)$$

Again, to make "copyless natural" meaningful in this context, we invoke Proposition 3.13 to see δ and κ as functions between polynomial functors in A.

This leads us to use the update functor $\mathsf{U} : A \mapsto 1 \oplus A \oplus 1$ and to define the application of updates to registers, of type $\mathsf{R}A \times \mathsf{U}A \to \mathsf{R}A$, to be δ followed by the map $(A \oplus 1) + 1 \to \mathsf{R}A$ which sends the components of $A \oplus 1$ that are in $\mathsf{R}A$ to themselves, and everything else to the "null value". As an direct consequence of the lemma, the desired invariant holds using

- the initial function $w \mapsto \langle \varepsilon|\underline{w}\rangle$,
- and the update oracle $a_1 \dots a_n \mapsto \langle \underline{\varepsilon}|a_1|\underline{a_2 \dots a_n}\rangle \dots \langle \underline{a_1 \dots a_{n-1}}|a_n|\underline{\varepsilon}\rangle$.

To fit Definition 3.10, we have to check that the initial function is recognizable and that the update oracle is a rational function; by definition, the latter amounts to saying that for any $a \in \Sigma$, the function $(w, v) \in (\Sigma^*)^2 \mapsto \langle \underline{w}|a|\underline{v}\rangle$ is recognizable. According to the definition of factorized output, the initial function factors through the semigroup homomorphism $\mathsf{F}! \circ h$, *whose codomain* $\mathsf{F}1$ *is finite*; therefore, the initial function is recognizable. The other recognizability condition holds for a similar reason.

To finish building our functorial streaming string transducer, we use the function κ from Lemma 3.18. Thanks to our invariant and to the equation concerning κ, it is immediate that the following choices lead to a functorial SST that indeed computes f. We take:

- the final data functor $\mathsf{K} : A \mapsto (1 \oplus A) \times A$,
- the final data function $w \in \Sigma^* \mapsto (\langle \underline{w}|\varepsilon\rangle$, some arbitrary fixed value in A) – once again, it is recognizable because $\mathsf{F}1$ is finite,
- and the final output function $\mathsf{R}A \times \mathsf{K}A \to A$ that proceeds as follows: first, it applies κ to get some value in $(A + 1) \times A$; if the left half of the pair is in A, it returns it; otherwise, it returns the right half.

This being done, let us discharge our only remaining subgoal.

Proof of Lemma 3.18. We cover here the part concerning δ; for κ, the arguments are similar and a bit simpler. We use the following claim, which is proved using mechanical diagram chasing (as detailed in the appendix). Recall that the merging, shape and view operations were introduced just before Lemma 3.14.

▷ Claim 3.19. $\langle wa|\underline{v}\rangle$ is obtained from $\langle w|a|\underline{v}\rangle$ by merging the first two parts in $A \oplus A \oplus 1$.

The above claim shows that the factorized output $\langle wa|\underline{v}\rangle$ is obtained from $\langle w|a|\underline{v}\rangle$ by a copyless natural function. In turn, $\langle w|a|\underline{v}\rangle$ is the image by the reconstruction function – which is copyless natural (Proposition 3.15) – of the following four items (the equalities below are proved similarly to Claims 3.17 and 3.19):

1. First view of $\langle w|a|\underline{v}\rangle$, which is equal to $\langle w|\underline{av}\rangle$ – this is the first argument which is passed, in the lemma statement, to the function δ that we want to define.

2. Second view of $\langle w|a|\underline{v}\rangle$, which is obtained by merging the first and third parts in $\langle \underline{w}|a|\underline{v}\rangle$.
3. Third view of $\langle w|a|\underline{v}\rangle$, which is equal to $\langle \underline{wa}|\underline{v}\rangle$.
4. Shape of $\langle w|a|\underline{v}\rangle$, which is equal to $\langle \underline{w}|\underline{a}|\underline{v}\rangle$.

To complete the proof, it remains to justify that the last three items above can be collectively obtained from the second argument given to δ, namely $\langle \underline{w}|a|\underline{v}\rangle$, by applying some copyless natural function. Each item is obtained separately by applying a natural function. Furthermore, the second item is obtained in a copyless way, while the last two items do not use A at all, and therefore they are obtained in a copyless way for trivial reasons, even when combined with the second item. ◀

4 Conclusions

In this paper, we have exhibited a concise algebraic characterization of the regular string-to-string functions, in the style of the definition of regular languages using recognizability by finite semigroups. To perform this extension from languages to functions, we have relied on the basic concepts of category theory: categories, functors, natural transformations.

It should be noted that our use of categories is quite different in spirit from many of the works that take a categorical perspective on automata-theoretic results – see for instance [12], whose introduction points to many further references. In such works, the correspondence between concrete automata models and their rephrasing as suitable (co)algebras or functors tends to be straightforward, with the technical focus lying elsewhere (typically, in generalizing constructions such as determinisation or minimisation). On the contrary, we define a truly new transducer model whose equivalence with the preexisting copyless streaming string transducers requires a non-trivial proof.

An advantage of our characterization of the regular string functions is that, as one would expect from an abstract result, it lends itself to generalizations.

Semigroup-to-semigroup functions. The notion of recognition by a finiteness-preserving transducer semigroup makes sense for functions between arbitrary semigroups. Furthermore, such functions are closed under composition (the proof of Proposition 3.3 works as it is). To check their robustness, it would be desirable to have a more concrete, machine-like model capturing the same function class; possibly a variant of streaming string transducers where the underlying finite automaton is morally "replaced" by a finite semigroup.

More string functions. Another direction is characterizing other classes of string-to-string functions, such as the rational functions or the polyregular functions [7]. In this paper, we have discovered that, somewhat mysteriously, combining two conditions – naturality and preserving finiteness – characterizes exactly the regular functions, which have linear growth. Perhaps there is some way of tweaking the definitions to describe, say, some class with polynomial growth. For instance, the squaring function (Example 2.7) seems to be recognized by a mixed-variance functor $A \mapsto (A \to A) \times A$ with a dinatural output mechanism.

Functions on other free algebras. The definition of a transducer semigroup can applied to other algebras, and not just semigroups. This may be done by taking some monad T and considering functions that can be decomposed, for some endofunctor F of the category of Eilenberg-Moore algebras for the monad T and some natural transformation out, as

$$\mathsf{T}\Sigma \xrightarrow{\text{some } \mathsf{T}\text{-algebra homomorphism}} \mathsf{FT}\Gamma \xrightarrow{\text{out}_{\mathsf{T}\Gamma}} \mathsf{T}\Gamma.$$

An example of this approach is forest algebras [6, Section 5], which are algebras for describing trees. Preliminary work shows that, in the case of forest algebras, the suitable version of Theorem 3.2 also holds, i.e. the finiteness-preserving functors lead to a characterization of the standard notion of regular tree-to-tree functions, namely MSO transductions (see [14, 9]). We believe that these results apply even further, namely for graphs of bounded treewidth, modeled using suitable monads [6, Section 6]. The crucial property is that Lemma 3.14, about reconstructing a coproduct from its views, holds for other monads than just the nonempty list monad for semigroups. Unfortunately, this lemma fails for some monads, such as the monad of formal linear combinations of strings that corresponds to weighted automata. In the future, we intend to conduct a more systematic investigation of the extent to which the characterizations from this paper can be generalized to other algebraic structures.

Abstract

This paper studies two-player zero-sum games played on graphs and makes contributions toward the following question: given an objective, how much memory is required to play optimally for that objective? We study regular objectives, where the goal of one of the two players is that eventually the sequence of colors along the play belongs to some regular language of finite words. We obtain different characterizations of the chromatic memory requirements for such objectives for both players, from which we derive complexity-theoretic statements: deciding whether there exist small memory structures sufficient to play optimally is NP-complete for both players. Some of our characterization results apply to a more general class of objectives: topologically closed and topologically open sets.

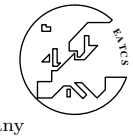
1 Introduction

Games on graphs is a fundamental model in theoretical computer science for modeling systems involving competing agents. Its applications include model-checking, program verification and synthesis, control theory, and reactive synthesis: in all cases, the system specification is turned into a winning objective for a player and the goal is to construct a winning strategy. Some central results in the field state that for some objectives, there exist memoryless optimal strategies, meaning not requiring any memory. For instance, the celebrated memoryless determinacy result for (infinite) parity games is a key ingredient in the modern proof of decidability of monadic second-order logic over infinite trees by Gurevich and Harrington [16].



Memory requirements. However for many objectives, some memory is required; a central question is therefore, stated informally:

Given an objective, how much memory is required to play optimally for this objective?

The first answers to this question, at the dawn of the study of games, were memory requirements for concrete objectives, such as Rabin objectives [22]. The work of Dziembowski, Jurdziński, and Walukiewicz [13] gave a computable characterization of memory requirements for the whole class of Muller objectives. This triggered the following long-term research goal: characterizing the memory requirements for ω-regular objectives.

Regular objectives. Many results have been obtained toward this research goal; we refer to the related works section in Section 3 for further details. The most pressing open question in that direction is regular objectives, meaning the special case of ω-regular objectives concerned with finite duration: in this setting, the objective is induced by a regular language over finite words and the goal of one of the players is that *eventually* the sequence of colors along the play belongs to this language. We call these *regular reachability objectives*. The opponent's objective is then to ensure that the sequence of colors *never* belongs to the language, describing *regular safety objectives*.

A first observation is that for such a regular (reachability or safety) objective, a deterministic finite automaton recognizing the regular language provides an upper bound on the memory requirements of both players. Indeed, playing with the extra information from the automaton reduces the game to a standard reachability or safety game, for which no further memory is required to make optimal decisions. Yet, as we will see, structures smaller than the minimal automaton recognizing the language may suffice for the players.

Chromatic memory. One of the many contributions of Kopczyński [18] in the study of memory for games on graphs is the notion of chromatic memory. In this model, the memory states are updated only using the sequence of colors seen along a play, and in particular do not depend on the graph itself (as opposed to chaotic memory, which may use information from the graph in its updates). Kopczyński conjectured [18] that for ω-regular objectives, chromatic and chaotic memory requirements coincide; unfortunately, this does not hold, as recently proved by Casares [8] (i.e., there are objectives for which the number of memory states required to play optimally in all arenas differs depending on the memory model). In our study, we will see another counterexample using regular objectives.

Contributions. We study the chromatic memory requirements of both regular reachability and regular safety objectives. For both cases, we give a combinatorial characterization of the memory structures sufficient to play optimally in all arenas (of any cardinality). As a by-product of the characterization we obtain complexity-theoretic statements: given as input a deterministic finite automaton representing the objective,

- deciding whether a memory structure suffices to play optimally in all arenas can be done in polynomial time;
- deciding the existence of a sufficient memory structure with a given number of states is NP-complete.

From our characterizations it also follows that for both regular reachability and safety objectives, chromatic and chaotic memory requirements do not coincide.

We also discuss when relevant the extension of our results to the more general class of topologically open and topologically closed objectives (called respectively *general reachability objectives* and *general safety objectives* for consistency in what follows), which include the regular reachability and regular safety objectives.

Implementation. In order to test ideas and conjectures, we have implemented algorithms that automatically build a memory structure with a minimal number of states, both for regular reachability and regular safety objectives. These algorithms are based on the theoretical analysis from this paper. Our implementation[1] uses SAT solvers provided by the Python package PySAT [17].

Structure of the paper. All required definitions are provided in Section 2. Section 3 includes an in-depth discussion of related works and a technical overview of the results and proofs: Section 3.1 for safety objectives, Section 3.2 for reachability objectives, and Section 3.3 for computational complexity results. Due to length constraints, only proof sketches are provided in this version of the article; complete proofs are available in the full version [4]. In particular, proofs for safety objectives are available in [4, Section 4], for reachability objectives in [4, Section 5], and for complexity-theoretic statements in [4, Section 6].

2 Preliminaries

Let C be a non-empty alphabet of *colors*.

Arenas. We study zero-sum turn-based games on graphs with two players, called $\mathcal{P}_1$ and $\mathcal{P}_2$. Players play on *arenas*, which are tuples $\mathcal{A} = (V, V_1, V_2, E)$ where V is a non-empty set of *vertices* such that $V = V_1 \uplus V_2$ (disjoint union) and $E \subseteq V \times C \times V$ is a *set of colored edges*. If $e = (v_1, c, v_2) \in E$, we write $\mathsf{in}(e) = v_1$, $\mathsf{col}(e) = c$, and $\mathsf{out}(e) = v_2$. Vertices in V_1 are controlled by $\mathcal{P}_1$ and vertices in V_2 are controlled by $\mathcal{P}_2$. An arena is *finite* if it has finitely many vertices and edges, and is *finitely branching* if for all $v \in V$, there are finitely many edges $e \in E$ such that $\mathsf{in}(e) = v$. Unless otherwise specified, we consider arenas of any cardinality. An arena $\mathcal{A} = (V, V_1, V_2, E)$ is a *one-player arena of* $\mathcal{P}_1$ (resp. *of* $\mathcal{P}_2$) if $V_2 = \emptyset$ (resp. $V_1 = \emptyset$).

A *history* on arena $\mathcal{A} = (V, V_1, V_2, E)$ is a finite sequence $\gamma = e_1 \dots e_n \in E^*$ such that for i, $1 \leq i \leq n-1$, we have $\mathsf{out}(e_i) = \mathsf{in}(e_{i+1})$. We write $\mathsf{out}(\gamma)$ for $\mathsf{out}(e_n)$. For convenience, we assume that for all $v \in V$, there is a distinct empty history λ_v such that $\mathsf{out}(\lambda_v) = v$. For $i \in \{1, 2\}$, we write $\mathsf{Hists}_i(\mathcal{A})$ for the set of histories γ on $\mathcal{A}$ such that $\mathsf{out}(\gamma) \in V_i$. A *play* on arena $\mathcal{A}$ is an infinite sequence $\pi = e_1 e_2 \dots \in E^\omega$ such that for $i \geq 1$, $\mathsf{out}(e_i) = \mathsf{in}(e_{i+1})$; play π is *from* v if $\mathsf{in}(e_1) = v$. If $\pi = e_1 e_2 \dots \in E^\omega$ is a play (resp. $\gamma = e_1 \dots e_n \in E^*$ is a history), we write $\mathsf{col}^\omega(\pi)$ (resp. $\mathsf{col}^*(\gamma)$) for the infinite sequence $\mathsf{col}(e_1)\mathsf{col}(e_2) \dots \in C^\omega$ (resp. the finite sequence $\mathsf{col}(e_1) \dots \mathsf{col}(e_n) \in C^*$).

Objectives. *Objectives* are subsets $W \subseteq C^\omega$. Given an objective W, we write $\overline{W} = C^\omega \setminus W$ for its complement. We focus on two types of objectives, both derived from a set $A \subseteq C^*$:

- the *general reachability objective derived from* A, denoted $\mathsf{Reach}(A)$, is the objective $\bigcup_{w \in A} wC^\omega$ of infinite words that have (at least) one finite prefix in A.
- the *general safety objective derived from* A, denoted $\mathsf{Safe}(A)$, is the objective $\overline{\bigcup_{w \in A} wC^\omega}$ of infinite words that have no finite prefix in A. We have $\mathsf{Safe}(A) = \overline{\mathsf{Reach}(A)}$.

General reachability and safety objectives are respectively the *topologically open* and *topologically closed sets*, at the first level of the Borel hierarchy. When A is a regular language, we call $\mathsf{Reach}(A)$ a *regular reachability objective* and $\mathsf{Safe}(A)$ a *regular safety objective*. We

[1] Our implementation is available at `https://github.com/pvdhove/regularMemoryRequirements`.

call an objective *regular* if it is a regular reachability or a regular safety objective. Our characterizations apply to regular reachability and safety objectives, but we sometimes discuss when we may generalize our results to the general case. For computational complexity questions, we restrict our focus to regular reachability and safety objectives so that an objective can be finitely represented as an automaton. The objectives that we consider are therefore very simple both in terms of their algebraic representation (using automata representing languages of finite words) and in terms of their topology (they are at the first level of the Borel hierarchy).

A *game* is a tuple $\mathcal{G} = (\mathcal{A}, W)$ where $\mathcal{A}$ is an arena and W is an objective.

Automata. A *deterministic automaton* is a tuple $\mathcal{D} = (Q, C, q_{\mathsf{init}}, \delta, F)$ where Q is a possibly infinite set of *states*, C is a non-empty *alphabet* (usually the set of colors), $q_{\mathsf{init}} \in Q$ is an *initial state*, $\delta \colon Q \times C \to Q$ is a (complete, deterministic) *update function*, and $F \subseteq Q$ is a set of *final states*. All automata in this work are deterministic, so we sometimes omit the word *deterministic*. Automaton $\mathcal{D}$ is *finite* if Q is finite. We write $\delta^* \colon M \times C^* \to M$ for the natural extension of δ to sequences of colors. The *language recognized by* $\mathcal{D}$, denoted $\mathcal{L}(\mathcal{D})$, is the set of finite words $w \in C^*$ such that $\delta^*(q_{\mathsf{init}}, w) \in F$. For $q_1, q_2 \in Q$, we write $\Pi^{\mathcal{D}}_{q_1,q_2}$ for the language of words $w \in C^*$ such that $\delta^*(q_1, w) = q_2$. We drop the superscript $\mathcal{D}$ if the automaton considered is clear in the context. We denote the empty word by ε.

Continuations. For an objective $W \subseteq C^\omega$ and $w \in C^*$, we define the *winning continuations of* w as the set $w^{-1}W = \{w' \in C^\omega \mid ww' \in W\}$ (this set is sometimes called a *left quotient* of W in the literature). Given an objective $W \subseteq C^\omega$, its *prefix preorder* $\preceq_W \subseteq C^* \times C^*$ is defined as $w_1 \preceq_W w_2$ if $w_1^{-1}W \subseteq w_2^{-1}W$. Its *prefix equivalence* $\sim_W \subseteq C^* \times C^*$ is defined as $w_1 \sim_W w_2$ if $w_1^{-1}W = w_2^{-1}W$. We denote $\prec_W = \preceq_W \setminus \sim_W$. We drop the subscript W when there is no ambiguity on the objective. The prefix preorder is a relation that is preserved by reading colors.

▶ **Lemma 1.** *Let $W \subseteq C^\omega$ be an objective. If $w_1 \preceq w_2$, then for all $w \in C^*$, $w_1 w \preceq w_2 w$.*

Starting from a general reachability or safety objective $W \subseteq C^\omega$ derived from a set $A \in C^*$, we can associate with W its minimal automaton $\mathcal{D}_W$ that "classifies" the equivalence classes of $\sim$. Formally, $\mathcal{D}_W = (Q, C, q_{\mathsf{init}}, \delta, F)$ where $Q = \{[w]_\sim \mid w \in C^*\}$ is the set of equivalence classes of $\sim$, $q_{\mathsf{init}} = [\varepsilon]_\sim$, $\delta([w]_\sim, c) = [wc]_\sim$, and $F = \{q_{\mathsf{fin}}\}$ where $q_{\mathsf{fin}} = [w]_\sim$ for some $w \in A$ (the choice of w does not matter). The transition function δ is well-defined: $w_1 \sim w_2$ implies $w_1 c \sim w_2 c$ for all $c \in C$. Notice that the final state of such an automaton is always absorbing, i.e., for all $c \in C$, $\delta(q_{\mathsf{fin}}, c) = q_{\mathsf{fin}}$. This matches the intuition that once a word of A is seen and the reachability (resp. safety) game is won (resp. lost), it stays that way for the rest of the game.

We have that a general reachability (resp. safety) objective W is equal to $\mathsf{Reach}(\mathcal{L}(\mathcal{D}_W))$ (resp. to $\mathsf{Safe}(\mathcal{L}(\mathcal{D}_W))$) – in examples, we will sometimes start from an automaton to generate an objective. Using the well-known Myhill-Nerode theorem [20], we obtain that a general reachability or safety objective W is regular if and only if $\sim$ has finitely many equivalence classes if and only if $\mathcal{D}_W$ is finite.

When considering a minimal automaton $\mathcal{D}_W = (Q, C, q_{\mathsf{init}}, \delta, F)$, for $q \in Q$, we abusively write $q^{-1}W$ for the set $w^{-1}W$, where w is any finite word such that $\delta^*(q_{\mathsf{init}}, w) = q$ (the choice of w does not matter). We extend $\preceq$ to automaton states ($q_1 \preceq q_2$ if $q_1^{-1}W \subseteq q_2^{-1}W$).

Preorders. Let $\preceq$ be a preorder on some set B. We say that two elements $b_1, b_2 \in B$ are *comparable for* $\preceq$ if $b_1 \preceq b_2$ or $b_2 \preceq b_1$. A set $\Gamma \subseteq B$ is a *chain for* $\preceq$ (resp. *antichain for* $\preceq$) if for all $b_1, b_2 \in \Gamma$, b_1 and b_2 are (resp. are not) comparable for $\preceq$. A preorder $\preceq$ is *well-founded* if every chain for $\preceq$ contains a minimal element for $\preceq$.

Memory structures. A *(chromatic) memory structure* is a tuple $\mathcal{M} = (M, m_{\mathsf{init}}, \alpha_{\mathsf{upd}})$ where M is a possibly infinite set of *states*, $m_{\mathsf{init}} \in M$ is an *initial state*, and $\alpha_{\mathsf{upd}} \colon M \times C \to M$ is a (deterministic, complete) *update function*. It is syntactically almost the same as a deterministic automaton, except that we do not specify final states. We recover notations α^*_{upd} and Π_{m_1,m_2} (for $m_1, m_2 \in M$) from automata. We let $\mathcal{M}_{\mathsf{triv}} = (\{m_{\mathsf{init}}\}, m_{\mathsf{init}}, (m_{\mathsf{init}}, c) \mapsto m_{\mathsf{init}})$ denote the only memory structure with a single state. The *size* of a memory structure is its number of states.

Strategies. Let $\mathcal{A} = (V, V_1, V_2, E)$ be an arena and $i \in \{1, 2\}$. A *strategy of $\mathcal{P}_i$ on $\mathcal{A}$* is a function $\sigma_i \colon \mathsf{Hists}_i(\mathcal{A}) \to E$ such that for all $\gamma \in \mathsf{Hists}_i(\mathcal{A})$, $\mathsf{out}(\gamma) = \mathsf{in}(\sigma_i(\gamma))$. Given a strategy σ_i of $\mathcal{P}_i$, we say that a play $\pi = e_1 e_2 \dots$ is *consistent with σ_i* if for all finite prefixes $\gamma = e_1 \dots e_j$ of π such that $\mathsf{out}(\gamma) \in V_i$, $\sigma_i(\gamma) = e_{j+1}$. For $v \in V$, we denote by $\mathsf{Plays}(\mathcal{A}, v, \sigma_i)$ the set of plays on $\mathcal{A}$ from v that are consistent with σ_i.

For $\mathcal{M} = (M, m_{\mathsf{init}}, \alpha_{\mathsf{upd}})$ a memory structure, a strategy σ_i of $\mathcal{P}_i$ on arena $\mathcal{A}$ is *based on (memory) $\mathcal{M}$* if there exists a function $\alpha_{\mathsf{nxt}} \colon V_i \times M \to E$ such that for all $v \in V_i$, $\sigma_i(\lambda_v) = \alpha_{\mathsf{nxt}}(v, m_{\mathsf{init}})$, and for all non-empty histories $\gamma \in \mathsf{Hists}_i(\mathcal{A})$, $\sigma_i(\gamma) = \alpha_{\mathsf{nxt}}(\mathsf{out}(\gamma), \alpha^*_{\mathsf{upd}}(m_{\mathsf{init}}, \mathsf{col}^*(\gamma)))$. A strategy is *memoryless* if it is based on $\mathcal{M}_{\mathsf{triv}}$. For conciseness, we sometimes abusively assume that a strategy of $\mathcal{P}_i$ based on $\mathcal{M}$ is a function $V_i \times M \to E$.

▶ Remark 2. This *chromatic* memory model only observes the sequence of *colors* seen, and not the precise edges that are taken during a play (i.e., the current memory state is determined by the word in C^* seen, not by the history in E^*). A memory structure observing the edges is sometimes called a *chaotic* memory [18] and, as was recently shown, may allow to play optimally with fewer memory states for some objectives [8]. However, this comes at the cost of needing to specialize the transition function of the memory structure for every arena – it does not provide an *arena-independent* memory structure [5]. The chaotic memory requirements of general safety objectives are characterized in [10] while, as far as we know, the chaotic memory requirements of general and regular reachability objectives are unknown. ⌟

Optimality. Let $\mathcal{G} = (\mathcal{A} = (V, V_1, V_2, E), W)$ be a game, and $v \in V$. We say that a strategy σ_1 of $\mathcal{P}_1$ on $\mathcal{A}$ is *winning from v for W* if for all $\pi \in \mathsf{Plays}(\mathcal{A}, v, \sigma_1)$, $\mathsf{col}^\omega(\pi) \in W$.

A strategy of $\mathcal{P}_1$ is *optimal for $\mathcal{P}_1$ in $(\mathcal{A}, W)$* if it is winning from all the vertices of $\mathcal{A}$ from which $\mathcal{P}_1$ has a winning strategy. We often write *optimal for $\mathcal{P}_1$ in $\mathcal{A}$* if the objective W is clear from the context.

▶ Remark 3. We stress that this notion of optimality requires a *single* strategy to be winning from *all* the winning vertices (a property sometimes called *uniformity*). Asking for uniformity may require strategies that are more complex to implement than just requiring winning strategies from individual vertices. Still, uniformity is a common requirement (see, e.g., [14, 21]) that comes at no extra cost in many well-studied situations [13, 12]. We discuss uniformity again in Remark 6.

Note also that there is no requirement on the behavior of an optimal strategy from vertices from which no strategy is winning, as we assume that the opponent plays rationally. In particular, even if winning becomes possible due to a mistake of the opponent after starting from a non-winning vertex, an optimal strategy needs not win. ⌟

Let $\mathcal{M}$ be a memory structure and $W \subseteq C^\omega$ be an objective. We say that $\mathcal{M}$ *suffices (to play optimally) for W (resp. in finite, finitely branching, one-player arenas)* if for all (resp. finite, finitely branching, one-player) arenas $\mathcal{A}$, $\mathcal{P}_1$ has an optimal strategy based on $\mathcal{M}$ in game $(\mathcal{A}, W)$.

3 Technical overview

In this section, we start with a more in-depth discussion of the related literature. We then present our main contributions (characterization of the memory requirements of safety objectives, of reachability objectives, and the computational complexity of the related decision problems) while describing and illustrating the main concepts used in our results. Complete proofs for the three kinds of contributions are available in the full version [4].

Related works. To classify the existing literature on memory for games, we identify two axes. The first is whether they concern chaotic memory or chromatic memory. The second is how the class of objectives is defined: either in automata-theoretic terms, typically as a subclass of ω-regular languages, or in topological terms, referring to the natural topology over the set of infinite words.

The result of Dziembowski, Jurdziński, and Walukiewicz [13] applies to the whole class of Muller objectives, which specify the set of colors which appears infinitely many times. It shows that Zielonka trees [23] can be used to compute chaotic memory requirements in polynomial time. Recently, Casares [8] has shown that this characterization does not extend to chromatic memory: deciding whether there is a memory structure of size k becomes NP-complete and equivalent to minimizing *transition-based Rabin automata*. In this direction, Casares, Colcombet and Lehtinen [9] showed that computing chaotic memory requirements for Muller objectives is equivalent to minimizing good-for-games automata. A result by Bouyer, Randour, and Vandenhove [7] provides a link between the chromatic memory requirements of all ω-regular objectives (not only Muller conditions) and their representation as *transition-based parity automata*, but with less tight bounds on the minimal memory structures.

Article [6] establishes the existence of finite-memory optimal strategies from topological properties of objectives. Although general reachability and safety objectives fit into their framework, there are major differences with our work: their framework is different (they study *concurrent* games that are not played *on graphs*), and their aim is to establish the existence of finite-memory optimal strategies for many objectives, but not to understand precisely the memory requirements of some class of objectives.

Regular objectives are also mentioned in [19], where the existence of finite-memory optimal strategies is shown for Boolean combinations of objectives involving regular objectives.

In another line of works, Gimbert and Zielonka [14] gave a characterization of all payoff functions (extending objectives to a quantitative setting) for which both players have memoryless optimal strategies, implying an important lifting result: the sufficiency of memoryless strategies in finite two-player arenas is implied by the existence of memoryless optimal strategies in both players' finite one-player arenas. Bouyer et al. [5] extended this to chromatic finite memory.

The work most related to the present paper is by Colcombet, Fijalkow, and Horn [10, 11], which gives a characterization of chaotic memory requirements for general safety objectives. Their constructions strongly rely on the model of chaotic memory; indeed, as a corollary of our results, we will see that already for regular safety objectives, chromatic and chaotic memory requirements do not coincide. Our first step is to obtain a characterization of chromatic memory requirements for (general and regular) safety objectives.

3.1 Monotony and safety objectives

Let us fix an objective $W \subseteq C^\omega$. In order to play optimally for W, a memory structure $\mathcal{M}$ needs to be able to distinguish between histories that are not comparable for $\preceq_W$: indeed, if two finite words $w_1, w_2 \in C^*$ are not comparable, we can construct an arena in which the opponent chooses between playing w_1 and playing w_2, and then the correct choice has to be made between a continuation only winning after w_1, and a continuation only winning after w_2. This motivates the following definition, which we call $\mathcal{M}$-*strong-monotony*.

▶ **Definition 4** ($\mathcal{M}$-strong-monotony). *Let $W \subseteq C^\omega$ be an objective and $\mathcal{M} = (M, m_{\mathsf{init}}, \alpha_{\mathsf{upd}})$ be a memory structure. We say that W is* $\mathcal{M}$-strongly-monotone *if for all $w_1, w_2 \in C^*$, $\alpha^*_{\mathsf{upd}}(m_{\mathsf{init}}, w_1) = \alpha^*_{\mathsf{upd}}(m_{\mathsf{init}}, w_2)$ implies that w_1 and w_2 are comparable for $\preceq_W$.*

Notice also that W is $\mathcal{M}$-strongly-monotone if and only if $\overline{W}$ is $\mathcal{M}$-strongly-monotone (as being comparable for $\preceq_W$ is equivalent to being comparable for $\preceq_{\overline{W}} = \succeq_W$). Although stated differently, a property called *strong monotony* was introduced in [1] and coincides with our definition of $\mathcal{M}_{\mathsf{triv}}$-strong-monotony. We can therefore see our definition as a reformulation and a generalization to handle arbitrary memory structures, rather than only the "memoryless memory structure" $\mathcal{M}_{\mathsf{triv}}$.

The discussion above implies that for a memory $\mathcal{M}$, $\mathcal{M}$-strong-monotony is necessary for $\mathcal{M}$ to be sufficient to play optimally. Depending on the type of objective (regular or general), we specify a class of arenas in which $\mathcal{M}$-strong-monotony can already be shown to be necessary. Intuitively, regularity allows to distinguish distinct objectives with ultimately periodic words, which can be encoded into a finite arena.

▶ **Lemma 5** (Necessity of $\mathcal{M}$-strong-monotony). *Let W be an objective and $\mathcal{M}$ a memory structure.*

1. *If W is regular and $\mathcal{M}$ suffices to play optimally for W in all finite one-player arenas, then W is $\mathcal{M}$-strongly-monotone.*
2. *In the general case, if $\mathcal{M}$ suffices to play optimally for W in all finitely branching one-player arenas, then W is $\mathcal{M}$-strongly-monotone.*

Complete proofs for this section can be found in [4, Section 4].

▶ Remark 6. This is the only result relying on the "uniformity" assumption (see Remark 3). This assumption is crucial to obtain this lemma with a hypothesis about *one-player* arenas. We provide additional details about the (small) cost of requiring uniformity w.r.t. memory requirements in two-player games in [4, Section 4]. ⌟

In the case of general reachability or safety objectives, it is useful to reformulate the notion of $\mathcal{M}$-strongly-monotone objectives using chains. Given a general reachability or safety objective W, its minimal automaton $\mathcal{D}_W = (Q, C, q_{\mathsf{init}}, \delta, F)$, and a memory structure $\mathcal{M} = (M, m_{\mathsf{init}}, \alpha_{\mathsf{upd}})$, we can associate with each state $m \in M$ the set $\Gamma^W_m \subseteq Q$ of states of $\mathcal{D}_W$ that can be reached "simultaneously". Formally, for $m \in M$,

$$\Gamma^W_m = \{\delta^*(q_{\mathsf{init}}, w) \in Q \mid w \in C^*, \alpha^*_{\mathsf{upd}}(m_{\mathsf{init}}, w) = m\}.$$

We drop the superscript W if there is no ambiguity. The following property follows from the definitions.

▶ **Lemma 7.** *Let W be a general reachability or safety objective and $\mathcal{M} = (M, m_{\mathsf{init}}, \alpha_{\mathsf{upd}})$ be a memory structure. Objective W is $\mathcal{M}$-strongly-monotone if and only if for all $m \in M$, the set Γ_m is a chain for $\preceq_W$.*

Our initial definition of $\mathcal{M}$-strong-monotony required that any two finite words reaching the same state of $\mathcal{M}$ must be comparable; in this reformulation, we focus instead on the minimal automaton of W and require that states of the automaton that can be reached along with the same state of $\mathcal{M}$ are comparable.

Our first characterization states that for general safety objectives, $\mathcal{M}$-strong-monotony also implies that $\mathcal{M}$ suffices to play optimally. We state two variants of the results: in the first one, we assume that the preorder $\preceq$ induced by the objective is well-founded (which includes the regular case), and the result holds for all arenas; in the second one, we make no such assumption, but the result holds only for finitely branching arenas. We will discuss why we do not have the result with none of these hypotheses in Remark 10.

▶ **Theorem 8** (Characterization for safety). *Let W be a general safety objective, and $\mathcal{M}$ be a memory structure.*

1. *If $\preceq_W$ is well-founded (in particular, if W is regular), then $\mathcal{M}$ suffices to play optimally for W if and only if W is $\mathcal{M}$-strongly-monotone.*
2. *In the general case, $\mathcal{M}$ suffices to play optimally for W in all finitely branching arenas if and only if W is $\mathcal{M}$-strongly-monotone.*

Proof sketch. We provide an overview of the proof of Theorem 8 (complete proof in [4, Section 4]). We discuss here the sufficiency of $\mathcal{M}$-strong-monotony (the necessity is easier and was stated in Lemma 5).

Let $\mathcal{M} = (M, m_{\mathsf{init}}, \alpha_{\mathsf{upd}})$ and let $\mathcal{D}_W = (Q, C, q_{\mathsf{init}}, \delta, F)$ be the minimal automaton of W. We assume that W is $\mathcal{M}$-strongly-monotone. Let $\mathcal{A} = (V, V_1, V_2, E)$ be an arena. As per the hypotheses, we require that $\preceq$ is well-founded or that $\mathcal{A}$ is finitely branching.

We want to build a strategy σ optimal for $\mathcal{P}_1$ in $\mathcal{A}$ such that $\sigma\colon V_1 \times M \to E$ is based on $\mathcal{M}$. The key to the proof is to understand the following sets of states of $\mathcal{D}_W$ in order to know what to play in each pair $(v, m) \in V_1 \times M$. For $v \in V$, $m \in M$, we define

$$Q_{v,m} = \{q \in \Gamma_m \mid \mathcal{P}_1 \text{ has a winning strategy for objective } q^{-1}W \text{ from } v\}.$$

States in $Q_{v,m}$ are states of $\mathcal{D}_W$ that could be reached while the memory state is m, by definition of Γ_m. Moreover, $\mathcal{M}$-strong-monotony tells us that each Γ_m is a chain for $\preceq$ (Lemma 7), so each $Q_{v,m}$ is too.

For given $v \in V_1$ and $m \in M$, we distinguish three possibilities.

- If $Q_{v,m}$ is empty, then this means that there is no state of Γ_m for which $\mathcal{P}_1$ can win from v (i.e., for all $q \in \Gamma_m$, $\mathcal{P}_1$ has no winning strategy for $q^{-1}W$ from v). In this case, we can define $\sigma(v, m)$ arbitrarily, as there is no hope to win.
- If $Q_{v,m}$ has a minimum $q_{v,m}$ for $\preceq$, then this minimum represents the worst (for $\preceq$) state of Γ_m for which $\mathcal{P}_1$ still has a winning strategy. We define $\sigma(v, m)$ as the edge played by such a winning strategy. Intuitively, this is the most robust way to play as it is a winning move for the worst possible state of Γ_m for which winning is possible. Notice that a non-empty $Q_{v,m}$ always has a minimum when $\preceq$ is well-founded.
- In case $Q_{v,m}$ is non-empty and has no minimum, then $\preceq$ is not well-founded, so we work under the hypothesis that $\mathcal{A}$ is finitely branching. We can then consider, for each $q \in Q_{v,m}$, the set of edges E_q that can be taken from v to win for $q^{-1}W$. Each E_q is finite and non-empty, and they are ordered for inclusion. We can then show that their intersection is non-empty, so there is an edge that can be taken in v to win for all $q \in Q_{v,m}$. We define $\sigma(v, m)$ as such an edge.

We have now defined a strategy σ based on $\mathcal{M}$ that makes local choices that are played by winning strategies for as many states of Γ_m (where m is the current memory state) as possible. Using the fact that W is a general safety condition, one can prove that this strategy is in fact optimal. ◀

A corollary of this characterization, by comparing to the characterization for chaotic memory in [10], is that chromatic and chaotic memory requirements differ already for regular safety objectives. We provide an instructive example below. Note that this provides a new simple kind of counterexample to Kopczyński's conjecture [18], which Casares [8] had already falsified with a Muller objective.

▶ **Example 9.** Let $C = \{a, b, c, d\}$. We consider the regular language recognized by the finite automaton $\mathcal{D}$ depicted in Figure 1 (left). It accepts the finite words that first see both a and b (in any order, possibly interspersed with c's and d's), and then see both c and d (in any order, possibly interspersed with a's and b's). This language can be described by the regular expression $C^*(aC^*b \mid bC^*a)C^*(cC^*d \mid dC^*c)C^*$. We write W for the induced regular safety objective: $W = \mathsf{Safe}(\mathcal{L}(\mathcal{D}))$.

The main claim is that the chaotic memory requirements for W are two states, which is easily obtained from the existing characterization [10] (this is the size of a maximal antichain for $\preceq$), while the chromatic requirements for W are three states. We depict a memory structure $\mathcal{M}$ with three states which makes W $\mathcal{M}$-strongly-monotone in Figure 1 (right). To check that W is indeed $\mathcal{M}$-strongly-monotone, we have to check that there is no pair of words $w_1, w_2 \in C^*$ such that w_1 and w_2 reach the same state of $\mathcal{M}$, but reach non-comparable states in $\mathcal{D}$. The only two pairs of non-comparable states in $\mathcal{D}$ are q_a and q_b, and q_c and q_d (besides these, states are ordered for $\preceq$ from right to left). We can check that for this choice of $\mathcal{M}$, $\Gamma_{m_1} = \{q_{\mathsf{init}}, q_a\}$, $\Gamma_{m_2} = \{q_b, q_{ab}, q_d, q_{cd}\}$, $\Gamma_{m_3} = \{q_b, q_{ab}, q_c, q_{cd}\}$. As these are all chains for $\preceq$, we have that W is $\mathcal{M}$-strongly-monotone.

It is not possible to find a chromatic memory structure $\mathcal{M}$ with *two* states which makes W $\mathcal{M}$-strongly-monotone (this can be checked by trying to assign transitions to two states while distinguishing non-comparable states, and observing that all cases fail). ⌟

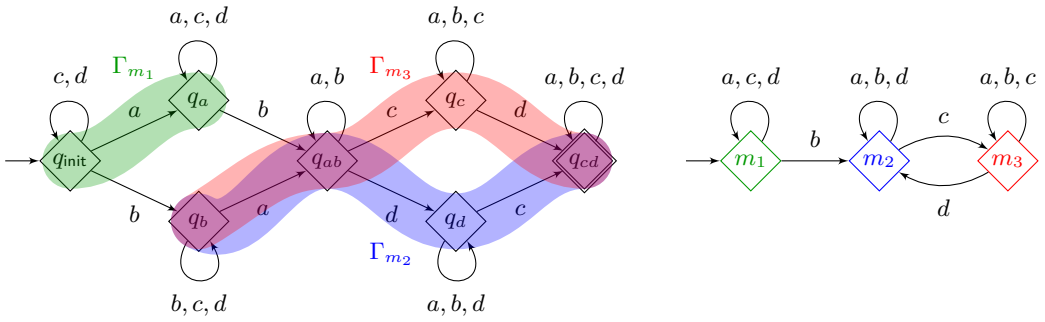


Figure 1 Example 9: automaton $\mathcal{D}$ (left) and a minimal memory structure $\mathcal{M}$ (right) such that $\mathsf{Reach}(\mathcal{L}(\mathcal{D}))$ and $\mathsf{Safe}(\mathcal{L}(\mathcal{D}))$ are $\mathcal{M}$-strongly-monotone. In figures, diamonds are used to depict automaton states and memory states, and accepting states are depicted with a double border.

To conclude this section, we discuss why, with neither the well-foundedness hypothesis nor the finitely branching hypothesis from Theorem 8, we cannot expect such a characterization.

▶ Remark 10. If the prefix preorder of an objective W is not well-founded, then there is an infinite decreasing sequence of finite words $w_1 \succ w_2 \succ \dots$ in C^*. This means that for all $i \geq 1$, there is $w'_i \in C^\omega$ such that $w_i w'_i \in W$, but for $j > i$, $w_j w'_i \notin W$. We can then build the infinitely branching arena depicted in Figure 2 in which $\mathcal{P}_2$ first chooses a word w_j, and $\mathcal{P}_1$ can win by playing a word w'_i with $i \geq j$. This requires infinite memory, even if W is $\mathcal{M}_{\mathsf{triv}}$-strongly-monotone. ⌟

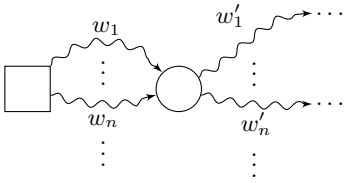

Figure 2 Infinite branching arena in which $\mathcal{P}_1$ needs memory beyond the $\mathcal{M}$-strong-monotony property in Remark 10. In figures, circles (resp. squares) represent arena vertices controlled by $\mathcal{P}_1$ (resp. $\mathcal{P}_2$), i.e., in V_1 (resp. V_2). Squiggly arrows indicate a sequence of edges.

3.2 Capturing progress and reachability objectives

To play optimally for general and regular reachability objectives with a memory $\mathcal{M}$, $\mathcal{M}$-strong-monotony is necessary (Lemma 5) but not enough: the following example shows that the memory structure must keep track of *progress*.

▶ **Example 11.** Let $C = \{a, b\}$. We consider the regular language $b^*a^+bC^*$ of words that have to see at least one a, followed by at least one b. This language is recognized by the finite automaton $\mathcal{D}$ in Figure 3 (left). We write W for the induced regular reachability objective: $W = \mathsf{Reach}(\mathcal{L}(\mathcal{D}))$.

In the arena in Figure 3 (center), $\mathcal{P}_1$ may win by starting a play with ab, but not without memory. The intuition is that playing a first makes some progress (it reaches an automaton state with more winning continuations), but is not sufficient to win, even if repeated. Therefore, in our memory structures, if a word makes some progress but without guaranteeing the win when repeated, we want the memory state to change upon reading that word. The memory structure in Figure 3 (right) is sufficient for W; in particular, seeing the first a, which makes progress from q_{init} to q_a, changes the memory state. ⌟

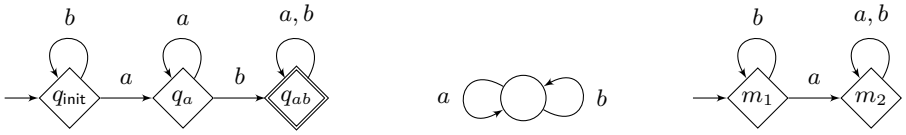

Figure 3 Example 11: automaton $\mathcal{D}$ (left), an arena requiring memory for $\mathsf{Reach}(\mathcal{L}(\mathcal{D}))$ (center), and a minimal sufficient memory structure (right).

We formalize this intuition in the following definition, which is a generalization of the *progress-consistency* property [3]. Notation Π_{m_1,m_2}, representing the finite words read from memory state m_1 to memory state m_2, was defined in Section 2.

▶ **Definition 12** ($\mathcal{M}$-progress-consistency)**.** *Let W be an objective and $\mathcal{M} = (M, m_{\mathsf{init}}, \alpha_{\mathsf{upd}})$ be a memory structure. We say that W is* $\mathcal{M}$-progress-consistent *if for all $m \in M$, for all $w_1 \in \Pi_{m_{\mathsf{init}},m}$, for all $w_2 \in \Pi_{m,m}$,*

$$w_1 \prec w_1w_2 \implies w_1(w_2)^\omega \in W.$$

Intuitively, this says that if it is possible to come back to the same memory state while reading a "word that makes progress" (i.e., that improves our situation by putting us in a position with more winning continuations), then repeating this word infinitely often from that point onward must be winning. The notion of $\mathcal{M}_{\mathsf{triv}}$-progress-consistency corresponds to the previous definition of *progress-consistency* [3].

The discussion above shows that $\mathcal{M}$-progress-consistency is necessary for a memory structure $\mathcal{M}$ to be sufficient to play optimally. As for $\mathcal{M}$-strong-monotony, we distinguish the regular case from the general case.

▶ **Lemma 13** (Necessity of $\mathcal{M}$-progress-consistency). *Let W be an objective and $\mathcal{M}$ a memory structure.*

1. *If W is regular and $\mathcal{M}$ suffices to play optimally for W in all finite one-player arenas, then W is $\mathcal{M}$-progress-consistent.*
2. *In the general case, if $\mathcal{M}$ suffices to play optimally for W in all finitely branching one-player arenas, then W is $\mathcal{M}$-progress-consistent.*

Complete proofs for this section can be found in [4, Section 5]. The following example should help the reader form the right intuition about $\mathcal{M}$-progress-consistency.

▶ **Example 14.** Let $C = \{a, b\}$. We consider the regular language of words containing *ababa* as a (non-necessarily contiguous) subword, recognized by the finite automaton $\mathcal{D}$ in Figure 4 (left). We consider the memory structure $\mathcal{M}$ remembering whether a or b was last seen, depicted in Figure 4 (right). The regular reachability objective $W = \mathsf{Reach}(\mathcal{L}(\mathcal{D}))$ is $\mathcal{M}$-progress-consistent. Indeed, let us first consider $m = m_b$ in the definition of $\mathcal{M}$-progress-consistency. A finite word w_1 reaching m_b in $\mathcal{M}$ necessarily reaches q_{init}, q_{ab}, or q_{abab} in Q (excluding the final state from the reasoning, as no progress is possible from it). After w_1, words w_2 that both (i) make progress ($w_1 \prec w_1w_2$) and (ii) are a cycle on m_b necessarily see both a and b. Therefore, $w_1(w_2)^\omega$ is always a winning word. The same reasoning holds for $m = m_a$. Notice that the memory states from the memory structure do not carry enough information to ascertain when a word of the language has been seen (i.e., when the game is won).

The upcoming Theorem 16 implies that $\mathcal{M}$ suffices to play optimally for $\mathcal{P}_1$. ⌟

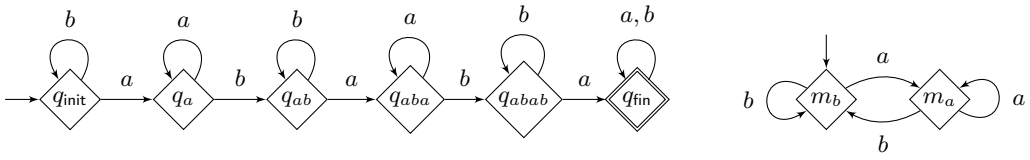

Figure 4 Example 14: automaton $\mathcal{D}$ (left) and memory structure $\mathcal{M}$ (right).

This need to capture *progress* was not necessary to understand the memory requirements of safety objectives, which may be explained by the following reasoning.

▶ Remark 15. Unlike general reachability objectives, all general safety objectives are $\mathcal{M}_{\mathsf{triv}}$-progress-consistent. Here is a proof of this statement. Let $W \subseteq C^\omega$ be a general safety objective. Let $w_1, w_2 \in \Pi^{\mathcal{M}_{\mathsf{triv}}}_{m_{\mathsf{init}}, m_{\mathsf{init}}} = C^*$ be such that $w_1 \prec w_1w_2$. This implies that w_1w_2, and therefore w_1, have a non-empty set of winning continuations. Assume by contradiction that $w_1(w_2)^\omega \notin W$. As W is a general safety objective, there is a smallest $n \geq 1$ such that $w_1(w_2)^n$ has no winning continuation. Hence, $w_1(w_2)^{n-1}$ still has some winning continuations, so $w_1(w_2)^n \prec w_1(w_2)^{n-1}$. This is a contradiction, as $w_1 \prec w_1w_2$ implies that $w_1(w_2)^{n-1} \preceq w_1w_2(w_2)^{n-1} = w_1(w_2)^n$ by Lemma 1. This property is, at least intuitively, a reason hinting that the memory requirements of safety objectives are lower and easier to understand than those for their complement reachability objective. ⌟

We have now discussed two necessary properties for a memory $\mathcal{M}$ to be sufficient to play optimally for an objective. For regular reachability objectives, it appears that the conjunction of these two properties is also sufficient.

▶ **Theorem 16** (Characterization for reachability). *Let W be a regular reachability objective and $\mathcal{M}$ be a finite memory structure. Memory $\mathcal{M}$ suffices to play optimally for W if and only if W is $\mathcal{M}$-strongly-monotone and $\mathcal{M}$-progress-consistent.*

Proof sketch. We provide an overview of the proof of Theorem 16 (complete proof in [4, Section 5]). We discuss here the sufficiency of $\mathcal{M}$-strong-monotony and $\mathcal{M}$-progress-consistency (their necessity is easier and was stated in Lemmas 5 and 13).

Let $\mathcal{D}_W = (Q, C, q_{\mathsf{init}}, \delta, F)$ be the minimal automaton of W (which is finite as W is regular), and $\mathcal{M} = (M, m_{\mathsf{init}}, \alpha_{\mathsf{upd}})$. We assume that W is $\mathcal{M}$-strongly-monotone and $\mathcal{M}$-progress-consistent. Let $\mathcal{A} = (V, V_1, V_2, E)$ be a (possibly infinite) arena. We construct an optimal strategy based on memory $\mathcal{M}$, using the same idea as in the proof for safety objectives (Theorem 8): we once again consider a strategy based on $\mathcal{M}$ making choices that are "locally optimal". We then show, thanks to our hypotheses ($\mathcal{M}$-strong-monotony and $\mathcal{M}$-progress-consistency), that this strategy must be optimal.

For $v \in V_1$, $m \in M$, we define

$$q_{v,m} = \min_{\preceq}\{q \in \Gamma_m \mid \mathcal{P}_1 \text{ has a winning strategy for objective } q^{-1}W \text{ from } v\}.$$

Every set Γ_m is a chain using $\mathcal{M}$-strong-monotony (Lemma 7) and is finite since $\mathcal{D}_W$ is finite. Hence, the minimum $q_{v,m}$ exists (except when the set is empty, but that means that the game cannot be won anymore – we ignore this case). Let $\sigma_{v,m}$ be a strategy winning for $q_{v,m}^{-1}W$ from v.

Now, just like for the proof for safety, we want to define $\sigma(v, m)$ as the first edge taken by $q_{v,m}$ from v – we play locally reasonable edges played by good strategies and hope that this creates a "globally" optimal strategy. However, this does not work in general, as any choice for the strategies $\sigma_{v,m}$ may not be good: indeed, such strategies may be winning, but may make unnecessary moves delaying the achievement of the objective. For instance, in the arena of Figure 3, a strategy playing bab^ω is winning for $q_{\mathsf{init}}^{-1}W$, but not as fast as possible (it takes three moves to create a word in $\mathcal{L}(\mathcal{D})$, while it is possible to do it in two moves). If, by imitating the first move of this strategy, we define $\sigma(v, m_1) = (v, b, v)$, we then get stuck and σ plays the losing word b^ω.

A way to remedy this is by formally defining the "time" taken by a strategy to guarantee a win, and choosing strategies $\sigma_{v,m}$ that win in the least time. When considering infinite two-player arenas, this time has to be defined using ordinals. If we do this, it is possible (though still quite involved) to show that σ defined as above is indeed optimal, thanks to $\mathcal{M}$-progress-consistency. ◀

▶ Remark 17. Unlike safety objectives, our characterization is only shown to hold for *regular* reachability objectives. We discuss in [4, Section 5] why our proof technique does not apply to general reachability objectives (even with $\preceq$ well-founded and finite branching of the arenas). ⌟

For objectives beyond reachability and safety, $\mathcal{M}$-strong-monotony and $\mathcal{M}$-progress-consistency may not imply the sufficiency of $\mathcal{M}$ to play optimally. For instance, with $C = \{a, b\}$, let us consider the objective

$$W = \{w \in C^\omega \mid a \text{ and } b \text{ are both seen infinitely often}\},$$

which is ω-regular (it can be recognized by a *deterministic Büchi automaton* with two states), but is not a general reachability nor safety objective. Objective W is $\mathcal{M}_{\mathsf{triv}}$-strongly-monotone and $\mathcal{M}_{\mathsf{triv}}$-progress-consistent, but $\mathcal{M}_{\mathsf{triv}}$ does not suffice to play optimally.

Lift for regular objectives. As a by-product of our results, we observe that for regular objectives, our characterizations deal with arbitrary arenas of any cardinality, but the properties used in the characterizations are already necessary in *finite one-player* arenas. This means that strategy-wise, to accomplish a regular objective, all the complexity already appears in finite graphs with no opponent. For the specific class of regular objectives that we study, this strengthens so-called *one-to-two-player lifts* from the literature [14, 5].

▶ **Theorem 18** (Finite-to-infinite, one-to-two-player lift). *Let W be a regular (reachability or safety) objective and $\mathcal{M}$ be a finite memory structure. Memory $\mathcal{M}$ suffices to play optimally for W (in all arenas) if and only if $\mathcal{M}$ suffices to play optimally for W in finite one-player arenas.*

Proof. The implication from left-to-right holds as this is the same property quantified over fewer arenas. We argue the other implication for each case.

For regular safety objectives W, we showed that if $\mathcal{M}$ suffices in finite one-player arenas, then W is $\mathcal{M}$-strongly-monotone (by Lemma 5 as W is regular), which implies that $\mathcal{M}$ suffices in all arenas (by Theorem 8 as W is a safety condition with a well-founded preorder).

For regular reachability objectives W, we showed that if $\mathcal{M}$ suffices in finite one-player arenas, then W is $\mathcal{M}$-strongly-monotone and $\mathcal{M}$-progress-consistent (by Lemmas 5 and 13 as W is regular), which implies that $\mathcal{M}$ suffices in all arenas (by Theorem 16 as W is a regular reachability objective). ◀

3.3 The complexity of finding small memory structures

We finally discuss the computational complexity of finding small memory structures for regular objectives. We formalize the question as two decision problems: given a regular reachability or safety objective, how much memory is required to play optimally for this objective?

Memory-Safe

Input: A finite automaton $\mathcal{D}$ inducing the regular safety objective $W = \mathsf{Safe}(\mathcal{L}(\mathcal{D}))$ and an integer $k \in \mathbb{N}$.

Question: Does there exist a memory structure $\mathcal{M}$ of size at most k which suffices to play optimally for W?

Memory-Reach

Input: A finite automaton $\mathcal{D}$ inducing the regular reachability objective $W = \mathsf{Reach}(\mathcal{L}(\mathcal{D}))$ and an integer $k \in \mathbb{N}$.

Question: Does there exist a memory structure $\mathcal{M}$ of size at most k which suffices to play optimally for W?

It follows from our characterizations (Theorems 8 and 16) that Memory-Safe is equivalent to asking whether there is a memory structure $\mathcal{M}$ of size at most k such that $\mathsf{Safe}(\mathcal{L}(\mathcal{D}))$ is $\mathcal{M}$-strongly-monotone, and Memory-Reach whether there is a memory structure $\mathcal{M}$ of size at most k such that $\mathsf{Reach}(\mathcal{L}(\mathcal{D}))$ is $\mathcal{M}$-strongly-monotone and $\mathcal{M}$-progress-consistent.

▶ Remark 19. The way k is encoded (in binary or in unary) has no impact on the complexity. Indeed, the input consists of the number k together with a (deterministic) automaton describing the objective. Since the automaton is an upper bound on the memory requirements (for both Memory-Safe and Memory-Reach), the problem is non-trivial only when k is smaller than the size of the automaton. Therefore, the size of the input is dominated by the size of the automaton in the non-trivial cases. ⌟

▶ **Theorem 20** (Complexity of Memory-Safe and Memory-Reach). *Both Memory-Safe and Memory-Reach are NP-complete.*

For NP-hardness, we construct a reduction from the Hamiltonian cycle problem which works for both Memory-Safe and Memory-Reach. Complete proofs for this section can be found in [4, Section 6].

Our main insight is to reformulate the notion of $\mathcal{M}$-strong-monotony (NP-membership of Memory-Safe follows from this reformulation). Let $W = \mathsf{Safe}(\mathcal{L}(\mathcal{D}))$ be a regular objective and $\mathcal{M} = (M, m_{\mathsf{init}}, \alpha_{\mathsf{upd}})$ be a memory structure. In Example 9, we have seen how to go from a memory structure $\mathcal{M}$ such that W is $\mathcal{M}$-strongly-monotone to a covering of the states of $\mathcal{D}$ by chains of states. We formulate exactly the requirements for such coverings in order to have a point of view equivalent to $\mathcal{M}$-strong-monotony. For $\Gamma \subseteq Q$ a set of automaton states and $c \in C$ a color, we define $\delta(\Gamma, c) = \{\delta(q, c) \mid q \in \Gamma\}$.

▶ **Definition 21** (Monotone decomposition). *Let $\mathcal{D} = (Q, C, q_{\mathsf{init}}, \delta, F)$ be an automaton. We say that the sets $\Gamma_1, \dots, \Gamma_k \subseteq Q$ form a* monotone decomposition of $\mathcal{D}$ *if*
(a) $Q = \bigcup_{i=1}^{k} \Gamma_i$,
(b) *for all $c \in C$, for all $i \in \{1, \dots, k\}$, there is $j \in \{1, \dots, k\}$ such that $\delta(\Gamma_i, c) \subseteq \Gamma_j$, and*
(c) *for all $i \in \{1, \dots, k\}$, Γ_i is a chain for $\preceq$.*

Note that the sets Γ_i do not have to be disjoint (as was illustrated in Example 9). If we only consider requirements (a) and (b) of this definition, we recover the definition of an *admissible decomposition*, which can be used to quotient an automaton [15]. Here, we add the additional requirement (c) that each set of states is a chain for $\preceq$. Note that there always exists an admissible decomposition with just one set (by taking $\Gamma_1 = Q$), but finding a small *monotone* decomposition may not be so easy. This point of view in terms of monotone decompositions turns out to be equivalent to our initial point of view in terms of $\mathcal{M}$-strong-monotony in the following sense.

▶ **Lemma 22.** *Let $\mathcal{D}$ be an automaton and W be equal to $\mathsf{Safe}(\mathcal{L}(\mathcal{D}))$ or $\mathsf{Reach}(\mathcal{L}(\mathcal{D}))$. Automaton $\mathcal{D}$ admits a monotone decomposition with k sets if and only if W is $\mathcal{M}$-strongly-monotone for some memory structure $\mathcal{M}$ of size k.*

It is instructive to reformulate the characterization of *chaotic* memory requirements from [10]: the original phrasing was that the number of memory states necessary and sufficient to play optimally for the safety objective W is the size of the largest antichain of $\preceq_W$. Using our terminology and Dilworth's theorem, it is equivalent to the smallest number of chains required to cover all states; that is, decompositions satisfying (a) and (c) in Definition 21, but not necessarily (b). Hence, it is smaller in general.

We finish this section with an overview of the proof of Theorem 20 (complete proofs in [4, Section 6]).

Proof sketch of Theorem 20. We first discuss membership in NP, and then NP-hardness.

Membership in NP. Problem Memory-Safe with inputs $\mathcal{D}$ and k was shown in Theorem 8 to be equivalent to the existence of a memory structure $\mathcal{M}$ of size k such that W is $\mathcal{M}$-strongly-monotone. This second problem is itself equivalent by Lemma 22 to the existence of a monotone decomposition of $\mathcal{D}$ with k sets. A monotone decomposition is a polynomial-size witness, and checking whether k sets of states form a monotone decomposition is done in polynomial time by checking the three conditions in the definition. This shows NP-membership of Memory-Safe.

For Memory-Reach, we use memory structures as polynomial-size witnesses. Let $\mathcal{D}$ be a finite automaton and $k \in \mathbb{N}$. Given a memory structure $\mathcal{M}$ of size k, we want to decide in polynomial time whether objective $\mathsf{Reach}(\mathcal{L}(\mathcal{D}))$ is $\mathcal{M}$-strongly-monotone and $\mathcal{M}$-progress-consistent. We have discussed how to check $\mathcal{M}$-strong-monotony in polynomial time through monotone decompositions. Checking $\mathcal{M}$-progress-consistency in polynomial time is slightly more involved and is described in [4, Section 6]: we reduce $\mathcal{M}$-progress-consistency to checking a polynomial number of emptiness queries of intersections of regular languages recognized by deterministic finite automata.

NP-hardness. As mentioned above, we prove NP-hardness of Memory-Safe using a reduction from the Hamiltonian cycle problem. The proof also applies to Memory-Reach, but we move this discussion to [4, Section 6]. In the following, a *(directed) graph* is a tuple $G = (V, E)$ with $E \subseteq V \times V$. A *Hamiltonian cycle of* G is a sequence $(u_1, \dots, u_n)$ in which each state of V appears exactly once, $(u_i, u_{i+1}) \in E$ for all i, $1 \leq i < n$, and $(u_n, u_1) \in E$.

We start from a directed graph $G = (V, E)$ and we intend to build an automaton $\mathcal{D}_G$ such that G has a Hamiltonian cycle if and only if $\mathcal{D}_G$ has a monotone decomposition with k sets, for a well-chosen k. We write $|V| = n$ and $|E| = m$. We assume $m \geq n$, otherwise G cannot have a Hamiltonian cycle. We define $\mathsf{Automaton}(G)$ as the automaton $(Q, \Sigma, \delta, q_{\mathsf{init}}, F)$ with $Q = V \uplus E$, $\Sigma = \{\mathsf{in}, \mathsf{out}\}$, and transitions such that for $v \in V$, $\delta(v, \mathsf{in}) = \delta(v, \mathsf{out}) = v$, and for $e = (v_1, v_2) \in E$, $\delta(e, \mathsf{in}) = v_1$ and $\delta(e, \mathsf{out}) = v_2$. We ignore q_{init} and F at the moment. This definition is inspired from a reduction in [2] (although the rest of the proof is different).

We also consider the *cycle graph with* n *vertices* $C_n = (V_C, E_C)$, with $V_C = \{v_1^C, \dots, v_n^C\}$ and $E_C = \{e_1^C, \dots, e_n^C\}$ such that $e_i^C = (v_i^C, v_{i+1}^C)$ for $1 \leq i < n$ and $e_n = (v_n^C, v_1^C)$. We now consider an automaton $\mathcal{D}_G = (Q, \Sigma, \delta, q_{\mathsf{init}}, F)$ based on the disjoint union $\mathsf{Automaton}(C_n) \uplus \mathsf{Automaton}(G)$ along with three extra states q_{init}, $\bot$, and $\top$. We illustrate this part of the construction in Figure 5.

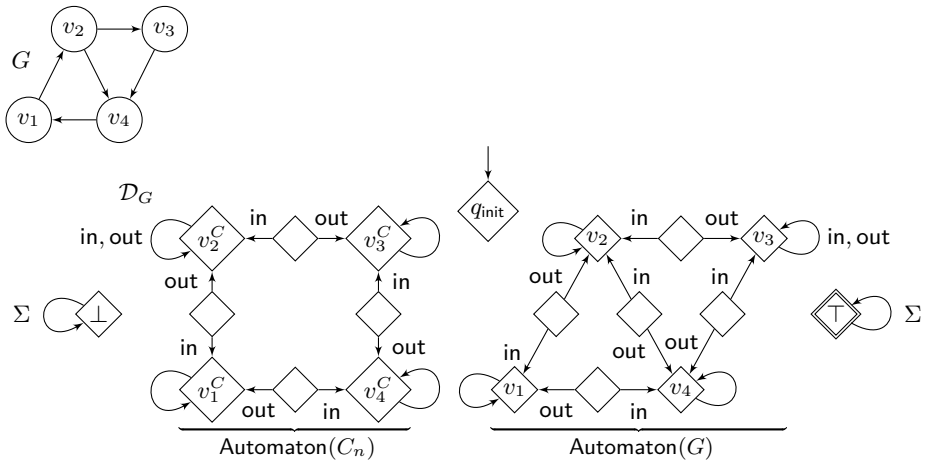

Figure 5 Illustration of automaton $\mathcal{D}_G$ starting from a graph G with four vertices. This is only a part of the full construction in [4, Section 6] to give an overview of the proof.

What is now missing is a way to induce an interesting ordering $\preceq$ – intuitively, we want $\bot$ to be the smallest state, $\top$ to be the largest, and all automaton states corresponding to vertices (resp. edges) of $\mathsf{Automaton}(C_n)$ to be smaller than all automaton states corresponding to vertices (resp. edges) of $\mathsf{Automaton}(G)$, while making all other pairs of states non-comparable. We can get this ordering by adding a letter to Σ for each state of $\mathcal{D}_G$ and defining the right transitions from q_{init} and to $\bot$ and $\top$.

In this way, we have that chains of $\mathcal{D}_G$ for $\preceq$ have at most 4 states, and chains with four states contain either $\bot$, $\top$, a vertex of C_n and a vertex of G, or $\bot$, $\top$, an edge of C_n and an edge of G. Moreover, the largest antichain of $\mathcal{D}_G$ for $\preceq$ has $n+m+1$ elements and is achieved by $V \cup E \cup \{q_{\mathsf{init}}\}$. By a counting argument, it is then possible to cover all states with $n+m+1$ chains if only if every vertex (resp. edge) of C_n is in a chain with one vertex (resp. edge) of G. A covering with $n+m+1$ chains therefore induces a bijection between V_C and V and an injection from E_C to E. To form a monotone decomposition, these chains still have to satisfy condition b from Definition 21. If it is possible to find $n+m+1$ such chains, we can show by reading in and out from chains containing edges that the cycle on C_n transfers to a Hamiltonian cycle on G. Reciprocally, if G has a Hamiltonian cycle, then we can find a natural correspondence between vertices (resp. edges) of C_n and vertices (resp. edges) of G that allows to define a monotone decomposition with $n+m+1$ sets. We have that G has a Hamiltonian cycle if and only if $\mathcal{D}_G$ has a monotone decomposition in $k = n+m+1$ sets. ◀

4 Conclusion

We have characterized the minimal memory structures sufficient to play optimally for regular reachability and safety objectives. In doing so, we were able to prove that related decision problems about regular objectives were NP-complete. Our characterizations were encoded into a SAT solver that automatically generates a minimal memory structure given a finite automaton as an input (link in Section 1).

This article can be seen as one step toward understanding more generally the (chromatic or chaotic) memory requirements of all ω-regular objectives, as well as synthesizing minimal memory structures for them. The chaotic memory requirements of regular reachability objectives are still unknown, as well as the chromatic memory requirements of larger classes of ω-regular objectives (such as, e.g., the objectives recognized by deterministic Büchi automata).

Abstract

We prove that for any monotone class of finite relational structures, the first-order theory of the class is NIP in the sense of stability theory if, and only if, the collection of Gaifman graphs of structures in this class is nowhere dense. This generalises results previously known for graphs to relational structures and answers an open question posed by Adler and Adler (2014). The result is established by the application of Ramsey-theoretic techniques and shows that the property of being NIP is highly robust for monotone classes. We also show that the model-checking problem for first-order logic is intractable on any monotone class of structures that is not (monadically) NIP. This is a contribution towards the conjecture that the hereditary classes of structures admitting fixed-parameter tractable model-checking are precisely those that are monadically NIP.

1 Introduction

The development of stability theory in classical model theory, originating with Shelah's classification programme fifty years ago [19, 2], has sought to distinguish *tame* first-order theories from *wild* ones. A key discovery is that combinatorial configurations serve as dividing lines in this classification.

Separately, in the development of finite model theory, there has been in interest in investigating *tame* classes of finite structures. Here tameness can refer to *algorithmic tameness*, meaning that algorithmic problems that are intractable in general may be tractable on a tame class; or it can refer to *model-theoretic tameness*, meaning that the class enjoys

some desirable model-theoretic properties that are absent in the class of all finite structures. See [6] for an exposition of these notions of tameness. The tame classes that arise in this context are often based on notions taken from the study of sparse graphs [15] and usually extended to classes of relational structures beyond graphs by applying them to the *Gaifman graphs* of such structures.

In the context of algorithmic tameness of sparse classes, this line of work culminated in the major result of Grohe et al. [10] showing that the problem of model checking first-order sentences is fixed-parameter tractable (FPT) on any class of graphs that is *nowhere dense*. This generalized a sequence of earlier results showing the tractability of the model checking problem on classes of graphs satisfying other notions of sparsity. Moreover, it is also known [13] that this is the limit of tractability for *monotone* classes of graphs. That is to say that (under reasonable assumptions) any monotone class of graphs in which first-order model checking is FPT is necessarily nowhere dense. These results underline the centrality of the notion of nowhere denseness in the study of sparse graph classes.

A significant line of recent research has sought to generalize the methods and results on tame sparse classes of graphs to more general classes that are not necessarily sparse. Interestingly, this has tied together notions of tameness arising in finite model theory and those in classical model theory. Notions arising from stability theory play an increasingly important role in these considerations (see [16, 8], for example). Central to this connection is the realisation that for well-studied notions of sparseness in graphs, the first-order theory of a sparse class $\mathcal{C}$ is stable. Thus, stability-theoretic notions of tameness, applied to the theory of a class of finite structures, generalize the notions of tameness emerging from the theory of sparsity.

A key result connecting the two directions is that a monotone class of finite graphs is stable if, and only if, it is nowhere dense. This connection between stability and combinatorial sparsity was established in the context of infinite graphs by Podewski and Ziegler [17] and extended to classes of finite graphs by Adler and Adler [1]. Indeed, for monotone classes of graphs, stability is a rather robust concept as the theory of such a class is stable if, and only if, it is NIP (that is, it does not have the independence property) and these conditions on monotone classes are in turn equivalent to it being monadically stable and monadically NIP (these notions are formally defined in Section 2 below).

A question posed by Adler and Adler is whether their result can be extended from graphs to structures in any finite relational language. We settle this question in the present paper by establishing Theorem 1 below. In the following $\mathsf{Gaif}(\mathcal{C})$ (respectively $\mathsf{Inc}(\mathcal{C})$) denotes the collection of Gaifman graphs (resp. incidence graphs) of structures in the class $\mathcal{C}$. Note that the extension from graphs to relational structures requires considerable combinatorial machinery in the form of Ramsey-theoretic results, which we detail in later sections. We also relate the characterization to the tractability of the classes. In summary, our key results are stated in the following theorem. See Section 2 for all the relevant definitions.

▶ **Theorem 1.** *Let $\mathcal{C}$ be a monotone class of finite structures in a finite relational language. Then, the following are equivalent:*

1. *$\mathcal{C}$ is NIP;*
2. *$\mathcal{C}$ is monadically NIP;*
3. *$\mathcal{C}$ is stable;*
4. *$\mathcal{C}$ is monadically stable;*
5. *$\mathsf{Gaif}(\mathcal{C})$ is nowhere dense;*
6. *$\mathsf{Inc}(\mathcal{C})$ is nowhere dense; and*
7. *(assuming $\mathsf{AW}[*] \neq \mathsf{FPT}$) $\mathcal{C}$ admits fixed-parameter tractable model checking.*

Moreover, the equivalence of the first six notions also holds for classes containing infinite structures.

Thus, for monotone classes of relational structures, the picture is clear. Beyond monotone classes, not every NIP class is stable or monadically NIP. However, it has been conjectured [22, 9] that for any hereditary class $\mathcal{C}$ of structures, the model checking problem on $\mathcal{C}$ is fixed-parameter tractable if, and only if, $\mathcal{C}$ is NIP. This has previously been established for monotone classes of graphs (by the results of Adler and Adler, combined with those of Grohe et al.) and for hereditary classes of ordered graphs by results of Bonnet et al.[3]. Our results also extend the classes for which this conjecture is verified to all monotone classes of relational structures.

We establish some necessary definitions and notation in Sections 2 and 3. The proof of Theorem 1 occupies the next two sections. The equivalence of the first four notions for any monotone class $\mathcal{C}$ is due to Braunfeld and Laskowski [4]. The equivalence of the fifth and sixth notions follows by results in sparsity theory (see [15]) which we recall in Section 6. We, therefore, establish the equivalence of the first with the fifth and the seventh. In Section 4 we show that if $\mathsf{Gaif}(\mathcal{C})$ is not nowhere dense, then $\mathcal{C}$ admits a formula with the independence property. That nowhere density of $\mathsf{Gaif}(\mathcal{C})$ implies tractability is implicit in [10]. We establish the converse of this statement in Section 5. Finally, we give an argument that $\mathsf{Gaif}(\mathcal{C})$ being nowhere dense implies monadic stability in Section 6.

2 Preliminaries

We assume familiarity with first-order logic and the basic concepts of model theory. We have tried to make this paper as self-contained as possible, but refer the reader to [11] for background and undefined notation. Throughout this paper, $\mathcal{L}$ denotes a finite, first-order, relational language. We write $\mathrm{ar}(R)$ for the arity of each relation symbol $R \in \mathcal{L}$. Tuples of elements or variables are denoted by overlined letters and given a tuple $\bar{a}$ and $k \leq |\bar{a}|$, we write $\bar{a}(k)$ to denote the k-th element of $\bar{a}$. Often we abuse notation and treat tuples as unordered sets; whether we refer to the ordered tuple or the unordered set should be clear from the context. For $n \in \mathbb{N}$, we write $[n]$ for the set $\{1, \dots, n\}$.

We adopt the convention of allowing finitely many constant symbols (i.e. parameters) in $\mathcal{L}$-formulas. Syntactically, these are to be understood as additional free variables, while semantically these have a fixed interpretation in every $\mathcal{L}$-structure. This is purely a notational convenience and has no effect on the applicability of our results. By a further abuse of notation, we do not distinguish between a parameter p and its interpretation p^M in an $\mathcal{L}$-structure, M.

2.1 Graphs and relational structures

An $\mathcal{L}$-structure is denoted by $(M, R^M)_{R \in \mathcal{L}}$, where M is its underlying set and $R^M \subseteq M^{\mathrm{ar}(R)}$ is the interpretation of the relation symbol $R \in \mathcal{L}$ in M. We write $\mathfrak{C}(\mathcal{L})$ for the class of all $\mathcal{L}$-structures. By abusing notation, often we do not distinguish between an $\mathcal{L}$-structure and its underlying set. For an $\mathcal{L}$-structure M and a subset $A \subseteq M$ we denote by $M[A]$ the substructure of M induced by A, i.e. the structure on domain A with $R^A = R^M \cap A$ for all $R \in \mathcal{L}$. A pointed $\mathcal{L}$-structure is a pair $(M, \bar{m})$ where $\bar{m}$ is a tuple of $|\bar{m}|$ labelled points of M. By the *equality type* of a tuple $\bar{m}$ from an $\mathcal{L}$-structure M, we mean the set $\Delta_=(\bar{m})$ of atomic formulas $\eta(\bar{x})$ using only the equality symbol such that $M \models \eta(\bar{m})$.

A *homomorphism* from an $\mathcal{L}$-structure M to an $\mathcal{L}$-structure N is a map $f : M \to N$ satisfying such that for all relation symbols $R \in \mathcal{L}$ and tuples $\bar{m} \in M^{\mathrm{ar}(R)}$, if $\bar{m} \in R^M$ then $f(\bar{m}) \in R^N$. A homomorphism of pointed structures $f : (M, \bar{m}) \to (N, \bar{n})$ is understood as a homomorphism $f : M \to N$ of the underlying $\mathcal{L}$-structures such that $f(\bar{m}) = \bar{n}$.

By a graph G we mean an $\{E\}$-structure such that $E^G \subseteq G^2$ is a symmetric, irreflexive binary relation. We write $E(G)$ rather than E^G for the edge set of a graph. Given a graph G and $r \in \mathbb{N}$, we write $G^{(r)}$ for the *r-subdivision of G*, i.e. the graph obtained by replacing every edge of G by a path of length $r+1$. We denote by K_n the complete graph on n vertices and by $K_{t,t}$ the complete bipartite graph with parts of size t. We write $G = (U, V; E)$ for a bipartite graph with parts U and V and edge set $E \subseteq U \times V$, and write $\mathfrak{B}$ for the class of all bipartite graphs.

We recall two ways of constructing a graph from a given relational structure M. First, the *Gaifman graph* of M which is the graph on vertex set M, whose edges are precisely the pairs (u, v) such that u and v appear together in a relation of M. Second, the *Incidence graph* of M which is the the bipartite graph with elements of M in one part, all tuples in all relations in the other part, and edges denoting membership of an element u in a tuple $\bar{v}$. More formally:

▶ **Definition 2** (Gaifman/Incidence graph). *Given an $\mathcal{L}$-structure $(M, R^M)_{M\in\mathcal{L}}$ we define the* Gaifman graph *of M, denoted $\mathsf{Gaif}(M)$, to be the graph on vertex set M with edges:*

$$E := \{(x, y) : \exists R \in \mathcal{L} \exists v_1, \ldots, v_{\mathrm{ar}(R)-2} \exists \sigma \in \mathcal{S}_{\mathrm{ar}(R)} (\sigma(x, y, v_1, \ldots, v_{\mathrm{ar}(i)-2}) \in R^M)\},$$

where $\mathcal{S}_n$ the symmetric group on n elements. Moreover, we define the Incidence graph *of M, denoted $\mathsf{Inc}(M)$, to be the bipartite graph $(M, \bigsqcup_{R\in\mathcal{L}} M^R, E')$, where*

$$E' := \{(x, \bar{z}) : x \in \bar{z}\}$$

For a class of relational structures $\mathcal{C}$, all in the same language, we define the Gaifman class *of $\mathcal{C}$ to be $\mathsf{Gaif}(\mathcal{C}) := \{\mathsf{Gaif}(M) : M \in \mathcal{C}\}$. Likewise, we define $\mathsf{Inc}(\mathcal{C}) := \{\mathsf{Inc}(M) : M \in \mathcal{C}\}$.*

2.2 Sparsity and stability

Throughout this paper, $\mathcal{C}$ refers to a class of $\mathcal{L}$-structures or graphs. We write $\mathrm{Th}(\mathcal{C})$ for the common theory of the class, i.e. the set of all first-order $\mathcal{L}$-sentences that hold in all structures in $\mathcal{C}$. We say that a class $\mathcal{C}$ is:

- *hereditary*, if $\mathcal{C}$ is closed under induced substructures, i.e. if $(M, R^M)_{R\in\mathcal{L}} \in \mathcal{C}$ then $(M', R^M \cap M')_{R\in\mathcal{L}} \in \mathcal{C}$ for any $M' \subseteq M$.
- *monotone*, if $\mathcal{C}$ is closed under weak substructures, i.e. if $(M, R^M)_{R\in\mathcal{L}} \in \mathcal{C}$ then $(M', R^{M'})_{R\in\mathcal{L}} \in \mathcal{C}$ for any $M' \subseteq M$ and $R^{M'} \subseteq R^M$.

▶ **Definition 3.** *Let $\mathcal{C}$ be a class of graphs. We say that $\mathcal{C}$ is* nowhere dense *if for every $r \in \mathbb{N}$ there is some $n \in \mathbb{N}$ such that for all $G \in \mathcal{C}$ we have that $K_n^{(r)}$ is not a subgraph of G.*

Nowhere density was introduced by Nešetřil and Ossona de Mendez [14], as a structural property of classes of finite graphs that generalises numerous well-behaved classes, including graphs of bounded degree, planar graphs, graphs excluding a fixed minor and graphs of bounded expansion. Nowhere dense classes play an important role in algorithmic graph theory, as several computationally hard problems become tractable when restricted to such classes.

Let us now recall some core notions of tameness from classification theory, adapted from the context of infinite structures to that of classes of (not necessarily infinite) structures.

▶ **Definition 4** (Order/Independence Property). *Let $\mathcal{C}$ be a class of $\mathcal{L}$-structures. We say that an $\mathcal{L}$-formula $\phi(\bar{x}, \bar{y})$ has:*

1. The Order Property in $\mathcal{C}$ *if for all $n \in \mathbb{N}$ there is some $M_n \in \mathcal{C}$ and sequences $(\bar{a}_i)_{i\in[n]}$ and $(\bar{b}_j)_{j\in[n]}$ of tuples from M_n such that:*

$$M_n \vDash \phi(\bar{a}_i, \bar{b}_j) \text{ if, and only if, } i < j.$$

2. The Independence Property in $\mathcal{C}$ *if for all bipartite graphs* $G = (U, V; E) \in \mathfrak{B}$ *there is some* $M_G \in \mathcal{C}$ *and sequences of tuples* $(\bar{a}_i)_{i \in U}$ *and* $(\bar{b}_j)_{j \in V}$ *such that:*

$$M_G \vDash \phi(\bar{a}_i, \bar{b}_j) \text{ if, and only if, } (i, j) \in E.$$

We say that $\mathcal{C}$ *is* stable *if no formula has the order property in* $\mathcal{C}$*. We say that* $\mathcal{C}$ *is* NIP *(No Independence Property) if no formula has the independence property in* $\mathcal{C}$*.*

An easy application of compactness reveals that a class $\mathcal{C}$ is stable (resp. NIP) if, and only if, all completions of $\mathrm{Th}(\mathcal{C})$ are stable (resp. NIP) in the standard model-theoretic sense (see for instance [20] for the standard model-theoretic definitions).

Given a class $\mathcal{C}$ of $\mathcal{L}$-structures and an expansion $\mathcal{L}' = \mathcal{L} \cup \{P_i : i \in I\}$ by unary predicates, we say that a class $\mathcal{C}'$ of $\mathcal{L}'$-structures is a *monadic expansion* of $\mathcal{C}$ if $\mathcal{C} = \{M' \restriction_{\mathcal{L}} : M' \in \mathcal{C}'\}$, where for an $\mathcal{L}'$-structure M' we write $M' \restriction_{\mathcal{L}}$ for the $\mathcal{L}$*-reduct* of M', i.e. the $\mathcal{L}$-structure obtained from M' by simply forgetting each relation symbol not in $\mathcal{L}$. In other words, $\mathcal{C}'$ is a monadic expansion of $\mathcal{C}$ if, for each structure $M \in \mathcal{C}$, $\mathcal{C}'$ contains at least one copy of M expanded with unary predicates which are interpreted freely, and no other structures.

▶ **Definition 5** (Monadic Stability/NIP)**.** *Let* $\mathcal{C}$ *be a class of* $\mathcal{L}$*-structures. We say that* $\mathcal{C}$ *is* monadically stable *(resp.* monadically NIP*) if all monadic expansions* $\mathcal{C}'$ *of* $\mathcal{C}$ *are stable (resp. NIP).*

The relationship between sparsity and stability is captured by the following theorem, which was established by Podewski and Ziegler [17], in the context of infinite graphs, and much later translated to the context of graph classes by Adler and Adler [1].

▶ **Theorem 6** (Adler, Adler [1]; Podewski, Ziegler [17])**.** *Let* $\mathcal{C}$ *be a nowhere dense class of graphs. Then* $\mathcal{C}$ *is monadically stable. Moreover, the following are equivalent when* $\mathcal{C}$ *is monotone:*

1. $\mathcal{C}$ *is NIP;*
2. $\mathcal{C}$ *is monadically NIP;*
3. $\mathcal{C}$ *is stable;*
4. $\mathcal{C}$ *is monadically stable;*
5. $\mathcal{C}$ *is nowhere dense.*

Furthermore, Adler and Adler asked if Theorem 6 can be generalised to arbitrary relational structures with finite signature. Recently, Braunfeld and Laskowski established a collapsing phenomeon akin to Theorem 6 for relational structures.

▶ **Theorem 7** (Braunfeld, Laskowski, [4])**.** *Let* $\mathcal{C}$ *be a hereditary class of structures. Then* $\mathcal{C}$ *is monadically NIP (resp. monadically stable) if, and only if,* $\mathcal{C}$ *is NIP (resp. stable). Moreover, if* $\mathcal{C}$ *is monotone then* $\mathcal{C}$ *is NIP if, and only if, it is stable.*

In light of the above, Theorem 1 answers the question of Adler and Adler affirmatively by connecting the picture arising in Theorem 7 with the sparsity-theoretic properties of the Gaifman class.

2.3 Model-checking

By model-checking on a class $\mathcal{C}$ we refer to the following parametrised decision problem:

Given: A FO-sentence ϕ and a structure $M \in \mathcal{C}$.

Parameter: $|\phi|$.

Decide: Whether or not M satisfies ϕ.

▶ **Definition 8.** *We say that $\mathcal{C}$ is* tractable*, or that the model-checking problem on a class $\mathcal{C}$ is fixed-parameter tractable, if there is an algorithm that decides on input (M, ϕ) whether $G \models \phi$, in time $f(|\phi|) \cdot |M|^{\mathcal{O}(1)}$ for some computable function f.*

Model-checking on the class of all graphs is complete with respect to the complexity class $\mathsf{AW}[*]$, which is conjectured to strictly contain the class FPT. We shall assume throughout that $\mathsf{AW}[*] \neq \mathsf{FPT}$.

All hereditary classes of graphs and relational structures that are known to admit tractable model-checking are NIP. Moreover, the robustness of NIP in hereditary classes hints at its potential necessity for tractability. This is the basis of the following conjecture:

▶ **Conjecture 9** ([22, 9, 3])**.** *Let $\mathcal{C}$ be a hereditary class of relational structures. Then $\mathcal{C}$ is tractable if, and only if, $\mathcal{C}$ is NIP.*

There is good evidence for a positive answer to this conjecture. Indeed, it is known to hold for:

- Monotone classes of graphs, where NIP coincides with nowhere density [10];
- Hereditary classes of ordered graphs, where NIP coincides with bounded twin-width [21, 3].

Although it is not explicitly stated in this form, a careful examination of the argument of [10] reveals that the following holds.

▶ **Theorem 10** (Grohe, Kreutzer, Siebertz, [10])**.** *Let $\mathcal{C}$ be a class of relational structures such that $\mathsf{Gaif}(\mathcal{C})$ is nowhere dense. Then $\mathcal{C}$ admits fixed-parameter tractable model-checking.*

2.4 Interpretations

Interpretations in classical model theory allow us to find structures in some language in a definable way inside a definable quotient of structures in some other language, mimicking, for instance, the way one can find the rational numbers inside the integers.

In our case, we focus on a restricted version of interpretations, which we call *simple interpretations* (possibly with parameters). Intuitively, a class of $\mathcal{L}'$-structures $\mathcal{D}$ can be interpreted in a class of $\mathcal{L}$-structures $\mathcal{C}$ if there is a uniform way of defining every structure in $\mathcal{D}$, in some (Cartesian power of some) structure from $\mathcal{C}$. More formally:

▶ **Definition 11** (Simple interpretation)**.** *Let $\mathcal{L}, \mathcal{L}'$ be two finite relational languages. A* simple interpretation with parameters $I : \mathfrak{C}(\mathcal{L}) \to \mathfrak{C}(\mathcal{L}')$ *consists of the following data:*

- *A* domain formula $\delta(\bar{x}, \bar{v}) \in \mathcal{L}$ *and, a function d which to each $M \in \mathfrak{C}(\mathcal{L})$ associates a tuple $\bar{d}(M)$ from $M^{|\bar{v}|}$.*
- *For each k-ary relation symbol $R(y_1, \ldots, y_k) \in \mathcal{L}'$ an* interpreting formula $\phi_R(x_1, \ldots, x_k, \bar{v}_R) \in \mathcal{L}$*, where $|\bar{x}_i| = |\bar{x}|$, for each $i \in [k]$, and a function c_R which to each $M \in \mathfrak{C}(\mathcal{L})$ associates a tuple $\bar{c}_R(M)$ from $M^{|\bar{v}_R|}$.*

In order to make our discussion of interpretations easier, we adopt the following notation. Given $M \in \mathfrak{C}(\mathcal{L})$ we write $I(M)$ for the $\mathcal{L}'$ structure on the set $\delta(M) := \{a \in M : M \vDash \delta(a, \bar{d}(M))\}$ with:

$$I(M) \vDash R(a_1, \ldots, a_k) \text{ if, and only if, } M \vDash \phi_R(a_1, \ldots, a_k, \bar{c}_R(M)),$$

for each k-ary relation symbol $R \in \mathcal{L}'$ and $a_1, \ldots, a_k \in \delta(M, \bar{d}(M))$. This dually gives a map $\widehat{I} : \mathcal{L}' \to \mathcal{L}$ mapping $\mathcal{L}'$-formulas to $\mathcal{L}$-formulas with parameters, such that for any $\mathcal{L}'$-sentence ϕ we have that:

$$M \models \widehat{I}(\phi) \text{ if, and only if, } I(M) \models \phi.$$

In order to be able to reduce the problem of FO model-checking from one class of structures to another, possibly in a different language, we are interested in interpretations that can be computed in polynomial time. More precisely we define the following notion:

▶ **Definition 12** (Polynomial interpretation). *Given classes of structures $\mathcal{C} \subseteq \mathfrak{C}(\mathcal{L})$ and $\mathcal{D} \subseteq \mathfrak{C}(\mathcal{L}')$ we say that $\mathcal{D}$ is* polynomially interpreted in $\mathcal{C}$, with parameters, *if there are:*

1. *A simple interpretation with parameters, $I : \mathfrak{C}(\mathcal{L}) \to \mathfrak{C}(\mathcal{L}')$, as in Definition 11, such that the functions d and $(c_R)_{R\in\mathcal{L}'}$ are computable in polynomial time; and*
2. *a polynomial-time computable map $f : \mathcal{D} \to \mathcal{C}$ such that for all $D \in \mathcal{D}$ we have that $D = I(f(D))$.*

In this case, we write $\mathcal{D} \leq_{\mathsf{P}} \mathcal{C}$.

The next lemma justifies why polynomial interpretations are particularly useful.

▶ **Lemma 13.** *The relations $\leq_{\mathsf{P}}$ is a quasi-order on the collection of classes of structures in finite relational languages. Moreover $\leq_{\mathsf{P}}$ preserves tractability, i.e. if $\mathcal{C}$ is tractable and $\mathcal{D} \preceq_{\mathsf{P}} \mathcal{C}$, then $\mathcal{D}$ is tractable.*

Proof. The first part of the lemma is immediate, so let us only discuss the second part. We reduce the problem of model checking in $\mathcal{D}$ to model checking in $\mathcal{C}$. Given an $\mathcal{L}'$-sentence ϕ and an $\mathcal{L}'$-structure $M \in \mathfrak{C}(\mathcal{L}')$, we can compute, by assumption, in polynomial time an $\mathcal{L}$-structure $f(D) \in \mathcal{C}$ such that $M = I(f(D))$. By assumption, we can also compute $I(f(D))$ in polynomial time, since the parameters in the domain and interpreting formulas are computable from M in polynomial time. Then, we have that:

$$f(D) \models \widehat{I}(\phi) \text{ if, and only if, } I(f(D)) = M \models \phi,$$

where $\widehat{I}(\phi)$ is obtained, essentially, as in the discussion after Definition 11, which can clearly be done in polynomial time, from ϕ. Since $\mathcal{C}$ is tractable, it follows that $\mathcal{D}$ is tractable. ◀

2.5 Ramsey Theory

A core technique that is used repeatedly in our arguments is that if a finite structure is large enough, then patterns in it are inevitable. This is the main idea of Ramsey theory, the relevant tools from which we recall here. The notation we use is standard, given a set S and $k \in \mathbb{N}$ we write $[S]^{(k)}$ for the collection of all k-element subsets of S.

▶ **Theorem 14** (Ramsey's Theorem, [18]). *There is a computable function $\mathcal{R} : \mathbb{N}^3 \to \mathbb{N}$ such that for all $m, k, r \in \mathbb{N}$ and for every colouring $\chi : [\mathcal{R}(m, k, r)]^{(k)} \to [r]$ there exists some $S \subseteq [\mathcal{R}(m, k, r)]$ of size m which is monochromatic.*

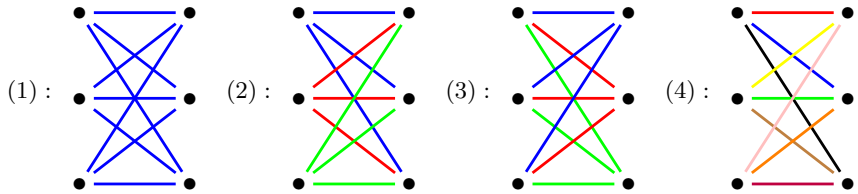
Another standard theorem from Ramsey theory that we make use of is the following well-known variant of Theorem 14:

▶ **Theorem 15** (Bipartite Ramsey Theorem). *There is a computable function $\mathcal{P} : \mathbb{N}^2 \to \mathbb{N}$ such that for all $m, r \in \mathbb{N}$ and all edge colourings of the complete bipartite graph $K_{\mathcal{P}(m,r),\mathcal{P}(m,r)}$ with r colours, there are subsets A, B of the two parts, both of size m, which induce a monochromatic copy of $K_{m,m}$.*

We also need to make use of the following Ramsey-theoretic result, where the number of colours is allowed to be possibly infinite. Of course, in this case, we cannot expect to find monochromatic subsets. Nonetheless, we can ensure that the behaviour of the colouring falls into one of few "canonical" cases on a large enough set. The original canonical Ramsey theorem is due to Erdős and Rado [7], but for the purposes of this paper, we are only interested in the bipartite version in its effective form.

▶ **Theorem 16** (Bipartite Canonical Ramsey Theorem, [12]). *There is a computable function $\mathcal{K} : \mathbb{N} \to \mathbb{N}$ such that for every $n \in \mathbb{N}$ and every edge-colouring of the complete bipartite graph $K_{\mathcal{K}(n),\mathcal{K}(n)}$ there exist subsets X,Y of the two parts, both of size n, such that one of the following occurs for all $x, x' \in X$ and $y, y' \in Y$:*

1. $\chi(x, y) = \chi(x', y')$;
2. $\chi(x, y) = \chi(x', y')$ *if, and only if,* $x = x'$;
3. $\chi(x, y) = \chi(x', y')$ *if, and only if,* $y = y'$;
4. $\chi(x, y) = \chi(x', y')$ *if, and only if,* $x = x'$ *and* $y = y'$.



Henceforth, we shall say that an edge colouring of a complete bipartite graph is *canonical of type* 1 (resp. $2, 3, 4$) if it satisfies condition 1 (resp. $2, 3, 4$) from Theorem 16 for all edges. More generally, we say that such a colouring is *canonical* whenever it is canonical of any type.

3 Path formulas

Recall that a formula $\phi(\bar{x})$ is called *primitive positive* if it has the form $\exists \bar{y} \psi(\bar{x}, \bar{y})$, where ψ is a conjunction of atomic formulas. Primitive positive formulas are also known as *conjunctive queries* in the database theory literature. The following association of a canonical structure with a primitive positive formula and conversely a canonical such formula with a finite structure goes back to Chandra and Merlin [5].

▶ **Definition 17** (Canonical structures). *Given a primitive positive formula $\phi(\bar{x}) = \exists \bar{y} \psi(\bar{x}, \bar{y})$ we define a pointed $\mathcal{L}$-structure $(\mathcal{M}_\phi, \bar{x})$ whose domain is the set $\{v_1, \ldots, v_r\}$ of variables of ϕ, and where each $R \in \mathcal{L}$ is interpreted as follows:*

$$\mathcal{M}_\phi \vDash R(v_1, \ldots, v_n) \text{ if, and only if, } R(v_1, \ldots, v_n) \text{ appears as a conjunct in } \psi(\bar{x}, \bar{y}).$$

The pointed elements $\bar{x}$ precisely correspond to the free variables of ϕ. This structure is unique, up to isomorphism, and we call it the canonical structure of ϕ.

Similarly, for every pointed $\mathcal{L}$-structure $(A, \bar{x})$ we may associate a primitive positive formula $\phi_A(\bar{x})$ so that $(\mathcal{M}_{\phi_A}, \bar{x}) = (A, \bar{x})$. We call this formula the *canonical formula* of $(A, \bar{x})$. Let $\phi(\bar{x})$ be a primitive positive formula and $(\mathcal{M}_\phi, \bar{x})$ its canonical structure. It is easy to see that for any $\mathcal{L}$-structure A and $\bar{a} \in A$ we have that $A \vDash \phi(\bar{a})$ if, and only if, there exists a homomorphism (of pointed structures) $h : (\mathcal{M}_\phi, \bar{x}) \to (A, \bar{a})$.

In our analysis, we argue that whenever a monotone class of relational structures has the independence property then this is witnessed by a certain kind of primitive positive formula. In the case of graphs, it is implicit in the work of Adler and Adler that the canonical structure of this primitive positive formula is a path in the standard graph-theoretic sense, i.e. a tuple $(x_1, \ldots, x_n)$ of pairwise distinct elements such that $E(x_i, x_{i+1})$ for all $i \in [n-1]$.

In this section, we introduce the analogue of (graph) paths that witnesses the independence property in general relational structures. We start with the following rather technical definition.

▶ **Definition 18** (Path). *By a* path of length n, *we mean an* $\mathcal{L}$*-structure* $\mathbf{P}$ *consisting of a sequence of pairwise disjoint tuples each consisting of pairwise different elements* $\bar{e}_1, \dots, \bar{e}_n$ *such that:*

- $\mathbf{P} = \bigcup_{i\in[n]} \bar{e}_i$*;*
- $|\bar{e}_i \cap \bar{e}_{i+1}| = 1$*, for all* $i < n$*;*
- $\bar{e}_i \not\subseteq \bar{e}_{i+1}$ *and* $\bar{e}_{i+1} \not\subseteq \bar{e}_i$*, for all* $i < n$*;*
- $\bar{e}_i \cap \bar{e}_j = \emptyset$*, for all* $j \in [n] \setminus \{i-1, i, i+1\}$*;*
- $R_i(\bar{e}_i)$*, for exactly one relation symbol* $R_i \in \mathcal{L}$*;*
- $R(\bar{a}) \implies \bar{a} = \bar{e}_i$ *for some* $i \in [n]$*, for all relation symbols* $R \in \mathcal{L}$ *and all tuples* $\bar{a} \in \mathbf{P}$*.*

We write $S(\boldsymbol{P}) = \bar{e}_1 \setminus \bar{e}_2$ *and call these the starting vertices, while we write* $F(\mathbf{P}) = \bar{e}_n \setminus \bar{e}_{n-1}$ *and call these the finishing vertices. We refer to the tuples* $\bar{e}_i$ *as the steps of the path, and to the singletons in* $\bar{e}_i \cap \bar{e}_{i+1}$ *as the joints of the path.*

Given a primitive positive formula $\phi(\bar{x}, \bar{y}, \bar{z})$ (where $\bar{z}$ is possibly empty), we say that ϕ is a *path formula* if there are $x_0 \in \bar{x}$ and $y_0 \in \bar{y}$ such that $\mathcal{M}_\phi$ is a path with $x_0 \in S(\mathcal{M}_\phi)$ and $y_0 \in F(\mathcal{M}_\phi)$. Similarly, we call ϕ a *simple path formula* if $\bar{x} \subseteq S(\mathcal{M}_\phi)$ and $\bar{y} \subseteq F(\mathcal{M}_\phi)$.

Note that technically, no graph G can be a path under the above definition. Indeed, the last condition ensures that $E(G)$ cannot be symmetric as no permutation of a tuple appearing in a relation R can appear in any other relation from $\mathcal{L}$. To avoid confusion, we always refer to paths in the standard graph-theoretic sense as *graph paths*.

Intuitively, a path formula $\phi(\bar{x}, \bar{y})$ plays the role of a higher arity graph path from $\bar{x}$ to $\bar{y}$. However, under enough symmetry, it is possible that we cannot definably tell the direction of ϕ, i.e. $\bar{x}$ and $\bar{y}$ look the same within ϕ. This is formalised in the following definition, and is important in the proof of Theorem 27.

▶ **Definition 19** (Symmetric path). *A* symmetric path *is a path* $\mathbf{P}$ *of length* n*, such that* $R_i = R_{n+1-i}$ *for all* $i \in [n]$*. A* symmetric path formula $\phi(\bar{x}, \bar{y}, \bar{z})$ *is a simple path formula with* $|\bar{x}| = |\bar{y}| = m$ *such that* $\mathcal{M}_\phi$ *is a symmetric path and there is an automorphism* f *of* $\mathcal{M}_\phi$ *which maps* $\bar{x} = (x_1, \dots, x_m) \mapsto (y_{\sigma(1)}, \dots, y_{\sigma(m)})$ *and* $\bar{y} = (y_1, \dots, y_m) \mapsto (x_{\sigma^{-1}(1)}, \dots, x_{\sigma^{-1}(m)})$*, for some* $\sigma \in \mathcal{S}_m$ *which is not the identity permutation. Moreover, if* ϕ *contains parameters then these must be fixed by* f*.*

Given an $\mathcal{L}$-structure and a graph path in $\mathsf{Gaif}(M)$, we may produce a path formula that describes a "type" for this path. This idea is captured by the following definition which is relevant for the proof of Lemma 21.

▶ **Definition 20** (Path type). *Let* M *be an* $\mathcal{L}$*-structure, and* $S = (u_1, \dots, u_n)$ *a graph path in* $\mathsf{Gaif}(M)$*. For every* $i \in [n-1]$ *we may associate a relation symbol* $R_i \in \mathcal{L}$*, elements* $v_{i,1}, \dots, v_{i,\mathrm{ar}(R_i)}$*, and a permutation* $\sigma_i \in \mathcal{S}_{\mathrm{ar}(R_i)}$ *such that* $\sigma_i(u_i, u_{i+1}, \bar{v}_i) \in R_i^M$*. Then we call the formula*

$$\phi(x, y, z_2, \dots, z_{n-1}) = \\ \exists \bar{v}_i \dots \bar{v}_{n-1}(R_1(\sigma_1(x, z_2, \bar{v}_1)) \wedge R_2(\sigma_2(z_2, z_3, \bar{v}_2)) \wedge \dots \wedge R_{n-1}(\sigma_{n-1}(z_{n-1}, y, \bar{v}_{n-1})))$$

a path type *for the graph path* $u_1, \dots, u_n$*.*

It is easy to see that whenever $S = (u_1, \dots, u_n)$ is a graph path in $\mathsf{Gaif}(M)$, then there is a path type ϕ for S such that $M \models \phi(u_1, u_n, u_2, \dots, u_{n_1})$. Clearly, this is not uniquely determined by S, as for the same graph path $u_1, \dots, u_n$ in $\mathsf{Gaif}(M)$ we can possibly obtain different sequences of relations $R_i, \dots R_{i-1}$ and permutations $\sigma_1, \dots, \sigma_{i-1}$ as in Definition 20.

4 From somewhere density to IP

The main result in this section is Theorem 23, where we prove that for any monotone class $\mathcal{C}$ of relational structures whose Gaifman class is somewhere dense, there is a path formula (in the sense of Definition 18) which codes the edge relation of all bipartite graphs uniformly over $\mathcal{C}$.

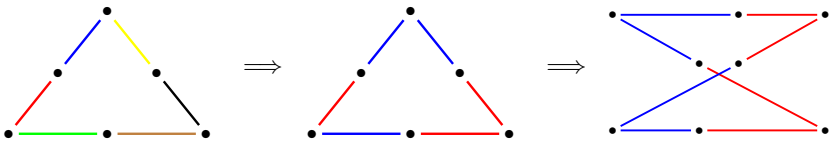
We work towards this theorem via two preparatory lemmas, which have the benefit of applying to classes that are not necessarily monotone. Intuitively, Lemma 21 tells us that if $\mathcal{C}$ is a monotone class of relational structure whose Gaifman class is somewhere dense, then we can find a path formula that codes the edge relation of all finite complete bipartite graphs in $\mathcal{C}$.

▶ **Lemma 21.** *Let $\mathcal{C}$ be a class of $\mathcal{L}$-structures such that $\mathsf{Gaif}(\mathcal{C})$ is somewhere dense. Then there is a path formula $\phi(x, y, \bar{z}) = \exists \bar{w} \psi(x, y, \bar{z}, \bar{w})$ of length ≥ 2 whose joints are precisely the variables in $\bar{z}$, and for each $n \in \mathbb{N}$ there is some $M_n \in \mathcal{C}$ and pairwise distinct elements $(a_i)_{i\in[n]}, (b_j)_{j\in[n]}, (\bar{c}_{i,j})_{(i,j)\in[n]^2}$ from M_n such that*

$$M_n \models \phi(a_i, b_j, \bar{c}_{i,j}), \text{ for all } i, j \in [n].$$

Proof. If $\mathsf{Gaif}(\mathcal{C})$ is somewhere dense, then there exists $r \in \mathbb{N}$ such that for all $n \in \mathbb{N}$ there is some $M_n \in \mathsf{Gaif}(\mathcal{C})$ with $K_n^{(r)} \leq \mathsf{Gaif}(M_n)$. Without loss of generality, we may assume that $r \geq 1$. Indeed, if $r = 0$ then $K_n^1 \leq K_{n^2} \leq \mathsf{Gaif}(M_{n^2})$ so we may pass to a subsequence of $(M_n)_{n\in\mathbb{N}}$ and relabel the indices appropriately.

For every $i < j$ from $[n]$ let $S^n_{i,j}$ be the graph path in $\mathsf{Gaif}(M_n)$ corresponding to the r-subdivision of the edge (i, j) from K_n, directed from i to j. Let $q \in \mathbb{N}$ be the maximum arity of a relation symbol $R \in \mathcal{L}$. Observe that there are at most $p = (|\mathcal{L}| \times q!)^{r+1}$ path types for each graph path $S^n_{i,j}$. By Ramsey's theorem we may find for each n some $\Sigma_n \subseteq [\mathcal{R}(n, 2, q)]$ of size n such that $S^{\mathcal{R}(n,2,q)}_{i,j}$ have the same path type for all $i < j$ from Σ_n. By passing to a subsequence of $(M_n)_{n\in\mathbb{N}}$ and relabelling indices, we may therefore assume that all the $S^n_{i,j}$ have the same path type. Let this be ϕ_n. Since there are only finitely many possible path types for every n, we may prune the sequence $(M_n)_{n\in\mathbb{N}}$ once again to ensure that the same path type $\phi(x, y, \bar{z})$ is obtained for all $n \in \mathbb{N}$. By definition, the joints of $\mathcal{M}_\phi$ are precisely the variables in $\bar{z}$, while $\mathcal{M}_\phi$ has length ≥ 2 since $r \geq 1$.



Work in M_{2n} and let $(a_i)_{i\in[n]}$ be the elements corresponding to $1, \ldots, n$ from $K^{(r)}_{2n}$, and $(b_j)_{j\in[n]}$ be those corresponding to $n + 1, \ldots, 2n$. Moreover, let $\bar{c}_{i,j}$ be the tuples obtained by removing a_i and b_j from the beginning and end respectively of the graph path $S^{2n}_{i,n+j}$. It is clear that the elements $(a_i)_{i\in[n]}, (b_j)_{j\in[n]}, (\bar{c}_{i,j})_{i,j\in[n]}$ are pairwise distinct. Since the path type of $S^{2n}_{i,n+j}$ is equal to ϕ for all $i, j \in [n]$, it follows that

$$M_{2n} \models \phi(a_i, b_j, \bar{c}_{i,j}), \text{ for all } i, j \in [n].$$

We finally pass to the subsequence $(M_{2n})_{n\in\mathbb{N}}$ and relabel. ◀

Having established that we may encode the edge relation of any complete bipartite graph, we want to use monotonicity in order to encode the edge relation of arbitrary bipartite graphs, and consequently, to witness the independence property. To achieve this, we must

ensure that the tuples used in the encoding are "sufficiently disjoint" so that the removal of the desired relations does in fact translate to the removal of an encoded edge. The following lemma is a step toward this.

▶ **Lemma 22.** *Let $\mathcal{C}$ be a class of $\mathcal{L}$-structures such that $\mathsf{Gaif}(\mathcal{C})$ is somewhere dense. Then there is a path formula $\phi(\bar{x},\bar{y},\bar{z}) = \exists\bar{w}\psi(\bar{x},\bar{y},\bar{z},\bar{w})$ of length ≥ 2 with parameters $\bar{p}$ whose joints are precisely the elements of $\bar{z}$, and for every $n \in \mathbb{N}$ there is some $M_n \in \mathcal{C}$ and tuples $(\bar{a}_i)_{i\in[n]}$, $(\bar{b}_j)_{j\in[n]}$, $(\bar{c}_{i,j})_{(i,j)\in[n]^2}$, $(\bar{d}_{i,j})_{i,j\in[n]^2}$ from M_n such that the following hold for all $i,i',j,j' \in [n]$:*

1. *$M_n \models \psi(\bar{a}_i,\bar{b}_j,\bar{c}_{i,j},\bar{d}_{i,j})$;*
2. *$\bar{a}_i(k) \neq \bar{a}_{i'}(k)$, for $i \neq i'$ and all $k \in [|\bar{x}|]$;*
3. *$\bar{b}_j(k) \neq \bar{b}_{j'}(k)$, for $j \neq j'$ and all $k \in [|\bar{y}|]$;*
4. *$\bar{c}_{i,j}(k) \neq \bar{c}_{i',j'}(k)$ and $\bar{c}_{i,j}(k) \neq \bar{c}_{i,j}(l)$, for $(i,j) \neq (i',j')$ and all $k \neq l$ from $[|\bar{z}|]$;*
5. *$\bar{d}_{i,j}(k) \neq \bar{d}_{i',j'}(k)$, for $(i,j) \neq (i',j')$ and all $k \in [|\bar{w}|]$.*

Proof. Let $\phi(x,y,\bar{z}) = \exists\bar{w}\psi(x,y,\bar{z},\bar{w})$ and $(M_n)_{n\in\mathbb{N}}$ be as in Lemma 21. For clarity, we write $(a^n_i)_{i\in[n]}, (b^n_j)_{j\in[n]}, (\bar{c}^n_{i,j})_{(i,j)\in[n]^2}$ to denote the elements of M_n from the same lemma. For each $n \in \mathbb{N}$, and for each pair $(i,j) \in [n]^2$, pick a tuple $\bar{d}^n_{i,j}$ of elements from M_n consisting of some arbitrarily fixed existential witnesses to $M_n \models \phi(a^n_i, b^n_j, \bar{c}^n_{i,j})$, i.e. $M_n \models \psi(a^n_i, b^n_j, \bar{c}^n_{i,j}, \bar{d}^n_{i,j})$ for all $i,j \in [n]$.

Let $m = |\bar{d}_{i,j}|$. By m applications of Theorem 16, we may assume that whether $\bar{d}^n_{i,j}(k) = \bar{d}^n_{i',j'}(k)$ depends on one of the four canonical cases from that theorem, and not on n. Indeed, for every $n \in \mathbb{N}$ and each $k \in [m]$, define colourings $\chi_{n,k}(i,j) = \bar{d}^n_{i,j}(k)$ of the edges of $K_{n,n}$. Let $\mathcal{K} : \mathbb{N} \to \mathbb{N}$ be the computable function guaranteed by Theorem 16 and write $\mathcal{K}^m$ for the composition of $\mathcal{K}$ with itself m times. It follows that the complete bipartite graph with parts of size $\mathcal{K}^m(n)$ contains subsets A_n, B_n of the two parts of size n, which induce a copy of $K_{n,n}$ on which $\chi_{\mathcal{K}^m(n),k}$ is canonical for all $k \in [m]$. We may thus restrict the argument on the subsequence $(M_{\mathcal{K}^m(n)})_{n\in\mathbb{N}}$ and the elements $a_i^{\mathcal{K}^m(n)}, b_j^{\mathcal{K}^m(n)}, \bar{c}_{i,j}^{\mathcal{K}^m(n)}, \bar{d}_{i,j}^{\mathcal{K}^m(n)}$ for $i \in A_n$ and $j \in B_n$ and relabel appropriately. For every $n \in \mathbb{N}$, after the relabelling, we have thus obtained a tuple $\bar{t}_n \in [4]^m$ such that $\chi_{n,k}$ is canonical of type $\bar{t}_n(k)$. Since there are only finitely many such $\bar{t}_n$, by the pigeonhole principle we may consider a subsequence of $(M_n)_{n\in\mathbb{N}}$ for which $\bar{t}_n$ is constant and equal to some $\bar{t} \in [4]^m$, and relabel once more.

We now proceed to sequentially remove elements from the tuples $\bar{d}^n_{i,j}$, and to either name them by a parameter, or to append them to one of a^n_i or b^n_j. Since $\bar{t}$ is constant for all n, exactly the same process is carried out to all tuples $\bar{d}_{i,j}$, and so we may concurrently move the corresponding variables from ϕ. So, if we fall into Case 1 for some k, i.e. if $\bar{t}(k) = 1$, then $\bar{d}_{i,j}(k)$ is the same for all i,j, and so we may name it by a parameter and remove it from every $\bar{h}_{i,j}$. If we fall into Case 2, then $\bar{d}_{i,j}(k) = \bar{d}_{i',j'}(k)$ if, and only if, $i = i'$. Then, for every $i \in [n]$ we may remove the common element $\bar{d}_{i,j}(k)$ from each $\bar{d}_{i,j}$ and append it to a_i, turning it into a tuple $\bar{a}_i$. We then adjust ϕ accordingly by shifting the corresponding variable v_k from $\bar{v}$ to x, which also becomes a tuple $\bar{x}$. Case 3 is symmetric to Case 2, only now we append $\bar{d}_{i,j}(k)$ to $\bar{b}_j$ and shift the variable v_k to $\bar{y}$. We may therefore assume that we fall into Case 4 for all the remaining $k \in [m]$.

We argue that the resulting formula and tuples satisfy the requirements of the lemma. Clearly, $M_n \models \phi(\bar{a}_i,\bar{b}_j,\bar{c}_{i,j},\bar{d}_{i,j})$ for all $n \in \mathbb{N}$ and $i,j \in [n]$. Condition 2 is also satisfied, since the original singletons $(a_i)_{i\in[n]}$ were pairwise disjoint, while for every $i \neq i'$ and $k \in [m]$ the elements $\bar{d}_{i,j}(k)$ and $\bar{d}_{i',j}(k)$, appended to a_i and $a_{i'}$ respectively, come from an instance of Case 2, and are therefore pairwise distinct. Likewise, condition 3 is satisfied. Since we have not interfered with the tuples $\bar{c}_{i,j}$ in the above process and these contain pairwise distinct elements by Lemma 21, Condition 4 is also satisfied. Finally, Condition 5 is trivially satisfied since the elements remaining in $\bar{d}_{i,j}$ fall into Case 4. ◀

▶ **Theorem 23.** *Let $\mathcal{C}$ be a monotone class of $\mathcal{L}$-structures such that $\mathsf{Gaif}(\mathcal{C})$ is somewhere dense. Then there is a path formula $\phi(\bar{x},\bar{y}) = \exists \bar{w}\psi(\bar{x},\bar{y},\bar{w})$ with parameters $\bar{p}$ and for each bipartite graph $G = (U,V;E) \in \mathfrak{B}$ there is some $M_G \in \mathcal{C}$ and sequences of tuples $(\bar{a}_u)_{u\in U}$ $(\bar{b}_v)_{v\in V}$, $(\bar{h}_{u,v})_{(u,v)\in E}$ from M_G such that:*

1. *$M_G \models \phi(\bar{a}_u,\bar{b}_v)$ if, and only if, $(u,v) \in E$ (so, in particular $\mathcal{C}$ is not NIP);*
2. *If $(u,v) \in E$ then $M_G \models \psi(\bar{a}_u,\bar{b}_v,\bar{h}_{u,v})$;*
3. *The equality type of $\bar{p}_{u,v} = \bar{a}_u^\frown \bar{b}_v^\frown \bar{h}_{u,v}$ is constant for all $(u,v) \in E(G)$;*
4. *Any two tuples in $\{\bar{a}_u,\bar{b}_v,\bar{h}_{u,v} : u \in U, v \in V\}$ are disjoint and do not intersect the parameters $\bar{p}$.*

Proof. Let $\phi(x,y,\bar{z}) = \exists \bar{w}\psi(x,y,\bar{z},\bar{w})$, with parameters $\bar{p}$, and $(M_n)_{n\in\mathbb{N}}$ be as in Lemma 22. For clarity, we again write $(a_i^n)_{i\in[n]}, (b_j^n)_{j\in[n]}, (\bar{c}_{i,j}^n)_{(i,j)\in[n]^2}$ to denote the elements from that lemma coming from M_n. Consider the tuples $\bar{p}_{i,j}^n = \bar{a}_i^n \frown \bar{b}_j^n \frown \bar{c}_{i,j}^n \frown \bar{d}_{i,j}^n$, and let $q = |\bar{p}_{i,j}^n|$. Observe that for every $n \in \mathbb{N}$, at most $q \cdot |\bar{p}|$ many tuples $\bar{p}_{i,j}^n$ intersect the parameters $\bar{p}$ because of the conditions in Lemma 22. By working with suitably large n and avoiding these tuples, we may relabel so that no $\bar{p}_{i,j}^n$ intersects $\bar{p}$.

For $i,j,k,l \in [n]$, we say that the tuples $\bar{p}_{i,j}^n$ and $\bar{p}_{k,l}^n$ *intersect trivially* whenever

$$\bar{p}_{i,j} \cap \bar{p}_{k,l} = \begin{cases} \bar{p}_{i,j}, & \text{if } i = k \wedge j = l \\ \bar{a}_i, & \text{if } i = k \wedge j \neq l \\ \bar{b}_j, & \text{if } i \neq k \wedge j = l \\ \emptyset, & \text{otherwise.} \end{cases}$$

Letting $f(n) = q \cdot (n-1)^2 + n$, we claim that for all $n \in \mathbb{N}$ and all $m \geq f(n)$ we may find a set $A_n \subseteq [f(n)]$ of size n so that $\bar{p}_{i,j}^m$ and $\bar{p}_{k,l}^m$ intersect trivially for all $i,j,k,l \in A_n$.

We show this by induction. Indeed, for $n = 1$ this is trivially true as $A_1 = [1]$ works for all $m \geq 1$. Suppose that the claim holds for $n-1$ and fix $m \geq f(n)$. Since $f(n) \geq f(n-1)$, by the induction hypothesis there is some $A_{n-1} \subseteq [f(n-1)] \subseteq [f(n)]$ of size $n-1$ so that $\bar{p}_{i,j}^m$ and $\bar{p}_{k,l}^m$ intersect trivially for all $i,j,k,l \in A_{n-1}$. Notice, that because of Lemma 22, for every fixed $\bar{p}_{i,j}$, there are at most q tuples $\bar{p}_{k,l}$ that do not intersect trivially with it. Hence, there are at most $q \cdot (n-1)^2$ elements $l \in [f(n)]$ such that $\bar{p}_{i,j}^m$ and $\bar{p}_{k,l}^m$ do not intersect trivially for all $i,j,k \in A_{n-1}$. Since $[f(n)]$ contains an additional n elements, we are guaranteed to find some $l \in [f(n)]$, which is not one of the $n-1$ elements of A_{n-1}, such that $\bar{p}_{i,j}^m$ and $\bar{p}_{k,l}^m$ intersect trivially for all $i,j,k \in A_{n-1}$. We may therefore let $A_n = A_{n-1} \cup \{l\}$.

Hence, we may consider the subsequence $(M_{f(n)})_{n\in\mathbb{N}}$ and relabel the tuples appropriately, so that all tuples $\bar{p}_{i,j}^n, \bar{p}_{k,l}^n$ intersect trivially for all $n \in \mathbb{N}$ and $i,j,k,l \in [n]$. Furthermore, by an application of Theorem 15, we may assume that the tuples $\bar{p}_{i,j}^n$ have the same equality type for all $i,j \in [n]$ and all $n \in \mathbb{N}$. More precisely, for every pair $(i,j) \in [n]^2$ let $\Delta_n(i,j) := \Delta_=(\bar{p}_{i,j}^n)$. Letting $q = |\bar{p}_{i,j}|$, it is easy to see that there are at most $p = 2^{q^2}$ sets $\Delta_n(i,j)$. It follows by Theorem 15, that there are subsets A, B of $[\mathcal{P}(n,2,p)]$ of size n such that $\Delta_{\mathcal{P}(n,2,p)}(i,j)$ is constant for all $i \in A$, $j \in B$. Hence, we may relabel appropriately so that $\Delta_n(i,j)$ is constant for all $i,j \in [n]$. Since there are only finitely many such sets, the pigeonhole principle implies that we may prune the sequence $(M_n)_{n\in\mathbb{N}}$ so that $\Delta_n(i,j)$ is uniformly constant for all $n \in \mathbb{N}$.

It follows that no tuple $\bar{a}_i^n$ can intersect a tuple $\bar{b}_j^n$. Indeed, since the equality types are constant, and in particular $\Delta_n(i,j) = \Delta_n(i,j')$, if $\bar{a}_i^n$ and $\bar{b}_j^n$ had an element in common then $\bar{b}_j^n(k) = \bar{b}_{j'}^n(k)$ for some k and all $j' \neq j$, contradicting the assumptions of Lemma 22. Likewise, no tuple $\bar{h}_{i,j}^n = \bar{c}_{i,j}^n \frown \bar{d}_{i,j}^n$ can intersect the tuples $\bar{a}_i$ or $\bar{b}_j$. Since the tuples $\bar{p}_{i,j}^n$ intersect trivially, this implies that any two tuples $\{\bar{a}_i^n, \bar{b}_j^n, \bar{h}_{i,j}^n : i,j \in A_n\}$ are pairwise disjoint, and furthermore do not intersect the parameters $\bar{p}$.

For every $n \in \mathbb{N}$, consider the weak substructure $M'_n \leq M_n$ consisting of the elements in $\bar{p}^n_{i,j}$ and the parameters $\bar{p}$, and containing solely the relations necessary to witness $M_n \models \psi(\bar{a}^n_i, \bar{b}^n_j, \bar{h}^n_{i,j})$. By monotonicity, $M'_n \in \mathcal{C}$. Notice that every tuple appearing in a relation of M'_n contains at least one element of $\bar{c}^n_{i,j}$ for some $i, j \in [n]$. Indeed, the elements of $\bar{c}_{i,j}$ correspond precisely to the joints of the paths $\phi(\bar{a}_i, \bar{b}_j)$, and since $\mathcal{M}_\phi$ has length ≥ 2 every path has at least one joint.

Finally, given $G = (U, V; E)$ with $U = V = [n]$, let $M_G \in \mathcal{C}$ be the induced substructure of M'_n obtained by removing $\bar{h}^n_{i,j}$ for all $(i, j) \notin E$. Since the tuples in $\{\bar{a}^n_i, \bar{b}^n_j, \bar{h}^n_{i,j} : i, j \in [n]\}$ are pairwise disjoint, it follows that $\bar{h}^n_{i,j} \in M_G$ for $(i, j) \in E(G)$. Hence, letting $\phi'(\bar{x}, \bar{y}) = \exists \bar{z} \phi(\bar{x}, \bar{y}, \bar{z})$, we see that $M_G \models \phi'(\bar{a}^n_i, \bar{b}^n_j)$ for all $(i, j) \in E(G)$. Moreover, $M_G \models \neg\phi(\bar{a}_i, \bar{b}_j)$ for $(i, j) \notin E(G)$. Indeed, since the elements of $\bar{c}^n_{i,j}$ are not in M_G for $(i, j) \notin E(G)$, the above observation implies that $M_G \models \neg\phi(\bar{a}_i, \bar{b}_j)$. ◀

Note that all of the above can be proved by working with an appropriate infinite model of $\mathrm{Th}(\mathcal{C})$ obtained by compactness, and applying the infinite versions of the different Ramsey theorems. We have chosen to give a finitistic proof, which is admittedly more involved, so that everything is carried out effectively. Therefore, if we assume that the *VC-dimension* of formulas in the class is computable, we may compute given r the maximum size of an r-subdivided clique occurring in the Gaifman graph of a structure in $\mathcal{C}$.

▶ **Definition 24.** *We say that a class $\mathcal{C}$ of structures is effectively NIP if there is a computable function $f : \mathbb{N} \to \mathbb{N}$ such that for all formulas $\phi(\bar{x}, \bar{y})$ and all structures $M \in \mathcal{C}$ there is no $n > f(|\phi|)$ and $(\bar{a}_i)_{i \in [n]}, (\bar{b}_J)_{J \subseteq [n]}$ with*

$$M \models \phi(\bar{a}_i, \bar{b}_J) \iff i \in J.$$

Recall that a class of graphs $\mathcal{C}$ is called *effectively nowhere dense* whenever there is a computable function $f : \mathbb{N} \to \mathbb{N}$ such that for all $r \in \mathbb{N}$ and for all $G \in \mathcal{C}$ we have that $K^{(r)}_{f(r)}$ is not a subgraph of G.

▶ **Corollary 25.** *Let $\mathcal{C}$ be a monotone and (monadically) NIP class of $\mathcal{L}$-structures in a finite relational language. Then $\mathsf{Gaif}(\mathcal{C})$ is nowhere dense. Moreover, if $\mathcal{C}$ is effectively NIP then $\mathsf{Gaif}(\mathcal{C})$ is effectively nowhere dense.*

5 Intractability

In this section, we prove that any monotone class of relational structures whose Gaifman class is somewhere dense polynomially interprets the class of all bipartite graphs, and is therefore intractable. Towards this, we first strengthen Theorem 23 to obtain a simple path formula ϕ as well as a computable function $\Phi : \mathfrak{B} \to \mathcal{C}$ such that ϕ codes the edge relation of G in $\Phi(G)$.

▶ **Lemma 26.** *Let $\mathcal{C}$ be a monotone class of $\mathcal{L}$-structures such that $\mathsf{Gaif}(\mathcal{C})$ is somewhere dense. Then there is a simple path formula $\phi(\bar{x}, \bar{y})$ with parameters $\bar{p}$ and a polynomial time computable function $\Phi : \mathfrak{B} \to \mathcal{C}$, such that for each bipartite graph $G = (U, V; E) \in \mathfrak{B}$ there are tuples $(\bar{a}_u)_{u \in U}$ $(\bar{b}_v)_{v \in V}$, $(\bar{h}_{u,v})_{(u,v) \in E}$ from $\Phi(G)$ satisfying:*

$$\Phi(G) \models \phi(\bar{a}_u, \bar{b}_v) \text{ if, and only if, } (u, v) \in E.$$

Given ϕ, the interpretation of the parameters $\bar{p}$ in $\Phi(G)$ can be computed in constant time from $G \in \mathfrak{B}$.

Proof. Let ϕ and $(M_G)_{G\in\mathfrak{B}}$ be as in Theorem 23. Consider the path $\mathcal{M}_\phi$. Observe that either there is a step $\bar{e}_i$ such that both $\bar{e}_i \cap \bar{x} = \bar{x}' \neq \emptyset$ and $\bar{e}_i \cap \bar{y} = \bar{y}' \neq \emptyset$, or there are $i < j$ and steps $\bar{e}_i$, $\bar{e}_j$ such that $\bar{e}_i \cap \bar{y} = \emptyset, \bar{e}_j \cap \bar{x} = \emptyset$ and $\bar{e}_i \cap \bar{x} = \bar{x}' \neq \emptyset, \bar{e}_j \cap \bar{y} = \bar{y}' \neq \emptyset$ and for all $k \in \{i+1, \dots, j-1\}$ we have that $\bar{e}_k \cap \bar{x} = \bar{e}_k \cap \bar{y} = \emptyset$. Consider the induced substructure $\mathcal{M}'$ of $\mathcal{M}_\phi$ consisting solely of the step $\bar{e}_i$ in the first case or the steps $\bar{e}_i, \dots, \bar{e}_j$ in the second, and let $\phi'(\bar{x}', \bar{y}') = \exists \bar{w}' \psi'(\bar{x}', \bar{y}', \bar{w}')$ be the canonical formula of $(\mathcal{M}', \bar{x}', \bar{y}')$. Clearly, ϕ' is a simple path formula, and it follows by construction that for each $G \in \mathfrak{B}$ we may pick minimal subtuples $\bar{a}'_u \subseteq \bar{a}_u, \bar{b}'_v \subseteq \bar{b}_v, \bar{c}'_{u,v} \subseteq \bar{c}_{u,v}\bar{h}'_{u,v} \subseteq \bar{h}_{u,v} \in M_G$ for all $u \in U, v \in V$ such that :

- $M_G \models \phi'(\bar{a}'_u, \bar{b}'_v)$ if, and only if $(u, v) \in E$, and
- $(u, v) \in E$ implies $M_G \models \phi'(\bar{a}'_u, \bar{b}'_v, \bar{c}'_{u,v}, \bar{h}'_{u,v})$.

Clearly, these new subtuples are mutually disjoint and do not intersect any of the parameters $\bar{p}' \subseteq \bar{p}$ that appear in ϕ'. We finally let M'_G be the induced substructure of M_G consisting solely of these subtuples. Since the equality type of all tuples $\bar{p}'_{u,v} = \bar{a}_u^\frown \bar{b}_v^\frown \bar{h}_{u,v}$ is uniformly constant by Theorem 23, it follows that M_G may be computed from $G = (U, V; E)$ by adding disjoint tuples $(\bar{a}_u^G)_{u\in U}, (\bar{b}_v^G)_{v\in V}, (\bar{h}_{u,v}^G)_{(u,v)\in E(G)}, \bar{p}^G$ of appropriate equality types to represent vertices and existential witnesses, and the relations specified by ϕ' to represent the edges. Clearly, the tuple $\bar{p}^G$ which interprets the parameters of ϕ' is obtained in constant time from G. ◀

With this, we proceed to show intractability for monotone classes with somewhere Gaifman class. Our proof is essentially based on the proof of [13, Theorem 6.1], which covers the case of graphs. There, monotonicity and somewhere density imply that for some $r \in \mathbb{N}$ we may find an r-subdivided copy of any finite graph G in our class. The aim is then to definably distinguish the native points of G from the subdivision points. Assuming this, G can be simply interpreted, defining an edge between two native points if there is a path of length r between them. The idea is to distinguish points by their degrees; however, while all subdivision points have degree two, other points in G may as well have degree two. To address this, we first pre-process G to obtain a graph G' by adding two pendant vertices to each non-isolated vertex. Then, G may be definably recovered from G', and moreover, given an r-subdivision of G', we can definably distinguish the subdivision points and the remaining points by their degrees. Our construction is essentially the same, although the degree of a subdivision point is bounded by the length of paths in the subdivision, rather than by two. Moreover, we ought to ensure that the formula coding paths is not symmetric, so as to avoid accidentally creating two disjoint copies of the graph we wish to interpret.

▶ **Theorem 27.** *Let $\mathcal{C}$ be a monotone class of $\mathcal{L}$-structures such that* $\mathsf{Gaif}(\mathcal{C})$ *is somewhere dense, and assume that* $\mathsf{AW}[*] \neq \mathsf{FPT}$. *Then* FO *model-checking on $\mathcal{C}$ is not fixed-parameter tractable.*

Proof. Let $\mathcal{C}$ satisfy the above, and assume that $\mathsf{AW}[*] \neq \mathsf{FPT}$. We argue that we may polynomially interpret the class of all bipartite graphs in $\mathcal{C}$.

Let $\phi(\bar{x}, \bar{y})$ be the simple path formula from Lemma 26. Without loss of generality, we may assume that ϕ is not symmetric (in the sense of Definition 19). Indeed, if ϕ is symmetric let $\sigma \in \mathcal{S}_n$ be the non-identity permutation from Definition 19, and consider the formula $\phi'(\bar{x}, \bar{y}) = \phi(\bar{x}, \sigma^{-1}(\bar{y}))$, where σ^{-1} is applied to the indices of $\bar{y}$. Clearly, ϕ' is no longer symmetric, while the tuples $(\bar{a}_u)_{u\in U}$ $(\sigma(\bar{b}_v))_{v\in V}$, $(\bar{h}_{u,v})_{(u,v)\in E}$ still satisfy the conditions in Lemma 26.

Now, let k the length of the path $\mathcal{M}_\phi$ and define the auxiliary map:

$$f : \mathfrak{B} \to \mathfrak{B}$$
$$G = (U, V; E) \mapsto (U', V'; E'),$$

where $U' := U \sqcup \{\dot{u}_{v,1}, \dots, \dot{u}_{v,k+1} : v \in V\}$, $V' := V \sqcup \{\dot{v}_{u,1}, \dots, \dot{v}_{u,k+1} : u \in U\}$, and $E' := E \sqcup \{(u, \dot{v}_{u,i}) : u \in U, i \in [k+1]\} \sqcup \{(v, \dot{u}_{v,i}) : v \in V, i \in [k+1]\}$.

This is clearly computable in polynomial time. Given $G = (U, V; E) \in \mathfrak{B}$, consider $\Phi \circ f(G) \in \mathcal{C}$ given from Theorem 23, and let:

$$\theta_U(\bar{x}) := \exists^{>k} \bar{y} \phi(\bar{x}, \bar{y}) \wedge \bar{x} \neq \bar{p} \text{ and } \theta_V(\bar{y}) := \exists^{>k} \bar{x} \phi(\bar{x}, \bar{y}) \wedge \bar{y} \neq \bar{p},$$

where $\bar{p}$ are the parameters of ϕ. Without loss of generality, we may assume that $|\bar{x}| = |\bar{y}|$, for if $m = |\bar{y}| < |\bar{x}| = n$, then we may take $\theta_V(\bar{y}, y_{m+1}, \dots, y_n)$ to be $\theta_V(\bar{y}) \wedge \bigwedge_{i=m}^{n-1}(y_i = y_{i+1})$, and similarly if $|\bar{x}| < |\bar{y}|$. So, let $\theta(\bar{x}) = \theta_V(\bar{x}) \vee \theta_U(\bar{x})$.

Observe that G is an induced subgraph of $f(G)$, so we may view $\Phi(G)$ as an induced substructure of $\Phi \circ f(G)$. Letting $\bar{p}_{u,v} = \bar{a}_u \frown \bar{b}_v \frown \bar{h}_{u,v}$, it holds that $\bar{p}_{u,v} \cap \bar{p} = \emptyset$ and

$$\bar{p}_{u,v} \cap \bar{p}_{u',v'} = \begin{cases} \bar{a}_u & \text{if } u = u'; \\ \bar{b}_v & \text{if } v = v'; \\ \emptyset & \text{otherwise.} \end{cases}$$

whenever $(u, v) \neq (u', v')$. Hence, the only non-parameter elements that appear more than k times within a path are those in the tuples $\bar{a}_u$ and $\bar{b}_v$ for $u \in U$ and $v \in V$, i.e. those tuples corresponding to the elements of G. Since ϕ is not symmetric, it follows that $\theta(\Phi \circ f(G)) = \{\bar{a}_u, \bar{b}_v : u \in U, v \in V\}$, and so the pair $I = (\theta(\bar{x}), \phi(\bar{x}, \bar{y}))$ is an interpretation with computable parameters such that $I(\Phi \circ f(G)) = G$ for all $G \in \mathfrak{B}$. It follows that $\mathfrak{B} \leq_P \mathcal{C}$, and therefore $\mathcal{C}$ is not tractable. ◀

6 From nowhere density to monadic stability

Here we establish that a class of structures with nowhere dense Gaifman graphs is monadically stable. This argument relies on the extension of Theorem 6 to coloured digraphs, and the equivalence of nowhere density for the classes of Gaifman graphs and incidence graphs.

▶ **Lemma 28** ([15, Proposition 5.7]). *Let $\mathcal{C}$ be a class of structures in a finite relational language. Then $\mathsf{Gaif}(\mathcal{C})$ is nowhere dense if, and only if, $\mathsf{Inc}(\mathcal{C})$ is nowhere dense.*

We enrich the definition of incidence graphs by colouring the edges to distinguish between the various relations in the original language, and to indicate that a point in the domain corresponds to the i^{th} point of an incident tuple. We also direct the edges from points in the original domain to incident tuples. This will allow us to easily recover the original structure via a simple interpretation.

▶ **Definition 29** (Coloured incidence graphs). *Let M be an $\mathcal{L}$-structure in a finite relational language. Write n for the maximum arity of a relation symbol in $\mathcal{L}$, and let $E_\mathcal{L}$ be the language containing binary relation symbols $\{R_i : i \in [n], R \in \mathcal{L}\}$. We define the* coloured incidence graph *of M to be the $E_\mathcal{L}$-structure $\mathsf{Inc}^{\mathsf{c}}(M)$ on domain $M \sqcup \bigsqcup_{R \in \mathcal{L}} R^M$ such that for all $R \in \mathcal{L}$ and $i \in [n]$*

$$(u, \bar{v}) \in R_i^{\mathsf{Inc}^{\mathsf{c}}(M)} \text{ if, and only if, } \bar{v} \in R^M \text{ and } \bar{v}(i) = u.$$

For a class $\mathcal{C}$ of $\mathcal{L}$-structures we write $\mathsf{Inc}(\mathcal{C})$ for the class $\{\mathsf{Inc}(M) : M \in \mathcal{C}\}$.

▶ **Theorem 30.** *Let $\mathcal{C}$ be a class of structures in a finite relational language. If $\mathsf{Gaif}(\mathcal{C})$ is nowhere dense, then $\mathcal{C}$ is monadically stable.*

Proof. By Lemma 28, $\mathsf{Gaif}(\mathcal{C})$ being nowhere dense implies that $\mathsf{Inc}(\mathcal{C})$ is nowhere dense. In turn, this implies that $\mathsf{Inc}^{\mathbf{c}}(\mathcal{C})$ is monadically stable by the generalisation of Theorem 6 to coloured directed graphs, mentioned in both [1] and [17]. It is easily observed that $\mathcal{C}$ is simply interpreted in $\mathsf{Inc}^{\mathbf{c}}(\mathcal{C})$ by the formulas $\delta(x) = \neg\exists y \bigvee_{R\in\mathcal{L}} \bigvee_{i\in[n]} R_i(y,x)$ and $\phi_R(x_1,\dots,x_{\mathrm{ar}(R)}) = \exists z \bigwedge_{i\in[\mathrm{ar}(R)]} R_i(x_i,z)$ for $R \in \mathcal{L}$. Since interpretations preserve monadic stability, $\mathcal{C}$ is monadically stable as well. ◀

An alternative proof of the theorem above is indicated in [1], which does not pass through incidence graphs but instead explicitly codes the relations into a graph via gadgets.

The hypothesis in the following corollary is weaker than demanding that $\mathsf{Gaif}(\mathcal{C})$ be nowhere dense, as witnessed by the class of finite cliques with countably many edge colours and no two edges receiving the same colour.

▶ **Corollary 31.** *Let $\mathcal{C}$ be a class of structures in an infinite relational language. If for every reduct to a finite language, $\mathsf{Gaif}(\mathcal{C}^-)$ is nowhere dense, then $\mathcal{C}$ is monadically stable.*

Proof. The failure of monadic stability is witnessed by a single formula in some unary expansion, which only uses finitely many relations. ◀

▶ **Corollary 32.** *Let M be a relational structure such that for every reduct M^- to a finite language, for every $r \in \mathbb{N}$ there is some $n \in \mathbb{N}$ with $K_n^{(r)} \not\leq \mathsf{Gaif}(M^-)$. Then M is monadically stable.*

Proof. Let $\mathcal{C}$ be the class of finite substructures of M. Given the assumption, the previous lemma implies $\mathcal{C}$ is monadically stable. By [4], this implies M is monadically stable. ◀

7 Conclusion

Our paper settles the question of Adler and Adler, showing that tameness for a monotone class of relational structures can be completely recovered from the structural sparsity of its Gaifman class. We believe that many results from the theory of sparse graphs will generalise to relational structures by working with the Gaifman class, and we plan to exhibit such generalisations in future work.

Although this has not been addressed thus far, monotonicity as defined for classes of relational structures does not fully correspond to monotonicity in the standard graph-theoretic sense. Indeed, in the graph-theoretic sense, a monotone class of graphs is one closed under removal of *undirected* edges, that is, simultaneous removal of pairs of relations $E(u,v), E(v,u)$. However, a monotone class of $\{E\}$-structures is one where we can remove any E relation (so possibly we can turn an undirected edge into a directed one). In future work, we aim to address this subtle difference by introducing *symmetrically monotone* classes, so that our results can extend to broader classes of relational structures, such as classes of undirected hypergraphs closed under removal of hyperedges.

Finally, our paper makes a significant contribution towards Conjecture 9, settling it for the case of monotone classes of structures. While the machinery used in this paper will certainly assist in tackling the full conjecture, we believe that new techniques are required for this task. Here, it is important to understand the role of linear orders in the collapse of monadic NIP and bounded twin-width for hereditary classes of ordered graphs, and to identify which model-theoretic conditions generalise this phenomenon to arbitrary hereditary graph classes.

Compositionality of Planar Perfect Matchings

A Universal and Complete Fragment of ZW-Calculus

Abstract

We exhibit a strong connection between the matchgate formalism introduced by Valiant and the ZW-calculus of Coecke and Kissinger. This connection provides a natural compositional framework for matchgate theory as well as a direct combinatorial interpretation of the diagrams of ZW-calculus through the perfect matchings of their underlying graphs.

We identify a precise fragment of ZW-calculus, the planar W-calculus, that we prove to be complete and universal for matchgates, that are linear maps satisfying the matchgate identities. Computing scalars of the planar W-calculus corresponds to counting perfect matchings of planar graphs, and so can be carried in polynomial time using the FKT algorithm, making the planar W-calculus an efficiently simulable fragment of the ZW-calculus, in a similar way that the Clifford fragment is for ZX-calculus. This work opens new directions for the investigation of the combinatorial properties of ZW-calculus as well as the study of perfect matching counting through compositional diagrammatical technics.

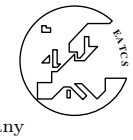
1 Introduction

A quantum computation mapping n qubits to m qubits corresponds to an isometric linear map $\mathbb{C}^{2^n} \to \mathbb{C}^{2^m}$. Due to the exponential size of their matrix representation, those linear maps are traditionally depicted as quantum circuits, an assemblage of elementary quantum gates similar to the more common boolean circuits. Given a quantum circuit $n \to m$, evaluating a coefficient of the corresponding $2^m \times 2^n$ matrix (i.e. evaluating the circuit



with a given input) typically requires an exponential time. However, there are some specific classes of quantum circuits – or fragments –, that can be classically simulated in polynomial time. Examples are the Clifford fragment (as asserted by the Gottesman-Knill theorem) as well as the fragment that will particularly interest us in this paper, the nearest-neighbour matchgates [24]. Investigating those tractable fragments allows a better understanding of the computational advantage of quantum computing. The reference for all elementary results on quantum circuits is [19].

Taking the diagrammatical circuit representation seriously led to developing graphical languages for quantum computing [7]. Those languages are equational theories described by elementary gates and local identities between diagrams. Such languages come with an interpretation into linear maps. A language is said universal for a class of linear maps if any linear map in the class is the interpretation of a diagram in the language. A language is said complete if two diagrams with the same interpretation are equivalent up to the equational theory, which means that they can be rewritten from one to the other using the local rewriting rules of the equational theory. In general, completeness is the most challenging property to prove.

The first quantum graphical language to appear was the ZX-calculus in 2008 [7]. It was rapidly known to be universal for all linear maps. However, providing a complete set of rewriting rules took another ten years (see [26] for an history of completeness) and first required a translation through another language, the ZW-calculus [12, 13].

The ZW-calculus was introduced in [8] as a graphical representation of the two kinds of tripartite entanglement for qubits, namely the GHZ-states and W-states. It then appeared that this calculus had very nice algebraic properties allowing the internal encoding of arithmetical operations. Those properties allowed the ZW-calculus to be the first proven universal and complete language for linear maps [12]. Despite this historical importance, the ZW-calculus gathered less attention than other languages, seen as more connected to quantum computing. Still, we must mention interesting connections with fermionic quantum computing [11], and recent works importing some ZW-calculus primitives into ZX-calculus to exploit their algebraic properties [20, 28]. In this paper, we show that ZW-calculus has very strong connections with a specific family of quantum circuits: the matchgates.

Matchgates were introduced in 2002 by Valiant [24]. They are linear maps defined by counting the perfect matching of a graph from which we remove some vertices depending on the inputs. This underlying combinatorial structure allows to classically simulate the corresponding quantum circuits by using the Polynomial FKT algorithm for perfect matchings counting [22, 15]. The theory of matchgates was then developed further to the concept of holographic algorithms [25]. We can notice that if some connections between graphical languages and holographic algorithms have been investigated [2], we are not aware of any diagrammatical approach to the original concept of matchgate before the present work, except a mention in [11].

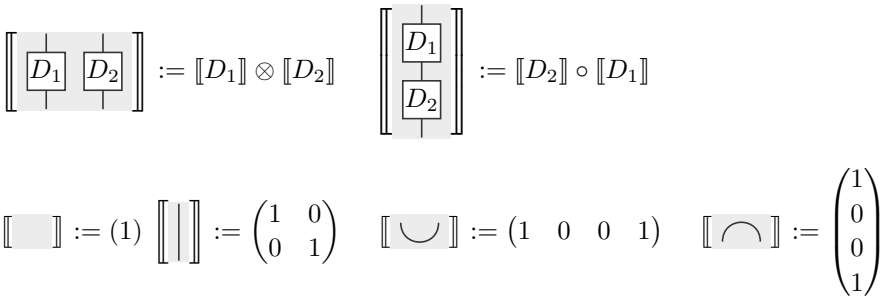
The main contribution of this paper is the introduction of a fragment of the ZW-calculus, that we call planar W-calculus. We show that this language is universal and complete for the planar matchgate fragment of quantum computation. The completeness proof relies on designing a normal form and a rewriting strategy to reach it. We also define a pro of matchgate computations by showing the compositionality of the matchgate identities introduced in [4]. The combinatorial characterisation of matchgate computations then directly follows from the correspondence with the graphical language. Hence one can see this paper as a reformulation of matchgate theory in a compositional framework.

The paper is structured as follows. Section 2 introduces our graphical primitives, their interpretation as linear maps and their combinatorial properties: the interpretation of a diagram can be deduced by counting the number of perfect matching of the underlying weighted graph. We present the generators and elementary rewrite rules of the language as

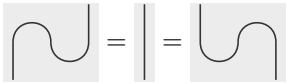
well as an essential syntactic sugar: the fermionic swap that emulates the swap gate, which is not part of our language. Section 3 introduces the normal form and proves the completeness of the language. In Section 4, we properly define a pro of matchgates characterised as the linear maps satisfying the matchgate identities. We show that our language is universal for matchgates, i.e., that the interpretation of a diagram is always a matchgate and that all matchgates correspond to a diagram. Finally, in Section 5, we sketch future directions of research suggested by the connection we identified between ZW-calculus and perfect matching counting.

2 Perfect Matchings and Planar W-Calculus

We define our fragment of the ZW-calculus, the *planar W-calculus*, denoted p**W**, by defining its diagrams. Any diagram with n inputs and m outputs $D : n \to m$ is interpreted as a linear map $[\![D]\!] : {}^{2^n} \to {}^{2^m}$ inductively as follows:



In particular, note that we do *not* use the usual swap diagram, hence the name *planar*. We do have, however, the so-called cup and cap satisfying the "snake equations":

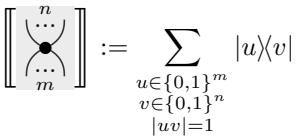


In the following, with $D : n \to n$, we may use the following notation: $D^{\otimes \vec{b}}$ when $\vec{b}$ is a bitstring, to represent $D^{b_1} \otimes ... \otimes D^{b_n}$ with $D^0 = id_n$ and $D^1 = D$. We call a diagram D a scalar if it has no input and no output, i.e. $D : 0 \to 0$. In the category-theoretic terminology, such a collection of diagrams defines a pro, a strict monoidal category whose monoid of objects is generated by a unique element, and not a prop, which requires the category to be symmetric, i.e. to have swap diagrams. Furthermore, the presence of the cups and caps make the category a compact-closed pro. We define **Qubit** to be the prop whose $n \to m$ morphisms are linear maps ${}^{2^n} \to {}^{2^m}$. Hence $[\![\cdot]\!] : \text{p}\mathbf{W} \to \mathbf{Qubit}$ is a pro morphism.

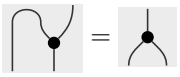
We add the two following generators: the black spider and the binary white spider, whose interpretations are detailed in the next sub-sections.

2.1 Black Spider

To manipulate binary words $\alpha \in \{0,1\}^n$ and $\beta \in \{0,1\}^m$, we will denote $\alpha \oplus \beta \in \{0,1\}^n$ the bitwise XOR (if $n = m$), $\alpha \cdot \beta \in \{0,1\}^{n+m}$ the concatenation, $|\alpha| \in \{0, ..., n\}$ the Hamming weight, i.e., the number of ones in the word α, and $|\alpha|_2 \in \{0,1\}$ the parity of this weight, 0 if even and 1 if odd. The *black spider* (or black node) is given by the following interpretation:

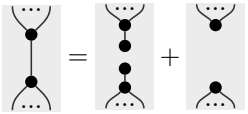


In other words, the black spiders gives an output 1 if and only if exactly one of its legs (either input or outputs) has value $|1\rangle$ and all the others $|0\rangle$. As inputs and outputs behave exactly the same, one can use cup and caps in order to transform inputs into outputs and vice-versa:



Moreover, as input order do not matter, one can bend the wires and move black spiders around, without altering the resulting linear map, we say that the black nodes are flexsymmetric [6]. Flexsymmetry of the black spider allows us to see diagrams as graphs with fixed inputs and outputs edges. Fixing the input and outputs edges, any graph isomorphism preserves the semantics.

With this graphical interpretation in mind, one can understand the interpretation of a scalar diagram, composed of only black spiders, as counting the number of perfect matchings in the underlying graph. To see this, one can use the interpretation of a single edge, which simply is the identity $|0\rangle\langle 0| + |1\rangle\langle 1|$. This interpretation gives a useful insight in the diagrams: given an edge, one can partition the set of perfect matchings between those that have this edge and those that don't:



In the case where the graph is an actual graph, without half edges, the resulting map is a scalar (no input or outputs). One can show by induction that this scalar corresponds to the number of ways of choosing a set of edges such that each vertex is covered by exactly one edge. In other ways, *the number of perfect matchings* of the graph.

2.2 Binary White Spider

The last generator of the planar W-calculus is the *binary white spider*, given, for any $r \in$, by:

$:= \begin{pmatrix} 1 & 0 \\ 0 & r \end{pmatrix}$

which corresponds to the usual binary white spider with weight r of the ZW-calculus. This binary spider corresponds to having a weight r on an edge of the graph. When $r \in \mathbb{N}$, the interpretation is straightforward: the white spider can be replaced by r edges:  .

And in particular,  .

Let us interpret the white spiders as weights on the edges of a planar graph G with black spiders on their vertices. Consider one perfect matching of the same graph G' without weights and consider one perfect matching P of G'. If the edge e that belongs to P has a weight $r \in \mathbb{N}$, then it can be replaced by r edges. In other words, the single perfect matching P is replaced by r perfect matchings when e has weight r. By doing this for every edges, one can see that each perfect matching in G' corresponds to a perfect matching of G with a *weight* that is the product of all its edge weights, instead of weight 1 in G'. For $r \in$, one cannot replace a white spider by a given number of edges, but the interpretation is the same: the edge contribute to the perfect matchings that contain it with a *weight* r.

▶ **Example 1.** 
$= 2 - 1 = 1$

Diagrams generated by the black and binary white node, within the framework described at the beginning of the section, are called p**W**-diagrams.

2.3 The FKT Algorithm

In general, counting the number of perfect matchings in a graph is an #P-complete problem [23]. However, for planar graphs the same problem turns out to be surprisingly easy, as Fisher, Temperley and Kastelyn showed that it is in P [22, 14]. The main idea behind the algorithm is that for planar graphs, it is possible to find a good orientation of the edges (called a Pfaffian orientation) in polynomial time such that the number of perfect matchings is the Pfaffian of the adjacency matrix A (actually its skew-symmetric version, called Tutte matrix) of the oriented graph. A result due to Cayley then shows that the Pfaffian is the square root of the determinant of A.

Note that one can find such an orientation for any planar graph, even weighted with complex weights, and the equality $pf(A) = \sqrt{det(A)}$ still holds. Therefore, computing the total *weight* of perfect matchings in a complex-weighted graph is in P.

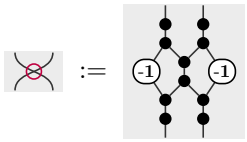
▶ **Proposition 2.** *Let D be a scalar* p**W***-diagram. Then $[\![D]\!]$ is computable in polynomial time in the number of black nodes.*

2.4 Fermionic Swap

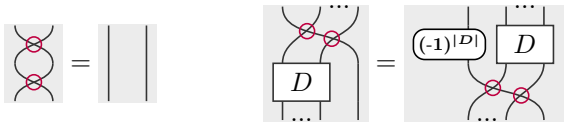
The usual ZW-calculus does have another generator that we did not explicitly include in our fragment, called the *fermionic swap*:

$:= \sum_{x,y\in\{0,1\}} (-1)^{xy} \, |xy\rangle\langle yx|$

However, it turns out that the fermionic swap is just syntactic sugar, and it is actually in our fragment:



Notice that the previous equation also appears in [5] to relate planar and non-planar matchgates. It is very useful to treat this piece of diagram as a generator of its own, especially as a particular kind of swap, which shares a lot of (but not all) properties of the symmetric braiding of props. In particular:



where $|D|$ is the number of black nodes in the diagram D.

3 Completeness

The planar W-calculus is introduced with an equational theory, given in Figure 1, relating together diagrams with the same semantics. This builds upon the more general equational theories for non-planar ZW-calculi, presented in [12, 13]. We write $\mathrm{pW} \vdash D_1 = D_2$ when one can turn diagram D_1 into diagram D_2 by applying the equations of Figure 1 locally.

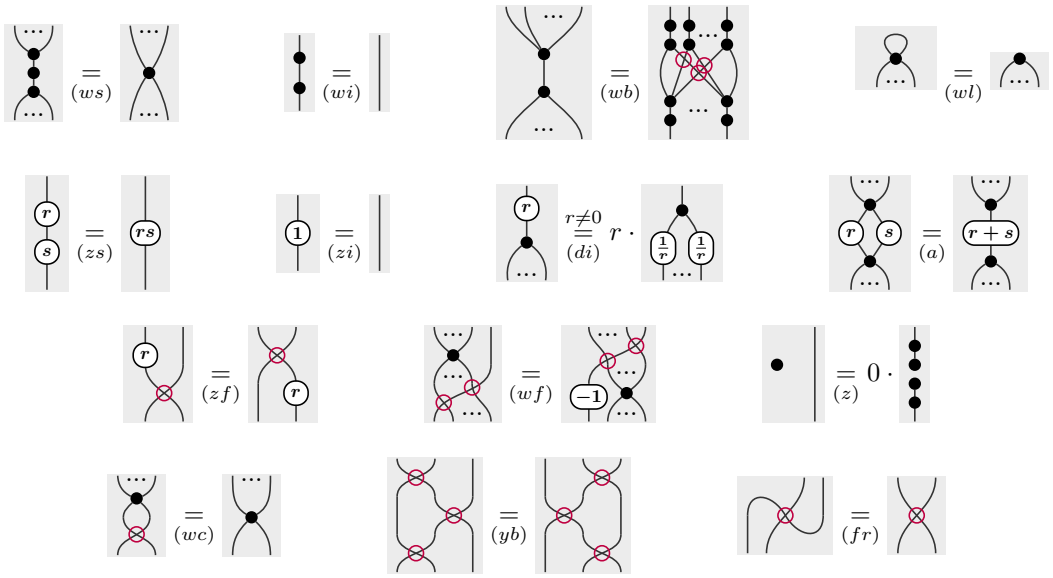


Figure 1 Axioms of the planar W-calculus.

▶ **Proposition 3.** *The equational theory of Figure 1 preserves the semantics:*

$$\mathrm{pW} \vdash D_1 = D_2 \quad \Longrightarrow \quad [\![D_1]\!] = [\![D_2]\!]$$

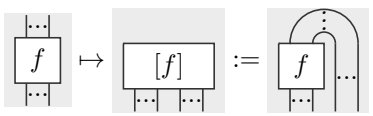
In the following, we will show that the converse also holds, that is, that whenever two diagrams have the same semantics, they can be turned into one another using the equational theory. Intuitively, this implies that the equational theory completely captures the interaction of generators with one another in the fragment.

To show this result, we give a notion of normal form, which we call W-graph-state with X-gates (WGS-X for short), then a refinement of that normal form (reduced WGS-X form) which can be shown to be unique, and we give a rewrite strategy (derivable from the equational theory) to turn any pW-diagram into this form.

3.1 Normal Form

The first step we take towards defining a normal form is a simplification, making use of the compact structure of the underlying pro, where we relate maps and states:

▶ **Proposition 4.** *There is an isomorphism between* $\mathrm{pW}(n, m)$ *and* $\mathrm{pW}(0, n + m)$ *defined as such:*



This isomorphism allows us only to consider states rather than maps in the following.

Then, we define W-graph-states, by first defining ordered weighted graphs:

▶ **Definition 5** (Ordered Weighted Graph). *$G = (V, E, w)$ is called an ordered weigthed graph if:*

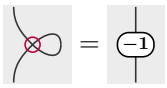
- *V is a set endowed with a total order $\prec$ (or equivalently a sequence)*
- *$E \subset V \times V$ is such that $(u, v) \in E \implies u \prec v$*
- *$w : E \to \mathbb{C} \setminus \{0\}$ maps each edge to its weight*

▶ **Definition 6** (W-Graph-State). *Let $G = (V, E, w)$ be an ordered weighted graph. Then,* $\mathrm{WGS}(G)$ *is defined as the* p**W***-diagram where:*

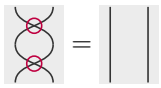
- *Each vertex in V gives a W-spider linked to an output through an additional*  *(the order on V gives the order of the outputs)*
- *Each (weighted) edge (u, v) gives a white dot with parameter $w((u, v))$ linked to the W-spiders obtained from u and v*
- *All wire crossings in* $\mathrm{WGS}(G)$ *are fermionic swaps* 
- *No output wire crosses another wire*
- *There are no self-intersecting wires*

When an edge has weight 1 we may ignore the white dot and represent the edge as a simple wire, since  . Notice that there are several ways to build $\mathrm{WGS}(G)$, but all of them are equivalent thanks to  and the axioms on the fermionic swap  , together with the provable identities in Lemmas 7 and 8:

▶ **Lemma 7.**



▶ **Lemma 8.**



▶ **Definition 9** (WGS-X form). *We say that a* p**W***-state D on n qubits is in:*

- ***WGS-X form*** *if there exist $s \in \mathbb{C}$, $G = ([1, n], E, w)$ an ordered graph, and $\vec{b} \in \{0, 1\}^n$ such that $D = s \cdot$*  $\circ\, \mathrm{WGS}(G)$.
- ***pseudo-WGS-X form*** *if it is in WGS-X form with potentially vertices linked to several outputs, additional*  *$(r \neq 0)$ on wires that do not correspond to edges in the graph, and potentially fermionic swaps*  *between outputs.*
- ***reduced WGS-X form*** *(rWGS-X) if it is in WGS-X form and:*

$$\forall i,\ (b_i = 0 \implies \nexists j,\ (i, j) \in E)$$

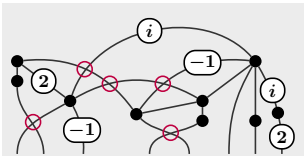
i.e. $b_i = 0$ is only possible if vertex i has no neighbour on its right.

▶ **Example 10.** $\mathrm{WGS}\left($  $\right) =$  where in the starting graph, vertices are ordered left to right, and edges with no indication of weight have weight 1.

If $\vec{b} = (0, 1, 1, 0, 1)$, then the obtained WGS-X state is:

$s \cdot$ 
where we used the fact that  is an involution to simplify the diagram. The WGS-X state is however not reduced, as both the first and fourth qubits have additional  applied to them, but still have neighbours on their right.

Finally, the following diagram is an example of a pseudo-WGS-X state:



3.2 Rewrite Strategy

We define in this section a rewrite strategy, derived from the equational theory, that will terminate in a normal form (WGS-X). Doing this naively is made difficult by the potential presence of fermionic swaps  wherever we are looking for patterns to rewrite. Thankfully, the last 5 equations in Figure 1, together with the above Lemmas 7 and 8 essentially tell us that we can treat those as usual swaps with the only catch that removing self loops or moving wires past black nodes adds a -1 weight to the wires.

In the upcoming rewrite strategy, we will hence only specify the patterns without potential fermionic swaps inside. Should there be some present, it is understood that they will be moved out of the pattern, before the rewrite occurs. The rules necessary for the rewrite strategy are given in Figure 2.

▶ **Proposition 11.** *The rewrite rules of Figure 2 are derivable from the equational theory of Figure 1 and hence are sound.*

For the rewrite strategy to terminate, we need to distinguish between different types of nodes:

▶ **Definition 12** (Boundary Node / Internal Node). *A node is a* boundary node of type 1 *if it is linked directly to an output (potentially through a white node). A node is a* boundary node of type 0 *if it is connected to a binary boundary node of type 1.*
We say that a black node of D is internal *if it is not a boundary node.*

Notice that diagrams in WGS-X, rWGS-X, or pseudo-WGS-X form, do not have internal nodes. The crux of the upcoming rewrite strategy is precisely to remove internal nodes. The rewrite strategy is laid out as follows:

▶ **Definition 13** (Rewrite Strategy). *The rewrite strategy is defined in 3 steps:*

1. *Apply the rewrites of Figure 2 in any order but following constraints, until none apply anymore. The diagram ends up in pseudo-WGS-X form.*

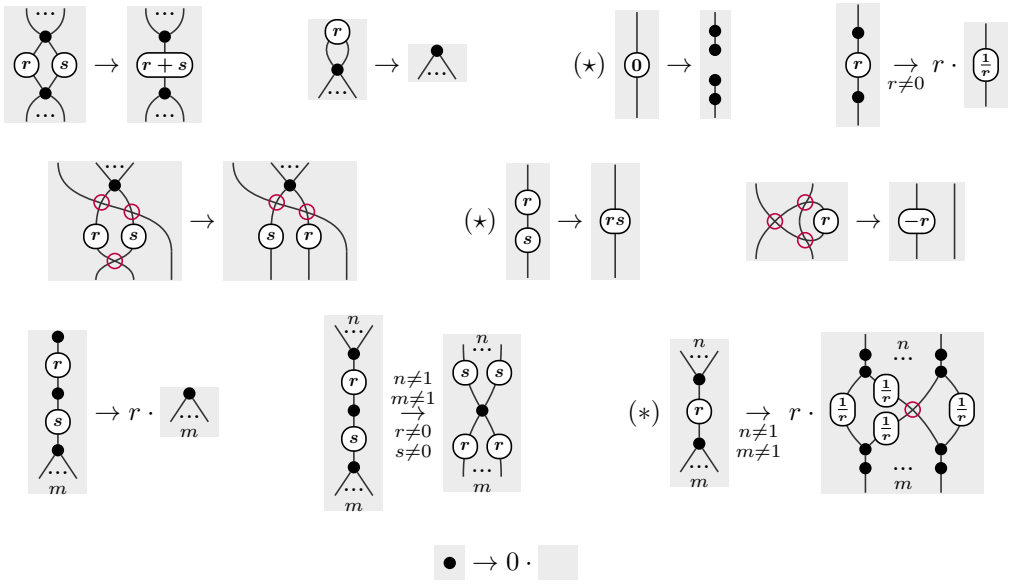


Figure 2 Rewrite rules. Rule $(\star)$ corresponds to the third axiom of Figure 1 with weights, i.e. the edges form a complete bipartite graph between the black nodes, with a fermionic swap at each crossing and weight $\frac{1}{r}$ on each edge. All the rules in this figure, except $(\star)$, are supposed to apply when any of the white nodes are replaced by identity (i.e. when their weight is 1). Rule $(*)$ can only be applied if at least one of the black nodes is internal, and if none of the other rules applies.

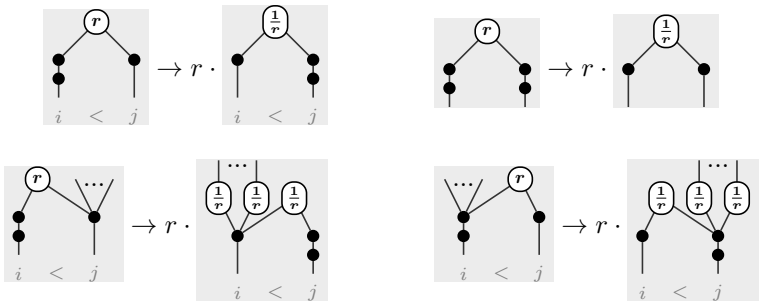

Figure 3 Rules for reduced WGS-X form, together with rule $(*)$ when the leftmost black node is a type-0 boundary node.

2. *First, whenever a type-1 boundary is linked to $n > 1$ outputs directly, apply*  *to the $n-1$ rightmost such outputs (the top black node then becomes a type-0 boundary node, the bottom one a type-1 boundary node). Then, push all potential fermionic swaps*  *between outputs inside the graph part. Finally, move boundary weights up into the edges of the WGS using*  *. The diagram ends up in WGS-X form.*
3. *Whenever a type-0 vertex in the graph has a right neighbour, depending on the arity of the nodes, apply rule $(*)$ or one of the rules of Figure 3 between the two nodes (and apply any other possible rule before going on).*

A claim was made in Definition 13 about the form of the diagram at the end of each step. Those claims are going to be proven in the following (Proposition 14). At the same time, we are going to show that the rewrite terminates.

▶ **Proposition 14** (Termination in rWGS-X form)**.** *The rewrite strategy terminates in a polynomial number of rewriting steps. Moreover, after Step 1 of the rewrite, the diagram is indeed in pseudo-WGS-X form, after Step 2, it is in WGS-X form, and after Step 3, it is in rWGS-X form.*

A key property of planar W calculus is that any multi-edge can be merged thanks to the first rule of Figure 2. In the case of the general ZW-calculus, the presence of both swaps and fermionic swaps do not allow us to merge all multi-edges. Indeed, different parallel edges, between the two same nodes, can make fermionic swaps with different other edges. The problem is that with the presence of multi-edges, rule $(*)$ does not necessarily lead to a reduction in the number of nodes and our rewriting strategy may not terminate.

An important operation on WGS-X states that has a simple graphical interpretation is the following:

▶ **Lemma 15.** *For any diagram D in WGS-X form $(s, G, \vec{b})$, applying*  *on the ith output can be turned into the WGS-X form $(s, G \setminus \{i\}, \vec{b} \setminus b_i)$, where $G \setminus \{i\}$ is defined as the graph G from which vertex i is removed (together with all edges linked to i and their weights), and similarly $\vec{b} \setminus b_i$ is defined as the sequence $\vec{b}$ from which ith element is removed.*

This allows us to prove the following:

▶ **Lemma 16.** *For any diagram D in WGS-X form $(s, G, \vec{b})$:*

$$[\![D]\!] = 0 \iff s = 0$$

We may then prove that 0-diagrams can be put in a very well-defined form:

▶ **Lemma 17.** *Let D be a WGS-X state such that $[\![D]\!] = 0$. Then D can be put in the WGS-X form $(0, G = ([1, n], \emptyset, \_), \vec{0})$, i.e.:*

$\mathrm{pW} \vdash D = 0 \cdot$ 

We are now able to prove the completeness of the equational theory.

▶ **Theorem 18.** *Let D_1 and D_2 be two* pW*-diagrams. Then:*

$$[\![D_1]\!] = [\![D_2]\!] \iff \mathrm{pW} \vdash D_1 = D_2$$

This last theorem, together with the fact that the rewriting in rWGS-X form is polynomial (Proposition 14) makes the problem of deciding whether two pW-diagrams are semantically equivalent a P problem.

4 Matchgates

This section aims at characterising exactly the linear maps that W-diagrams represent.

4.1 Matchgate Identities

Valiant first introduced matchgate identities to characterise $2 \to 2$ matchgates, a family of linear maps described in a combinatorial way [24]. In [4], the matchgate identities have been extended to characterise matchgates of any size. In the literature, there is a close link between

matchgate identities and the Grassman-Plucker identities applied to Pfaffians. It is not the case here, as the diagrammatic technics allow us to directly link matchgate identities to matchings without the intermediate of the Pfaffian. We can fully recover the connection with Pfaffians through the Fetcher-Kasteleyn-Temperley algorithm for counting perfect matchings [15, 22], more details on this are outlined in Section 5. Many of the proofs of this section are inspired by the very useful clarification of matchgate theory presented in [5]. Notice that contrary to the literature that differentiates between matchgrids, matchcircuits or matchnets, we will only use the term matchgate for any linear map satisfying the matchgate identities.

Recall that for binary words $\alpha \in \{0,1\}^n$ and $\beta \in \{0,1\}^m$, $\alpha \oplus \beta \in \{0,1\}^n$ is the bitwise XOR (if $n = m$), $\alpha \cdot \beta \in \{0,1\}^{n+m}$ the concatenation, $|\alpha| \in \{0, ..., n\}$ the Hamming weight, i.e., the number of ones in the word α, and $|\alpha|_2 \in \{0,1\}$ the parity of this weight, 0 if even and 1 if odd.

▶ **Definition 19** (Matchgate Identities). *A tensor $\Gamma \in \mathbb{C}^{2^n}$ satisfies the **matchgate identities** (MGIs) if for all $\alpha, \beta \in \{0,1\}^n$:*

$$\sum_{k=1}^{|\alpha \oplus \beta|} (-1)^k \Gamma_{\alpha \oplus e_{p_k}} \Gamma_{\beta \oplus e_{p_k}} = 0$$

Where $e_{p_k} \in \{0,1\}^n$ is the binary word which is zero everywhere except in position p_k, which is the kth position in the set $\{p_1, ..., p_{|\alpha \oplus \beta|}\} \subseteq \{1, ..., n\}$ of positions in which the words α and β differs.

The matchgate identities are not linear, so the set of matchgates is not a subspace of the vector space $\mathbb{C}^{2^n}$ but an algebraic variety [4]. In general, those identities are not algebraically independent, i.e. are not all strictly necessary to describe match-tensors.

Indeed, there are numerous symmetries in those identities. For example, the case $\alpha = \beta$ directly gives empty sums and exchanging α and β gives the same identity. Interestingly, one can replace half of the identities with a parity condition.

▶ **Proposition 20** (Parity condition [5]). *If Γ satisfies the matchgate identities then it satisfies the **parity condition**: for all $\alpha, \beta \in \{0,1\}^n$, $|\alpha|_2 \neq |\beta|_2 \Rightarrow \Gamma_\alpha \Gamma_\beta = 0$.*

The parity condition splits match-tensors into two groups, the one with odd parity, such that $|\alpha|$ even implies $\Gamma_\alpha = 0$, and the one of even parity, such that $|\alpha|$ odd implies $\Gamma_\alpha = 0$. In particular, the parity condition directly implies that all terms in identities with $|\alpha|_2 \neq |\beta|_2$ are zero. Notice that the parity condition is not sufficient. We still need matchgate identities in general.

However, the parity condition is sufficient for $n \leq 3$, but not anymore for $n = 4$, the original case considered by Valiant [24]. In particular, for $n = 0$, the matchgate identities are trivially true; hence they are satisfied by all scalars (processes $0 \to 0$).

4.2 The Pro of Matchgates

We will now use the matchgates to define a pro. So far, matchgate identities have been used to characterise vectors seen as tensors, without consideration of inputs and outputs. To apply them to linear maps $f : n \to m$, we will use the state form: $[f] : 0 \to n + m$ described in Proposition 4. It allows us to define matchgates.

▶ **Definition 21** (Matchgates). *A **matchgate** is a linear map $f : \mathbb{C}^{2^n} \to \mathbb{C}^{2^m}$ such that $[f]$ satisfies the matchgate identities.*

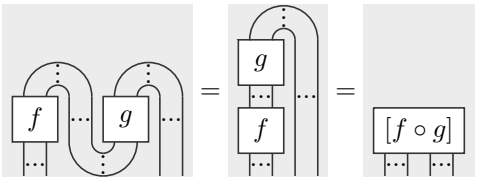
We would like to define a sub-pro of **Qubit** whose processes are matchgates, however, there are a few properties to check before that. We start by showing stability by the tensor product.

▶ **Lemma 22.** *Given two linear maps $f : a \to b$ and $g : c \to d$ whose state forms $[f] \in \mathbb{C}^{2^{a+b}}$ and $[g] \in \mathbb{C}^{2^{c+d}}$ satisfy the matchgate identities, then $[f \otimes g] \in \mathbb{C}^{2^{a+c+b+d}}$ satisfies the matchgate identities.*

The next thing to check is stability by composition; this follows from the following result:

▶ **Lemma 23.** *If $\Gamma \in \mathbb{C}^{2^{n+2}}$ satisfies the matchgate identities, then the tensor obtained by contracting two consecutive indices satisfies the matchgate identities.*

Notice that the consecutive indices assumption is essential here. Without it, we could easily construct the swap gate that does not satisfy the matchgate identities. To be able to contract consecutive indices is enough to show the stability by composition. The idea is to iterate contraction on consecutive indices until we obtain enough cups to use the snake equation, pictorially:

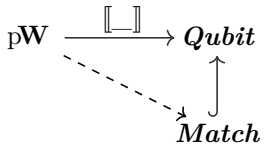


Now that we have stability by tensor and composition, it only remains to show the identities are matchgates. id_0 is a scalar, so directly a matchgate. The state-form of id_1 is the cap which is a matchgate as it satisfies the parity condition (sufficient for $n = 2$). The fact that all id_n are matchgates follows from stability by the tensor product. We can now state the main theorem of this subsection.

▶ **Theorem 24 (Match).** *The matchgates form a pro **Match**, which is a sub-pro of **Qubit**.*

Notice that **Match** is compact closed since the cup and the cap are both matchgates. Hence we can also use process/state duality in **Match** without any worry. As expected, all W-diagrams represent matchgates.

▶ **Lemma 25.** *The functor $[\![\_]\!] : \mathrm{pW} \to$ **Qubit** factorises through **Match**, i.e., the interpretations of diagrams in W are matchgates.*



Proof. We have to prove that the interpretation of any pW diagram is a matchgate. To do so, as matchgates are stable by composition and tensor product we only have to check that the interpretations of the generators are matchgates. The state forms of the generators have at most three outputs (n-ary spiders can be decomposed into binary and ternary spiders), so it is sufficient to check the parity condition, which is indeed satisfied by the interpretations of the generators. ◀

4.3 Universality

Now that we proved that all pW-diagrams represent matchgates, it remains to show that all matchgates can be represented by a pW diagram, in other words, that pW is universal for **Match**. This will require a few additional properties of matchgates, adapting some results of [5].

▶ **Lemma 26.** *If Γ satisfies the matchgate identities and $\Gamma_{\mathbf{0}} = 1$, where $\mathbf{0}$ is binary word full of 0, then it is uniquely determined by its coefficients Γ_α where $|\alpha| = 2$.*

Proof. If $|\alpha| = 0$ then we already know that $\Gamma_\alpha = 1$ and the parity condition implies that $\Gamma_\alpha = 0$ if $|\alpha| = 1$. We show that for all α with $3 \leq |\alpha|$, we can express Γ_α from coefficients Γ_β where all βs have strictly smaller Hamming weights. Let i be the first position where α and $\mathbf{0}$ differ, the matchgate identity corresponding to $\alpha \oplus e_i$ and $\mathbf{0} \oplus e_i$ is:

$$\sum_{k=1}^{|\alpha|} (-1)^k \Gamma_{\alpha \oplus e_i \oplus e_{p_k}} \Gamma_{e_i \oplus e_{p_k}} = 0$$

Here the p_k are exactly the position where α is 1, in particular $i = p_1$ so:

$$\Gamma_\alpha = \Gamma_\alpha \Gamma_{\mathbf{0}} = \sum_{k=2}^{|\alpha|} (-1)^k \Gamma_{\alpha \oplus e_i \oplus e_{p_k}} \Gamma_{e_i \oplus e_{p_k}}$$

For $k \geq 2$, We have $|e_i \oplus e_{p_k}| = 2$ and $|\alpha \oplus e_i \oplus e_{p_k}| = |\alpha| - 2$ so Γ_α is completely determined by coefficients corresponding to strictly smaller Hamming weight. It follows that all Γ_α can be expressed from the Γ_βs with $|\beta| = 2$. ◀

We will now be able to reuse the normal form from Section 3 to construct diagrams representing any matchgate.

▶ **Lemma 27** (Universality)**.** pW *is universal for* ***Match****.*

Proof. Relying on process/state duality, we only consider states $0 \to n$. Given Γ satisfying the matchgate identities, we will construct a W diagram D such that $[\![D]\!] = \Gamma$. We start by considering the case where $\Gamma_{\mathbf{0}} = 1$. Then we construct a weighted graph G on n vertices setting the weight of the edge (i, j) to $\Gamma_{e_i \oplus e_j}$. We then take D to be the diagram in graph form corresponding to G. By construction we then have $[\![D]\!]_{\mathbf{0}} = 1$ and $[\![D]\!]_{e_i \oplus e_j} = \Gamma_{e_i \oplus e_j}$ for all $i \neq j$. Furthermore, by Lemma 25, $[\![D]\!]$ is a matchgate so by Lemma 26, $[\![D]\!] = \Gamma$.

Now if $\Gamma_{\mathbf{0}} \neq 1$: First if $\Gamma_{\mathbf{0}} \neq 0$ then $\Gamma' = \frac{1}{\Gamma_{\mathbf{0}}}\Gamma$ is of the right form so we can obtain D by adding a floating edge of weight $\Gamma_{\mathbf{0}}$ to the diagram D' representing Γ'. The last case is $\Gamma_{\mathbf{0}} = 0$, then if $\Gamma = 0$ we can represent Γ by any diagram and a floating black node, else let β be such that $\Gamma_\beta \neq 0$, then Γ' defined as $\Gamma'_\alpha = \Gamma_{\alpha \oplus \beta}$ satisfies $\Gamma'_{\mathbf{0}} \neq 0$ and there is a diagram D' representing Γ'. A diagram D representing Γ is then obtained by plugging binary black nodes to the outputs of D' corresponding to the positions where β is 1. ◀

Notice that since **Match** is a sub-pro of **Qubit**, the completeness proof of Section 3 still holds in **Match**. It provides us with a universal and complete graphical language for matchgates.

▶ **Theorem 28.** pW *is universal and complete for* ***Match****.*

5 Further Work

The proper definition and axiomatisation of the p**W**-calculus pave the way to diverse investigations of the connection between combinatorics and quantum computing. We briefly outline in this last section some very promising directions that are the subjects of ongoing research.

5.1 New Simulation Techniques for Quantum Circuits

The identification of a fragment of the ZX-calculus exactly corresponding to the efficiently simulable Clifford gate [3] allows to design new rewrite-based simulation technics for quantum circuits introduced in [16]. Those algorithms have a parametrised complexity which is polynomial in the number of Clifford gated but exponential in the number of T-gates (a gate outside of the Clifford fragment sufficient to reach approximate universality).

Similarly, we have identified an efficiently simulable fragment of ZW-calculus: the p**W**-calculus exactly corresponding to matchgates. Adding the swap gate to p**W** we obtain another fragment of ZW which is exactly the fermionic ZW-calculus introduced in [11]. This calculus is universal for **Qubit** modulo an encoding trick: the dual-rail encoding. Equivalently, LFM is ZW where white nodes are contrived to have even arities, so adding arity one white nodes (corresponding to preparing $|+\rangle$ states) is enough to recover the full ZW-calculus, which is universal for **Qubits**. This situation suggests the possibility of designing rewrite-based simulation algorithms with complexities parametrised by the number of swap gates and/or $|+\rangle$ preparation. It would lead to a brand new kind of quantum simulation technics exploiting the combinatorial structure of matchgate and directly connected to classical perfect matching counting algorithms.

5.2 Combinatorial Interpretation of Full ZW-Calculus

In Section 2, we provided a combinatorial interpretation of p**W**-diagrams *via* perfect matchings in planar graphs. This combinatorial approach directly extends to LFM-calculus *via* perfect matchings in arbitrary graphs (which is #P-complete). Furthermore, we can also extend the interpretation to the full ZW-calculus, where white nodes can have arbitrary arities. To do so, we must consider hypergraph matchings, i.e., subsets of hyperedges covering each vertex exactly once. The arbitrary arity white nodes here play the role of hyperedges, and the black nodes, the role of vertices. Thus, the interpretation of ZW-scalars is the number of hypergraph matchings of the hypergraph underlying the diagram. Notice that hypergraph matching is also presented as the set cover problem in the literature. The full ZW-calculus could offer new perspectives on set cover in the same way that p**W** does for perfect matchings. In particular, some reduction results appear to have very clear diagrammatical proofs.

Aside from perfect matchings, it seems that graphical languages can encode other counting problems on graphs or hypergraphs. Designing such languages could shed a new tensorial/diagrammatical light on the corresponding combinatorial problems. Those approaches are reminiscent of the recent ZH-based algorithm for #Sat, introduced in [17] and related works linking graphical languages and counting complexity [9, 10]. Conversely, the question of applying similar combinatorial interpretations to other graphical languages as ZX-calculus [7], or ZH-calculus [1] is also worth being investigated.

5.3 Towards a Diagrammatic Approach of Perfect Matching Counting

In Section 2, we used the Fletcher-Kasteleyn-Temperley algorithm as a black box to compute the interpretation of p**W**-scalars in polynomial time. However, it seems possible to achieve the same result with purely diagrammatical technics. In fact, applying the rewriting strategy described in Section 3 to a scalar reduces it to a normal form from which we can directly read the interpretation. It seems very probable that this requires only a polynomial number of rewrites.

This provides a way to count perfect matchings without referring to Pfaffian computation, and conversely, it gives a new algorithm to compute Pfaffians based on rewriting.

The FKT algorithm only applies to a specific class of graphs, called Pfaffian graphs, i.e., the graphs admitting a Pfaffian orientation. In particular, all planar graphs are Pafaffian [14]. It seems that Pfaffian orientiation are directly connected to the behavior of fermionic swap and their lack of naturality which introduces -1 weights in the edges. More generally, all graphs not containing $K_{3,3}$ are Pfaffian [27, 18] (we recall that planar graphs are precisely the graphs not containing neither $K_{3,3}$ nor K_5 as minors). Moreover, there also exists a polynomial time algorithm for K_5-minor-free graphs [21] based on graph decomposition. There is a large amount of work in perspective, re-expressing in diagrammatic terms those different variations and understanding adequately how our rewriting rules could encode the minor constraints.

Formalising and implementing those different algorithms is the object of ongoing work. The main difficulty is to identify the suitable data structures to manipulate the topological data of a given diagram, equivalently, the specific planar embedding of the corresponding graph.

Abstract

Regular functions of infinite words are (partial) functions realized by deterministic two-way transducers with *infinite* look-ahead. Equivalently, Alur et. al. have shown that they correspond to functions realized by deterministic Muller streaming string transducers, and to functions defined by MSO-transductions. Regular functions are however not computable in general (for a classical extension of Turing computability to infinite inputs), and we consider in this paper the class of *deterministic regular functions* of infinite words, realized by deterministic two-way transducers *without* look-ahead. We prove that it is a well-behaved class of functions: they are computable, closed under composition, characterized by the *guarded* fragment of MSO-transductions, by deterministic Büchi streaming string transducers, by deterministic two-way transducers with *finite* look-ahead, and by finite compositions of sequential functions and one fixed basic function called map-copy-reverse.

1 Introduction

Transducers extend automata with output mechanisms, turning finite state machines from language acceptors to computational models for functions. Inspired by a seminal work by Engelfriet and Hoogeboom [22], the last decade has seen an increasing interest in characterizing the class of functions defined by deterministic two-way transducers over finite words (2-dT), now called the class of *regular functions of finite words*. This class admits several (effective) characterizations: it corresponds to the functions definable by MSO-transductions [22], by an MSO-based logic on origin graphs [15], by an extension of regular expressions called combinator expressions [4, 5, 20], and computed by *copyless streaming string transducers* (SST) (a deterministic one-way model which uses registers to store and update partial output words [2]). Moreover, the class of regular functions over finite words is closed under composition [11], and it has decidable equivalence problem [25].

▶ **Example 1.1.** Let Σ be an alphabet, the function map-copy-reverse : $(\Sigma \uplus \{|\})^* \to (\Sigma \uplus \{|\})^*$ takes any word of the form $u_1|\dots|u_n$ where each u_i is $|$-free, and outputs $u_1|\widetilde{u_1}|\dots|u_n|\widetilde{u_n}$, where $\widetilde{u_i}$ is the mirror image of u_i. The function map-copy-reverse is regular.

Regular functions can also be characterized as the compositions of sequential functions (functions computed by deterministic *one-way* finite transducers) and map-copy-reverse [6].

Regular functions of infinite words. The class of regular functions has been extended to infinite words in [3], and defined as the class of functions definable by MSO-transductions over infinite words. Equivalently, they have been shown to be the functions realized by deterministic two-way transducers with regular look-ahead, and by streaming string transducers with a Muller selection condition (the register holding the final output word is selected depending on the set of states seen infinitely often). As for finite words, regular functions of infinite words are closed under composition, and have decidable equivalence problem [3].

▶ **Example 1.2.** Let $\Sigma = \{a, b, c\}$ be an alphabet, and consider the function double : $\Sigma^\omega \to \Sigma^\omega$ which behaves like the identity function except that any occurrence of a is replaced by aa if there exists a b in the future of that occurence. For example, $(ab)^\omega$ is mapped to $(aab)^\omega$ and $acaab(ac)^\omega$ is mapped to $aacaaaab(ac)^\omega$. The function double is regular, as it can be realized by a one-way transducer which, when reading an a, uses regular look-aheads to determine whether there exists a b or not in the future, and produces either a or aa accordingly.

▶ **Example 1.3.** Let $\Sigma' = \{a, b, 1, 2\}$ and consider the function copy which maps:

- $u_1\sigma_1 u_2 \dots \sigma_n u \mapsto u_1^{\sigma_1}\sigma_1 \dots u_n^{\sigma_n}\sigma_n u$ where $u_1u_2\dots u_n u \in \{a,b\}^\omega$ and $\sigma_1, \dots, \sigma_n \in \{1,2\}$;
- $u_1\sigma_1 \dots u_i\sigma_i \cdots \mapsto u_1^{\sigma_1}\sigma_1 \dots u_i^{\sigma_i}\sigma_i \dots$ (if there are infinitely many $\sigma_i \in \{1,2\}$).

For example, $\mathsf{copy}(ab2a1b^\omega) = abab2a1b^\omega$ and $\mathsf{copy}((a2)^\omega) = (aa2)^\omega$. The function copy is regular, for instance realized by a deterministic two-way transducer which, using two-wayness, makes one or two passes on the blocks u_i, depending on whether they are followed by $\sigma_i = 2$. On the first pass, it always outputs what it reads, so that if no separator in $\{1,2\}$ is ever read again (which means it is reading the infinite suffix u), then it outputs u.

Despite the robustness of the class of regular functions of infinite words, witnessed by its various characterizations and algorithmic properties, they suffer from a severe downside when it comes to computability. Indeed, there are regular functions of infinite words which are *not* computable. At this point, we make clear what is meant by computability, since the input is infinite. We refer the reader to [18, 19] (and the references therein) for a formal definition of computability, and rather give intuitions here. A function f of infinite words is computable if there is a Turing machine with an infinite read-only tape which contains some infinite input word u in the domain of the function, a bidirectional working tape, and a write-only left-to-right output tape, such that by reading longer and longer input prefixes, the machine writes longer and longer prefixes of $f(u)$ on the output tape. Informally, it is an algorithm which takes the input as a stream and is able to produce the output as a stream, so that infinitely often, at least one output symbol is produced. For instance, the function double above is not computable. On reading prefixes of the form ac^n for increasing values of n, it can safely output one a symbol, but not more. Indeed, if it outputs one more a, then it is a wrong output for continuation c^ω, and if it outputs a c, then it is a wrong output for continuation b^ω, as $\mathsf{double}(ac^nc^\omega) = ac^\omega$ and $\mathsf{double}(ac^nb^\omega) = aac^nb^\omega$. Its implementation by a two-way transducer indeed requires an infinite look-ahead to check the absence of a b in the future. On the other hand, copy is realized by a deterministic two-way transducer with *no* look-ahead, so it is computable. So, deterministic two-way transducers

with (infinite) look-ahead, and their equivalent model Muller streaming string transducers, *cannot* be considered as models of computation for infinite word functions. This was observed in [19], where it is shown that the problem of deciding whether a given regular function of infinite words is computable is PSPACE-C. On the other hand, deterministic two-way transducers *without look-ahead* are a proper model of computation for functions of infinite words.

Deterministic regular functions of infinite words. Motivated by the latter observation, the class of functions computed by deterministic two-way transducers *without* look-ahead, coined the class of *deterministic regular functions*, was introduced in [9], where it is shown that they are also equivalently computed by Büchi SST (BSST). In BSST, there is one special designated register $\mathfrak{out}$ in which to write the output word, which is required to be updated with at least one new symbol infinitely often. For example, copy can be implemented by a single-state BSST with two registers $\mathfrak{out}$ and $\mathfrak{r}$, updated as follows. On reading $\sigma \in \{a, b\}$, it performs the updates $\mathfrak{out} \mapsto \mathfrak{out}.\sigma$ and $\mathfrak{r} \mapsto \mathfrak{r}.\sigma$, on reading 1, it does $\mathfrak{out} \mapsto \mathfrak{out}.1$ and $\mathfrak{r} \mapsto \varepsilon$, and on reading 2, it does $\mathfrak{out} \mapsto \mathfrak{out}.\mathfrak{r}.2$ and $\mathfrak{r} \mapsto \varepsilon$.

Several important questions remain on the class of deterministic regular functions, such as whether it is closed under composition, whether it can be logically characterized by a natural fragment of MSO-transductions, and whether they can be obtained as finite compositions of "simple" functions. In this paper, we provide positive answers to these questions.

Contributions. Concerning the class of deterministic regular functions, our main results are:

- its effective closure under composition;
- its characterization by means of finite compositions of sequential functions and an extension of map-copy-reverse to infinite words;
- a logical characterization by a natural syntactic fragment of MSO-transductions, the guarded fragment, called MSOT_g.

An MSO-transduction is defined as an MSO-interpretation, where the predicates of the output word structure, namely the successor and label relations, are defined by MSO formulas with two and one free first-order variables respectively, interpreted over a fixed number of copies of the input. The guarded fragment is defined by a classical restriction (see e.g. [24] and references therein) on the MSO formulas composing the MSO-transduction. They have to be prefixed by an existential quantifier $\exists \mathsf{g}$, where g is a word position, and all quantifiers of the formula are guarded by the guard $x \leq \mathsf{g}$ (and $\forall x \in X, x \leq \mathsf{g}$ for any set variable X). So, guarded MSO formulas on infinite words, only speak about finite prefixes. Consider again the function copy. Two copies of the input are needed to account for potential duplication of the blocks, but the presence or not of a successor edge between two nodes of the output word structure, only depends on local properties, which are definable by guarded MSO formulas. E.g., such a property may be "if position $x+1$ is labeled 2, then there is a successor between the 1st copy of x and the 2nd copy of first position of the block to which x belongs".

In general, guarded MSO formulas can test non-local properties, which is the main source of technical difficulties in the paper. It is illustrated by the next example.

▶ **Example 1.4.** The function replace : $\{0, a, b\}^\omega \multimap \{a, b\}^\omega$ of domain $\mathsf{Dom}(\mathsf{replace}) = \{u \in \{0, a, b\}^\omega : |u|_a{=}\infty \text{ or } |u|_b{=}\infty\}$ and mapping $0^{n_1}\sigma_1 0^{n_2}\sigma_2 \cdots \mapsto \sigma_1{}^{n_1+1}\sigma_2{}^{n_2+1}\cdots$ if $\sigma_i \in \{a, b\}$ and $n_i \in \mathbb{N}$, is deterministic regular. Replacing a zero at position x by a or b depends on the next non-zero symbol in the future of x, which can be arbitrarily faraway, but occurs in a finite prefix if $u \in \mathsf{Dom}(\mathsf{replace})$. This property is expressible with a guarded MSO formula, which defines the position holding this non-zero symbol as a guard.

Proof techniques and additional results. We now give an overview of the proof techniques used to show the logical characterization, along with some other interesting and useful results. We prove that deterministic two-way transducers (2-dT) are expressively equivalent to MSOT_g. The conversion of 2-dT into MSOT_g is standard and follows the same line as [22]. The converse is more involved and requires new techniques. First, we convert MSOT_g-transductions into deterministic two-way transducers with *finite look-ahead* (2-$\mathsf{dT}^{\mathsf{FLA}}$), which account for non-local, but finite, properties, as illustrated before. 2-$\mathsf{dT}^{\mathsf{FLA}}$ are equipped with regular languages of finite words on their transitions, which act as finite look-aheads in the following sense: when the reading head is at some position i of an infinite word u, in some state q, a transition from q with look-ahead L is enabled if there exists a position $j \geq i$, called witness, such that the infix $u[i{:}j]$ starting at position i and ending at position j, belongs to L. If no transition is enabled at state q, the computation fails. To ensure determinism, if several transitions are enabled, only the transition with minimal (i.e. smallest) witness j is triggered, and a disjointness requirement on the look-aheads make sure that this j is unique. The condition to consider only the transition with minimal witness j is crucial to ensure that 2-$\mathsf{dT}^{\mathsf{FLA}}$ define only computable functions. Indeed, a 2-$\mathsf{dT}^{\mathsf{FLA}}$ can be executed as follows: all finite look-aheads, supposed for instance to be finitely represented by DFA, are executed in parallel. By the minimality requirement for j and the disjointness of look-aheads, *as soon as* a prefix is accepted by one look-ahead DFA, the corresponding transition is triggered.

Adding look-aheads to two-way transducers in order to capture MSO-transductions is standard on finite words [22, 14], for example because the "moves" of the MSO-transduction depends on non-local properties. Look-aheads are then directly removed by using the closure under composition of deterministic two-way transducers [11]. Closure under composition of deterministic two-way transducers on infinite words is, to the best of our knowledge, unknown, and instead we give a direct proof of finite look-ahead removal. It is our main technical result: any 2-$\mathsf{dT}^{\mathsf{FLA}}$ is effectively equivalent to some 2-dT. To prove this result, classical techniques, such as Hopcroft-Ullman construction [1] or the tree outline construction [16] do not apply, as they heavily rely on the fact that words are finite. In our setting, we instead use a new technique, based on summarizing the computations of the look-aheads into trees which we prove to be bounded. As a side result of finite look-ahead removal, we prove that 2-dT (and so deterministic regular functions) are closed under composition. Classically, closure under composition of MSO-transductions is direct, by formula substitutions [14]. This technique however does not apply here, as the guarded MSO formulas are not syntactically closed under formula substitution, making the correspondence between MSOT_g and 2-dT crucial to obtain closure under composition of MSO_g-transductions.

Structure of the paper. In Section 2, we introduce the class of deterministic regular functions. In Section 3, we prove its closure under composition and the decomposition result. In Section 4, we introduce guarded MSO-transductions and state the logical characterization. Since its proof is based on a compilation into deterministic two-way transducers with finite look-ahead, we prove in Section 5 how to remove those look-aheads. Finally, we prove the logical characterization in Section 6. All transformations are effective in the paper. Some proofs are only sketched or simply omitted, but the proof details can be found in [10].

2 Deterministic regular functions

In this section, we introduce the class of *deterministic regular functions of infinite words* and recall that it can be described by two computation models: *deterministic two-way transducers* and *deterministic Büchi streaming string transducers*.

Notations. Letters Σ, Γ denote alphabets, i.e. finite sets of letters. The set Σ^* (resp. Σ^+, Σ^ω) denotes the set of finite words (resp. non-empty finite words, infinite words) over the alphabet Σ. Let $\Sigma^\infty := \Sigma^* \cup \Sigma^\omega$. If $u \in \Sigma^\infty$, we let $|u| \in \mathbb{N} \cup \{\infty\}$ be its length, $|u|_\sigma \in \mathbb{N} \cup \{\infty\}$ be the number of occurrences of $\sigma \in \Sigma$ and $u[i] \in \Sigma$ be the i-th letter of u for $1 \leq i \leq |u|$. If $1 \leq i \leq j \leq |u|$, $u[i{:}j]$ stands for $u[i] \cdots u[j]$. We write $u[i{:}]$ for $u[i{:}|u|]$. If $j > |u|$ we let $u[i{:}j] := u[i{:}|u|]$. If $j < i$ we let $u[i{:}j] := \varepsilon$. In this paper, functions are *by default* partial (i.e. possibly with non-total domain). A (partial) function f from S to T is denoted $f : S \rightharpoonup T$, and its domain is denoted $\mathsf{Dom}(f) \subseteq S$. A total function from S to T is denoted $f : S \to T$.

Two-way transducers. Let us recall the syntax of two-way transducers. We consider here that the machines work on infinite words, and have a Büchi acceptance condition.

▶ **Definition 2.1** (Two-way transducer). *A* deterministic two-way transducer (2-dT) *denoted* $\mathcal{T} = (\Sigma, \Gamma, Q, q_0, F, \delta, \lambda)$ *consists of:*

- *an input alphabet* Σ *and an output alphabet* Γ*;*
- *a finite set of states* Q *with an initial state* $q_0 \in Q$ *and a set of final states* $F \subseteq Q$*;*
- *a transition function* $\delta : Q \times (\Sigma \uplus \{\vdash\}) \rightharpoonup Q \times \{\triangleleft, \triangleright\}$*;*
- *an output function* $\lambda : Q \times (\Sigma \uplus \{\vdash\}) \rightharpoonup \Gamma^*$ *with same domain as* δ*.*

A *configuration* of $\mathcal{T}$ over $u \in (\Sigma \cup \{\vdash\})^\infty$ is a tuple (q, i) where $q \in Q$ is the current state and $1 \leq i \leq |u|$ is the current position of the reading head. The *transition relation* $\to$ is defined as follows. Given a configuration (q, i), let $(q', \star) := \delta(q, u[i])$. Then $(q, i) \to (q', i')$ whenever either $\star = \triangleleft$ and $i' = i - 1$ (move left), or $\star = \triangleright$ and $i' = i + 1$ (move right). A *run* over u is a (finite or infinite) sequence of consecutive configurations $(q_1, i_1) \to (q_2, i_2) \to \cdots$.

Now, we define the infinite output produced by $\mathcal{T}$ when given the infinite word $u \in \Sigma^\omega$ as input. First, we let $u[0] := \vdash$, i.e. we force the symbol $\vdash$ to be used to mark the beginning of the input. An *accepting* run is an infinite run that starts in $(q_0, 0)$, visits infinitely often configurations of the form (q, i) with $q \in F$ and such that $i_n \to \infty$ when $n \to \infty$ (without this last condition, the transducer may enter an infinite loop without reading its whole input). The partial function $f : \Sigma^\omega \rightharpoonup \Gamma^\omega$ computed by $\mathcal{T}$ is defined as follows. Let $u \in \Sigma^\omega$ be such that there exists a (unique) accepting run $(q_0^u, i_0^u) \to (q_1^u, i_1^u) \to \cdots$ labelled by $\vdash u$. Let $v := \prod_{j=1}^{\infty} \lambda(q_j^u, (\vdash u)[i_j^u]) \in \Gamma^* \cup \Gamma^\omega$ be the concatenation of the outputs produced along this run. If $v \in \Gamma^\omega$, we define $f(u) := v$. Otherwise $f(u)$ is undefined.

▶ **Definition 2.2.** *The class of* deterministic regular functions of infinite words *is the class of (partial) functions computed by deterministic two-way transducers.*

We have explained in Example 1.3 how to compute the function copy using a 2-dT (without look-aheads). Observe that the function replace from Example 1.4 can be computed in a similar fashion. Hence both functions are deterministic regular.

▶ **Example 2.3.** Let us extend the function map-copy-reverse of Example 1.1 to infinite words. Let Σ be an alphabet, we define map-copy-reverse : $(\Sigma \uplus \{|\})^\omega \to (\Sigma \uplus \{|\})^\omega$ as follows:

- map-copy-reverse$(u_1|u_2|\cdots) := u_1|\widetilde{u_1}|u_2|\widetilde{u_2}|\cdots$ with $u_i \in \Sigma^*$ for all $i \geq 0$;
- map-copy-reverse$(u_1|\cdots|u_n|u) := u_1|\widetilde{u_1}|\cdots|u_n|\widetilde{u_n}|u$ for $u_i \in \Sigma^*$ and $u \in \Sigma^\omega$.

This function is deterministic regular since we can build a 2-dT that processes twice each $|$-free factor (or only once for the last infinite one if it exists).

Büchi Streaming String Transducers. Now, we describe a model of a one-way machine with registers which captures deterministic regular functions of infinite words. Over finite words, it is well-known that deterministic two-way transducers are equivalent to *copyless streaming string transducers* [2]. A similar equivalence holds for the class of *regular functions of infinite words*, which can equivalently be described by *deterministic two-way transducers with regular look-aheads* or *copyless streaming string transducers with Muller conditions* [3]. However, Muller conditions enable to check regular properties of the infinite input, and thus describe functions which are not (Turing) computable [3]. Now, let us recall the model of *Büchi deterministic streaming string transducer* (BSST), introduced by Carton and Douéneau-Tabot in [9], that captures exactly the class of deterministic regular functions.

Formally, a Büchi deterministic streaming string transducer consists of a one-way deterministic automaton with a finite set $\mathfrak{R}$ of registers that store words from Γ^*. We use a distinguished register $\mathfrak{out}$ to store the output produced when reading an infinite word. The registers are modified when reading the input using *substitutions*, i.e. mappings $\mathfrak{R} \to (\Gamma \uplus \mathfrak{R})^*$. We denote by $\mathcal{S}_{\mathfrak{R}}^{\Gamma}$ the set of these substitutions. They can be extended morphically from $(\Gamma \uplus \mathfrak{R})^*$ to $(\Gamma \uplus \mathfrak{R})^*$ by preserving the elements of Γ.

▶ **Example 2.4** (Substitutions). Let $\mathfrak{R} = \{\mathfrak{r}, \mathfrak{s}\}$ and $\Gamma = \{b\}$. Consider $\tau_1 := \mathfrak{r} \mapsto b, \mathfrak{s} \mapsto b\mathfrak{r}\mathfrak{s}b$ and $\tau_2 := \mathfrak{r} \mapsto \mathfrak{r}b, \mathfrak{s} \mapsto \mathfrak{r}\mathfrak{s}$, then $\tau_1 \circ \tau_2(\mathfrak{r}) = \tau_1(\mathfrak{r}b) = bb$ and $\tau_1 \circ \tau_2(\mathfrak{s}) = \tau_1(\mathfrak{r}\mathfrak{s}) = bb\mathfrak{r}\mathfrak{s}b$.

▶ **Definition 2.5.** *A* Büchi deterministic streaming string transducer (BSST) *denoted by* $\mathcal{T} = (\Sigma, \Gamma, Q, F, q_0, \delta, \mathfrak{R}, \mathfrak{out}, \lambda)$ *consists of:*

- *a finite input (resp. output) alphabet* Σ *(resp.* Γ*);*
- *a finite set of states* Q *with* $q_0 \in Q$ *initial and* $F \subseteq Q$ *final;*
- *a transition function* $\delta : Q \times \Sigma \rightharpoonup Q$*;*
- *a finite set of registers* $\mathfrak{R}$ *with a distinguished output register* $\mathfrak{out} \in \mathfrak{R}$*;*
- *an update function* $\lambda : Q \times \Sigma \rightharpoonup \mathcal{S}_{\mathfrak{R}}^{\Gamma}$ *such that for all* $(q, \sigma) \in \mathsf{Dom}(\lambda) = \mathsf{Dom}(\delta)$*:*
  - $\lambda(q, \sigma)(\mathfrak{out}) = \mathfrak{out} \cdots$*;*
  - *there is no other occurrence of* $\mathfrak{out}$ *among the* $\lambda(q, \sigma)(\mathfrak{r})$ *for* $\mathfrak{r} \in \mathfrak{R}$*.*

This machine defines a partial function $f : \Sigma^\omega \rightharpoonup \Gamma^\omega$ as follows. For $i \geq 0$ let $q_i^u := \delta(q_0, u[1{:}i])$ (when defined). For $i \geq 1$, we let $\lambda_i^u := \lambda(q_{i-1}^u, u[i])$ (when defined) and $\lambda_0^u(\mathfrak{r}) = \varepsilon$ for all $\mathfrak{r} \in \mathfrak{R}$. For $i \geq 0$, let $[\![\cdot]\!]_i^u := \lambda_0^u \circ \cdots \circ \lambda_i^u$. By construction $[\![\mathfrak{out}]\!]_i^u$ is a prefix of $[\![\mathfrak{out}]\!]_{i+1}^u$ (when defined). If $[\![\mathfrak{out}]\!]_i^u$ is defined for all $i \geq 0$, q_i^u is a state of F infinitely often, and $|[\![\mathfrak{out}]\!]_i^u| \to +\infty$, then we let $f(u) := \bigvee_i [\![\mathfrak{out}]\!]_i^u$ (the symbol $\vee$ is used to denote the unique $v \in \Gamma^\omega$ such that $[\![\mathfrak{out}]\!]_i^u$ is a prefix of v for all $i \geq 0$). Otherwise $f(u)$ is undefined.

▶ **Example 2.6.** The function replace from Example 1.4 can be computed by a BSST. For all $i \geq 1$, it crosses the block 0^{n_i} and computes 1^{n_i} and 2^{n_i} in two registers. Once it sees σ_i it adds in $\mathfrak{out}$ the register storing ${\sigma_i}^{n_i}$.

▶ **Definition 2.7** (Copyless, bounded copy). *We say that a substitution* $\tau \in \mathcal{S}_{\mathfrak{R}}^{B}$ *is* copyless *(resp.* K-bounded*) if for all* $\mathfrak{r} \in \mathfrak{R}$*,* $\mathfrak{r}$ *occurs at most once in* $\{\tau(\mathfrak{s}) : \mathfrak{s} \in \mathfrak{R}\}$ *(resp. for all* $\mathfrak{r}, \mathfrak{s} \in \mathfrak{R}$*,* $\mathfrak{r}$ *occurs at most* K *times in* $\tau(\mathfrak{s})$*). We say that a* BSST $\mathcal{T} = (\Sigma, \Gamma, Q, q_0, \delta, \mathfrak{R}, \mathfrak{out}, \lambda)$ *is* copyless *(resp.* K-bounded*) if for all* $u \in \Sigma^\omega$ *and* $i \leq j$ *such that* $\lambda_i^u \circ \cdots \circ \lambda_j^u$ *is defined, this substitution is copyless (resp.* K*-bounded).*

▶ Remark 2.8. The composition of two copyless substitutions is copyless, hence a BSST is copyless as soon as $\lambda(q, \sigma)$ is copyless for all $q \in Q$ and $\sigma \in \Sigma$. However, K-boundedness is not necessarily preserved under composition.

Observe that the BSST described in Example 2.6 is copyless. Now, we recall the result of Carton and Douéneau-Tabot that proves equivalence between two-way transducers, copyless, and bounded copy Büchi deterministic streaming string transducers.

▶ **Theorem 2.9** ([9, Theorem 3.7]). *The following machines compute the same class of partial functions over infinite words:*

1. *deterministic two-way transducers* (2-dT)*;*
2. *K-bounded deterministic Büchi streaming string transducers* (K*-bounded* BSST)*;*
3. *copyless deterministic Büchi streaming string transducers* (*copyless* BSST)*.*

Furthermore, all the conversions are effective.

▶ Remark 2.10. The original proof of [9] which transforms a 2-dT into a BSST only considers machines where all states are final. Nevertheless, the proof can easily be adapted to transducers with non-final states. Furthermore, given a BSST (possibly with non-final states) one can build an equivalent BSST where all states are final by [9, Lemma D.1] (the Büchi conditions are hidden in the fact that the output must be infinite). All in all, all the models (with all states final or not) exactly capture the class of deterministic regular functions.

Finally, we recall the domains of deterministic regular functions. We say that a language is *Büchi deterministic* if it is accepted by a deterministic Büchi automaton (see e.g. [26]).

▶ **Proposition 2.11** ([9]). *If f is deterministic regular, then* Dom(f) *is Büchi deterministic.*

3 Composition and decomposition theorems

In this section, we show that deterministic regular functions are closed under composition, and that conversely they can be written as the composition of some "basic" functions.

It is known since [11] (resp. [3]) that the class of regular functions of finite (resp. infinite) words is closed under composition. We transport this result to deterministic regular functions of infinite words in Theorem 3.1. However, its proof is not an immediate extension of the regular case, and it illustrates the main difficulty of this paper: since look-aheads are not allowed, it is complex for a 2-dT to check if some property happens *after* its current position.

▶ **Theorem 3.1.** *Deterministic regular functions are (effectively) closed under composition.*

Proof idea. The approach is to compose the two transducers directly (using a product construction); the difficulty in the composition of two computations arises when one transducer is moving forward and the other backward. In that case, we need to rewind the computation of the transducer that moves backward by one computation step.

To recover the previous configuration look-ahead comes in handy. As mentioned above, (infinite) look-aheads are not permitted, but we use a weaker form of *finite* look-aheads (to be introduced in Section 5) which does not increase the expressiveness of deterministic two-way transducers over infinite words (and can be effectively removed), see Theorem 5.2. Finite look-aheads account for non-local but finite properties. The look-ahead we define basically re-traces the computation that the two-way transducer has taken so far. Note that this is indeed a finite property as only a prefix of the input has been visited by the computation of the two-way transducer. ◀

As an easy consequence of Theorem 3.1, let us observe that deterministic regular functions (effectively) preserve Büchi deterministic languages by inverse image. Analogue results hold for regular functions of finite (resp. infinite) words with regular languages.

▶ **Proposition 3.2.** *If $f : \Sigma^\omega \rightharpoonup \Gamma^\omega$ is deterministic regular and $L \subseteq \Gamma^\omega$ is Büchi deterministic, then $f^{-1}(L) \subseteq \Sigma^\omega$ is (effectively) Büchi deterministic.*

Proof. The function $f \circ \mathsf{id}_L$ (where $\mathsf{id}_L : \Gamma^\omega \rightharpoonup \Gamma^\omega$ is the identity function restricted to L) is deterministic regular. Its domain $f^{-1}(L)$ is Büchi deterministic by Proposition 2.11. ◀

Let us now focus on the converse of Theorem 3.1, i.e. showing that any deterministic regular function can be written as a composition of "basic" functions. As mentioned in introduction, regular functions of finite words can be written as compositions of map-copy-reverse (see Example 1.1) and sequential functions (computed by one-way transducers).

▶ **Theorem 3.3** ([6, Theorem 13])**.** *Over finite words, a function is regular if and only if it can (effectively) be written as a composition of* map-copy-reverse *and sequential functions.*

To state our similar result for deterministic regular functions of infinite words, we first recall formally the definition of sequential functions of infinite words.

▶ **Definition 3.4** (Sequential functions)**.** *A* deterministic one-way transducer *is a* 2-dT $(\Sigma, \Gamma, Q, q_0, F, \delta, \lambda)$ *such that for all $q \in Q$ and $\sigma \in (\Sigma \uplus \{\vdash\})$, $\delta(q, \sigma)$ has shape $(\_, \triangleright)$ (when defined). The class of (partial) functions over infinite words computed by one-way deterministic transducers is called* sequential functions of infinite words.

▶ **Example 3.5.** Any function that replaces some letter of its input by another letter is sequential. The functions replace and map-copy-reverse of Examples 1.4 and 2.3 are *not* sequential (this can be shown using a pumping argument). Observe that replace can be written as the composition of: a sequential function that replaces each $\sigma_i \in \{1, 2\}$ by $\sigma_i|$, the function map-copy-reverse, and finally a sequential function that uses the first copy of each block to determine the value of σ_i, and transforms the (mirror) second copy accordingly.

Now, we state the decomposition result, that also uses map-copy-reverse from Example 2.3. Its proof is somehow technical and it illustrates once more the main difficulty of this paper: deterministic regular functions are not able to check many properties about the "future".

▶ **Theorem 3.6.** *A function is deterministic regular if and only if it can (effectively) be written as a composition of* map-copy-reverse *and sequential functions of infinite words.*

Proof idea. In the case of finite words, the proofs of [7, 6] rely on Simon's factorization forests theorem [27]. They first build a factorization forest, and then use its structure to simulate the runs of a transducer. Furthermore, over finite words, such forests can be computed by a *rational function*, which is a composition of sequential functions and map-copy-reverse. We follow a similar proof sketch for infinite words, but the main issue is that factorization forests can no longer be computed by a composition of sequential functions and map-copy-reverse (their structure may depend on regular properties of the input). Thus we use instead a weakened version of forests, introduced by Colcombet under the name of *forward Ramseyan splits* [12]. Such splits can be computed with a sequential function. Our new techniques show how to simulate the runs of a transducer by using a forward Ramseyan split. ◀

4 Guarded MSO-transductions

In this section, we define the logic MSO over finite and infinite words, as well as MSO-transductions, and its guarded fragment. We also state the logical characterization of deterministic regular functions (Theorem 4.8).

MSO on infinite words. Infinite words over Σ are seen as structures of domain $\mathbb{N}$, over the signature $\mathcal{W}_\Sigma = \{S(x,y), (\sigma(x))_{\sigma\in\Sigma}\}$ which consists of the successor predicate $S(x,y)$, naturally interpreted as the successor over $\mathbb{N}$, and unary predicates $\sigma(x)$ for all $\sigma \in \Sigma$, interpreted as the set of positions labelled σ. Given an infinite word $u \in \Sigma^\omega$, we denote by G_u the structure it induces, and just u when it is clear that u denotes the structure G_u.

Monadic second-order formulas are defined as first-order logic formulas, which can additionally use quantifiers $\exists X, \forall X$ over sets of positions, and membership atomic formulas of the form $x \in X$, where x is a first-order variable while X is a set variable. We denote by $\mathsf{MSO}[\Sigma, S, \leq]$ (or just MSO when the predicates are clear from the context), the set of monadic second-order formulas over the word signature $\mathcal{W}_\Sigma$ extended with the order predicate $\leq$ (interpreted by the natural order on $\mathbb{N}$). It is well-known that the predicate $\leq$ is syntactic sugar. The semantics is defined as expected (details can be found in [28, 14] for instance). For a formula ϕ with sets of free first-order and set variables $\overline{x}, \overline{X}$ (we use the tuple notation which implicitly assumes an order between variables), we may write it $\phi(\overline{x}, \overline{X})$ to explicit the free variables of ϕ. We also denote by $Free(\phi)$ the free (first-order and set) variables of ϕ.Given a word w, an n-tuple of positions $\overline{p}$ of w and an m-tuple $\overline{P}$ of sets of positions of w, we write $w \models \phi(\overline{p}, \overline{P})$ to mean that the structure induced by w is a model of ϕ under assignments $\overline{p}$ and $\overline{P}$.

▶ **Example 4.1.** The formula $\mathsf{first}(x) = \forall y \cdot \neg S(y,x)$ is satisfied by any word and position x such that x is the first position to the left.

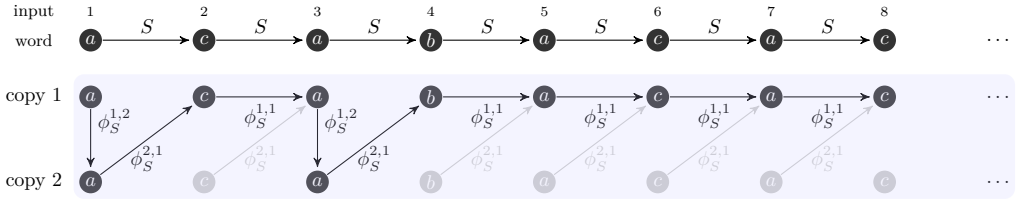
Over an alphabet Σ, any *closed* formula $\phi \in \mathsf{MSO}$ *defines* a regular language $L_\phi = \{u \in \Sigma^\omega \mid u \models \phi\}$. By Büchi-Elgot-Trakhtenbrot's theorem [29, 8, 21], it is known MSO defines precisely the class of regular languages over alphabet Σ: for any language L over Σ, L is regular if and only if $L = L_\phi$ for some $\phi \in \mathsf{MSO}$. MSO formulas can also be interpreted over finite word structures, whose domains are the (finite) set of word positions. It is also well-known that a language of finite words is regular iff it is MSO-definable.

MSO-transductions of infinite words. MSO-transductions define transformations of graph structures, and have been studied in the context of finite words by Engelfriet and Hoogeboom in [22] (see also [14] for a more recent introduction to MSO-transductions). The main result of [22] is a Büchi-like theorem: a function of finite words is MSO-definable if and only if it is regular (i.e. recognizable by a deterministic two-way transducer). This result was then lifted to functions of infinite words in [3], but deterministic two-way transducers may need infinite look-aheads to capture the full expressive power of MSO-transductions.

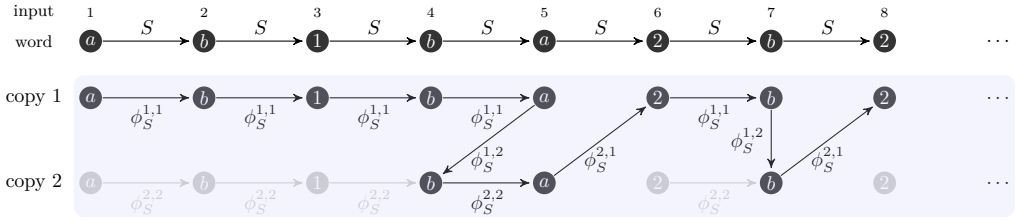
In an MSO-transduction, the output word structure is defined via an MSO interpretation over a fixed number k of copies of the input word (seen as a structure). Therefore, the nodes of the output word are copies 1 to k of the nodes of the input word. Output nodes are pairs (i,c) (often denoted i^c), for every copy c and input node i.

The output label and successor predicates are defined by MSO formulas with one and two free first-order variables respectively, interpreted over the input structure. For instance, over the output alphabet $\Gamma = \{a,b\}$, to set all the output labels to a, one just specifies the formulas $\phi_a^c(x) = \top$ and $\phi_b^c(x) = \bot$ for all copies c. The output successor predicate relates input nodes of possibly different copies, and is therefore defined by formulas of the form $\phi_S^{c,d}(x,y)$, indexed by copies $c, d \in \{1, \ldots, k\}$.

Finally, there is one distinguished copy c_0 together with a formula $\phi_{\text{fst}}^{c_0}(x)$, which must be satisfied by at most one node x. Intuitively, if the output structure is a word, this formula defines the first node of the output word. The domain of the output structure is composed of



(a) Input and output structures of the MSO-transduction for the function double of Example 1.2 on input word $acab(ac)^\omega$.



(b) Input and output structures of the MSO-transduction for the function copy of Example 1.3 on input word $ab1ba2b2\dots$.

Figure 1

all nodes that can be reached from the initial node x^{c_0} by following multiple successor edges. In general, the output structure of an input word u by an MSO-transduction $\mathcal{T}$ might not be an infinite word structure, in which case u is not in the domain of the function defined by $\mathcal{T}$.

Formally, an MSO-*transduction* over an input alphabet Σ and output alphabet Γ is a tuple $\mathcal{T} = (k, (\phi^c_\gamma(x))_{1\le c\le k, \gamma\in\Gamma}, (\phi^{c,d}_S(x,y))_{1\le c,d\le k}, c_0, \phi^{c_0}_{\text{fst}}(x))$ where $k \in \mathbb{N}\setminus\{0\}$, $1 \le c_0 \le k$ and for all input $u \in \Sigma^\omega$, there is at most one position i such that $u \models \phi^{c_0}_{\text{fst}}(i)$. We may omit c_0 in the tuple above.

We now formally define the semantics of MSO-transductions. Let $u \in \Sigma^\omega$ and $N \subseteq \mathbb{N}\times\{1,\dots,k\}$. We first define the set of output nodes that can be reached from N in zero or more steps. We let $\mathsf{Post}^0_u(N) = N$ and for all $\ell > 0$,

$$\mathsf{Post}^\ell_u(N) = \{j^d \mid \exists i^c \in \mathsf{Post}^{\ell-1}_u(N) \cdot u \models \phi^{c,d}_S(i,j)\} \text{ and } \mathsf{Post}^*_u(N) = \bigcup_{\ell\ge 0} \mathsf{Post}^\ell_u(N)$$

Given an MSO-transduction $\mathcal{T}$ as above, and input word $u \in \Sigma^\omega$, the *output structure*, denoted $\mathcal{T}(u)$, is the structure over signature $\mathcal{W}_\Gamma$ defined by the following interpretation:

- the domain is $D = \mathsf{Post}^*_u(\{i^{c_0} \mid u \models \phi^{c_0}_{\text{fst}}(i)\})$ (note that the argument of Post^*_u is either empty or a singleton)
- a node $i^c \in D$ is labelled $\gamma \in \Gamma$ if $u \models \phi^c_\gamma(i)$
- a node j^d is a successor of a node i^c if $u \models \phi^{c,d}_S(i,j)$.

The output structure $\mathcal{T}(u)$ may not be a word structure. For instance, a node might have multiple labels, $\mathcal{T}(u)$ may contain cycles, or branching. So we restrict semantically the function defined by $\mathcal{T}$ to word structures. Formally, the *function defined by* $\mathcal{T}$ is the function $[\![\mathcal{T}]\!] : \Sigma^\omega \rightharpoonup \Gamma^\omega$ whose graph is:

$$\{(u,v) \in \Sigma^\omega \times \Gamma^\omega \mid G_v \text{ (the structure associated with } v) \text{ is isomorphic to } \mathcal{T}(u)\}$$

We denote by MSOT the set of MSO-transductions and say that a function $f : \Sigma^\omega \rightharpoonup \Gamma^\omega$ is MSOT-definable if $f = [\![\mathcal{T}]\!]$ for some $\mathcal{T} \in \mathsf{MSOT}$.

▶ **Example 4.2.** We consider again the function double of Example 1.2, illustrated on Figure 1a and show how to define it with an MSO-transduction. Since some a must be duplicated, two copies are needed, so $k = 2$. Labels are preserved: $\phi^c_\sigma(x) = \sigma(x)$ for all $c \in \{1, 2\}$ and $\sigma \in \Sigma$. The first copy c_0 is 1, and $\phi^{c_0}_{\text{fst}}(x) = \mathsf{first}(x)$. The successor formulas distinguish if there is a b in the future or not. First, from the 2nd to the 1st copy, there is always a successor relation from a node to its successor in copy 1: $\phi^{2,1}_S(x, y) = S(x, y)$. There is a successor from x^1 to y^2 if $x = y$, x is labelled a and there is a b in the remaining infinite suffix starting at x: $\phi^{1,2}_S(x, y) = a(x) \wedge (x = y) \wedge \exists z \cdot x \leq z \wedge b(z)$. On the first copy, it depends on the label of the input: $\phi^{1,1}_S(x, y) = S(x, y) \wedge (a(x) \to (\forall z \geq x \cdot \neg b(z))$. On the second copy, there is never a predicate edge: $\phi^{2,2}_S = \bot$. On Figure 1a, the interpretation of those formulas is depicted, in bold if they are part of the output word, in light grey otherwise. One can see that the output structure induced by all the descendants of the first node (by the transitive closure of the successor relation) is isomorphic to the structure $G_{aacaab(ac)^\omega}$.

The function copy of Example 1.3, illustrated in Figure 1b, is definable by an MSOT with two copies ($k = 2$). Formulas $\phi^{c_0}_{\text{fst}}$ and ϕ^c_σ are the same as for double. Then:

$$\phi^{1,1}_S(x, y) = \phi^{2,2}_S(x, y) = S(x, y) \wedge \neg 2(y) \qquad \phi^{2,1}_S(x, y) = S(x, y) \wedge 2(y)$$
$$\phi^{1,2}_S(x, y) = \exists \mathsf{g} \cdot y < x \leq \mathsf{g} \wedge 2(\mathsf{g}) \wedge \forall z \leq y \cdot (S(z, y) \to (1(z) \vee 2(z))) \wedge$$
$$\forall t \cdot (y \leq t \leq x) \to (a(t) \vee b(t))$$

The class of regular functions of infinite words has been defined in [3] as the class of functions recognizable by deterministic two-way transducers extended with regular (infinite) look-ahead: to take a transition, such a transducer can query a regular oracle on the infinite current suffix (given as a deterministic parity automaton for example). Equivalently, this class corresponds to functions recognizable by (deterministic) SST: they work as BSST but are not forced to output the content of a special register infinitely often. Instead, the output of a run depends on the set of states that are seen infinitely often along that run, and can be "computed" only once the infinite input has been processed (see [3]) for more details. The following provides a logical characterization of the class of regular functions:

▶ **Theorem 4.3** ([3]). *A function $f : \Sigma^\omega \rightharpoonup \Gamma^\omega$ is regular if and only if it is* MSOT*-definable.*

The definition of MSOT in [3] is slightly different, but equivalent, to the definition we take in this paper.

Guarded MSO-transductions of infinite words. Guarded MSO formulas are a syntactical restriction of MSO formulas. This restriction requires all the free variables and quantifiers to be guarded by a first-order variable g, in the sense that quantifiers should only talk about positions which are *before* g (i.e. smaller than g). Intuitively, the satisfiability of a guarded formula on an infinite word only depends on the finite prefix up to position g. Formally, given two first-order variables x and g, we let $\mathsf{G}(x, \mathsf{g})$ be the formula $x \leq \mathsf{g}$ (x is guarded by g), and for a set variable X, we let $\mathsf{G}(X, \mathsf{g})$ be the formula $\forall x \in X, \mathsf{G}(x, \mathsf{g})$. Then, an MSO formula φ is *guarded by some variable g* if it is equal to $\psi(\mathsf{g}) \wedge \bigwedge_{\alpha \in Free(\psi)} \mathsf{G}(\alpha, \mathsf{g})$ for some $\psi(\mathsf{g})$ such that all its quantified subformulas, i.e. subformulas of the form $QX \cdot \psi'$ or $Qx \cdot \psi'$ for some $Q \in \{\exists, \forall\}$, are in one of the following forms:

$$(1)\ \forall x \cdot \mathsf{G}(x, \mathsf{g}) \to \zeta \quad (2)\ \exists x \cdot \mathsf{G}(x, \mathsf{g}) \wedge \zeta \quad (3)\ \forall X \cdot \mathsf{G}(X, \mathsf{g}) \to \zeta \quad (4)\ \exists X \cdot \mathsf{G}(X, \mathsf{g}) \wedge \zeta$$

An MSO formula is *guarded* if it is of the form $\exists \mathsf{g} \cdot \varphi$ where φ is guarded by g. We denote by MSO_g the set of guarded MSO-formulas. For conciseness, we may write $\forall x : \mathsf{g} \cdot \zeta$ instead of $\forall x \cdot \mathsf{G}(x, \mathsf{g}) \to \zeta$, and $\exists x : \mathsf{g} \cdot \zeta$ instead of $\exists x \cdot \mathsf{G}(x, \mathsf{g}) \wedge \zeta$ (and similarly for set variables).

▶ **Example 4.4.** All the formulas of the MSO-transduction of Example 4.2 defining the function double are guarded, or trivially equivalent to a guarded formula. For example, the formula $\mathsf{first}(x)$ is equivalent to the guarded formula $\exists \mathsf{g} \cdot x \leq \mathsf{g} \wedge \forall y \leq \mathsf{g} \cdot \neg S(y, x)$.

The order predicate $x \leq y$ is definable by the guarded formula $\exists \mathsf{g} \cdot x \leq \mathsf{g} \wedge y \leq \mathsf{g} \wedge y = \mathsf{g}$. Since $\neg(x \leq y)$ is equivalent to $y \leq x \wedge y \neq x$, we easily get that any MSO_g-formula ϕ is equivalent to an MSO_g-formula ψ in which the order predicate is only used to guard quantifiers, by existentially quantifying a global guard, guarding all the local guards used to define the atomic formulas of the form $z \leq t$ occurring in ϕ (assumed to occur positively).

▶ Remark 4.5. MSO_g formulas only talk about prefixes, in the following sense: If $\varphi = \exists \mathsf{g} \cdot \psi(\mathsf{g})$ is a closed guarded formula and $w \in \Sigma^\omega$, then $w \models \varphi$ if and only if there exists a finite prefix u of w such that $u \models \psi(\ell)$, where ℓ is the last position of u. This allows us to get the following immediate characterization: A language $L \subseteq \Sigma^\omega$ is MSO_g-definable if and only if there exists a regular language $F \subseteq \Sigma^*$ such that $L = F\Sigma^\omega$.

▶ **Definition 4.6** (Guarded MSO-transductions)**.** *A* guarded MSO-transduction *(*MSOT_g*) is an* MSO*-transduction all formulas of which are guarded.*

▶ **Example 4.7.** As explained in Example 4.4, all formulas of the MSO-transduction of Example 4.2 defining double are guarded, or trivially equivalent to a guarded formula.

We can now state the logical characterization of deterministic regular functions:

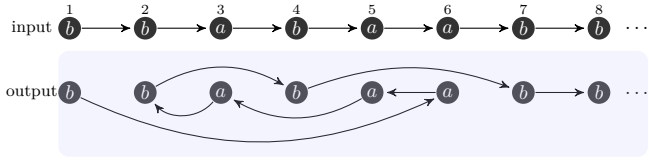
▶ **Theorem 4.8** (Logical characterization)**.** *A function $f : \Sigma^\omega \rightharpoonup \Gamma^\omega$ is deterministic regular if and only if it is* MSOT_g*-definable.*

The proof is given in Section 6. As an application of this result, since deterministic regular functions are (effectively) closed under composition by Theorem 3.1, we obtain that MSOT_g are (effectively) closed under composition as well. This is a well-known result for MSOT over finite strings [22], infinite strings [3] and more generally any structure [13], yet with purely logic-based and direct proofs, while we use here involved automata-based arguments (look-ahead removal). Indeed, composition closure of MSOT is obtained by formula substitutions. To compose two MSOT $\mathcal{T}_2 \circ \mathcal{T}_1$, the predicates occurring in $\mathcal{T}_2$ are substituted by their definition in $\mathcal{T}_1$. Such a direct proof idea does not work in the guarded fragment MSOT_g, as guarded formulas are not closed under negation.

Guarded MSO-transductions with order. We conclude this section by discussing an alternative definition of MSO_g-transductions, denoted $\mathsf{MSOT}_g[\leq]$, where instead of defining the output successor relation, it requires to define the total order $\leq$ of the output structure, with MSO_g formulas. This however allows to define uncomputable functions (in the sense of [18], see also Section 1), as stated by the following proposition:

▶ **Proposition 4.9.** *There exists an* $\mathsf{MSOT}_g[\leq]$ *which defines an uncomputable function.*

To prove this proposition, we show that the following uncomputable function h is definable with $\mathsf{MSOT}_g[\leq]$. Let $\Sigma = \Gamma = \{a, b\}$ and $\mathsf{er}_b : \Sigma^* \to \Sigma^*$ the (erasing) morphism defined by $\mathsf{er}_b(a) = a$ and $\mathsf{er}_b(b) = \varepsilon$. The function $h : \Sigma^\omega \rightharpoonup \Gamma^\omega$ is defined on inputs of the form bub^ω, for $u \in \{a, b\}^*$, by $h(bub^\omega) = b\mathsf{er}_b(u)b^\omega$. It can be shown that h is definable by a 1-copy $\mathsf{MSOT}_g[\leq]$. An example of output structure on input $bbabaab^\omega$ is given below (we depict only the successor predicate and not the order):



The output order formula for instance states that the b occurrences are ordered according to their input order, while the a occurrences are ordered in reverse. Moreover, it states that the first b occurrence is smaller than any a occurence, and that any a occurrence is smaller that any b occurrence but the first one.

Without the guarded restriction, it is known that two definitions of MSOT, with successor or with order, both define the class of regular functions of infinite words.

5 Two-way transducers with finite look-ahead

We extend deterministic two-way transducers with finite look-ahead. Transitions are additionally labelled by a regular language of *finite words*, called (finite) look-ahead. A transition with look-ahead L can only be taken if the remainder of the input sequence has a prefix that belongs to L. Such a finite prefix is called a *look-ahead witness* for L. To ensure determinism, if several look-aheads succeed, it is required that there is a unique shortest look-ahead witness. The transducer follows the transition which minimizes the length of the witness. If no look-aheads succeed the computation fails.

▶ **Definition 5.1** (Finite look-ahead). *A* deterministic two-way transducer with finite look-ahead (2-dT$^{\mathsf{FLA}}$) *is a tuple* $\mathcal{T} = (\Sigma, \Gamma, Q, q_0, F, \delta, \lambda)$ *where* $\Sigma, \Gamma, Q, q_0, F, \lambda$ *are defined as for deterministic two-way transducers w/o look-ahead,* δ *is a transition function* $Q \times (\Sigma \uplus \{\vdash\}) \times \mathcal{R}^*(\Sigma)) \rightharpoonup Q \times \{\triangleright, \triangleleft\}$ *where* $\mathcal{R}^*(\Sigma)$ *is the set of all regular languages of* finite *words over* Σ*. The function* δ *is required to have finite domain. The* look-ahead *for a transition* $(q, \sigma, L) \mapsto (q, d)$ *is* L*. Furthermore, we require that if* $\delta(q, \sigma, L)$ *and* $\delta(q, \sigma, L')$ *are defined, then* $L \cap L' = \emptyset$ *for all* $L, L' \in \mathcal{R}^*(\Sigma)$*,* $q \in Q$ *and* $\sigma \in \Sigma$*. Finally, it is assumed that the look-ahead languages are represented by deterministic finite automata.*

The semantics of a deterministic two-way transducer with finite look-ahead remains unchanged compared to the model without look-ahead. The only difference in the presence of look-ahead is when a transition is enabled: A transition with look-ahead L can only be taken if the remainder of the input sequence has a prefix that belongs to L. Formally, in a configuration (q, i) over input u, a transition of the form $\delta(q, \sigma, L)$ where $L \subseteq \Sigma^*$ is enabled if $u[i] = \sigma$ and there exists some $i < j$ such that $u[i{+}1{:}j] \in L$. The word $u[i{+}1{:}j]$ is called a *witness* for L. To ensure determinism, whenever the transducer is in a configuration (q, i), if several look-aheads $L_1, \ldots, L_k$ are enabled, the triggered transition is the unique (ensured by the disjointness requirement) transition with shortest witness.

Removing finite look-ahead. We know that infinite look-ahead is strictly more expressive than finite look-ahead. The natural question is how much expressiveness is gained by adding finite look-ahead to deterministic two-way transducers w/o look-ahead. As already explained in the introduction, any function defined by such a transducer is (Turing machine) computable: A Turing machine can memorize where it is in the input, verify which look-ahead succeeds, and continue the computation from the memorized position. A two-way transducer does not have the ability to memorize a position arbitrarily far away in the input. Hence, verifying (in the absence of some look-ahead "oracle") that some finite prefix of the remainder of

the input is a witness for some look-ahead and returning to a specific position becomes a problem to be solved. This problem is not unique to two-way transducers over infinite words, it also appears when some regular property of the remainder of a finite input word must be checked and subsequently the two-way transducer must return to the position it has been in before checking the property. On finite words, this task can be handled using the Hopcroft-Ullman [1] or the improved tree-outline construction [16]. However, these constructions rely on the fact that the input word is finite. We prove that this task can be also accomplished for infinite words using different techniques.

In the following, we show that no expressiveness is gained by allowing finite look-ahead.

▶ **Theorem 5.2** (Finite look-ahead removal). *Given a* 2-$\mathsf{dT}^{\mathsf{FLA}}$*, one can effectively construct an equivalent* 2-dT*.*

Proof sketch. The proof is divided into two parts. The main part is to translate a given 2-$\mathsf{dT}^{\mathsf{FLA}}$ into an equivalent BSST with bounded copy. We then use Theorem 2.9 to obtain an equivalent 2-dT. Given a deterministic two-way transducer *without* look-ahead, the standard approach to obtain an equivalent SST is to simulate the right-to-right runs of the deterministic two-way transducer on the so-far read prefix of the infinite input, store their outputs in registers and compose these registers in the right way (with the output of the "main" left-to-right run) to re-create the output of the two-way transducer. Since the two-way transducer is deterministic there is a global bound on the number of different right-to-right runs on any prefix of the input. The constructions presented in [3, 17, 9] are all built on this idea. In [2], equivalence between SST and two-way transducers on finite words is shown but the work exhibits no direct translation.

Our goal is to design a similar construction for deterministic two-way transducers *with* finite look-ahead. The main difficulty is that there is no global bound on the number of different runs that can occur on a prefix, if one takes additionally into account all the runs of the look-ahead automata that have been triggered so far. Alternatively, such a transducer can be seen as a non-deterministic transducer, which guesses which finite look-ahead will succeed and verifies it a posteriori, but there can be many look-ahead automata running in parallel.

Hence, we extend the standard construction to go from a deterministic two-way transducer to an SST by additionally taking all the possible look-ahead choices into account. This approach results in a tree structure representation of the possible runs (similar to a standard run-tree of a non-deterministic automaton, here the non-determinism is the look-ahead choice). A branch in such a tree corresponds to a possible run and the nodes additionally contain information to detect when look-ahead choices succeed or are doomed to fail. The size of the tree representations is kept bounded by sharing information and a relevant pruning strategy. The strategy takes care of removing branches whose look-ahead choices *cannot succeed* and (prefixes of) branches where the look-ahead choices *already have succeeded*. Applying this construction to a deterministic two-way transducer without look-ahead yields the standard translation construction. ◀

6 Logic-transducer correspondence: proof of Theorem 4.8

In this section, we give an overview of the proof of the logical characterization of Theorem 4.8. We first prove that any deterministic regular function is MSOT_g-definable. The proof is standard and uses same ideas as for regular functions of finite words [22] and infinite words [3].

▶ **Lemma 6.1.** *If a function* $f : \Sigma^\omega \multimap \Gamma^\omega$ *is deterministic regular, then it is* MSOT_g*-definable.*

Proof. The main idea is to define in MSOT_g the runs of a 2-$\mathtt{dT}$. Each copy of the MSOT_g represents a state of the 2-$\mathtt{dT}$, and there is a successor edges between node x^p to node y^q, where x, y are input positions and p, q are states, if and only if there exists a *finite* run from configuration (p, x) to configuration (q, y) which produces output symbols only in configuration (p, x) and (q, y). This property can be expressed by an MSO_g formula. ◀

Proving the converse of Lemma 6.1 is more involved. We first go to an intermediate model with MSO instructions, in the spirit of [22], called *jumping* MSO_g-transducers, proved to be equivalent to 2-$\mathtt{dT}$. It is a finite-state model which can (i) test MSO_g properties of the current position (called look-around), (ii) test safety constraints defined by MSO formulas, and (iii) jump from one position to another one with binary MSO_g formulas. Formally, it has a finite set of states (all final), and transitions are of the form $p \xrightarrow{\phi_{\mathrm{la}}(x)|w,\phi_{\mathrm{mv}}(x,y),\phi_{\mathrm{sf}}(x)} q$ where p, q are states, $\phi_{\mathrm{la}}, \phi_{\mathrm{mv}}$ are MSO_g formulas, ϕ_{sf} is an MSO formula, and w is a finite word. Look-around occurring on transitions with same source state are assumed to be pairwise disjoint (their conjunction is not satisfiable). The initial configuration is $(q_0, 0)$ where q_0 is the initial state. Whenever it is in a configuration (q, i), over an infinite word $u \in \Sigma^\omega$, it enables the transitions whose look-around $\phi_{\mathrm{la}}(i)$ holds on u, and select the transition with shortest witness. Call t this transition. It triggers t only if there exists j such that $\phi_{\mathrm{mv}}(i, j)$ holds and for all $k \geq i$, $u[{:}k] \models \phi_{\mathrm{sf}}(i)$ (otherwise the computation fails). It then outputs γ and moves to some position j such that $\phi_{\mathrm{mv}}(i, j)$ holds. Note that there could be several j, and therefore several runs on the same input in general. We thus make the following *assumption*, which can be described informally as follows: for any reachable configuration of the transducer from the initial configuration, there is always a unique j. Formally, for all infinite sequence of configurations $(q_0, i_0 = 0)(q_1, i_1)(q_2, i_2)\ldots$, for all $k \geq 0$, for any transition t triggered from configuration (q_k, i_k) to (q_{k+1}, i_{k+1}), if $\phi_{\mathrm{mv}}(x, y)$ is the jumping formula of t, then i_{k+1} is the unique position such that $\phi_{\mathrm{mv}}(i_k, i_{k+1})$ holds. As for two-way transducers, a sequence of configurations $(q_0, i_0 = 0)(q_1, i_1)\ldots$ is *accepting* if $\lim_{k\to\infty} i_k = \infty$ and it produces an infinite word.

We show that this model defines deterministic regular functions:

▶ **Lemma 6.2.** *Any jumping* MSO_g*-transducer defines a deterministic regular function.*

Sketch of proof. The proof goes in two steps. First, it is shown that jumping MSO_g-transducers are equivalent to *walking* MSO_g-transducers, i.e. MSO_g-transducers which moves (backward or forward) between successive positions. This step is standard (it appears e.g. in [22] in the non-guarded setting). Then, walking MSO_g-transducers are shown to be equivalent to an extension of 2-$\mathtt{dT}$ with finite look-around and safety constraints, then proved to be equivalent to 2-$\mathtt{dT}$ by transforming look-arounds into look-aheads, and then removing look-aheads (based on the techniques of Section 5) and safety constraints. ◀

▶ **Lemma 6.3.** *Any* MSO_g*-transduction is equivalent to a jumping* MSO_g*-transducer.*

Proof. Let $\mathcal{T} = (k, (\phi^c_\gamma)_{c\in[k],\gamma\in\Gamma}, (\phi^{c,d}_S)_{c,d\in[k]}, \phi^{c_0}_{\mathrm{fst}}(x))$ be an MSOT_g defining f. We construct a jumping MSO_g-transducer $\mathcal{T}'$ equivalent to $\mathcal{T}$. The set of states of $\mathcal{T}'$ is $\{0, 1\ldots, k\}$. In state 0, $\mathcal{T}'$ first jumps to the initial position, i.e. the position y which satisfies $\phi^{c_0}_{\mathrm{fst}}(y)$ and moves to state c_0. This is done by a transition going from state 0 to state c_0, with the trivial look-around and safety constraint $\top$, and the move $\phi_{\mathrm{mv}}(x, y) := \mathsf{first}(x) \wedge \phi^{c_0}_{\mathrm{fst}}(y)$. Then, it follows the successor relation of $\mathcal{T}$, and uses the label formulas to determine which label to output. Using safety constraints, $\mathcal{T}'$ also makes sure that the output graph structure is a word structure. In particular, they express that for any reachable node, there is exactly one label and at most one successor. There is no need to check that there is *at least* one

successor, because if there is none, then the run of $\mathcal{T}'$ stops and the input is not accepted, which is consistent with the semantics of $\mathcal{T}$ (the input is also rejected by $\mathcal{T}$ in that case). There is also no need to check that there is no cycle, because if there is some, then $\mathcal{T}'$ will never visit all input positions, and hence the input will be rejected, which is again consistent with the semantics of $\mathcal{T}$. Formally, for all copies $c, d \in \{1, \dots, k\}$ and output label γ, since $\phi_S^{c,d}(x,y)$ and $\phi_\gamma(x)$ are guarded, there are of the form $\phi_S^{c,d}(x,y) = \exists \mathsf{g} \cdot \psi_S(x,y,\mathsf{g})$ and $\phi_\gamma(x) = \exists \mathsf{g} \cdot \psi_\gamma(x,\mathsf{g})$. Then we add the following transition to $\mathcal{T}'$, from c to d:

$$c \xrightarrow{\phi_{\mathrm{la}}(x) := \exists \mathsf{g} \exists z \leq \mathsf{g} \cdot \psi_S^{c,d}(x,z,\mathsf{g}) \wedge \psi_\gamma^c(x,\mathsf{g}) \wedge \mathsf{disj}_{c,d,\gamma}(x,\mathsf{g}) \mid \gamma, \phi_{\mathrm{mv}}(x,y) := \phi_S^{c,d}(x,y), \phi_{\mathrm{sf}}(x)} d$$

in which $\mathsf{disj}_{c,d,\gamma}(x,\mathsf{g}) = \forall \mathsf{g}' \leq \mathsf{g} \cdot \bigwedge_{\gamma' \neq \gamma} \neg \psi_{\gamma'}^c(x,\mathsf{g}') \wedge \bigwedge_{d' \neq d} \forall z' \leq \mathsf{g}' \cdot \neg \psi_S^{c,d'}(x,z',\mathsf{g}')$ ensures disjointness of the look-around, and $\phi_{\mathrm{sf}}(x)$ equals

$$\begin{array}{ll} (\bigwedge_{d' \neq d} \forall y \cdot \neg \phi_S^{c,d'}(x,y)) \wedge & \text{no successor of } x \text{ in any copy } d' \neq d \\ (\forall y \forall y' \cdot (\phi_S^{c,c}(x,y) \wedge \phi_S^{c,c}(x,y')) \rightarrow y = y') \wedge & \text{at most one successor of } x \text{ in copy } c \\ (\bigwedge_{\gamma' \neq \gamma} \neg \phi_{\gamma'}^c(x) & \text{no other label for } x \end{array}$$

At this point, we remind the reader that safety constraints are not required to be defined by guarded formulas, as they are regular properties of finite words. However, the look-around and jumping formulas must be guarded, and it is indeed the case in the transition above.

Finally, note that $\mathcal{T}'$ satisfies the requirement that on infinite sequences of configurations $(q_0, i_0) \dots$, for all $k \geq 0$, i_{k+1} is the unique successor of i_k by the jumping formula. Indeed, if a sequence of configurations of $\mathcal{T}'$ is infinite, it implies that all safety constraints are satisfied, and they precisely make sure that there is no branching. ◀

As a corollary of Lemmas 6.3 and 6.2, we obtain the converse direction of Theorem 4.8:

▶ **Corollary 6.4.** *Any* MSOT_g*-definable function* f *is deterministic regular.*

7 Conclusion

In this paper, we have shown that the class of deterministic regular functions is characterized by computational models such as deterministic two-way transducers, deterministic two-way transducers with *finite* (regular) look-aheads, Büchi SST, by the logical formalism of *guarded* MSO-transductions, and by finite compositions of sequential functions and map-copy-reverse. The transformations between those models are effective. We have also shown that it is closed under composition, by extending to infinite words the known composition closure of deterministic two-way transducers, yet with new proof techniques. It is also conjectured that the class of deterministic regular functions is equal to the class of *continuous* regular functions (for the Cantor topology). It is already known that it includes the continuous letter-to-letter rational functions [23] and the strictly larger class of continuous rational functions [9]. All this, together with the fact that deterministic regular functions are computable, unlike regular functions, shows the robustness of this class.

Characterising Memory in Infinite Games

Antonio Casares
LaBRI, Université de Bordeaux, France

Pierre Ohlmann
University of Warsaw, Poland

Abstract

This paper is concerned with games of infinite duration played over potentially infinite graphs. Recently, Ohlmann (TheoretiCS 2023) presented a characterisation of objectives admitting optimal positional strategies, by means of universal graphs: an objective is positional if and only if it admits well-ordered monotone universal graphs. We extend Ohlmann's characterisation to encompass (finite or infinite) memory upper bounds.

We prove that objectives admitting optimal strategies with ε-memory less than m (a memory that cannot be updated when reading an ε-edge) are exactly those which admit well-founded monotone universal graphs whose antichains have size bounded by m. We also give a characterisation of chromatic memory by means of appropriate universal structures. Our results apply to finite as well as infinite memory bounds (for instance, to objectives with finite but unbounded memory, or with countable memory strategies).

We illustrate the applicability of our framework by carrying out a few case studies, we provide examples witnessing limitations of our approach, and we discuss general closure properties which follow from our results.

1 Introduction

1.1 Context

Games and strategy complexity. We study zero-sum turn-based games on graphs, in which two players, that we call Eve and Adam, take turns in moving a token along the edges of a given (potentially infinite) edge-coloured directed graph. Vertices of the graph are partitioned into those belonging to Eve and those belonging to Adam. When the token lands in a vertex owned by player X, it is this player who chooses where to move next. This interaction, which is sometimes called a play, goes on in a non-terminating mode, producing an infinite sequence

of colours. We fix in advance an objective W, which is a language of infinite sequences of colours; plays producing a sequence of colours in W are considered to be winning for Eve, and plays that do not satisfy the objective W are winning for the opponent Adam.

In order to achieve their goal, players use strategies, which are representations of the course of all possible plays together with instructions on how to act in each scenario. In this work, we are interested in optimal strategies for Eve, that is, strategies that guarantee a victory whenever this is possible. More precisely, we are interested in the complexity of such strategies, or in other words, in the succinctness of the representation of the space of plays. The simplest strategies are those that assign in advance an outgoing edge to each vertex owned by Eve, and always play along this edge, disregarding all the other features of the play. All the information required to implement such a strategy appears in the game graph itself. These strategies are called positional (or memoryless). However, in some scenarios, playing optimally requires distinguishing different plays that end in the same vertex; one should remember other features of plays. An example of such a game is given in Figure 1.

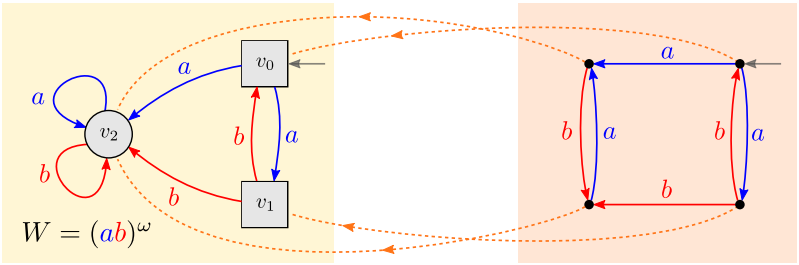

Figure 1 On the left, a game with objective $W = (ab)^\omega$; in words, Eve should ensure that the play alternates between a-edges and b-edges. We represent Eve's vertices as circles and Adam's as squares. On the right, a winning strategy for Eve which uses one state of memory for v_0, one state of memory for v_1, and two states of memory for v_2. Note that two states of memory for v_2 are required here: a positional strategy would always follow the same self-loop and therefore cannot win. One can prove that any game with objective W which is won by Eve can be won even when restricting to strategies with two states of memory, that is, the memory requirements for W is exactly two.

Given an objective W, the question we are interested in is:

"What is the minimal strategy complexity required for Eve to play optimally in all games with objective W?"

Positional objectives and universal graphs. As mentioned above, an important special case is that of positional objectives, those for which Eve does not require any memory to play optimally. A considerable body of research, with both theoretical and practical reach, has been devoted to the study of positionality. By now it is quite well-understood which objectives are positional for both players (bi-positional), thanks to the works of Gimbert and Zielonka [13] for finite game graphs, and of Colcombet and Niwiński [9] for arbitrary game graphs. However, a precise understanding of which objectives are positional for Eve – regardless of the opponent – remains somewhat elusive, even though this is a more relevant question in most application scenarios.

A recent progress in this direction was achieved by Ohlmann [19, 20], using totally ordered monotone universal graphs. Informally, an edge-coloured graph is universal with respect to a given objective W if it satisfies W (all paths satisfy W), and homomorphically embeds all graphs satisfying W. An ordered graph is monotone if its edge relations are monotone:

$$v \geq u \xrightarrow{c} u' \geq v' \implies v \xrightarrow{c} v', \text{ for every colour } c.$$

Ohlmann's main result is a characterisation of positionality (assuming existence of a neutral letter): an objective is positional if and only if it admits well-ordered monotone universal graphs.

From positionality to finite memory. Positional objectives have good theoretical properties and do often arise in applications (in particular, parity, Rabin or energy objectives). It is also true, however, that this class lacks in expressivity and robustness: only a handful of objectives are positional, and very few closure properties are known to hold for positional objectives.

In contrast, objectives admitting optimal finite memory strategies are much more general; for instance they encompass all ω-regular objectives [14] (in fact, it was recently established [3] that optimal finite chromatic memory for both players characterises ω-regularity). Moreover, in practice, finite memory strategies can be implemented by means of a program, and memory bounds for Eve directly translates in space and time required to implement controllers, which gives additional motivation for their systematic study.

Formally, when moving from positionality to finite memory, a few modelling difficulties arise, giving rise to a few different notions. Most prominently, one may or may not include uncoloured edges (ε-edges) in the game, over which the memory state cannot be updated; additionally one may or may not restrict to chromatic memories, meaning those that record only the colours that have appeared so far. We now discuss some implications of these two choices.

It is known that allowing ε-edges impacts the difficulty of the games, in the sense that it may increase the memory required for winning strategies [5, 15, 23], thus leading to two different notions of memory (that we call ε-memory and ε-free memory). It is natural to wonder whether one of the two notions should be preferred over the other. We argue that allowing ε-edges turns out to be more natural in many applications. First, we notice that currently existing characterisations of the memory (for Muller objectives [12] and for topologically closed objectives [8]) do only apply to the case of ε-memory. More importantly, games induced by logical formulas in which players are interpreted as the existential player (controlling existential quantifiers and disjunctions) and the universal player (controlling universal quantifiers and conjunctions) naturally contain ε-edges (along which the memory indeed should not be allowed to be updated).

It was originally conjectured by Kopczyński [15] that chromatic strategies have the same power than non-chromatic ones. It was not until recently that this conjecture was refuted [5], and since then several works have provided new examples separating both notions [6, 17, 18]. It now appears from recent dedicated works [2, 3, 4, 5] that chromatic memory is an interesting notion in itself.

The main challenge in the study of strategy complexity is to prove upper bounds on memory requirements of a given objective. A great feature of Ohlmann's result [20] is that it turns a question about games to a question about graphs, which are easier to handle. Despite its recent introduction, Ohlmann's framework has already proved instrumental for deriving general positionality results in the context of objectives recognised by finite Büchi automata [1].

1.2 Contribution

The present paper builds on the aforementioned work of Ohlmann by extending it to encompass the more general setting of finite (or infinite) memory bounds. This yields the first known characterisation results for objectives with given memory bounds, and provides a (provably) general tool for establishing memory upper bounds.

Doing so requires relaxing from totally to partially ordered graphs, while keeping the same monotonicity requirement, along with some necessary technical adjustments. We essentially prove that the memory of an objective corresponds to the size of antichains in its well-founded monotone universal graph; however it turns out that the precise situation is more intricate. It is summed up in Figure 2 and explained in more details below.

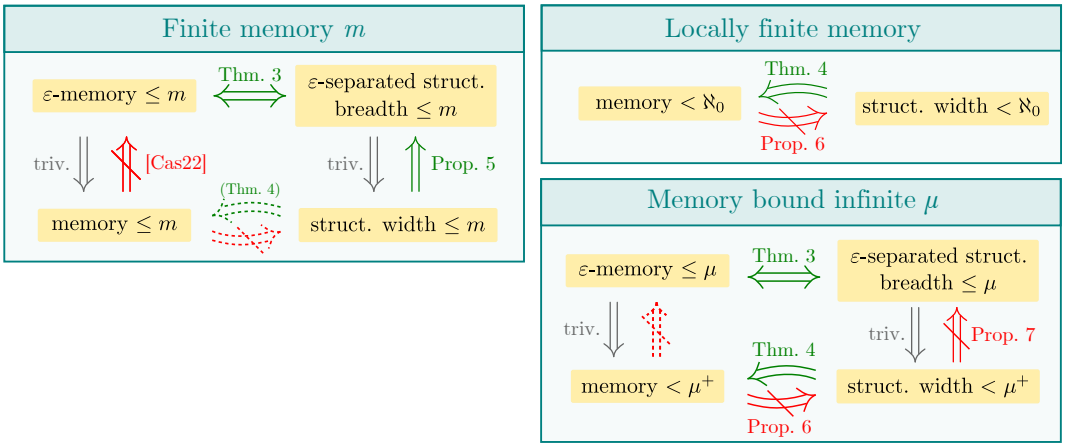

Figure 2 A summary of our main contributions. The three larger boxes correspond to the three regimes encompassed by our results: finite memory, locally finite memory and larger cardinal bounds. Each of the smaller boxes correspond to classes of objectives, where "struct." stands for "existence of well-founded monotone universal graphs"; for example, the box labelled "ε-separated struct. breadth $\leq m$" stands for "existence of ε-separated well-founded monotone universal graphs of breadth $\leq m$". The dotted implications follow from combining other implications in the figure. For $m = 1$, all notions collapse to a single equivalence, which corresponds to Ohlmann's characterisation.

It is convenient for us to define strategies directly as graphs (see Figure 1 for an example, and Section 2 for formal details), which allows us in particular to introduce new classes of objectives such as those admitting locally finite memory, discussed in more details below. For the well-studied case of finite memory bounds, our definition of memory coincides with the usual one.

Universal structures for memory. Our main contribution lies in introducing generalisations of Ohlmann's structures, and proving general connections between existence of such universal structures for a given objective W, and memory bounds for W (Section 3).

The first variant we propose is obtained by relaxing the monotonicity requirement to partially ordered graphs; Theorem 4 states that (potentially infinite) bounds on antichains of a well-founded monotone universal graph translate to memory bounds.

The second variant we propose, called ε-separated structures, is tailored to capture ε-memory. These are monotone graphs where the partial order coincides with $\xrightarrow{\varepsilon}$ and is constrained to be a disjoint union of well-orders; the breadth of such a graph refers to the number of such well-orders. Theorem 3 states that the existence of such universal structures of breadth μ actually characterises having ε-memory $\leq \mu$. Additionally, we define chromatic ε-separated structures (over which each colour acts uniformly), and establish that they capture ε-chromatic memory.

Applying (infinite) Dilworth's theorem we obtain that for finite m, one may turn any monotone graph of width m to an ε-separated one with breadth m (Proposition 5), and therefore in the setting of finite memory, the two notions collapse.

We are able to establish most (but not all) of our results in the more general framework of quantitative valuations; similarly as Ohlmann [20], we show how the notions instantiate in the qualitative case, and how they can be simplified assuming prefix-invariance properties.

Counterexamples for a complete picture. We provide additional negative results which set the limits of our approach, completing the picture in Figure 2. Namely, we build two families of counterexamples that are robust to larger cardinals; these give general separations of ε-free memory and ε-memory (Proposition 7), and negate the possibility of a converse for Theorem 4 (Proposition 6). This supports our informal claim that ε-memory is better behaved than ε-free memory.

Closure properties. Finally, we discuss how our characterisations can be exploited for deriving closure properties on some classes of objectives (Section 4). Apart from Ohlmann's result on lexicographic products of prefix-independent positional objectives [20], no such closure properties are known. Extending Ohlmann's proof to our framework, we prove that if W_1 and W_2 are prefix-independent objectives with ε-memory m_1 and m_2, then their lexicographical product $W_1 \ltimes W_2$ has ε-memory $\leq m_1 m_2$.

We then propose a new class of objectives with good properties, namely, objectives with locally finite memory: for each game, there exists a strategy which uses a finite (though possibly unbounded, even when the game is fixed) amount of memory states for each vertex. These objectives are connected with the theory of well-quasi orders (wqo), since they correspond to monotone universal graphs which are well-founded and have finite antichains. We obtain from the fact that wqo's are closed under intersections, that intersections of objectives with finite ε-memory have locally finite memory; an example is given by conjunctions of energy objectives which have unbounded finite memory even though energy objectives are positional. This hints at a general result, which is not implied by our characterisations but we conjecture to be true, that objectives with finite (possibly unbounded) memory are closed under intersection.

We end our paper by providing yet another application of our characterisation, establishing that prefix-independent Σ_2^0 objectives with finite memory are closed under countable unions. As of today, this is the only known (non-obvious) closure property pertaining to objectives with finite memory.

2 Preliminaries

For a finite or infinite word $w \in C^* \cup C^\omega$ we denote by w_i the letter at position i and by $|w|$ its length.

2.1 Graphs and morphisms

Graphs, paths and trees. A *C-pregraph* G, where C is a (potentially infinite) set of colours, is given by a set of vertices $V(G)$, and a set of coloured directed edges $E(G) \subseteq V(G) \times C \times V(G)$. We write $v \xrightarrow{c} v'$ for an edge (v, c, v'), say that it is outgoing from v, incoming in v' and has colour c. A *C-graph* G is a C-pregraph without sinks: from all $v \in V(G)$ there exists an outgoing edge $v \xrightarrow{c} v' \in E(G)$. We often say c-edges to refer to edges with colour c, and sometimes C'-edges for $C' \subseteq C$ for edges with colour in C'.

A *path* in a pregraph G is a finite or infinite sequence of edges of the form $\pi = (v_0 \xrightarrow{c_0} v_1)(v_1 \xrightarrow{c_1} v_2)\dots$, which for convenience we denote by $\pi = v_0 \xrightarrow{c_0} v_1 \xrightarrow{c_1} \dots$. We say that π is a path from v_0 in G. By convention, the empty path is a path from v_0, for any $v_0 \in V(G)$. If π is a finite path, it is of the form $v_0 \xrightarrow{c_0} v_1 \xrightarrow{c_1} \dots \xrightarrow{c_{n-1}} v_n$, and in this case we say that it is a path from v_0 to v_n in G.

Given a subset $X \subseteq V(G)$ of vertices of a pregraph G, we let $G|_X$ denote the *restriction* of G to X, which is the graph given by $V(G|_X) = X$ and $E(G|_X) = E(G) \cap (X \times C \times X)$. Given a vertex $v \in V(G)$, we let $G[v]$ denote the restriction of G to vertices reachable from v.

A *C-tree* (resp. *C-pretree*) T is a C-graph (resp. C-pregraph) with an identified vertex $t_0 \in V(T)$ called its *root*, with the property that for each $t \in V(T)$, there is a unique path from t_0 to t. Note that since graphs have no sinks, trees are necessarily infinite. We remark that $T[t]$ represents the *subtree rooted at t* (if T is a tree, $T[t]$ is also a tree with root t).

When it is clear from context, we omit C and simply say "a graph" or "a tree".

The *size* of a graph G (and by extension, of a tree) is the cardinality of $V(G)$.

Morphisms. A *morphism* ϕ between two graphs G and H is a map $\phi\colon V(G) \to V(H)$ such that for each edge $v \xrightarrow{c} v' \in E(G)$ it holds that $\phi(v) \xrightarrow{c} \phi(v') \in E(H)$. We write $\phi : G \to H$ in this case, and sometimes say that H embeds G. Note that morphisms preserve paths: if $v_0 \xrightarrow{c_0} v_1 \xrightarrow{c_1} \dots$ is a path in G, then $\phi(v_0) \xrightarrow{c_0} \phi(v_1) \xrightarrow{c_1} \dots$ is a path in H. An *isomorphism* is a bijective morphism whose inverse is a morphism; two graphs are isomorphic if they are connected by an isomorphism (stated differently, they are the same up to renaming the vertices). The composition of two morphisms is a morphism.

2.2 Valuations, games, strategies and memory

Valuations and objectives. A *C-valuation* is a map $\mathrm{val} : C^\omega \to X$, where X is a complete linear order (that is, a total order in which all subsets have both a supremum and an infimum). The *value* $\mathrm{val}_G(v_0)$ of a vertex $v_0 \in V(G)$ in a graph G is the supremum value of infinite paths from v, where the value of an infinite path $\pi = v_0 \xrightarrow{c_0} v_1 \xrightarrow{c_1} \dots$ is defined to be $\mathrm{val}(\pi) = \mathrm{val}(c_0 c_1 \dots)$.

In the important special case where $X = \{\bot, \top\}$, $\bot < \top$, we identify val with $W = \mathrm{val}^{-1}(\bot) \subseteq C^\omega$, and say that val (or W) is an *objective*. In a graph G, a path with value $\bot$ (equivalently, whose sequence of colours belongs to W) is said to *satisfy* W, and a vertex v_0 with value $\bot$ (equivalently, all paths from v_0 satisfy W) is also said to satisfy W. A graph is said to satisfy W if all its vertices satisfy it.

Games. A *C-game* is a tuple $\mathcal{G} = (G, V_{\mathrm{Eve}}, v_0, \mathrm{val})$, where G is a C-graph, V_{Eve} is a subset of $V(G)$, $v_0 \in V(G)$ is an identified initial vertex, and $\mathrm{val} : C^\omega \to X$ is a C-valuation. We interpret V_{Eve} to be the set of vertices controlled by the first player, *Eve*, and we will write $V_{\mathrm{Adam}} = V(G) \setminus V_{\mathrm{Eve}}$ for the vertices controlled by her opponent, *Adam*. A game is played as follows: starting from v_0, successive moves are played where the player controlling the current vertex v chooses an outgoing edge $v \xrightarrow{c} v'$ and proceed to v'. This interaction goes on forever, producing and infinite path π from v_0. Eve's goal is to minimise the value of the produced path π, whereas Adam aims to maximise it.

In this paper, we are interested in questions of strategy complexity for Eve: if she wins, how much memory is required/sufficient? Formally, these are independent of questions of determinacy (is there a winner?). As a result, we will only ever consider strategies for Eve.

Strategies. A *strategy* in the game $\mathcal{G}$ is a tuple $\mathcal{S} = (S, \pi_{\mathcal{S}}, s_0)$ where S is a graph, $\pi_{\mathcal{S}}$ is a morphism $\pi_S \colon S \to G$ called the *$\mathcal{S}$-projection* and $s_0 \in V(S)$ satisfying:

- $\pi_{\mathcal{S}}(s_0) = v_0$,
- for all $v \in V_{\text{Adam}}$, all outgoing edges $v \xrightarrow{c} v' \in E(G)$ and all $s \in \pi_{\mathcal{S}}^{-1}(v)$, there is $s' \in \pi^{-1}(v')$ such that $s \xrightarrow{c} s' \in E(S)$.

Note that the requirements that S is a graph and $\pi_{\mathcal{S}}$ a morphism impose that for all $v \in V_{\text{Eve}}$ and $s \in \pi_{\mathcal{S}}^{-1}(v)$, s has an outgoing edge $s \xrightarrow{c} s' \in E(S)$ satisfying $\pi_{\mathcal{S}}(s) = v \xrightarrow{c} \pi_{\mathcal{S}}(s') \in E(G)$.

We remark that we do not impose that for each $v \in V_{\text{Eve}}$ and $s \in \pi_{\mathcal{S}}^{-1}(v)$, s has *exactly one* outgoing edge. Stated differently, non-determinism is allowed in this definition of strategy. As the upcoming definition of value of a strategy will clarify, we can interpret that Adam decides how to resolve this non-determinism.

On an informal level, a strategy $\mathcal{S} = (S, \pi_{\mathcal{S}}, s_0)$ from $v_0 \in G$ is used by Eve to play in the game $\mathcal{G}$ as follows:

- whenever the game is in a position $v \in V(G)$, the strategy is in a position $s \in \pi_{\mathcal{S}}^{-1}(v)$;
- initially, the position in the game is v_0, and the position in the strategy is $s_0 \in \pi_{\mathcal{S}}^{-1}(v_0)$;
- if the position v in the game belongs to V_{Adam}, and Adam chooses the edge $v \xrightarrow{c} v'$ in G, then the strategy state is updated following an edge $s \xrightarrow{c} s'$ in S with $\pi_{\mathcal{S}}(s') = v'$, which exists by definition of $\mathcal{S}$ (if multiple options exist, Adam chooses one);
- if the position v in the game belong to V_{Eve}, then the strategy specifies at least one successor $s \xrightarrow{c} s'$ from the current $s \in \pi^{-1}(v)$, and the game proceeds along the edge $v \xrightarrow{c} \pi(s')$ (if multiple options exist in the strategy, which corresponds to the non-determinism mentioned above, then Adam chooses one).

Note that infinite sequences of colours produced when playing as above are exactly labels of infinite paths from s_0 in S.

The *value* $\text{val}(\mathcal{S})$ of a strategy $\mathcal{S}$ is $\text{val}_S(s_0)$. The *value* $\text{val}(\mathcal{G})$ of a game is the infimum value among its strategies. If val is an objective, we say that $\mathcal{S}$ is *winning* if $\text{val}_S(s_0) = \bot$, and we say that Eve *wins* a game $\mathcal{G}$ if $\text{val}(\mathcal{G}) = \bot$.

The following observation is standard (it is usually taken as the definition of a strategy).

▶ **Lemma 1.** *The value of a game is reached with strategies that are trees.*

Memory. For a strategy $\mathcal{S} = (S, \pi_{\mathcal{S}}, s_0)$, we interpret the fibres $\pi_{\mathcal{S}}^{-1}(v)$ as memory spaces. Given a cardinal μ, we say that $\mathcal{S}$ has *memory* strictly less than μ, (resp. less than μ) if for all $v \in V(G)$, $|\pi_{\mathcal{S}}^{-1}(v)| < \mu$ (resp. $|\pi_{\mathcal{S}}^{-1}(v)| \leq \mu$). As it will appear later on, it is convenient for us to be able to use both strict and non-strict inequalities. By means of clarity and conciseness, we usually simply write "$\mathcal{S}$ has memory $< \mu$" (resp. $\leq \mu$) instead of "$\mathcal{S}$ has memory stricly less than μ (resp. less than μ)".

We say that a valuation val has *memory strictly less than* μ, or $< \mu$, (resp. less than μ, or $\leq \mu$) if in all games with valuation val, the value is reached with strategies with memory $< \mu$.

Conversely, we say that val has *memory at least* μ, or $\geq \mu$, if it does not have memory $< \mu$: there exists a game with valuation val in which Eve cannot reach the value with strategies with memory $< \mu$.

We say that val is *positional* if it has memory ≤ 1.

Product strategies, chromatic strategies. A strategy $\mathcal{S} = (S, \pi_{\mathcal{S}}, s_0)$ in the game $\mathcal{G}$ is a *product strategy* over a set M if $V(S) \subseteq V(G) \times M$, with $\pi_{\mathcal{S}}(v, m) = v$. We call the elements of M *memory states*. Note that the memory in a product strategy over M is $\leq |M|$, since

fibers are included in M. A product strategy is *chromatic* if there is a map $\delta : M \times C \to M$ such that for all $(v, m) \xrightarrow{c} (v', m') \in E(S)$ we have $m' = \delta(m, c)$. We say in this case that δ is the *update function* of $\mathcal{S}$. In words, the update of the memory state in a chromatic strategy depends only on the current memory state and the colour that is read. A valuation val has *chromatic memory* $< \mu$ (resp. $\leq \mu$) if in all games with valuation val, the value is reached with chromatic strategies with memory $< \mu$ (resp. $\leq \mu$).

ε-games and ε-strategies. Fix a set of colours C, a fresh colour $\varepsilon \notin C$, and let $C^\varepsilon = C \sqcup \{\varepsilon\}$. The *$C$-projection* of an infinite sequence $w \in (C^\varepsilon)^\omega$ is the (finite or infinite) sequence $w_C \in C^* \cup C^\omega$ obtained by removing all ε's in w. Given a C-valuation $\mathrm{val} : C^\omega \to X$, define its *$\varepsilon$-extension* val^ε to be given by

$$\mathrm{val}^\varepsilon(w) = \begin{cases} \mathrm{val}(w_C), & \text{if } |w_C| = \infty, \\ \inf\limits_{w' \in C^\omega} \mathrm{val}(w_C w'), & \text{otherwise.} \end{cases}$$

It is the unique extension of val with ε as a strongly neutral colour, in the sense of Ohlmann [20]. In particular, if W is an objective and $w \in C^*$, $w\varepsilon^\omega \in W^\varepsilon$ unless w has no winning continuation in W.

An *ε-game* $\mathcal{G}$ is a C^ε-game with valuation val^ε. An *ε-strategy* over such a game is a product strategy $\mathcal{S} = (S, \pi_\mathcal{S}, s_0)$ over some set M such that $(v, m) \xrightarrow{\varepsilon} (v', m') \in E(S)$ implies $m = m'$. Intuitively, Eve is not allowed to update the state of the memory when an ε-edge is traversed. The *memory of an ε-strategy* is defined to be $|M|$. A valuation val has *ε-memory* $< \mu$ (resp. $\leq \mu$) if in all ε-games with valuation val^ε, the value is attained by ε-strategies with memory $< \mu$ (resp. $\leq \mu$).

Note that by definition, a chromatic strategy over M with update function δ is an ε-strategy if and only if for all $m \in M$ it holds that $\delta(m, \varepsilon) = m$. We call such a strategy an *ε-chromatic strategy*. A valuation val has *ε-chromatic memory* $< \mu$ (resp. $\leq \mu$) if in all ε-games with valuation val^ε, the value is attained by ε-chromatic strategies with memory $< \mu$ (resp. $\leq \mu$).

Whenever we want to emphasise that we consider games (resp. strategies, memory) without ε, we might add the adjective *ε-free*.

2.3 Monotonicity and universality

Monotonicity. A partially ordered graph $(G, \leq)$ is *monotone* if

$u \geq v \xrightarrow{c} v' \geq u'$ implies $u \xrightarrow{c} u'$ in G.

A partially ordered graph $(G, \leq)$ is called *well-monotone* if it is monotone and it is well-founded as a partial order. We say that the *width* of a partially ordered graph is $< \mu$ (resp. $\leq \mu$) if it does not contain antichains of size μ (resp. of size strictly greater than μ).

ε-separation. An *ε-separated monotone graph over a set M* is a C^ε-graph G such that $\xrightarrow{\varepsilon}$ defines a partial order making G monotone ($v \leq v' \iff v' \xrightarrow{\varepsilon} v \in E(G)$), and moreover $V(G)$ is partitioned into $(V_m)_{m \in M}$ such that for all $m \in M$, $\xrightarrow{\varepsilon}$ induces a total order over V_m, and there are no ε-edges between different parts: $v \xrightarrow{\varepsilon} v' \in E(G)$ implies that $v, v' \in V_m$ for some $m \in M$. See Figure 3. We define the *breadth* of such a graph as $|M|$.

An ε-separated monotone graph G over M is *chromatic* if there is a map $\delta : M \times C \to M$ such that for all $v \xrightarrow{c} v' \in E(G)$ with $v \in V_m$ and $v' \in V_{m'}$ we have $m' = \delta(v, m)$. We also say in this case that δ is the *update function* of G.

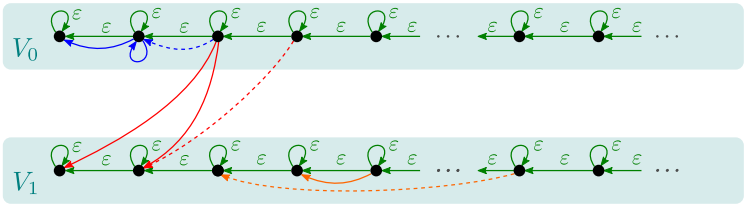

Figure 3 An ε-separated chromatic monotone graph of breadth 2. Note that $\xrightarrow{\varepsilon}$ defines a total order on each V_i (edges following from transitivity are not represented). Many edges which follow from monotonicity are not depicted, the dotted edges give a few examples.

Universality. Given a C-valuation val, a C-graph G and a cardinal κ, we say that G is (κ, val)-*universal* if for all C-trees T of cardinality $< \kappa$, there exists a morphism $\phi : T \to G$ such that $\mathrm{val}_G(\phi(t_0)) \leq \mathrm{val}_T(t_0)$, where t_0 is the root of T. We say that ϕ *preserves the value* at the root to refer to this property (we remark that, in that case, $\mathrm{val}_G(\phi(t_0)) = \mathrm{val}_T(t_0)$, since the other inequality always holds).

▶ Remark 2. An example where the definition with graphs is too constrained to capture memory is given in Proposition 22 from the full version [7].

3 Universal structures characterise memory

Statement of the main results. We start with our characterisations of ε-memory and ε-chromatic memory via (chromatic) ε-separated universal graphs.

▶ **Theorem 3.** *Let* val *be a valuation. If for all cardinals κ there exists an ε-separated (chromatic) and well-monotone $(\kappa, \mathrm{val}^\varepsilon)$-universal graph of breadth $\leq \mu$, then* val *has ε(-chromatic)-memory $\leq \mu$. The converse holds if* val *is an objective (in both the chromatic and non-chromatic cases).*

Our second result concerns ε-free memory. It is stated with strict inequalities, which are relevant in this case and allow for more precision. However, we do not have a converse statement; in fact, the converse cannot hold (see also Figure 2 and Proposition 7).

▶ **Theorem 4.** *Let* val *be a valuation. If for all cardinals κ there exists a well-monotone (κ, val)-universal graph of width $< \mu$, then* val *has ε-free memory $< \mu$.*

As we will see in Proposition 5, the two results above collapse for finite cardinals.

We give the main ideas of the proofs of these two theorems, in both cases we extend the proofs from Ohlmann [20]. The full proofs can be found in Sections 3.2 and 3.3 in the full version [7].

Proof sketch of Theorem 4 and of $\Longrightarrow$ in Theorem 3. We discuss the proof of Theorem 4 (the proof of the first implication in Theorem 3 follows the same structure). In this case, assuming existence of a universal structure, we prove upper bounds in the memory of a valuation. This is done using a strategy-folding procedure that is guided by the morphism towards the universal structure. Let $(U, \leq)$ be a well-monotone (κ, val)-universal graph of width $< \mu$. Suppose that $\mathcal{G}$ is a game of cardinality $\leq \kappa$ with valuation val, and let $\mathcal{T} = (T, \pi_{\mathcal{T}}, t_0)$ be a strategy for Eve given by a tree. By universality of U, there is a morphism $\phi\colon T \to U$ preserving the value at the root of T.

For each vertex v of the game we consider the set $\phi(\pi_{\mathcal{T}}^{-1}(v))$ in U. Since U is well-founded and of width $< \mu$, the set M_v of minimal elements of $\phi(\pi_{\mathcal{T}}^{-1}(v))$ has size strictly less than μ. This allows us to define a strategy over $\bigcup_v \{v\} \times M_v$ which simulates the strategy $\mathcal{T}$ as follows: we take a representative $t_{(v,m)} \in \pi_{\mathcal{T}}^{-1}(v)$, and for each $m \in M_v$, we follow the decisions made at $t_{(v,m)}$ when we are in (v, m).

To define the update of the memory, for each move $v \xrightarrow{c} v' \in E(G)$ and edge $t_{(v,m)} \xrightarrow{c} t' \in E(T)$, we consider the image $\phi(t') \in U$. By definition, there is an element m' in $M_{v'}$ smaller that $\phi(t')$, so we let $(v, m) \xrightarrow{c} (v', m')$. By monotonicity it follows that this strategy has the same value than $\mathcal{T}$. If U is assumed to be (chromatic) ε-separated, it follows directly that the obtained strategy is a (chromatic) ε-strategy. ◀

Proof sketch of $\Longleftarrow$ in Theorem 3. We prove the following result: given a C^ε-tree T satisfying an objective W, there exists an ε-separated well-monotone graph U of breadth $\leq \mu$ and a morphism $T \to U$ preserving the value at the root. Once this is proved, applying it to the tree T_{Univ} consisting of a root connected by an ε-edge to every C^ε-tree $< \kappa$ satisfying W yields a (κ, W^ε)-universal graph.

In order to prove this result, we consider the following game: Adam controls the vertices from T, and for each non-empty set $A \subseteq V(T)$, we add a vertex v_A controlled by Eve with ε-edges back and forth from any vertex in A. This game is won by Eve: whenever Adam chooses an edge $t \xrightarrow{\varepsilon} v_A$ she just need to respond $v_A \xrightarrow{\varepsilon} t$. Since W has ε-memory $\leq \mu$, Eve has a winning ε-strategy $\mathcal{S}$ over $V(S) = V(G) \times M$ with $|M| \leq \mu$.

We define the wanted morphism $\phi\colon T \to S$ in a top-down fashion using the properties of a strategy: $\phi(t_0) = s_0$ and if $\phi(t) = (t, m)$ and $t \xrightarrow{c} t' \in E(T)$, we set $\phi(t') = (t', m')$ where m' is such that $(t, m) \xrightarrow{c} (t', m') \in E(S)$. This morphism preserves the value of t_0, because $\mathcal{S}$ is a winning strategy. With some addition technical tweaks we transform S into an ε-separated graph U of breadth $\leq \mu$ while maintaining a value-preserving morphism $\phi\colon T \to U$. ◀

Applying Dilworth's Theorem [11], we prove that the two notions of graphs collapse (both characterise ε-memory) when dealing with objectives and finite memory bounds.

▶ **Proposition 5.** *Let W be an objective and $m \in \mathbb{N}$. If for all cardinals κ there exists a well-monotone graph which is (κ, W)-universal and has width $\leq m$, then for all cardinals κ there is also an ε-separated well-monotone (κ, W^ε)-universal graph of breadth $\leq m$, and therefore W has ε-memory $\leq m$.*

An objective $W \subseteq C^\omega$ is said to be *prefix-independent* if for all colours $c \in C$ it holds that $cW = W$. It is not difficult to prove (this was already done by Ohlmann [20]) that when considering prefix-independent objectives, one can use a simpler definition of universality, namely, a graph U is (κ, W)-*universal (for prefix-independent objectives)* if U satisfies W and embeds any tree of cardinality $< \kappa$ which satisfies W.

Some concrete examples. We start by illustrating the notions presented until now and some methods to derive universality proofs with a few simple concrete examples of objectives.

For many more examples, as well as the missing proofs of this paragraph, we refer to the Section 4 of the full version [7]. There, we also re-obtain in our framework the general characterisations of [8] for topologically closed objectives, and of [12] for Muller objectives.

Objective $W_1 = \{w \in \{a, b\}^\omega \mid a$ and b occur infinitely often in $w\}$. We show, for each cardinal κ, an ε-separated chromatic and well-monotone $(\kappa, W_1^\varepsilon)$-universal graph of breadth 2. This implies that the ε-chromatic memory of W_1 is at most 2.

Fix a cardinal number κ and consider the graph U from Figure 4. It is easy to check that U is an ε-separated monotone graph over the set $M = \{a, b\}$ and that it is indeed chromatic and satisfies W. We sketch a universality proof. Since W_1 is prefix-independent, we show that U embeds any tree of cardinality $< \kappa$ which satisfies W.

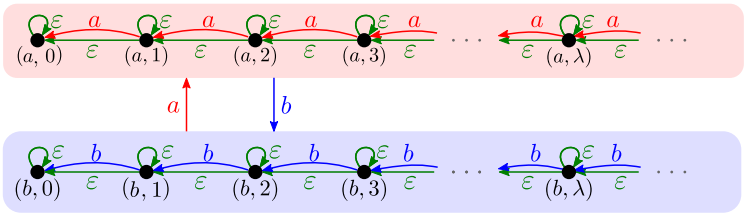

Figure 4 Universal graph for W_1. The order coincides with $\xrightarrow{\varepsilon}$ (as required by the definition of ε-separated graphs). Edges following from monotonicity are not represented. An edge between boxes indicates that all edges are put between vertices in the respective boxes.

Let T be a C-tree of size $< \kappa$ which satisfies W, and let t_0 be its root. Note that all paths from t_0 eventually visit a b-edge; there is in fact an ordinal $\lambda_0 < \kappa$ (defined by induction) which counts the maximal amount of a-edges seen from t_0 before a b-edge is seen; we set $\phi(t_0)$ to be (a, λ_0).

Then for each edge $t_0 \xrightarrow{c} t \in E(T)$ we proceed as follows.

- If $c \in \{a, \varepsilon\}$, we iterate exactly the same process on t, but the ordinal count will on the number of a's will have decreased (or even strictly decreased if $c = a$) from t_0 to t, which guarantees that $\phi(t_0) \xrightarrow{a} \phi(t)$ is indeed an edge in U.
- If $c = b$, then we iterate the same process of t but inverting the roles of a and b; thus $\phi(t)$ is of the form (b, λ_b) for some $\lambda_b < \kappa$, and the edge $\phi(t_0) \xrightarrow{b} \phi(t)$ belongs to U, as required.

This concludes the top-down construction of ϕ and the universality proof.

It is not difficult to find lower bounds to see that the ε-free memory of W_1 is ≥ 2. For example, a game with just one vertex controlled by Eve where she can choose to produce a or b provides this lower bound. Therefore, the exact memory of W_1 is 2, for all the different notions of memory.

Objective $W_2 = (C^*a)^m C^{\geq n} a C^\omega$ with $C = \{a, b\}$ and $m, n \geq 1$. We provide a universal graph of width $n+1$ which proves that the ε-memory is $\leq n+1$. A matching lower bound on the ε-free memory follows from the game depicted on Figure 5. We remark that from the minimal automaton for the regular language $L = (C^*a)^m C^{\geq n} a$ we only obtain an upper bound of $n + m + 1$ on the memory.

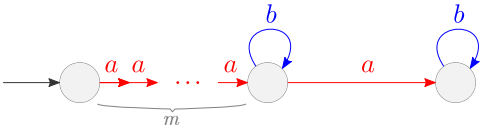

Figure 5 A game where Eve requires memory $n+1$ to ensure objective W_2.

The well-monotone graph U depicted in Figure 6 proves the $n+1$ upper bound on the ε-memory. Actually, it turns out that even the ε-chromatic memory of W_2 is $n+1$, which requires a more subtle construction presented in the full version.

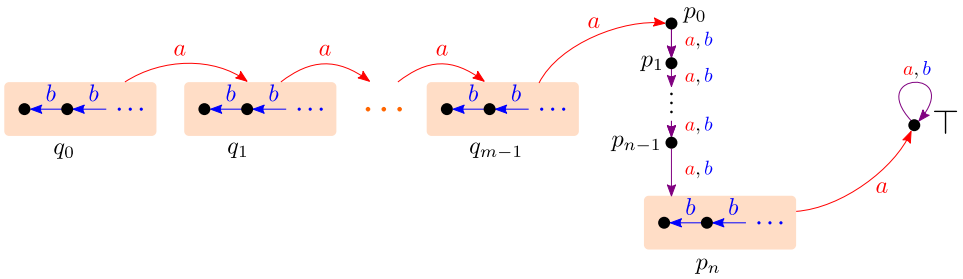

Figure 6 A well-monotone graph U which has width $n+1$ and is universal for W_2.

Objective $W_3 = \{w \in C^\omega \mid w$ contains infinitely often bb or (finitely often b and $aa)\}$ over $C = \{a, b, c\}$. Figure 7 depicts a deterministic parity automaton $\mathcal{A}$ of size 3 recognising W_3; this gives an upper bound of 3 on the memory of W_3. The game depicted on the right of Figure 7 witnesses that Eve requires ε-free memory ≥ 2: positional strategies are losing, but she wins by answering b to b and a to c.

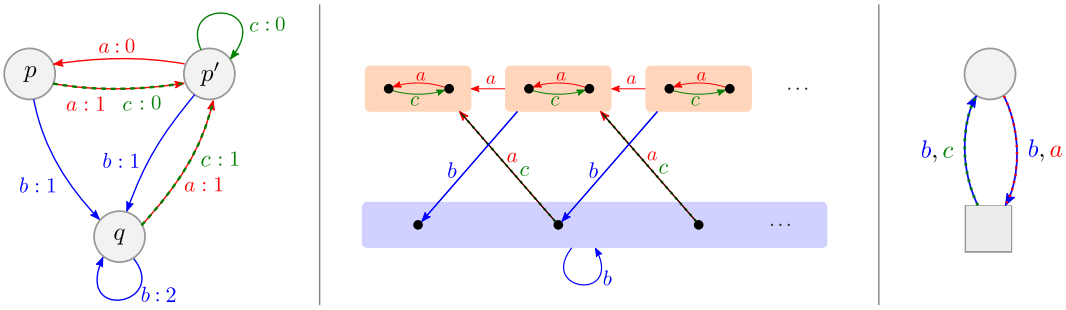

Figure 7 On the left, a deterministic parity automaton $\mathcal{A}$ with three states recognising W_3 (we use max-parity semantics). In the middle, an ε-separated chromatic universal graph U of breadth 2 for W_3; as always, edges following from monotonicity are omitted. On the right, a game witnessing that Eve requires ε-free memory ≥ 2.

The graph U depicted in the middle of Figure 7 is an ε-separated chromatic well-monotone universal graph for W_3 of breadth 2, providing the upper bound of 2 on all the types of memory for W_3.

Counterexamples. We now provide two negative results. First, we show that the converse of Theorem 4 does not hold, even in the case of objectives.

▶ **Proposition 6.** *For each cardinal μ, the objective $W_\mu = \{w_0 w_1 \cdots \in \mu^\omega \mid \forall i, w_i \neq w_{i+1}\}$ satisfies that*

1. *the ε-free memory of W_μ is ≤ 2;*
2. *the ε-free memory of W_μ^ε is $\geq \mu$; and therefore the ε-memory of W_μ is $\geq \mu$; and*
3. *there is κ such that any monotone (κ, W_μ)-universal graph has width $\geq \mu$.*

Second, we prove that Proposition 5 cannot hold if the bound on the size of the antichains of the graph is not finite.

▶ **Proposition 7.** *For any infinite cardinal μ, the objective $W_\mu = \{(w, w') \in (\mu \times \mu)^\omega \mid \nexists i$ such that $w_i < w_{i+1}$ and $w'_i < w'_{i+1}\}$ is such that*

- *for all cardinals κ there exists a well-monotone (κ, W_μ)-universal graph whose antichains have cardinality $< \aleph_0$; and*
- *there is an ε-game with objective W_μ^ε requiring ε-memory $\geq \mu$.*

4 Closure properties

Lexicographical products. We provide a study of lexicographical products, as introduced by Ohlmann [20], whose result we generalize to finite memory bounds.

Given two prefix-independent objectives W_1 and W_2 over disjoint sets of colours C_1 and C_2, we define their *lexicographical product* $W_1 \ltimes W_2$ over $C = C_1 \sqcup C_2$ by

$$W_1 \ltimes W_2 = \{w \in C^\omega \mid [w^2 \text{ is infinite and in } W_2] \text{ or } [w^2 \text{ is finite and } w^1 \in W_1]\},$$

where w^1 (resp. w^2) is the (finite or infinite) word obtained by restricting w to occurrences of letters from C_1 (resp. C_2) in the same order. Note that if w^2 is finite then w^1 is infinite, which is why the product is well defined.

We now define the *lexicographical product* $(U, \leq)$ of two ordered graphs $(U_1, \leq_1)$ and $(U_2, \leq_2)$. Intuitively, each vertex in U_2 is replaced by a copy of U_1. (see also Figure 8).

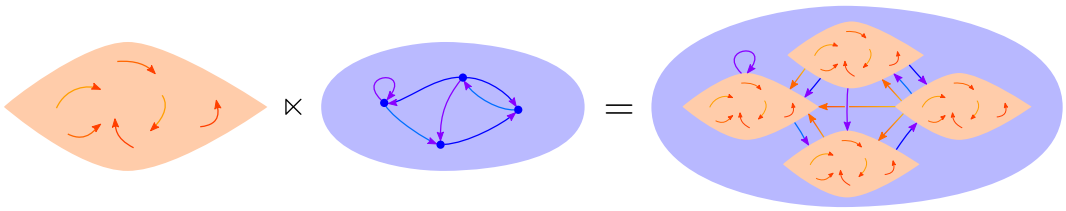

Figure 8 Illustration of the lexicographical product of two ordered graphs.

Formally $U_1 \ltimes U_2 = U$ is defined over the lexicographical product of $(V(U_1), \leq_1)$ and $(V(U_2), \leq_2)$, that is $V(U) = V(U_1) \times V(U_2)$ and $\leq$ is the lexicographical product of $\leq_1$ and $\leq_2$. Its edges are:

$$\begin{aligned} E(U) \quad = \quad & \{(u_1, u_2) \xrightarrow{c_1} (u_1', u_2') \mid c_1 \in C_1 \text{ and } (u_2 >_2 u_2' \text{ or } [u_2 = u_2' \text{ and } u_1 \xrightarrow{c_1} u_1'])\} \\ \cup \quad & \{(u_1, u_2) \xrightarrow{c_2} (u_1', u_2') \mid c_2 \in C_2 \text{ and } u_2 \xrightarrow{c_2} u_2'\}. \end{aligned}$$

We now state our main result in this section, a direct extension of [20, Theorem 18].

▶ **Theorem 8.** *Let W_1 and W_2 be two prefix-independent objectives over disjoint sets of colours C_1 and C_2. Let κ be a cardinal and let $(U_1, \leq)$ and $(U_2, \leq)$ be monotone graphs which are respectively (κ, W_1) and (κ, W_2)-universal. Then $U_1 \ltimes U_2$ is monotone and $(\kappa, W_1 \ltimes W_2)$-universal.*

Using Theorems 3 and 4 together with Proposition 5, we deduce the following result.

▶ **Corollary 9.** *Let W_1 and W_2 be two prefix-independent objectives over disjoint sets of colours C_1 and C_2, and assume that W_1 (resp. W_2) has ε-memory $\leq n_1 \in \mathbb{N}$ (resp. $\leq n_2$). Then, their lexicographical product $W_1 \ltimes W_2$ has ε-memory $\leq n_1 n_2$.*

Combining objectives with locally finite memory. When applied to $\mu = \aleph_0$, since well-founded orders with bounded antichains correspond to well-quasi-orders (wqo's), Theorem 4 states that the existence of universal monotone graphs which are wqo's for a given objective (or even, a valuation) entails *locally finite memory*, meaning that for any ε-free game there is an optimal strategy $\mathcal{S}$ such that for all vertices v, the amount of memory used at v (that is, the cardinality of $\pi_{\mathcal{S}}^{-1}(v)$) is finite. Unfortunately this is not a characterisation: Proposition 6 applied to $\mu = \aleph_0$ gives an objective with ε-free memory 2 but which does not admit such universal structures. Still, by combining our knowledge so far with a few additional insights

stated below, we may derive some strong closure properties pertaining to objectives with locally finite memory. In the sequel, we will simply say *monotone wqo* for a well-monotone graph whose antichains are finite.

Given two partially ordered sets $(U_1, \leq_1)$ and $(U_2, \leq_2)$, we define their *(direct) product* to be the partially ordered set $(U_1 \times U_2, \leq)$, where

$$(u_1, u_2) \leq (u_1', u_2') \iff [u_1 \leq u_1'] \text{ and } [u_2 \leq u_2'].$$

Note that if $\leq_1$ and $\leq_2$ are well-founded, then so is $\leq$. However, there may be considerable blowup on the size of antichains, for instance, $\omega \times \omega$ has arbitrarily large (finite) antichains whereas ω is a total order. However, it is a well-known fact that the product of two wqo's is also a wqo (see for instance [10]), that is, one may not go from finite to infinite antichains.

Given two partially ordered C-graphs $(G_1, \leq_1)$ and $(G_2, \leq_2)$, we define their *(direct) product* to be the partially ordered C-graph G defined over the product of $(V(G_1), \leq_1)$ and $(V(G_2), \leq_2)$ by

$$E(G) = \{(v_1, v_2) \xrightarrow{c} (v_1', v_2') \mid v_1 \xrightarrow{c} v_1' \in E(G_1) \text{ and } v_2 \xrightarrow{c} v_2' \in E(G_2)\}.$$

Note that if $(G_1, \leq_1)$ and $(G_2, \leq_2)$ are monotone, then so is their product. Therefore, if $(G_1, \leq_1)$ and $(G_2, \leq_2)$ are monotone wqo's, then so is their product. Our discussion hinges on the following result.

▶ **Lemma 10.** *Let κ be a cardinal, and $W_1, W_2 \subseteq C^\omega$ be two objectives. Let $(U_1, \leq_1)$ and $(U_2, \leq_2)$ be two C-graphs which are (κ, W_1) and (κ, W_2)-universal, respectively. Then their product U is $(\kappa, W_1 \cap W_2)$-universal.*

Therefore, by combining this lemma with the fact that wqo's are closed under product, we obtain that if two objectives W_1 and W_2 have monotone wqo's as universal graphs, then so does their intersection, hence, from Theorem 4, $W_1 \cap W_2$ has locally finite memory. In particular, thanks to Theorem 3, we get the following weak closure property.

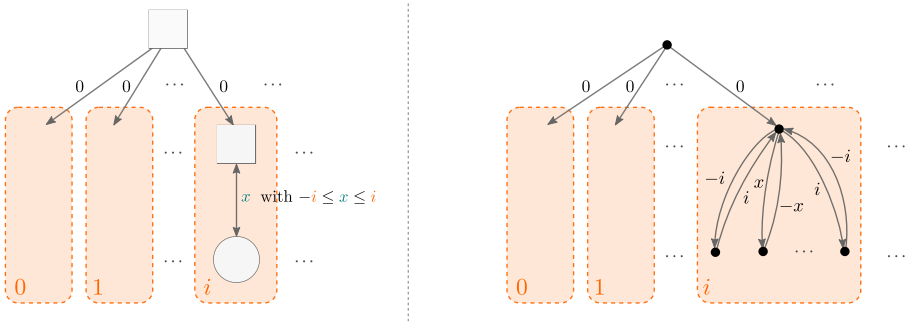

Figure 9 A game where initially, Adam chooses an upper bound i, then the players alternate in choosing integers in $[-i, i]$. Eve wins if the partial sums of the weights remain bounded both from above and below (bi-boundedness objective). She can ensure a win by simply playing the opposite of Adam in each round (this strategy is represented on the right-hand side), which requires unbounded but locally finite memory. Since bi-boundedness objectives are intersections of two positional objectives (being bounded from above and from below), our results in this section ensure that any game with a bi-boundedness objective has optimal locally finite memory strategies.

▶ **Corollary 11.** *Let W_1 and W_2 be two objectives which have monotone wqo's as universal graphs. Then so does $W_1 \cap W_2$. In particular the intersection of two objectives with finite ε-memory has locally finite memory.*

The upper bound stated in Corollary 11 is met: Figure 9 gives an example where W_1 and W_2 are positional but $W_1 \cap W_2$ has ε-free memory $> n$ for all $n \in \mathbb{N}$.

Although our results fall short of implying such a strong closure property, we may still state the following conjecture:

▶ **Conjecture 12.** *Objectives with ε-free memory $< \aleph_0$ are closed under intersection.*

Unions of prefix-independent $\mathbf{\Sigma_2^0}$ objectives. The Cantor topology on C^ω naturally provides a way to define general families of objectives that have been well-studied in the literature of formal languages (we refer to [21] for a general overview). In particular, some of these classes of objectives are given by the different levels of the Borel hierarchy; the lowest levels are Σ_1^0, consisting on the open subsets, and Π_1^0, consisting on the closed subsets. The level Σ_{n+1}^0 (resp. Π_{n+1}^0) contains the countable unions (resp. countable intersections) of subsets in Π_n^0 (resp. Σ_n^0).

We now prove that prefix-independent objectives in Σ_2^0 with ε-memory $\leq m \in \mathbb{N}$ are closed under countable unions. We recall that Σ_2^0 objectives are those of the form $W_{\mathcal{L}} = \{w \in C^\omega \mid w \text{ has finitely many prefixes in } \mathcal{L}\}$, where $\mathcal{L} \subseteq C^*$ is an arbitrary language of finite words [22].

▶ **Theorem 13.** *Prefix-independent Σ_2^0 objectives with ε-memory $\leq m \in \mathbb{N}$ are closed under countable unions.*

Our proof relies on the definition of the *direct sum* of a family of universal graphs (obtained by concatenating them) and the following lemma.

▶ **Lemma 14.** *Let $W_0, W_1, \dots \subseteq C^\omega$ be prefix-independent Σ_2^0 objectives, κ be a cardinal, and $U_0, U_1, \dots$ be C-graphs such that for each i, U_i is (W_i, κ)-universal. Let $W = \bigcup_i W_i$. Then the graph $U \ltimes \kappa$, where U is the direct sum of the U_i's, and κ is the edgeless graph with κ vertices, is (κ, W)-universal.*

Proof sketch. Let T be a tree of cardinality $< \kappa$ satisfying W. Since W is prefix-independent, proving that there is $t \in V(T)$ inducing a subtree $T[t]$ such that $T[t] \to U$ is enough to derive universality of $U \ltimes \kappa$ (in the full version [7], this useful fact is stated as Lemma 10). Since U is the direct sum of the U_i's and since each U_i is κ-universal for W_i, this amounts to showing that there is $i \in \mathbb{N}$ and $t \in T$ such that $T[t]$ satisfies W_i. Assume otherwise. Take $e = e_0 e_1 \cdots \in \mathbb{N}^\omega$ to be a word over the naturals with infinitely many occurrences of each natural, for instance $e = 010120123\dots$. For each $i \in \mathbb{N}$, let $\mathcal{L}_i \subseteq C^*$ be such that $W_i = \{w \in C^\omega \mid w \text{ has finitely many prefixes in } \mathcal{L}_i\}$.

We now construct an infinite path $\pi = \pi_0 \pi_1 \dots$ starting from the root t_0 in T such that for each i, the coloration $w_0 \dots w_i$ of $\pi_0 \dots \pi_i$ belongs to $\mathcal{L}_{e_i}$. This implies that the coloration w of π has infinitely many prefixes in each of the $\mathcal{L}_i$'s, therefore it does not belong to W, a contradiction. Assume $\pi = \pi_0 \dots \pi_{i-1} : t_0 \overset{w_0 \dots w_{i-1}}{\rightsquigarrow} t$ constructed up to π_{i-1}. Since by assumption, $T[t]$ does not satisfy W_{e_i}, there is a path $\pi' : t \overset{w}{\rightsquigarrow}$ such that $w \notin W_{e_i}$. By prefix-independence of W_{e_i}, we get $w_0 \dots w_{i-1} w \notin W_{e_i}$, thus w has a prefix w_i such that $w_0 \dots w_{i-1} w_i \in \mathcal{L}_{e_i}$; this allows us to augment π as required and conclude our proof. ◀

The theorem follows from Lemma 14, Theorem 3 and Proposition 5 and the fact that antichains in the well-founded graph $U \times \kappa$ are no larger than those in U.

5 Conclusion

In this paper, we have extended Ohlmann's work [20] to the study of the memory of objectives. We have introduced different variants of well-monotone universal graphs adequate to the various models of memory appearing in the literature, and we have characterised the memory of objectives through the existence of such universal graphs (Theorems 3 and 4).

Possible applications. We expect these results to have two types of applications. The first one is helping to find tight bounds for the memory of different families of objectives. We have illustrated this use of universal graphs by providing non-trivial tight bounds on the memory of some concrete examples. In the full version [7, Section 4], we further recover known results about the memory of topologically closed objectives [8] and Muller objectives [12]. While finding universal graphs and proving their correctness might be difficult, we believe that they are a useful support to guide our intuition, and they provide a standardised method to formalise proofs of upper bounds on memory requirements.

The second kind of application discussed in the paper is the study of combinations of objectives. We have used our characterizations to bound the memory requirements of finite lexicographical product of objectives (Section 4). We have also established that intersections of objectives with finite ε-memory always have locally finite ε-free memory. Finally, we have proved that prefix-independent Σ^0_2 objectives with finite ε-memory are closed under countable unions. We believe that the new angle offered by universal graphs will help to better understand general closure properties of memory.

Open questions. Many questions remain open. First of all, as discussed in Section 4, we have proved that objectives admitting universal monotone wqo's are closed by intersection. However, we do not know whether the larger class of objectives with unbounded finite ε-free memory is closed under intersection (Conjecture 12). A related question is therefore understanding what are exactly the objectives admitting universal monotone wqo's.

In the realm of positional objectives, a long-lasting open question is Kopczyński's conjecture [15]: are unions of prefix-independent positional objectives positional? This conjecture has recently been disproved for finite game graphs by Kozachinskiy [16], but it remains open for arbitrary game graphs. We propose a generalisation of Kopczyński's conjecture in the case of ε-memory.

▶ **Conjecture 15.** *Let $W_1 \subseteq C^\omega$ and $W_2 \subseteq C^\omega$ be two prefix-independent objectives with ε-memory $\leq n_1, n_2$, respectively. Then $W_1 \cup W_2$ has ε-memory $\leq n_1 n_2$.*

Objectives that are ω-regular (those recognised by a deterministic parity automaton, or, equivalently, by a non-deterministic Büchi automaton) have received a great deal of attention over the years. However, very little is known about their memory requirements, and even about their positionality. By now, thanks to a recent work of Bouyer, Casares, Randour and Vandenhove [1], which relies on Ohlmann's characterisation, positionality is understood for objectives recognised by deterministic Büchi automata.

Characterising positionality or memory requirements for other general classes of ω-regular objectives, such as those recognised by deterministic co-Büchi automata or by deterministic automata of higher parity index remains an open and challenging endeavour. Similarly, one may turn to (non-necessarily ω-regular) objectives with topological properties, for instance, it is not known by now which topologically open objectives (or, recognised by infinite deterministic reachability automata) are positional, or finite memory. We hope that the newly available tools presented in this paper will help progress in this direction.

Approximate Model Counting: Is SAT Oracle More Powerful Than NP Oracle?

Abstract

Given a Boolean formula ϕ over n variables, the problem of model counting is to compute the number of solutions of ϕ. Model counting is a fundamental problem in computer science with wide-ranging applications in domains such as quantified information leakage, probabilistic reasoning, network reliability, neural network verification, and more. Owing to the #P-hardness of the problems, Stockmeyer initiated the study of the complexity of approximate counting. Stockmeyer showed that $\log n$ calls to an NP oracle are necessary and sufficient to achieve (ε, δ) guarantees. The hashing-based framework proposed by Stockmeyer has been very influential in designing practical counters over the past decade, wherein the SAT solver substitutes the NP oracle calls in practice. It is well known that an NP oracle does not fully capture the behavior of SAT solvers, as SAT solvers are also designed to provide satisfying assignments when a formula is satisfiable, without additional overhead. Accordingly, the notion of SAT oracle has been proposed to capture the behavior of SAT solver wherein given a Boolean formula, an SAT oracle returns a satisfying assignment if the formula is satisfiable or returns unsatisfiable otherwise. Since the practical state-of-the-art approximate counting techniques use SAT solvers, a natural question is whether an SAT oracle is more powerful than an NP oracle in the context of approximate model counting.

The primary contribution of this work is to study the relative power of the NP oracle and SAT oracle in the context of approximate model counting. The previous techniques proposed in the context of an NP oracle are weak to provide strong bounds in the context of SAT oracle since, in contrast to an NP oracle that provides only one bit of information, a SAT oracle can provide n bits of information. We therefore develop a new methodology to achieve the main result: a SAT oracle is no more powerful than an NP oracle in the context of approximate model counting.

1 Introduction

Let ϕ be a Boolean formula over n propositional variables. An assignment $s \in \{T, F\}^n$ is called a *satisfying assignment* if it makes ϕ evaluate to true. Let $\mathsf{sol}(\phi)$ denote the set of all satisfying assignments. The model counting problem is to compute $|\mathsf{sol}(\phi)|$ for a given ϕ. It is a fundamental problem in computer science and has numerous applications across different fields such as quantified information leakage, probabilistic reasoning, network reliability, neural network verification, and the like [12, 13, 17, 9, 8, 1]. The seminal work of Valiant [17] showed that the problem of model counting is #P-complete, and consequently, one is often interested in approximate variants of the problem. In this paper, we consider the following problem:

Approximate Model Counting

Input A formula ϕ, tolerance parameter $\varepsilon > 0$, and confidence parameter $\delta \in (0, 1)$.
Output Compute an estimate Est such that

$$\Pr\left[\frac{|\mathsf{sol}(\phi)|}{1+\epsilon} \leq \mathsf{Est} \leq (1+\epsilon)|\mathsf{sol}(\phi)|\right] \geq 1-\delta.$$

Stockmeyer [16] initiated the study of the complexity of approximate model counting. Stockmeyer's seminal paper made two foundational contributions: the first contribution was to define the query model that could capture possible natural algorithms yet amenable enough to theoretical tools to allow non-trivial insight. To this end, Stockmeyer proposed the query model wherein one can construct an arbitrary set S and query an NP oracle to determine if $|\mathsf{sol}(\phi) \cap S| \geq 1$. Stockmeyer showed that under the above-mentioned query model, $\log n$ calls to an NP oracle are necessary and sufficient (for a fixed ε and δ). Furthermore, Stockmeyer introduced a hashing-based algorithmic procedure to achieve the desired upper bound that makes $O(\log n)$ calls to NP-oracle. The lack of availability of powerful reasoning systems for problems in NP dissuaded the development of algorithmic frameworks based on Stockmeyer's hashing-based framework until the early 2000s [10].

Motivated by the availability of powerful SAT solvers, there has been a renaissance in the development of hashing-based algorithmic frameworks for model counting, wherein a call to an NP oracle is handled by an SAT solver in practice. The current state-of-the-art approximate model counter, ApproxMC [4], relies on the hashing-based framework and is able to routinely handle problems involving hundreds of thousands of variables. The past decade has witnessed a sustained interest in further enhancing the scalability of these approximate model counters. It is perhaps worth highlighting that Stockmeyer's query model captures queries by ApproxMC.

While the current state-of-the-art approximate model counters rely on the hashing-based framework, they differ significantly from Stockmeyer's algorithm for approximate model counting. The departures from Stockmeyer's algorithm have been deliberate and have often been crucial to attaining scalability. In particular, ApproxMC crucially exploits the underlying SAT solver's ability to return a satisfying assignment to attain scalability. In this context, it is worth highlighting that, unlike an NP oracle that only returns the answer Yes or No for a given Boolean formula, all the known SAT solvers are capable of returning a satisfying assignment if the formula is satisfiable without incurring any additional overhead. Observe that one would need n calls to an NP oracle to determine a satisfying assignment. From this viewpoint, an NP oracle does not fully capture the behavior of an SAT solver, and one needs a different notion to model the behavior of SAT solver.

Delannoy and Meel [7] sought to bridge the gap between theory and practice by proposing the notion of a SAT oracle. Formally, a SAT oracle takes in a Boolean formula ϕ as input and returns a satisfying assignment $s \in \mathsf{sol}(\phi)$ if ϕ is satisfiable and $\perp$, otherwise. It is worth highlighting that we may need n calls to an NP oracle to simulate a query to a SAT oracle, and therefore, it is conceivable for an algorithm to make $O(\log n)$ calls to a SAT oracle but $O(n \log n)$ calls to an NP oracle. Delannoy and Meel showcased precisely such behavior in the context of *almost-uniform generation*. Their proposed algorithm, UniSamp makes $O(\log n)$ calls to a SAT oracle and would require $O(n \log n)$ calls to an NP oracle if one were to replace a SAT oracle with an NP oracle. At the same time, it is not necessary that there would be a gap of n calls for every algorithm: simply consider the problem of determining whether a formula is satisfiable or not. Only one call to an NP oracle (and similarly to a SAT oracle) suffices.

Furthermore, the notion of the SAT oracle has the potential to be a powerful tool to explain the behavior of algorithms, as highlighted by Delannoy and Meel. Given access to an NP oracle, the sampling algorithm due to Jerrum, Valiant, and Vazirani [11] (referred to as JVV algorithm) makes $O(n^2 \log n)$ calls to an NP oracle as well as a SAT oracle, i.e., there are no savings from the availability of a SAT oracle. On the other hand, the algorithm, UniSamp makes $O(\log n)$ and $O(n \log n)$ calls to SAT and an NP oracle respectively. Therefore, the NP oracle model would indicate that one should expect the performance gap between JVV and UniSamp to be linear, while the SAT oracle model indicates an exponential gap. The practical implementations of JVV and UniSamp indeed indicate the performance gap between them to be exponential rather than linear. Therefore, analyzing problems under the SAT oracle model has the promise to have wide-ranging consequences.

In this paper, we analyze the complexity of the problem of approximate model counting given access to a SAT oracle. Our study is motivated by two observations:

O1 The modern state-of-the-art hashing-based techniques differ significantly from Stockmeyer's algorithmic procedure and, in particular, exploit the availability of SAT solvers. Yet, they make $O(\log n)$ calls to a SAT oracle, which coincides with the number of NP oracle calls in Stockmeyer's algorithmic procedure.

O2 Stockmeyer provided a matching lower bound of $\Omega(\log n)$ on the number of NP calls, which follows from the simple observation that for a fixed ε, there are $\Theta(n)$ possible outputs that an algorithm can return. Since every NP call returns an answer, Yes or No, the trace of an algorithm can be viewed as a binary tree such that every leaf represents a possible output value. Therefore, the height of the tree (i.e., the number of NP calls) must be $\Omega(\log n)$. Since a SAT oracle returns a satisfying assignment (i.e., provides n bits of information), the trace of the algorithm is no longer a binary tree, and therefore, Stockmeyer's analysis does not extend to the case of SAT oracles for approximate model counting.

To summarize, the best-known upper bound for SAT oracle calls for approximate model counting is $O(\log n)$, which matches the upper bound for NP oracle calls. However, the technique developed in the context of achieving a lower bound for NP oracle calls does not apply to the case of SAT oracle. Therefore, one wonders whether there exist algorithms with a lower number of SAT oracle calls. In other words, are SAT oracles more powerful than NP oracles for the problem of approximate model counting?

The primary contribution of this work is to resolve the above challenge. In contrast to the problem of uniform sampling, we reach a starkly different conclusion: SAT oracles are no more powerful than NP oracles in the context of approximate model counting. Formally, we prove the following theorem:

▶ **Theorem 1.1.** *For any $\epsilon, \delta \in (0,1)$, given a formula ϕ, computation of (ε, δ)-approximation of $|\mathsf{sol}(\phi)|$ requires $\tilde{\Omega}(\log n)$[1] queries to a SAT oracle.*

The establishment of the above theorem turned out to be highly challenging as the existing approaches in the context of NP oracles are not applicable to the SAT oracles. We provide an overview of our approach below.

1.1 Technical Overview

In order to provide the lower bound on the number of queries required by the SAT oracle, we work with a stronger SAT oracle model. In particular, an answer from a (standard) SAT oracle does not provide any extra guarantee/information other than that the returned assignment is a satisfying assignment of the queried formula. Our lower bound works even if we consider that the returned satisfying assignment is chosen randomly from the set of satisfying assignments. More specifically, we consider a stronger model, namely SAT-Sample *oracle*, which returns a uniformly chosen solution of a queried formula ϕ whenever the formula is satisfiable. It is worth remarking that while a SAT oracle can be simulated by only n queries to an NP oracle, the best-known technique to simulate SAT-Sample makes $O(n^2 \log n)$ queries to an NP oracle [2, 7]. We prove the following theorem which implies Theorem 1.1.

▶ **Theorem 1.2.** *For any $\epsilon < 1/2$ and any $\delta \leq 1/6$, given a formula ϕ, computation of (ε, δ)-approximation of $|\mathsf{sol}(\phi)|$ requires $\tilde{\Omega}(\log n)$ queries to a* SAT-Sample *oracle.*

Although we consider $\epsilon < 1/2$ and $\delta \leq 1/6$ in the above theorem and provide the proof accordingly, our proof works even for any constant $\epsilon, \delta \in (0,1)$. Another thing to remark is that in our proof, we allow even exponential (in the size of the original formula) size formula to be queried in the SAT-Sample oracle, making our result stronger than what is claimed in the above theorem.

Let us assume that Alg is an algorithm that (ϵ, δ)-approximates $|\mathsf{sol}(\phi)|$ for any given input ϕ (on n variables) by making q queries to a SAT-Sample oracle. We will refer to such an algorithm as a SAT-Sample counter. We would like to prove a lower bound on q.

The main technical difficulty in proving our lower bound results comes from the enormous power of a SAT-Sample oracle compared to an NP oracle. An NP oracle can only provide a YES or NO answer, restricting the number of possible answers (from the NP oracle) to 2^q for a q-query counter with an NP oracle. On the other hand, since a SAT-Sample oracle returns a (random) satisfying assignment (if a satisfying assignment exists), the number of possible answers can be 2^{nq}. Further, any counter can be adaptive – it can choose the next query adaptively based on the previous queries made and their corresponding answers. In general, proving a non-trivial (tight) lower bound for any adaptive algorithm turns out to be one of the notorious challenges, and the difficulty in proving such a lower bound arises in other domains like data structure lower bound, property testing, etc. One of the natural ways to prove any lower bound is to use the information-theoretic technique. However, one of the main challenges in applying such techniques in the adaptive setting is that conditional mutual information terms often involve complicated conditional distributions that are difficult to analyze.

To start with, we argue that we can assume that the SAT-Sample counter is "semi-oblivious" in nature. The number of satisfying assignments of a formula does not change by any permutation of the elements in $\{T, F\}^n$, and the SAT-Sample counter can only get

[1] The tilde hides a factor of $\log \log n$.

elements of $\mathsf{sol}(\phi)$ by querying the SAT-Sample oracle. So we argue that the only useful information of the i^{th} query set (that is, the set of satisfying assignments of the formula that is given to the SAT-Sample oracle) is the size of its intersection with the previous $(i-1)$ query sets and their corresponding answers. We formalize it in Section 3.1.

We next use Yao's minimax principle to prove a lower bound on the number of queries to a SAT-Sample oracle made by a deterministic "Semi-oblivious counter" when the input formula ϕ is drawn from a "hard" distribution.

For the hard distribution, we construct $O(n^{3/4})$ formulas ϕ_ℓ for each value of ℓ in the set $\{\lfloor n^{1/4} \rfloor, \lfloor n^{1/4} \rfloor + 1, \ldots, \lceil n^{3/4} \rceil\}$. The formulas ϕ_ℓ are chosen in such a way that $|\mathsf{sol}(\phi_\ell)| \approx 2|\mathsf{sol}(\phi_{\ell+1})|$ thereby approximately counting the number of satisfying assignments (upto a multiplicative $(1+\epsilon)$-factor for small constant ϵ) reduces to the problem of determining the value of ℓ. The hard distribution is obtained by picking an ℓ uniformly at random from the set $\{\lfloor n^{1/4} \rfloor, \lfloor n^{1/4} \rfloor + 1, \ldots, \lceil n^{3/4} \rceil\}$ and using the corresponding formula ϕ_ℓ.

Finally, we show the lower bound using information theory. At a high level, we show that the information gained about ℓ by the knowledge of obtained samples is small unless we make $\tilde{\Omega}(\log n)$ oracle calls (Lemma 9). Then we turn to Fano's Inequality (Theorem 3) which links the error probability of a counter to the total information gain. Showing that the information gained by samples is small boils down to showing that the KL-divergence of the conditional distribution over the samples is small for all formulas ϕ_ℓ (shown in the proof of the third part of Lemma 9). The difficulty in showing the above bound comes from the fact that the samples are adaptive and may not always be concentrated around the expectation. To overcome the above challenge, we first define an indicator random variable Y_i to denote whether, at the i^{th} query, the concentration holds (see the definition in Equation 10). Then we split it into cases: In the first case, we argue for the situation when concentration may not hold at some step of the algorithm (if $Y_i = 1$ for some $i \in [q]$). The second case is when concentration holds (if $Y_i = 0$ for all $i \in [q]$). We believe that the technique developed in this paper can be a general tool to show sampling lower bounds in a number of other settings.

2 Notations and Preliminaries

For any integer m, let $[m]$ denote the set of integers $\{1, 2, \ldots, m\}$. For a formula ϕ over variable set $\mathsf{vars}(\phi) = \{v_1, \ldots, v_n\}$, we denote by $\mathsf{sol}(\phi)$ the set of satisfying assignments of ϕ. If ϕ is not satisfiable then $\mathsf{sol}(\phi) = \emptyset$. We can interpret $\mathsf{sol}(\phi)$ as a subset of $\{T, F\}^n$. On the other hand, for any subset $A \subset \{T, F\}^n$ we denote by ψ_A the formula whose set of satisfying assignments is exactly A; that is, $\mathsf{sol}(\psi_A) = A$.

Oracles and query model

In our context of Boolean formulas, an *NP oracle* takes in a Boolean formula ϕ as input and returns Yes if ϕ is satisfiable (i.e., $\mathsf{sol}(\phi) \neq \emptyset$), and No, otherwise. Modern SAT solvers, besides determining whether a given formula is satisfiable or not, also return a satisfying assignment (arbitrarily) if the formula is satisfiable. This naturally motivates us to consider an oracle, namely SAT-Sample *oracle*, that takes in a Boolean formula ϕ as input and, if ϕ is satisfiable, returns a satisfying assignment uniformly at random from the set $\mathsf{sol}(\phi)$, and $\perp$, otherwise.

We rely on the query model introduced by Stockmeyer [16]: For a given ϕ whose model count we are interested in estimating, one can query the corresponding (NP/SAT) oracle with formulas of the form $\phi \wedge \psi_A$, where, as stated earlier, ψ_A is an (arbitrary) formula whose set of solutions is A. We will use ϕ_A as a shorthand to represent $\phi \wedge \psi_A$. Throughout

this paper, we consider the above query model with query access to the SAT-Sample oracle. One call to the SAT-Sample oracle will be called a SAT-Sample query. By abuse of notation, we sometimes say "A is queried" to refer to the formula ϕ_A.

k-wise independent hash functions

Let n, m, k be positive integers and let $H(n, m, k)$ denote the family of *k-wise independent hash functions* from $\{T, F\}^n$ to $\{T, F\}^m$. For any $\alpha \in \{T, F\}^m$, and $h \in H(n, m, k)$, let $h^{-1}(\alpha)$ denote the set $\{s \in \{T, F\}^n \mid h(s) = \alpha\}$.

It is well-known (e.g., see [5]) that for any integer n, m, k, one can generate an explicit family of k-wise independent hash functions in time and space $poly(n, m, k)$. Moreover, for any $\alpha \in \{T, F\}^m$, $h^{-1}(\alpha)$ (where $h \in H(n, m, k)$) can be specified by a Boolean formula of size $poly(n, m, k)$.

Concentration inequalities for limited independence

▶ **Lemma 1** ([15]). *If X is a sum of k-wise independent random variables, each of which is confined to $[0, 1]$ with $\mu = \mathbb{E}[X]$ then*

1. *For any $\gamma \leq 1$ and $k \geq \gamma^2\mu$, $\Pr[|X - \mu| \geq \gamma\mu] \leq exp(-\gamma^2\mu/3)$.*
2. *For any $\gamma \geq 1$ and $k \geq \gamma\mu$, $\Pr[|X - \mu| \geq \gamma\mu] \leq exp(-\gamma\mu/3)$.*

Basics of information theory

Let X and Y be two random variables over the space $\mathcal{X} \times \mathcal{Y}$. The mutual information $I(X;Y)$ between random variables X and Y is the reduction in the entropy of X given Y and hence

$$I(X;Y) = H(X) - H(X|Y) \leq H(X) \tag{1}$$

where $H(X) = -\sum_{x \in \mathcal{X}} \Pr[X = x] \log \Pr[X = x]$ is the Shannon entropy of X and $H(X|Y)$ is the conditional entropy of X given Y.

The *Kullback–Leibler divergence* or simply *KL divergence* (also called relative entropy) between two discrete probability distributions P and Q defined on same probability space $\mathcal{X}$ is given by :

$$KL(P||Q) := \sum_{x \in \mathcal{X}} p(x) \log \frac{p(x)}{q(x)}$$

where p and q are probability mass functions of P and Q respectively.

If the joint distribution of X and Y is $Q_{X,Y}$ and marginal distributions Q_X and Q_Y respectively, then the mutual information $I(X;Y)$ can also be equivalently defined as:

$$I(X;Y) := KL(Q_{X,Y}||Q_X \times Q_Y).$$

For three random variables X, Y, Z, the *conditional mutual information* $I(X;Y|Z)$ is defined as

$$I(X;Y|Z) := \mathbb{E}_Z[KL(Q_{(X,Y)|Z}||Q_{X|Z} \times Q_{Y|Z})].$$

For any three random variables X, Y, Z, the *chain rule* for mutual information says that

$$I(X;(Y,Z)) = I(X;Y) + I(X;Z|Y).$$

If Z is a discrete random variable taking values in $\mathcal{Z}$ then we have

$$\mathbb{E}_Z[KL(Q_{(X,Y)|Z}||Q_{X|Z} \times Q_{Y|Z})] = \sum_{z\in\mathcal{Z}} Q_Z(z) \cdot KL(Q_{(X,Y)|Z=z}||Q_{X|Z=z} \times Q_{Y|Z=z})$$

$$= \sum_{z\in\mathcal{Z}} Q_Z(z) \cdot I(X;Y|Z=z).$$

▶ **Lemma 2** ([14]). *Let $P_X, P_Z, P_{Z|X}$ be the marginal distributions corresponding to a pair (X,Z), where X is discrete. For any auxiliary distribution Q_Z, we have*

$$I(X,Z) = \sum_x P_X(x) KL(P_{Z|X}(\cdot|x)||P_Z) \leq \max_x KL(P_{Z|X}(\cdot|x)||Q_Z).$$

▶ **Theorem 3** (Fano's inequality). *Consider discrete random variables X and $\hat{X}$ both taking values in $\mathcal{V}$. Then*

$$\Pr[\hat{X} \neq X] \geq 1 - \frac{I(X;\hat{X}) + \log 2}{\log|\mathcal{V}|}.$$

Consider the random variables $X, Z, \hat{X}$. If the random variable $\hat{X}$ depends only on Z and is conditionally independent on X, then we have

$$I(X;\hat{X}) \leq I(X;Z). \tag{2}$$

This inequality is known as the *data processing inequality*. For the further exposition, readers may refer to any standard textbook on information theory (e.g., [6]).

MiniMax theorem

Yao's minimax principle [18] is a standard tool to show lower bounds on the worst-case performance of randomized algorithms. Roughly speaking, it says that to show a lower bound on the performance of a randomized algorithm R, it is sufficient to show a lower bound on any deterministic algorithm when the instance is randomly drawn from some distribution.

Consider a problem over a set of inputs $\mathcal{X}$. Let Γ be some probability distribution over $\mathcal{X}$ and let $X \in \mathcal{X}$ be an input chosen as per Γ. Any randomized algorithm R is essentially a probability distribution over the set of deterministic algorithms, say $\mathcal{T}$. By Yao's minimax principle,

$$\max_{X\in\mathcal{X}} \Pr[R \text{ gives wrong answer on } X] \geq \min_{T\in\mathcal{T}} \Pr_{X\sim\Gamma}[T \text{ gives wrong answer on } X].$$

3 Lower Bound on the number of queries to SAT-Sample oracle

In this section, we will prove Theorem 1.2, which implies Theorem 1.1. Let Alg be an adaptive randomized algorithm that given as input ϕ over n variables $\mathsf{vars} = \{v_1, \ldots, v_n\}$ and output Est that is an (ϵ,δ)-approximation of $\mathsf{sol}(\phi)$. The only way Alg accesses the input ϕ is by making queries to the SAT-Sample oracle, that is, obtaining random satisfying assignments from $\mathsf{sol}(\phi_A)$, where $\phi_A = \phi \wedge \psi_A$. We will prove that Alg has to make at least $\tilde{\Omega}(\log n)$ such queries to the SAT-Sample oracle.

We will start by arguing that we can assume that the adaptive algorithm Alg has some more structure. In particular, in Section 3.1 we will argue (in the same lines as in [3]) that we can assume Alg is a *semi-oblivious counter* (Definition 4).

We use Yao's Min-max technique to argue that obtaining a lower bound on a (randomized) semi-oblivious counter is the same as obtaining a lower bound on a (deterministic) semi-oblivious counter when the input is drawn from the worst possible distribution over the set of formulas on n variables. In Section 3.2 we present the "hard" distribution that would help us prove the lower bound against any deterministic semi-oblivious counter. In Section 3.2.1 we present some properties of the hard instance that would be used for the final lower bound proof.

Finally in Section 3.3 we will use an information-theoretic argument to give a lower bound on the query complexity of any deterministic semi-oblivious counter and hence prove Theorem 1.2.

A note on the use of auxiliary variables in the queries to the SAT-Sample oracle

One thing we observe is that our lower bound proof does not assume that in the input formula ϕ all the variables are influential. In other words, we can assume that ϕ is on n variables, the actual number of variables in ϕ may be significantly less. All we need for our lower bound proofs to go through is that the queries to the SAT-Sample oracle made by the algorithm are to $\phi \wedge \psi_A$ where the ψ is a formula over n variables. And the lower bound on the query complexity that we prove (Theorem 1.2) is $\tilde{O}(\log n)$. Hence, as long as the number of variables used in the queries to the SAT-Sample oracle is at most polynomial in the actual number of variables in the input formula ϕ, our lower bound holds.

3.1 Semi-oblivious counter

Suppose given a formula ϕ over n variables, a counter Alg makes q calls to the SAT-Sample oracle with queried formulas $\phi_{A_1}, \cdots, \phi_{A_q}$ respectively, where each $A_i \subseteq \{T,F\}^n$. (Recall, $\phi_{A_i} = \phi \wedge \psi_{A_i}$, where ψ_{A_i} denote the formula having $\mathsf{sol}(\psi_{A_i}) = A_i$.) Note, the i-th SAT-Sample oracle call by the counter Alg is specified by the set A_i. During the i-th call (for $1 \leq i \leq q$), suppose the counter Alg receives a sample $s_i \in A_i \cup \{\perp\}$. Note that the oracle calls made by Alg can be *adaptive*, i.e., the sets $A_1, \cdots, A_q$ are not fixed in advance – the counter Alg fixes A_i only after seeing the samples $s_1, \cdots, s_{i-1}$ (outcomes of all the previous oracle calls).

We now define a special type of randomized SAT-Sample counter, referred to as *semi-oblivious counter*, which at any point of time queries the SAT-Sample oracle only by looking into the configuration of the previous step. We will later argue that to prove a query lower bound for general SAT-Sample counters, it suffices to consider semi-oblivious counters. In other words, semi-oblivious counters are as "powerful" as general SAT-Sample counters.

We first provide intuition for *semi-oblivious counter*. Note that permuting the variables of any formula ϕ permutes the set of satisfying assignments $\mathsf{sol}(\phi)$ but $|\mathsf{sol}(\phi)|$ is unchanged. Since a SAT-Sample counter needs to determine $|\mathsf{sol}(\phi)|$ only (not $\mathsf{sol}(\phi)$), the final output by the SAT-Sample counter, in some sense, should be based only on the relations between the samples and the query sets (not on their actual values). Before providing a formal definition, let us first introduce some terminology.

Given a family of sets $\mathcal{A} = \{A_1, \cdots, A_i\}$, (where $A_i \subseteq \{T,F\}^n$), the *atoms* generated by $\mathcal{A}$, denoted by $\mathsf{At}(\mathcal{A})$, are (at most) 2^i distinct sets of the form $\cap_{j=1}^{i} C_j$ where $C_j \in \{A_j, \{T,F\}^n \setminus A_j\}$. For example, if $i = 2$, then $\mathsf{At}(A_1, A_2) = \{A_1 \cap A_2, A_1 \setminus A_2, A_2 \setminus A_1, (A_1 \cup A_2)^c\}$.

▶ **Definition 4** (Semi-oblivious counter). *A semi-oblivious counter is a randomized algorithm T that, given any formula ϕ, at any step i, works in the following three phases:*

- ***Semi-oblivious choice:*** *Let $\mathcal{A}_{i-1} = \{A_1, \cdots, A_{i-1}\}$, $S_{i-1} = \{s_1, \cdots, s_{i-1}\}$, $C_{i-1} = \{c_1, \cdots, c_{i-1}\}$ be the set of first $i-1$ query sets, the set of first $i-1$ samples obtained, the set of first $i-1$ configurations, respectively. Only based on C_{i-1} (without knowing the set S_{i-1}), T does the following:*
  - *For each $A \in \mathsf{At}(\mathcal{A}_{i-1})$, it generates an integer k_i^A between 0 and $|A \setminus S_{i-1}|$. (k_i^A indicates how many unseen elements from the atom A of the previous query sets are to be included in the next query set.)*
  - *It chooses a set of indices $K_i \subseteq \{1, \cdots, i-1\}$. ($K_i$ specifies the index set of previous samples that are to be included in the next query set.)*
- ***Query set generation:*** *In this phase, it decides the query set A_i as follows:*
  - *Let us define the* candidate unseen set family *as*

$$\mathcal{U}_i := \{U \subseteq \{T,F\}^n \setminus S_{i-1} \mid \forall A \in \mathsf{At}(\mathcal{A}_{i-1}), |U_i \cap A| = k_i^A\}.$$

    The algorithm T chooses a set U_i uniformly at random from the candidate unseen set family $\mathcal{U}_{i-1}$.
  - *Let us denote $O_i := \{s_j \mid j \in K_i\}$. The algorithm T decides the query set to be $A_i = U_i \cup O_i$.*
- ***Oracle call:*** *It places a query to the* SAT-Sample *oracle with the formula ϕ_{A_i}. Let the i-th* configuration *c_i specify whether $s_i = \perp$, or for which $j \in K_i$, $s_i = s_j$, or for which $A \in \mathsf{At}(\mathcal{A}_{i-1})$, $s_i \in A \cap U_i$.*

In the end (after placing $q = q(n)$ SAT-Sample *oracle calls), depending on the set of all the configurations C_q, T outputs an estimate on the $|\mathsf{sol}(\phi)|$.*

From now on, for brevity, we use $\mathsf{At}(U_i)$ to denote the set $\{U_i \cap A \mid A \in \mathsf{At}(\mathcal{A}_{i-1})\}$. Next, we show that if there exists a general SAT-Sample counter, then there also exists a semi-oblivious counter. The proof is inspired by the argument used in [3] and is given in Appendix A.

▶ **Lemma 5.** *If there is an algorithm that, given any input ϕ on n variables, outputs an (ϵ, δ)-approximation of $|\mathsf{sol}(\phi)|$ while placing at most $q = q(n)$* SAT-Sample *oracle calls, then there also exists a (randomized) semi-oblivious counter that, given input ϕ, outputs an (ϵ, δ)-approximation of $|\mathsf{sol}(\phi)|$ while also placing at most q* SAT-Sample *oracle calls.*

Suppose all the internal randomness of a semi-oblivious counter is fixed. (Since in the proof of Theorem 1.1, we will first apply Yao's minimax principle, it suffices to only consider deterministic decision trees.) Then, a semi-oblivious counter T can be fully described by a decision tree R where the path from the root to any node v at depth i (more precisely, the edges of this path) corresponds to the configuration of the first $i-1$ samples. Note that fixing the configurations of the samples till $i-1$ queries (and the internal randomness) fixes the size of an atom $A \in At(A_1, \cdots, A_i)$ (and hence of each A_j for $j \leq i$). Formally,

(i) A path (from root) to any node v at depth i is associated with a sequence of query sets $\mathcal{A}_{i-1} = (A_1, \cdots, A_{i-1})$ such that the sizes of all atoms $A \in \mathsf{At}(\mathcal{A}_{i-1})$ are fixed.

(ii) The node v is labeled by a vector $\boldsymbol{k}_v = (k_i^A)_{A \in \mathsf{At}(\mathcal{A}_{i-1})}$ and a set $K_v \subseteq [i-1]$ which are used to determine the next query set $A_i = O_i \cup U_i$. (Again, $|U_i| = \sum_{A \in \mathsf{At}(\mathcal{A}_{i-1})} k_i^A$ and the set U_i is fixed.) A_i is used to place the next SAT-Sample oracle call.

(iii) For every possible value of the configuration at step i, there is a corresponding child of the node v, with the corresponding edge labeled by the value of the configuration.

For any node v, we use $A_v = O_v \cup U_v$ to denote the (random) query set (corresponding to the node v) determined by the $\boldsymbol{k}_v$ and K_v. Note that $|U_v| = \sum_{A \in \mathsf{At}(\mathcal{A}_{i-1})} k_i^A$. Further, we use $\mathcal{A}_v := (A_1, \cdots, A_v)$ for the sequence of query sets corresponding to a path to v and node v. Observe the number of possible outcomes of the counter T at any step i is at most $i + 2^i + 1 \leq 2^{q+1}$ (since $i \leq q$). So the total number of nodes in the decision tree corresponding to the semi-oblivious counter T is at most $2^{O(q^2)}$.

3.2 Hard instance

We will provide a set of inputs $\mathcal{X}$ (which, in our case, will be a set of formulas) and a distribution Γ over $\mathcal{X}$. Then we will show that any deterministic semi-oblivious counter D (note that D knows $\mathcal{X}$ and Γ) which receives as input a formula $\phi \in \mathcal{X}$ randomly drawn as per distribution Γ and returns an (ϵ, δ)-approximation of $\mathsf{sol}(\phi)$, must make $\tilde{\Omega}(\log n)$ queries to the SAT-oracle.

Let $k = (\log n)^9$. Let $\mathcal{X}$ be the set of all formulas (with n variables). We now define the hard distribution Γ over $\mathcal{X}$ as follows by describing the procedure of picking a formula in $\mathcal{X}$ according to Γ.

1. Pick $\ell \in \{\lfloor n^{1/4} \rfloor, \lfloor n^{1/4} \rfloor + 1, \ldots, \lceil n^{3/4} \rceil\}$ uniformly at random.
2. Draw a hash function $h_\ell \leftarrow H(n, \ell, k)$ uniformly at random.
3. Let ϕ_ℓ be the formula whose set of satisfying assignments is $h_\ell^{-1}(F^\ell)$. (Recall, $h_\ell : \{T, F\}^n \to \{T, F\}^\ell$.)
4. The formula ϕ_ℓ is the picked formula.

3.2.1 Properties of the hard instance

Let $f_\ell := \mathbb{E}[|\mathsf{sol}(\phi_\ell)|] = \mathbb{E}[|h_\ell^{-1}(F^\ell)|]$ for $\ell \in \{\lfloor n^{1/4} \rfloor, \lfloor n^{1/4} \rfloor + 1, \ldots, \lceil n^{3/4} \rceil\}$. Observe, it follows from the construction of ϕ_ℓ and the properties of hash functions that $f_\ell = \frac{2^n}{2^\ell}$.

▶ **Lemma 6.** *With probability at least $1 - n2^{-n/20}$, we have*

$$\text{for all } \ell,\ ||\mathsf{sol}(\phi_\ell])| - f_\ell| \leq 2^{-n/10} f_\ell. \tag{3}$$

Proof. It is straightforward to see that the variance of $|\mathsf{sol}(\phi_\ell)|$ is $Var[|\mathsf{sol}(\phi_\ell)|] \leq f_\ell$. So by Chebyshev's inequality,

$$\Pr\left[||\mathsf{sol}(\phi_\ell)| - f_\ell| \geq 2^{-n/5} f_\ell\right] \leq \frac{2^{n/5}}{f_\ell} \leq \frac{2^{n/5} \cdot 2^\ell}{2^n} \leq 2^{-n/20}.$$

The lemma now follows from a union bound over all ℓ. ◀

▶ **Definition 7.** *Once $\ell \in \{\lfloor n^{1/4} \rfloor, \lfloor n^{1/4} \rfloor + 1, \ldots, \lceil n^{3/4} \rceil\}$ has been picked in Step 1 of the construction of the hard instance (Section 3.2), let for any $S \subseteq \{T, F\}^n$*

$$\mathsf{N}_\ell(S) = \mathbb{E}\left[|\mathsf{sol}(\phi_\ell) \cap S|\right],$$

where the expectation is over the choice of the hash function is Step 2 of the construction of the hard instance.

Note that for any $S \subseteq \{T, F\}^n$ the value of $\mathsf{N}_\ell(S)$ is $|S|/2^\ell$.

▶ **Lemma 8.** *With probability at least $1 - \frac{2^{O(q^2)}}{n^{(\log n)^4}}$, the following holds:*
For any node v in the decision tree R and any atom $A \in \mathsf{At}(U_v)$,

1. *If $\mathsf{N}_\ell(U_v) < \frac{1}{n^{(\log n)^4}}$ then $|U_v \cap \mathsf{sol}(\phi_\ell)| = 0$. Similarly, if $\mathsf{N}_\ell(A) < \frac{1}{n^{(\log n)^4}}$ for any atom $A \in \mathsf{At}(U_v)$ then $|A \cap \mathsf{sol}(\phi_\ell)| = 0$*

2. *If* $\mathsf{N}_\ell(U_v) \geq (\log n)^5$ *then* $\frac{1}{2}\mathsf{N}_\ell(U_v) \leq |U_v \cap \mathsf{sol}(\phi_\ell)| \leq \frac{3}{2}\mathsf{N}_\ell(U_v)$. *Similarly, if* $\mathsf{N}_\ell(A) \geq (\log n)^5$ *then* $\frac{1}{2}\mathsf{N}_\ell(A) \leq |A \cap \mathsf{sol}(\phi_\ell)| \leq \frac{3}{2}\mathsf{N}_\ell(A)$
3. *If* $\mathsf{N}_\ell(U_v) \leq (\log n)^5$ *then* $|U_v \cap \mathsf{sol}(\phi_\ell)| \leq 2(\log n)^5$. *Similarly, if* $\mathsf{N}_\ell(A) \leq (\log n)^5$ *then* $|A \cap \mathsf{sol}(\phi_\ell)| \leq 2(\log n)^5$.

Proof. From Markov's inequality, we have

$$\Pr[|U_v \cap \mathsf{sol}(\phi_\ell)| \geq 1] \leq \Pr\left[|U_v \cap \mathsf{sol}(\phi_\ell)| \geq \left(\frac{1}{\mathsf{N}_\ell(U_v)} - 1\right)\mathsf{N}_\ell(U_v)\right] \leq 2\mathsf{N}_\ell(U_v)$$

Taking a union bound over all nodes v with $\mathsf{N}_\ell(U_v) < \frac{1}{n^{(\log n)^4}}$ and all possible values of ℓ (which can take $O(n^{3/4})$ values), we get the first part.

From the first part of the Lemma 1, by setting $\gamma = 1/2$, we have

$$\Pr[|U_v \cap \mathsf{sol}(\phi_\ell)| \geq \mathsf{N}_\ell(U_v)] \leq \exp\left(-\frac{\mathsf{N}_\ell(U_v)}{12}\right)$$

for all nodes v in R such that $\mathsf{N}_\ell(U_v) \geq (\log n)^5$ (note that we have $k = (\log n)^9 > \gamma^2\mathsf{N}_\ell(U_v)$). Taking a union bound over all such nodes v and all possible values of ℓ, we get the second bound.

Let $\gamma_v = \frac{(\log n)^5}{\mathsf{N}_\ell(U_v)}$. Since $k = (\log n)^9 > \gamma_v\mathsf{N}_\ell(U_v)$, from the second part of Lemma 1, we have

$$\Pr[|U_v \cap \mathsf{sol}(\phi_\ell)| \geq \gamma_v\mathsf{N}_\ell(U_v)] \leq \exp\left(-\gamma_v\frac{\mathsf{N}_\ell(U_v)}{3}\right) \leq O\left(\frac{1}{n^{(\log n)^4}}\right).$$

for all nodes v such that $\mathsf{N}_\ell(U_v) \leq (\log n)^5$. Taking a union bound over all such nodes v and all possible values of ℓ, we get the third part. ◀

3.3 Proof of Theorem 1.2

Proof of Theorem 1.2. By Lemma 5 and Yao's minmax theorem we can assume that our SAT-Sample counter Alg is a (deterministic) semi-oblivious counter whose input is a randomly chosen formula $\phi \in \phi_n$, as per distribution Γ and Alg returns Est which is an $(\epsilon, 2/3)$-approximation of $|\mathsf{sol}(\phi)|$. We will prove that Alg must make $q = \tilde{\Omega}(\log n)$ many SAT-oracle calls.

Recall the distribution Γ (Section 3.2) over the set of all formulas. We can assume that the input to Alg is ϕ_ℓ, where ℓ is uniformly drawn from the set $\{\lfloor n^{1/4}\rfloor, \lfloor n^{1/4}\rfloor + 1, \ldots, \lceil n^{3/4}\rceil\}$.

Consider the path taken by the semi-oblivious counter Alg in the decision tree. Let the ith query made by Alg (that is at vertex v_i) be $A_i = U_i \cup O_i$ (as in Definition 4). Let Z_i be the configuration (denoted as c_i in Definition 4) of the sample from A_i. Note that the domain of Z_i is $\Omega_i := O_i \cup \mathsf{At}(U_i) \cup \perp$.

Let Good be the event that the condition in Equation 3 (in Lemma 6) and the condition in Lemma 8 holds. Note that by Lemma 6 and Lemma 8 if $q \leq \log n$ then

$$\Pr[\mathsf{Good}] = 1 - o(1). \tag{4}$$

Let X be the random variable that takes values in $\{\lfloor n^{1/4}\rfloor, \lfloor n^{1/4}\rfloor + 1, \ldots, \lceil n^{3/4}\rceil\}$ uniformly at random (in Step 1 of the construction of hard instance). Note that by the triangle inequality

$$|\mathsf{Est} - |\mathsf{sol}(\phi_\ell)|| \geq \left|\mathsf{Est} - \frac{2^n}{2^\ell}\right| - \left|\frac{2^n}{2^\ell} - |\mathsf{sol}(\phi_\ell)|\right|. \tag{5}$$

By Lemma 6 we know that with probability at least $(1 - 1/6)$, we have $|\frac{2^n}{2^\ell} - |\mathsf{sol}(\phi_\ell)|| \leq \frac{1}{2^{n/10}} \cdot \frac{2^n}{2^\ell}$. On the other hand, since Alg outputs an (ϵ, δ)-approximation of $|\mathsf{sol}(\phi)|$ (with $\epsilon < 1/2$ and $\delta < 1/6$), Equation 5 implies that with probability at least $(1 - \frac{1}{6} - \delta) \geq \frac{2}{3}$ we have

$$\left|\mathsf{Est} - \frac{2^n}{2^\ell}\right| \leq \left(\epsilon + \frac{1}{2^{n/10}}\right)\frac{2^n}{2^\ell} \leq \frac{1}{2} \cdot \frac{2^n}{2^\ell}, \tag{6}$$

where the last inequality follows from the fact that $\epsilon \leq 1/3$. Since $|\frac{2^n}{2^\ell} - \frac{2^n}{2^{\ell'}}| > \frac{1}{2} \cdot \frac{2^n}{2^\ell}$ for any integer $\ell' \neq \ell$, so Equation 6 is satisfied only when $\hat{X}$ is same as the picked ℓ (that is $\hat{X} = X$) where,

$$\hat{X} = \underset{\ell \in \{\lfloor n^{1/4} \rfloor, \lfloor n^{1/4} \rfloor + 1, \ldots, \lceil n^{3/4} \rceil\}}{\arg\min} \left|\frac{2^n}{2^\ell} - \mathsf{Est}\right|.$$

Hence, assuming Good

$$\frac{1}{3} \geq \Pr[\hat{X} \neq X]. \tag{7}$$

By Fano's Inequality (Theorem 3)

$$\Pr[\hat{X} \neq X] \geq 1 - \frac{I(X; \hat{X})}{O(\log n)} \tag{8}$$

Since the final outcome of the algorithm is determined by the outcome at each step, i.e., $\boldsymbol{Z} = (Z_1, \ldots, Z_q)$, so by the data processing inequality (Equation 2), we have

$$I(X; \hat{X}) \leq I(X; Z_1, \ldots, z_q). \tag{9}$$

Let Y_i be the random variable that defined as

$$Y_i = \begin{cases} 1 & \text{if } \frac{1}{n^{(\log n)^4}} \leq \mathsf{N}_\ell(U_i) \leq n^{(\log n)^4} \\ 0 & \text{otherwise} \end{cases} \tag{10}$$

Again by the data-processing inequality (Equation 2), we have

$$I(X; Z_1, \ldots, Z_q) \leq I(X; Y_1, Z_1, \ldots, Y_q, Z_q). \tag{11}$$

By the chain rule of mutual information, we have

$$I(X; Y_1, Z_1, \ldots, Y_q, Z_q) = \sum_{i \in [q]} I(X; Y_i, Z_i | Y_1, Z_1, \ldots, Y_{i-1}, Z_{i-1}) \tag{12}$$

Finally, we will show, in the following lemma, that conditioned on the fact Good happens we can upper bound $I(X; Y_1, Z_1, \ldots, Y_q, Z_q)$ by $O(\log \log n)$.

▶ **Lemma 9.** $I(X; (Y_1, Z_1, \ldots, Y_q, Z_q)) \leq q(O(\log \log n) + O(\log q) + \frac{2^{2q} poly(\log n)}{n^{(\log n)^3}})$.

We defer the proof of Lemma 9 and complete the proof of Theorem 1.2 assuming Lemma 9.

From the Equations 7, 8, 9, 11 and Lemma 9, we have that assuming Good happens

$$\begin{aligned}
\frac{1}{3} \geq & \Pr[\hat{X} \neq X] && \text{[From Equation 7]}\\
\geq & 1 - \frac{I(X;\hat{X})}{O(\log n)} && \text{[From Equation 8]}\\
\geq & 1 - \frac{I(X;Z_1,\ldots,z_q)}{O(\log n)} && \text{[From Equation 9]}\\
\geq & 1 - \frac{I(X;Y_1,Z_1,\ldots,Y_q,Z_q)}{O(\log n)} && \text{[From Equation 11]}\\
\geq & 1 - \frac{I(X;Y_1,Z_1,\ldots,Y_q,Z_q)}{O(\log n)} && \text{[From Equation 12]}\\
\geq & 1 - \frac{q \log\log n}{\log n} && \text{[From Lemma 9]}
\end{aligned}$$

Thus, from Equation 4, if $q \leq \log n$

$$1 - \frac{q \log\log n}{\log n} \leq \frac{1}{3} + \Pr[\mathsf{Good}] \leq \frac{1}{3} + O(1)$$

which implies

$$q = \Omega\left(\frac{\log n}{\log\log n}\right).$$ ◀

3.3.1 Proof of Lemma 9

▶ **Lemma 10.** *The following holds:*

1. *Conditioned on event that $Y_j = 1$ for some $j \leq i$,*
$$I(X; Z_i | Y_1, Z_1, \ldots, Y_{i-1}, Z_{i-1}, Y_i) \leq O(\log\log n),$$
2. $I(X, Y_i | Y_1, Z_1, \ldots, Y_{i-1}, Z_{i-1}) \leq 1$,
3. *Conditioned on the event that $Y_1 = 0, \ldots, Y_{i-1} = 0$,*
$$I(X, Z_i | Y_1, Z_1, \ldots, Y_{i-1}, Z_{i-1}, Y_i) \leq O(\log q) + \frac{2^{2q} poly(\log n)}{n^{(\log n)^3}}.$$

Proof. We will prove Part 1, 2, and 3 one by one.

Proof of Part 1. We will prove that conditioned on event that $Y_j = 1$ for some $j \leq i$,

$$I(X; Z_i | Y_1, Z_1, \ldots, Y_{i-1}, Z_{i-1}, Y_i) \leq O(\log\log n).$$

From (1), we have

$$I(X, Z_i | Y_1, Z_1, \ldots, Y_{i-1}, Z_{i-1}, Y_i) \leq H(X | Y_1, Z_1, \ldots, Y_{i-1}, Z_{i-1}, Y_i).$$

Note that if $Y_j = 1$ then by definition of Y_j we have $\frac{1}{n^{(\log n)^4}} \leq \frac{|U_j|}{2^\ell} \leq n^{(\log n)^4}$, that is,

$$\frac{|U_j|}{n^{(\log n)^4}} \leq 2^\ell \leq |U_j| n^{(\log n)^4}.$$

Note that by definition of the semi-oblivious counter the sets $|U_1|, \ldots, |U_i|$ are deterministically determined by $Z_1, \ldots, Z_i$. Thus, there are $O(\log(n^{(\log n)^4})) = O((\log n)^5)$ possible values of ℓ and hence

$$H(X | Y_1, Z_1, \ldots, Y_{i-1}, Z_{i-1}) \leq O(\log\log n).$$

This proves the first part.

Proof of Part 2. Since Y_i can take only binary values, we have

$$I(X, Y_i | Y_1, Z_1, \ldots, Y_{i-1}, Z_{i-1}) \leq 1.$$

This proves Part 2.

Proof of Part 3. We will now prove the upper bound on $I(X; (Y_i, Z_i) | Y_1, Z_1, \ldots, Y_{i-1}, Z_{i-1})$ for each $i \in [q]$, conditioned on $Y_j = 0$ for all $j \in [i]$.

Note that $Z_1, \ldots, Z_{i-1}$ fixes the size of O_i and each atoms in $\mathsf{At}(U_i)$. Note that the domain of Z_i, i.e., Ω_i is $\perp \cup O_i \cup \mathsf{At}(U_i)$. Let $r = |O_i| + 2 \leq q + 2$.

We define an auxiliary distribution $Q_{(Y_i,Z_i)}$ as follows:

$$Q_{(Y_i,Z_i)}(y_i, z_i) := Q_{Y_i}(y_i) Q_{Z_i|Y_i}(z_i | y_i)$$

where, $Q_{Y_i}(0) = Q_{Y_i}(1) = 1/2$ and

$$Q_{Z_i|Y_i}(z_i|y_i) = \begin{cases} \frac{1}{r}, & z_i \in O_i \cup \perp \\ \frac{1}{r} \cdot \frac{|z_i|}{|U_i|}, & z_i \in \mathsf{At}(U_i) \end{cases}$$

Let $P_X, P_Z, P_{Z|X}$ be the marginal distributions corresponding to a pair (X, Z). Conditioned on $Y_j = 0$ for all $j \in [i]$ and $Z_j = z_j$ for all $j \in [i-1]$ for any $(z_1, \ldots, z_{i-1}) \in \Omega_1 \times \cdots \times \Omega_{i-1}$, we have for any $\ell \in \mathcal{X}$ (note that, for brevity, we have ignored the conditioning on $Y_1, Z_1, \ldots, Y_{i-1}, Z_{i-1}$, in the expression below)

$$KL(P_{Z_i|X}(\cdot|X = \ell) || Q_{Z_i}) = \sum_{z_i \in \Omega_i} P_{Z_i|X}(z_i|X = \ell) \log \frac{P_{Z|X}(z_i|X = \ell)}{Q_{Z_i}(z_i)} \tag{13}$$

Note that if $z_i \in \perp \cup O_i$ then $Q_{Z_i}(z_i) = \frac{1}{r} \geq \frac{1}{q+2}$. Hence,

$$\frac{P_{Z_i|X}(z_i|X = \ell)}{Q_{Z_i}(z_i)} \leq q + 2 \leq 2q.$$

Now we consider the case when $z_i \in \mathsf{At}(U_i)$.

If $\mathsf{N}_\ell(z_i) \geq (\log n)^5$ then from Lemma 8 we have

$$P_{Z_i|X}(z_i|X = \ell) = \frac{|z_i \cap \mathsf{sol}(\phi_\ell)|}{|U_i \cap \mathsf{sol}(\phi_\ell)|} \leq 3\mathsf{N}_\ell(z_i)/\mathsf{N}_\ell(U_i).$$

Note that

$$Q_{Z_i}(z_i) = \frac{1}{r} \cdot \frac{|z_i|}{|U_i|} \geq 2q\mathsf{N}_\ell(z_i)/\mathsf{N}_\ell(U_i).$$

Therefore, we have

$$\frac{P_{Z_i|X}(z_i|X = \ell)}{Q_{Z_i}(z_i)} \leq O(q).$$

For the case when $\mathsf{N}_\ell(z_i) < \frac{1}{n^{(\log n)^4}}$, we have $|z_i \cap \mathsf{sol}(\phi_\ell)| = 0$. Hence the sum

$$\sum_{z_i} P_{Z_i|X}(z_i|X = \ell) \log \frac{P_{Z|X}(z_i|X = \ell)}{Q_{Z_i}(z_i)}$$

when, $z_i \in \perp \cup O_i$ or $z_i \in \mathsf{At}(U_i)$ such that $\mathsf{N}_\ell(z_i) \geq (\log n)^5$ or $\mathsf{N}_\ell(z_i) < \frac{1}{n^{(\log n)^4}}$, is at most $O(\log q)$.

Now we bound the sum

$$\sum_{z_i} P_{Z_i|X}(z_i|X=\ell)\log\frac{P_{Z|X}(z_i|X=\ell)}{Q_{Z_i}(z_i)}$$

when $z_i \in \mathsf{At}(U_i)$ such that

$$\frac{1}{n^{(\log n)^4}} < \mathsf{N}_\ell(z_i) < (\log n)^5.$$

If $\mathsf{N}_\ell(z_i) \le (\log n)^5$ then we have

$$|z_i \cap \mathsf{sol}(\phi_\ell)| \le 2(\log n)^5$$

and thus

$$P_{Z_i|X}(z_i|X=\ell) \le \frac{4(\log n)^5}{\mathsf{N}_\ell(U_i)}.$$

Note that

$$Q_{Z_i}(z_i) = \frac{1}{r}\cdot\frac{|z_i|}{|U_i|} \ge \frac{1}{2q}\mathsf{N}_\ell(z_i)/\mathsf{N}_\ell(U_i).$$

Hence,

$$\frac{P_{Z|X}(z_i|X=\ell)}{Q_{Z_i}(z_i)} \le O(q(\log n)^5/\mathsf{N}_\ell(z_i)).$$

Therefore, we have

$$\begin{aligned}
&\sum_{z_i:\frac{1}{n^{(\log n)^4}}<\mathsf{N}_\ell(z_i)\le(\log n)^5} P_{Z_i|X}(z_i|X=\ell)\log\frac{P_{Z|X}(z_i|X=\ell)}{Q_{Z_i}(z_i)}\\
&< \sum_{z_i:\frac{1}{n^{(\log n)^4}}<\mathsf{N}_\ell(z_i)\le(\log n)^5} \frac{4(\log n)^5}{\mathsf{N}_\ell(U_i)}\log(2q(\log n)^5/\mathsf{N}_\ell(z_i))\\
&\le 2^q\frac{8(\log n)^5}{n^{(\log n)^4}}\log(2q(\log n)^5 n^{(\log n)^4})\\
&\le \frac{2^{2q}poly(\log n)}{n^{(\log n)^4}}.
\end{aligned}$$

The second last inequality follows because there are at most 2^q possible values of such z_i, $\mathsf{N}_\ell(U_i) \ge n^{(\log n)^3}/2$ and $\mathsf{N}_\ell(z_i) \ge \frac{1}{n^{(\log n)^3}}$.

Now by Lemma 2 conditioned on the event that $Y_j = 0$ for all $j \le i$ we have

$$\begin{aligned}
I(X;Z_i|Y_1,Z_1,\ldots,Y_{i-1},Z_{i-1},Y_i) &\le KL(P_{Z_i|X}(\cdot|X=\ell)||Q_{Z_i})\\
&\le O(\log q) + \frac{2^{2q}poly(\log n)}{n^{(\log n)^3}}.
\end{aligned}$$

◀

Proof of Lemma 9. We will first prove that for any i

$$I(X;(Y_i,Z_i)|Y_1,Z_1,\ldots,Y_{i-1},Z_{i-1}) \le O(\log\log n) + O(\log q) + \frac{2^{2q}poly(\log n)}{n^{(\log n)^3}}.$$

By the chain rule of mutual information,

$$\begin{aligned}
&I(X;(Y_i,Z_i)|Y_1,Z_1,\ldots,Y_{i-1},Z_{i-1})\\
=&I(X;Y_i|Y_1,Z_1,\ldots,Y_{i-1},Z_{i-1})+I(X;Z_i|Y_1,Z_1,\ldots,Y_{i-1},Z_{i-1},Y_i)\\
\leq&O(\log\log n)+O(\log q)+\frac{2^{2q}poly(\log n)}{n^{(\log n)^3}},
\end{aligned}$$

where the last inequality follows from Lemma 10.

Again by the chain rule of mutual information, we have

$$\begin{aligned}
&I(X;(Y_1,Z_1,\ldots,Y_q,Z_q))\\
=&\sum_{i=1}^{q} I(X;(Y_i,Z_i)|Y_1,Z_1,\ldots,Y_{i-1},Z_{i-1})\\
\leq& q(O(\log\log n)+O(\log q)+\frac{2^{2q}poly(\log n)}{n^{(\log n)^3}}).
\end{aligned}$$

◀

4 Conclusion

In this paper, we study the power of SAT oracles in the context of approximate model counting and show a lower bound of $\tilde{\Omega}(\log n)$ on the number of oracle calls. This is in contrast to other settings where a SAT oracle is provably more powerful than an NP oracle. In fact, we prove that even with a much more powerful oracle (namely SAT-Sample oracle), the number of queries needed to approximately count the number of satisfying assignments of a Boolean formula is $\tilde{\Omega}(\log n)$.

A Proof of Lemma 5

Consider any general SAT-Sample counter, T. We will show that there exists a semi-oblivious counter that performs similarly. Given a sequence of query-sample pairs $\{(A_1, s_1), \ldots, (A_{i-1}, s_{i-1})\}$, we say the query A_i is a good strategy by T (given $\{(A_1, s_1), \ldots, (A_{i-1}, s_{i-1})\}$) if the counter T can return the correct output by fixing the next query to A_i. It suffices to show that, given a sequence of query-sample pairs $\{(A_1, s_1), \ldots, (A_{i-1}, s_{i-1})\}$, if A_i is a good strategy then any A'_i is also a good strategy if $A'_i \cap \{s_1, \ldots, s_{i-1}\} = A_i \cap \{s_1, \ldots, s_{i-1}\}$ and $|A'_i \cap A| = |A_i \cap A|$ for atoms $A \in At(A_1, \ldots, A_{i-1})$. This means that to fix the next query, all it requires to fix the intersection size with each atom $A \in At(A_1, \ldots, A_i)$ and a subset of $\{s_1, \ldots, s_{i-1}\}$ (to be included in next query). We prove it in the following claim.

▷ Claim 11. Suppose A_i is a good strategy for $\{(A_1, s_1), \ldots, (A_{i-1}, s_{i-1})\}$. Consider A'_i such that $A'_i \cap \{s_1, \ldots, s_{i-1}\} = A_i \cap \{s_1, \ldots, s_{i-1}\}$ and $|A'_i \cap A| = |A_i \cap A|$ for atoms $A \in At(A_1, \ldots, A_{i-1})$. Then A'_i is also a good strategy for $\{(A_1, s_1), \ldots, (A_{i-1}, s_{i-1})\}$.

Proof. We denote by $\mathcal{S}_N$ the symmetric group acting on a set of size N. Any $\sigma \in \mathcal{S}_N$ can be thought of acting on any set of size N (by thinking the elements of the set as numbered $1, \ldots, N$ and σ acting on the set $[N]$). For any element x in the set, we will denote by $\sigma(x)$ the element after the action of σ. For any $\sigma \in \mathcal{S}_N$ and set A (with $|A| = N$) we denote by $\sigma(A)$ the following set $\sigma(A) := \{\sigma(x) \mid x \in A\}$.

Let $\sigma \in \mathcal{S}_{2^n}$ be a permutation acting on the set $\{T, F\}^n$. For any ϕ observe that $|\mathsf{sol}(\phi)| = |\sigma(\mathsf{sol}(\phi))|$. Since any counter estimates $|\mathsf{sol}(\phi)|$ only, we observe that if A_i is a good strategy for $\{(A_1, s_1), \ldots, (A_{i-1}, s_{i-1})\}$ then $\sigma(A_i)$ is also a good strategy for $\{(\sigma(A_1), \sigma(s_1)), \ldots, (\sigma(A_{i-1}), \sigma(s_{i-1})\}$ for any $\sigma : \{T, F\}^n \to \{T, F\}^n$ that preserves the atoms $\mathsf{At}(A_1, \ldots, A_{i-1})$ and the elements $\{s_1, \ldots, s_{i-1}\}$.

Since $|A'_i \cap A| = |A_i \cap A|$ for atoms $A \in At(A_1, \ldots, A_{i-1})$ and $A'_i \cap \{s_1, \ldots, s_{i-1}\} = A_i \cap \{s_1, \ldots, s_{i-1}\}$, there exists a σ such that $\sigma(A_j) = A_j$, $\sigma(s_j) = s_j$ for all $j \leq i-1$ and also $\sigma(A_i) = A'_i$. By our earlier observation, A'_i is also a good strategy for $\{(A_1, s_1), \ldots, (A_{i-1}, s_{i-1})\}$. ◁

The Identity Problem in $\mathbb{Z} \wr \mathbb{Z}$ Is Decidable

Ruiwen Dong ✉
Department of Computer Science, University of Oxford, UK

Abstract

We consider semigroup algorithmic problems in the wreath product $\mathbb{Z} \wr \mathbb{Z}$. Our paper focuses on two decision problems introduced by Choffrut and Karhumäki (2005): the *Identity Problem* (does a semigroup contain the neutral element?) and the *Group Problem* (is a semigroup a group?) for finitely generated sub-semigroups of $\mathbb{Z} \wr \mathbb{Z}$. We show that both problems are decidable. Our result complements the undecidability of the *Semigroup Membership Problem* (does a semigroup contain a given element?) in $\mathbb{Z} \wr \mathbb{Z}$ shown by Lohrey, Steinberg and Zetzsche (ICALP 2013), and contributes an important step towards solving semigroup algorithmic problems in general metabelian groups.

1 Introduction

The computational theory of groups and semigroups is one of the oldest and most well-developed parts of computational algebra. Dating back to the work of Markov [24] in the 1940s, the area plays an essential role in analysing system dynamics, with notable applications in automata theory and program analysis [5, 9, 11, 16]. See [19] for an all-encompassing survey on this topic. Among the most prominent problems in this area are *Semigroup Membership* and *Group Membership*, proposed respectively by Markov and Mikhailova in the 1940s and 1960s. For these decision problems, we work in a fixed group G. The input is a finite set of elements $\mathcal{G} \subseteq G$, plus a distinguished element $g \in G$. Denote by $\langle \mathcal{G} \rangle$ the semigroup generated by $\mathcal{G}$, and by $\langle \mathcal{G} \rangle_{grp}$ the group generated by $\mathcal{G}$.

(i) *(Semigroup Membership)* decide whether $\langle \mathcal{G} \rangle$ contains g.
(ii) *(Group Membership)* decide whether $\langle \mathcal{G} \rangle_{grp}$ contains g.

In this paper, we consider two problems closely related to (i) and (ii): the *Identity Problem* and the *Group Problem*, both introduced by Choffrut and Karhumäki [9] in 2005.

(iii) *(Identity Problem)* decide whether $\langle \mathcal{G} \rangle$ contains the neutral element I of G.
(iv) *(Group Problem)* decide whether $\langle \mathcal{G} \rangle$ is a group, in other words, whether $\langle \mathcal{G} \rangle = \langle \mathcal{G} \rangle_{grp}$.

In general matrix groups, Semigroup Membership is undecidable by a classical result of Markov [24]. All four problems remain undecidable even for integer matrix groups of dimension four [4, 25]. Notably, using an embedding of the *Identity Correspondence Problem*, Bell and Potapov [4] showed undecidability of the Identity Problem and the Group Problem in the group $\mathsf{SL}(4, \mathbb{Z})$ of 4×4 integer matrices of determinant one. On the other hand, in the

group $\mathsf{SL}(2,\mathbb{Z})$, all four problems are decidable with various degrees of complexity [3, 9, 21]. In particular, the Identity Problem and the Group Problem in $\mathsf{SL}(2,\mathbb{Z})$ are both **NP**-complete by a result of Bell, Hirvensalo, and Potapov [3].

In this paper we focus on these decision problems in the *wreath product* $\mathbb{Z} \wr \mathbb{Z}$. The wreath product is a fundamental construction in group and semigroup theory. A great number of important groups can be constructed using the wreath product, notably *metabelian groups*. Metabelian groups are groups whose commutator is abelian: these are the simplest generalization of abelian groups. Algorithmic problems in metabelian groups have been the focus of active research since the 1970s [2, 8, 26], with a classic result of Romanovskii [27] showing decidability of Group Membership in all finitely presented metabelian groups. A key part of Romanovskii's proof is to embed metabelian groups into quotients of wreath products. In fact, the Magnus embedding theorem [23] states that every finitely generated free metabelian group can be embedded in a wreath product $\mathbb{Z}^m \wr \mathbb{Z}^n$. Therefore, understanding the wreath product $\mathbb{Z} \wr \mathbb{Z}$ is the most crucial step towards studying general metabelian groups. Apart from its interest within group theory, the wreath product also plays an important role in the algebraic theory of automata. The Krohn–Rhodes theorem [20] states that every finite semigroup (and correspondingly, every finite automaton) can be decomposed into elementary components using wreath products.

One easy way to understand the wreath product $\mathbb{Z} \wr \mathbb{Z}$ is through its isomorphism to a matrix group [23] over the Laurent polynomial ring $\mathbb{Z}[X^{\pm}]$:

$$\mathbb{Z} \wr \mathbb{Z} \cong \left\{ \begin{pmatrix} X^b & y \\ 0 & 1 \end{pmatrix} \;\middle|\; y \in \mathbb{Z}[X^{\pm}], b \in \mathbb{Z} \right\}. \tag{1}$$

Consider the four aforementioned decision problems in $\mathbb{Z} \wr \mathbb{Z}$. Since $\mathbb{Z} \wr \mathbb{Z}$ is metabelian [17], the classic result of Romanovskii [27] shows decidability of Group Membership in $\mathbb{Z} \wr \mathbb{Z}$. If we retrace the proof of Romanovskii, one can reduce Group Membership in $\mathbb{Z} \wr \mathbb{Z}$ to solving systems of linear equations over the ring $\mathbb{Z}[X^{\pm}]$, which can then be decided using Gröbner bases. For Semigroup Membership in $\mathbb{Z} \wr \mathbb{Z}$, Lohrey, Steinberg and Zetzsche showed its undecidability using an encoding of 2-counter machines [22]. Decidability of the Identity Problem and the Group Problem in $\mathbb{Z} \wr \mathbb{Z}$ remained an intricate open problem. A recent paper by Dong [12] gave a partial decidability result when the generators all satisfy $b = \pm 1$. Dong's idea was to represent a product of elements in $\mathbb{Z} \wr \mathbb{Z}$ as a walk on $\mathbb{Z}$. When the generators all satisfy $b = \pm 1$, this walk can be decomposed into simple cycles, and the Group Problem reduces to solving a *single* homogeneous linear equation over the semiring $\mathbb{N}[X]$. Extending Dong's result to arbitrary generators is highly challenging: the structure of the walk becomes much more complex when we allow steps of arbitrary length. In this paper, we combine a series of new ideas from graph theory and algebraic geometry to show full decidability of the Identity Problem and the Group Problem in $\mathbb{Z} \wr \mathbb{Z}$.

The first main idea of this paper is to reduce both problems to solving a *system* of homogeneous linear equations over the semiring $\mathbb{N}[X^{\pm}]$, in addition to two *degree constraints*. We use a highly non-trivial graph theoretic construction to establish this reduction. The second main idea of this paper is to generalize a local-global principle by Einsiedler, Mouat and Tuncel [13] to solve these linear equations with degree constraints. In particular, the original local-global principle by Einsiedler et al. is not compatible with the degree constraints which are essential in our reduction. We introduce new ideas to prove a generalized local-global principle that incorporates these additional degree constraints.

We now mention some other known decidability results in wreath products. In [14], Ganardi, König, Lohrey and Zetzsche showed that for every non-trivial finitely generated abelian group G, the *knapsack problem* in $G \wr \mathbb{Z}$ is **NP**-complete. Notably, this result applies to $\mathbb{Z} \wr \mathbb{Z}$. In [22], Lohrey, Steinberg and Zetzsche showed decidability of the *Rational Subset*

Membership Problem (which subsumes all four decision problems mentioned in the beginning) in the wreath product $H \wr V$, where H is a finite and V is virtually free. In [7], Cadilhac, Chistikov and Zetzsche proved decidability of Rational Subset Membership in the *Baumslag-Solitar groups* $\mathsf{BS}(1,p)$. This group can be considered as an analogue of $(\mathbb{Z}/p\mathbb{Z}) \wr \mathbb{Z}$ "with carrying". In [17], Kharlampovich, López, and Myasnikov showed decidability of solving Diophantine equations in certain metabelian groups, including $\mathbb{Z} \wr \mathbb{Z}$ and $\mathsf{BS}(1,p)$. Many of these results are closely related to automata theory, which we draw inspiration from.

A natural follow-up to our work would be trying to solve the Identity Problem and the Group Problem in *all* finitely presented metabelian groups. This boils down to deciding both problems in quotients of $\mathbb{Z}^m \wr \mathbb{Z}^n$. One encounters some difficulties when trying to generalize our approach to $\mathbb{Z}^m \wr \mathbb{Z}^n$. Notably, decomposition of walks in $\mathbb{Z}^n$ are much more complex, and we can no longer reduce these problems to solving a finite system of equations. We also point out that one cannot go much further beyond metabelian groups (which are 2-step solvable groups), since there exist 3-step solvable groups with undecidable word problem [18].

2 Preliminaries

Words, semigroups and graphs

Let G be an arbitrary group. Let $\mathcal{G} = \{g_1, \ldots, g_a\}$ be a finite set of elements in G. Considering $\mathcal{G}$ as an alphabet, denote by $\mathcal{G}^*$ the set of words over $\mathcal{G}$. For an arbitrary word $w = g_{i_1} g_{i_2} \cdots g_{i_m} \in \mathcal{G}^*$, by multiplying consecutively the elements appearing in w, we can evaluate w as an element $\pi(w)$ in G. We say that the word w *represents* the element $\pi(w)$. The semigroup $\langle \mathcal{G} \rangle$ generated by $\mathcal{G}$ is hence the set of elements in G that are represented by *non-empty* words in $\mathcal{G}^*$.

A word w over the alphabet $\mathcal{G}$ is called *full-image* if every letter in $\mathcal{G}$ has at least one occurrence in w. The following observation shows that deciding the Group Problem amounts to finding a full-image word representing the neutral element.

▶ **Lemma 2.1.** *Let $\mathcal{G} = \{g_1, \ldots, g_a\}$ be a set of elements in a group G. The semigroup $\langle \mathcal{G} \rangle$ is a group if and only if the neutral element I of G is represented by a full-image word over $\mathcal{G}$.*

The following lemma shows that decidability of the Group Problem implies decidability of the Identity Problem.

▶ **Lemma 2.2** ([4])**.** *Given a finite subset $\mathcal{G}$ of a group G, the semigroup $\langle \mathcal{G} \rangle$ contains the neutral element I if and only if there exists a non-empty subset $\mathcal{H} \subseteq \mathcal{G}$ such that $\langle \mathcal{H} \rangle$ is a group. In particular, if the Group Problem is decidable in the group G, then the Identity Problem is also decidable.*

For detailed definition of graph theory terms, see [6]. All graphs considered in this paper will be directed multigraphs. For a graph G, we denote by $V(G)$ its set of vertices and by $E(G)$ its set of edges. For a (directed) edge e, we denote by $s(e)$ the starting vertex of e.

A *loop* is an edge that starts and ends at the same vertex. A *circuit* is a path that starts and ends at the same vertex. An *Euler path* of a graph G is a path that uses each edge exactly once. An *Euler circuit* is an Euler path that starts and ends at the same vertex. We call a graph *Eulerian* if it contains an Euler circuit. It is easy to see that attaching a circuit to an Eulerian graph still results in an Eulerian graph.

Laurent polynomials and the wreath product $\mathbb{Z} \wr \mathbb{Z}$

A (univariate) *Laurent polynomial* with coefficients over $\mathbb{R}$ is an expression of the form

$$f = \sum_{i=p}^{q} a_i X^i, \quad \text{where } p, q \in \mathbb{Z} \text{ and } a_i \in \mathbb{R}, i = p, p+1, \ldots, q.$$

If $p > q$, then f is understood to be zero. Otherwise, $p \leq q$, and we suppose $a_p \neq 0$, $a_q \neq 0$. In this case, we call p the *negative degree* of f, denoted by $\deg_-(f)$, and call q the *positive degree* of f, denoted by $\deg_+(f)$. We call a_p the *negative leading coefficient* of f, denoted by $\mathrm{lc}_-(f)$, and call a_q the *positive leading coefficient* of f, denoted by $\mathrm{lc}_+(f)$. Define additionally $\deg_-(0) = +\infty$, $\deg_+(0) = -\infty$ and $\mathrm{lc}_-(0) = \mathrm{lc}_+(0) = 0$. In this paper, all polynomials will be univariate Laurent polynomials. The set of all polynomials with coefficients over $\mathbb{R}$ forms a ring and is denoted by $\mathbb{R}[X^{\pm}]$. One can define $\mathbb{Q}[X^{\pm}]$ and $\mathbb{Z}[X^{\pm}]$ similarly by restricting the coefficients a_i to $\mathbb{Q}$ and $\mathbb{Z}$.

Given a tuple of polynomials $\boldsymbol{f} = (f_1, \ldots, f_n) \in (\mathbb{R}[X^{\pm}])^n$ and $r \in \mathbb{R}$, one naturally defines the evaluation $\boldsymbol{f}(r) \coloneqq (f_1(r), \ldots, f_n(r)) \in \mathbb{R}^n$. The definition of leading coefficients also extends to tuples of polynomials by $\mathrm{lc}_*(\boldsymbol{f}) \coloneqq (\mathrm{lc}_*(f_1), \ldots, \mathrm{lc}_*(f_n)) \in \mathbb{R}^n$, where $* \in \{+, -\}$.

Consider the semiring $\mathbb{R}_{\geq 0}[X^{\pm}]$ of polynomials with positive coefficients: these are expressions of the form $f = \sum_{i=p}^{q} a_i X^i$ where $p, q \in \mathbb{Z}$ and $a_i \in \mathbb{R}_{\geq 0}, i = p, p+1, \ldots, q$. Define further $\mathbb{R}_{\geq 0}[X^{\pm}]^* \coloneqq \mathbb{R}_{\geq 0}[X^{\pm}] \setminus \{0\}$. One can define $\mathbb{N}[X^{\pm}]$ and $\mathbb{N}[X^{\pm}]^*$ similarly by restricting the coefficients a_i to $\mathbb{N}$.

An element $f = \sum_{i=p}^{q} a_i X^i \in \mathbb{R}_{\geq 0}[X^{\pm}]^*$ is called *gap-free* if $a_i \neq 0$ for all $i = p, p+1, \ldots, q$. Is it easy to see that, given arbitrary $M, N \in \mathbb{Z}_{>0}$ and $f \in \mathbb{R}_{\geq 0}[X^{\pm}]^*$, the polynomial $(X^{-M} + X^{-M+1} + \cdots + X^N)^n \cdot f$ is gap-free for all large enough n.

A *monomial* is a polynomial $f = a_i X^i$ with only one term (including zero). Let $d \geq 1$ be a positive integer. One can define the semirings

$$\mathbb{N}[X^{\pm d}] \coloneqq \left\{ \sum_{i=p}^{q} a_{di} X^{di} \in \mathbb{N}[X^{\pm}] \right\}, \quad \mathbb{N}[X^{\pm d}]^* \coloneqq \mathbb{N}[X^{\pm d}] \setminus \{0\}.$$

These are polynomials whose monomials have degrees divisible by d. Similarly, if $a_{di} \neq 0$ for all $i = p, \ldots, q$, we will call $\sum_{i=p}^{q} a_{di} X^{di}$ gap-free. Note that whether a polynomial is gap-free depends on the polynomial ring we consider it in.

Similarly one can define the rings $\mathbb{Z}[X^{\pm d}]$, $\mathbb{Q}[X^{\pm d}]$ and $\mathbb{R}[X^{\pm d}]$. Furthermore, we define the field of rational functions $\mathbb{Q}(X)$ to be the set of expressions of the form $\frac{f}{g}$, where $f, g \in \mathbb{Q}[X^{\pm}]$. Similarly, $\mathbb{Q}(X^d)$ is defined as the set of expressions $\frac{f}{g}$, where $f, g \in \mathbb{Q}[X^{\pm d}]$.

The wreath product $\mathbb{Z} \wr \mathbb{Z}$ has several equivalent definitions. Here, we introduce the one most convenient to our purpose.

▶ **Definition 2.3.** The wreath product $\mathbb{Z} \wr \mathbb{Z}$ is a group whose elements are pairs of the form (y, b), where $y \in \mathbb{Z}[X^{\pm}]$ and $b \in \mathbb{Z}$. The neutral element in $\mathbb{Z} \wr \mathbb{Z}$ is given by $(0, 0)$. Multiplication is defined by $(y, b) \cdot (y', b') = (y + X^b \cdot y', b + b')$, and inversion is defined by $(y, b)^{-1} = (X^{-b} \cdot y, -b)$. Note that the element (y, b) corresponds to the matrix $\begin{pmatrix} X^b & y \\ 0 & 1 \end{pmatrix}$ under the isomorphism (1) in the introduction.

The wreath product $\mathbb{Z} \wr \mathbb{Z}$ can be embedded into the larger group $\mathbb{Q}(X) \rtimes \mathbb{Z}$, whose elements are pairs of the form (y, b) with $y \in \mathbb{Q}(X)$ and $b \in \mathbb{Z}$ and whose multiplication and inversion are defined using the same formulas as in $\mathbb{Z} \wr \mathbb{Z}$.

3 Overview of proof

The main result of this paper is the decidability of the Identity Problem and the Group Problem in $\mathbb{Z} \wr \mathbb{Z}$. In view of Lemma 2.2, it suffices to prove decidability of the Group Problem. In this section we give an overview of its proof.

Our proof proceeds in three steps. As a first step we reduce the Group Problem in $\mathbb{Z} \wr \mathbb{Z}$ to deciding whether a system of linear equations in $\mathbb{R}[X^{\pm}]$ has solution in $\mathbb{R}_{\geq 0}[X^{\pm}]^*$ with two additional degree constraints (see Proposition 3.2 and Corollary 3.3). As the second step we prove a local-global principle that further reduces solving linear equations over $\mathbb{R}_{\geq 0}[X^{\pm}]^*$ to solving a family of "local" equations over $\mathbb{R}_{>0}$ (see Proposition 3.4). As the third step, we show that solving these "local" equations can be done using the first order theory of the reals as well as Gröbner basis techniques (see Proposition 3.5 and 3.6).

Let $\mathcal{G}$ be a finite subset of $\mathbb{Z} \wr \mathbb{Z}$. Write $\mathcal{G} = \{(y_a, b_a) \mid a \in A\}$ where A is a finite set of indices. Divide A into three subsets of indices $A = I \cup J \cup K$ where

$$I \coloneqq \{i \mid b_i > 0\}, \quad J \coloneqq \{j \mid b_j < 0\}, \quad K \coloneqq \{k \mid b_k = 0\}. \tag{2}$$

First, we exclude the easy case where I or J is empty.

▶ **Proposition 3.1.** *Suppose $I = \emptyset$ or $J = \emptyset$. The semigroup $\langle \mathcal{G} \rangle$ is a group if and only if $I = J = \emptyset$ and $\sum_{k \in K} n_k y_k = 0$ for some positive integers $n_k \in \mathbb{Z}_{>0}$. In particular, this is decidable by integer programming.*

A simple proof of Proposition 3.1 is given in the Appendix A. For the rest of this paper, we will suppose $I \neq \emptyset$ and $J \neq \emptyset$.

Define

$$d \coloneqq \gcd\left(\{b_a \mid a \in I \cup J\}\right).$$

For each pair $(i, j) \in I \times J$, define the rational function

$$h_{(i,j)} \coloneqq \frac{y_i}{1 + X^d + \cdots + X^{b_i - d}} + \frac{y_j}{X^{-d} + X^{-2d} + \cdots + X^{-|b_j|}} \in \mathbb{Q}(X). \tag{3}$$

By direct computation we have

$$(y_i, b_i)^{|b_j|} \cdot (y_j, b_j)^{b_i} = \left(h_{(i,j)} \cdot (1 + X^d + \cdots + X^{b_i |b_j| - d}), 0\right). \tag{4}$$

One can also take (4) as the definition of $h_{(i,j)}$.

A subset S of $I \times J$ is called *double-full* if for every $i \in I$ there exists $j_i \in J$ such that $(i, j_i) \in S$, and for every $j \in J$ there exists $i_j \in I$ such that $(i_j, j) \in S$. The following proposition reduces the Group Problem in $\mathbb{Z} \wr \mathbb{Z}$ to solving linear equations over $\mathbb{N}[X^{\pm d}]^*$.

▶ **Proposition 3.2.** *The semigroup $\langle \mathcal{G} \rangle$ is a group if and only if there exist a double-full set $S \subset I \times J$ and polynomials $f_{(i,j)}, f_k \in \mathbb{N}[X^{\pm d}]^*$ for $(i, j) \in S, k \in K$ that satisfy the following three conditions.*

(i) ***(Single linear equation)*** *The following equation over $\mathbb{Q}(X)$ is satisfied:*

$$\sum_{(i,j) \in S} f_{(i,j)} \cdot h_{(i,j)} + \sum_{k \in K} f_k \cdot y_k = 0. \tag{5}$$

(ii) ***(Positive degree bound)*** *We have:*

$$\deg_+\left(\sum\nolimits_{(i,j) \in S} f_{(i,j)}\right) + d \geq \deg_+\left(\sum\nolimits_{k \in K} f_k\right). \tag{6}$$

(iii) ***(Negative degree bound)*** *We have:*

$$\deg_- \left(\sum\nolimits_{(i,j)\in S} f_{(i,j)} \right) \leq \deg_- \left(\sum\nolimits_{k\in K} f_k \right). \tag{7}$$

The proof of Proposition 3.2 will be given in Section 4. The idea is roughly as follows. By Lemma 2.1, $\langle \mathcal{G} \rangle$ is a group if and only if there is a full-image word $w \in \mathcal{G}^*$ that represents the neutral element. For the "only if" statement of Proposition 3.2, we will represent w as a walk over $\mathbb{Z}$, and decompose the walk into "primitive circuits". Each primitive circuit contributes a multiple of $h_{(i,j)}$ or y_k to the element represented by w. Since w represents the neutral element, this results in the linear equation in Condition (i). Conditions (ii) and (iii) will stem from the connectedness of the walk. The "if" statement is significantly harder. Given the polynomials $f_{(i,j)}, f_k$, we will construct an Eulerian graph G by attaching long "elementary circuits" in a way that corresponds to the coefficients of $f_{(i,j)}, f_k$. We then read a word w from an Euler circuit of G. Condition (i) will make sure w represents the neutral element. However, making sure G is connected is highly non-trivial and will be the main difficulty of the proof. In particular, Conditions (ii)-(iii) will be crucial. This concludes the idea of the proof for Proposition 3.2.

Note that Proposition 3.2 involves finding solutions over $\mathbb{N}[X^{\pm d}]^*$ for linear equations with coefficients in $\mathbb{Q}(X)$. When $d > 1$, this is inconvenient, so we now further reduce Proposition 3.2 to finding solutions over $\mathbb{R}_{\geq 0}[X^{\pm}]^*$ for a *system* of linear equations. For each $(i,j) \in I \times J$, since the denominator of $h_{(i,j)}$ is an element in $\mathbb{Q}[X^{\pm d}]$, there exist $h_{(i,j),0}, \ldots, h_{(i,j),d-1} \in \mathbb{Q}(X)$ such that $h_{(i,j)}$ can be written as

$$h_{(i,j)} = h_{(i,j),0}(X^d) + h_{(i,j),1}(X^d) \cdot X + \cdots + h_{(i,j),d-1}(X^d) \cdot X^{d-1}. \tag{8}$$

Similarly, for each $k \in K$, there exist $y_{k,0}, \ldots, y_{k,d-1} \in \mathbb{Q}[X^{\pm}]$ so that y_k can be written as

$$y_k = y_{k,0}(X^d) + y_{k,1}(X^d) \cdot X + \cdots + y_{k,d-1}(X^d) \cdot X^{d-1}. \tag{9}$$

The following corollary shows that, using the elements $h_{(i,j),m}, y_{k,m}$ defined in (8) and (9), we can rewrite the conditions in Proposition 3.2 using only variables in $\mathbb{R}_{\geq 0}[X^{\pm}]^*$ instead of $\mathbb{N}[X^{\pm d}]^*$. See Appendix A for a simple proof of Corollary 3.3.

▶ **Corollary 3.3.** *The semigroup $\langle \mathcal{G} \rangle$ is a group if and only if there exist a double-full set $S \subset I \times J$ and polynomials $f_S, f_K, f_{(i,j)}, f_k \in \mathbb{R}_{\geq 0}[X^{\pm}]^*$ for $(i,j) \in S, k \in K$ that satisfy the following three conditions.*

(i) ***(System of linear equations)*** *The following linear equations over $\mathbb{R}(X)$ are satisfied:*

$$\sum_{(i,j)\in S} f_{(i,j)} h_{(i,j),m} + \sum_{k\in K} f_k y_{k,m} = 0, \quad m = 0, \ldots, d-1, \tag{10}$$

$$f_S = \sum_{(i,j)\in S} f_{(i,j)}, \qquad f_K = \sum_{k\in K} f_k. \tag{11}$$

(ii) ***(Positive degree bound)*** *We have:*

$$\deg_+ (f_S) + 1 \geq \deg_+ (f_K). \tag{12}$$

(iii) ***(Negative degree bound)*** *We have:*

$$\deg_- (f_S) \leq \deg_- (f_K). \tag{13}$$

For brevity, from now on we denote $\mathbb{A} \coloneqq \mathbb{R}[X^{\pm}]$ and $\mathbb{A}^+ \coloneqq \mathbb{R}_{\geq 0}[X^{\pm}]^*$. Denote also $n \coloneqq 2 + |S| + |K|$. Define the following subset of $\mathbb{A}^n$:

$$\mathcal{M} \coloneqq \left\{ \boldsymbol{f} = \left(f_S, f_K, (f_{(i,j)})_{(i,j)\in S}, (f_k)_{k\in K}\right) \in \mathbb{A}^n \;\middle|\; \boldsymbol{f} \text{ satisfies (10) and (11)} \right\}. \tag{14}$$

That is, $\mathcal{M}$ is the set of solutions of the linear equations (10)-(11). Using linear algebra over the polynomial ring $\mathbb{A}$ (see [1]), one can effectively compute a set of vectors $\boldsymbol{g}_1, \ldots, \boldsymbol{g}_m \in \mathbb{A}^n$ such that

$$\mathcal{M} = \{\phi_1 \boldsymbol{g}_1 + \cdots + \phi_m \boldsymbol{g}_m \mid \phi_1, \ldots, \phi_m \in \mathbb{A}\}. \tag{15}$$

One can even suppose $\boldsymbol{g}_1, \ldots, \boldsymbol{g}_m \in (\mathbb{Q}[X^{\pm}])^n$ since $h_{(i,j)}$ and y_k all have rational coefficients. A set $\mathcal{M}$ of the form (15) will be called a $\mathbb{A}$-*submodule* of $\mathbb{A}^n$, and the elements $\boldsymbol{g}_1, \ldots, \boldsymbol{g}_m$ will be called a *basis* of $\mathcal{M}$.

Corollary 3.3 actually states the following: the semigroup $\langle \mathcal{G} \rangle$ is a group if and only if $\mathcal{M}$ contains an element $\boldsymbol{f} = (f_S, f_K, \ldots) \in (\mathbb{A}^+)^n$ such that $\deg_+(f_S) + 1 \geq \deg_+(f_K)$ and $\deg_-(f_S) \leq \deg_-(f_K)$. The key to deciding the existence of $\boldsymbol{f}$ is the following proposition, which can be considered as a local-global principle that generalizes a result of Einsiedler, Mouat and Tuncel [13].

▶ **Proposition 3.4.** *Let $\mathcal{M}$ be a $\mathbb{A}$-submodule of $\mathbb{A}^n$. Then $\mathcal{M}$ contains an element $\boldsymbol{f} = (f_S, f_K, \ldots) \in (\mathbb{A}^+)^n$ with $\deg_+(f_S) + 1 \geq \deg_+(f_K)$ and $\deg_-(f_S) \leq \deg_-(f_K)$, if and only if the following three conditions are all satisfied.*

(i) ***(Existence of $\boldsymbol{f}_r$ for all $r \in \mathbb{R}_{>0}$)*** *For each $r \in \mathbb{R}_{>0}$, there exists $\boldsymbol{f}_r \in \mathcal{M}$ such that*

$$\boldsymbol{f}_r(r) \in \mathbb{R}^n_{>0}. \tag{16}$$

(ii) ***(Existence of $\boldsymbol{f}_\infty$)*** *There exists $\boldsymbol{f}_\infty = (f_{\infty,S}, f_{\infty,K}, \ldots) \in \mathcal{M}$ such that*

$$\mathrm{lc}_+(\boldsymbol{f}_\infty) \in \mathbb{R}^n_{>0} \quad \text{and} \quad \deg_+(f_{\infty,S}) + 1 \geq \deg_+(f_{\infty,K}). \tag{17}$$

(iii) ***(Existence of $\boldsymbol{f}_0$)*** *There exists $\boldsymbol{f}_0 = (f_{0,S}, f_{0,K}, \ldots) \in \mathcal{M}$ such that*

$$\mathrm{lc}_-(\boldsymbol{f}_0) \in \mathbb{R}^n_{>0} \quad \text{and} \quad \deg_-(f_{0,S}) \leq \deg_-(f_{0,K}). \tag{18}$$

The proof of Proposition 3.4 will be given in Section 5. The original result of Einsiedler et al. [13, Theorem 1.3] gives a similar local-global principle without the degree constraints on f_S and f_K. While our proof follows the main steps of the original proof, we need to introduce new arguments in order for the degree constraint to stay compatible with the local-global principle.

One direction of the implication in Proposition 3.4 is clear. In fact, if $f \in \mathbb{A}^+$ and $r \in \mathbb{R}_{>0}$, then we have $f(r) \in \mathbb{R}_{>0}$ and $\mathrm{lc}_+(f), \mathrm{lc}_-(f) \in \mathbb{R}_{>0}$. Therefore, if $\mathcal{M}$ contains an element $\boldsymbol{f} = (f_S, f_K, \cdots) \in (\mathbb{A}^+)^n$ with $\deg_+(f_S) + 1 \geq \deg_+(f_K)$ and $\deg_-(f_S) \leq \deg_-(f_K)$, then simply take $\boldsymbol{f}_r = \boldsymbol{f}_\infty = \boldsymbol{f}_0 = \boldsymbol{f}$ for all r: Equation (16) is satisfied for all r as well as (17) and (18); hence all three conditions are satisfied.

On the other hand, if the Equation (16) as well as (17) and (18) can be satisfied *individually* by different $\boldsymbol{f}_r, \boldsymbol{f}_\infty, \boldsymbol{f}_0$, we cannot *a priori* find an element $\boldsymbol{f} \in \mathcal{M}$ in $(\mathbb{A}^+)^n$. Such an element $\boldsymbol{f}$ would *simultaneously* satisfy Equations (16) for all $r \in \mathbb{R}_{>0}$ as well as (17) and (18). The key idea of proving this non-trivial direction is that if all three conditions (i)-(iii) are satisfied, then we can "glue" these different $\boldsymbol{f}_r, \boldsymbol{f}_\infty$ and $\boldsymbol{f}_0$ together to obtain a single $\boldsymbol{f}$ that satisfies Equation (16) for *all* r as well as (17) and (18). While this idea comes from the original

proof, the difficult part in our generalization is to make sure the degree constraints are still satisfied after the gluing procedure. In the end, we multiply this $\boldsymbol{f}$ by a "large enough" polynomial to obtain an element in $(\mathbb{A}^+)^n$, using a theorem of Handelman (Theorem 5.3).

The following two propositions show that Conditions (i), (ii) and (iii) of Proposition 3.4 are all decidable.

▶ **Proposition 3.5.** *Let $\mathcal{M}$ be an $\mathbb{A}$-submodule of $\mathbb{A}^n$. Given as input a finite basis of $\mathcal{M}$, it is decidable whether for every $r \in \mathbb{R}_{>0}$ there exists $\boldsymbol{f}_r \in \mathcal{M}$ with $\boldsymbol{f}_r(r) \in \mathbb{R}^n_{>0}$.*

▶ **Proposition 3.6.** *Let $* \in \{+, -\}$, $a \in \mathbb{Z}$ and $\mathcal{M}$ be an $\mathbb{A}$-submodule of $\mathbb{A}^n$. Given as input a finite basis of $\mathcal{M}$, it is decidable whether there exists $\boldsymbol{f} = (f_S, f_K, \cdots) \in \mathcal{M}$ such that*

$$\mathrm{lc}_*(\boldsymbol{f}) \in \mathbb{R}^n_{>0} \quad \text{and} \quad \deg_*(f_S) + a \geq \deg_*(f_K)\,. \tag{19}$$

Proposition 3.5 and 3.6 will be proven in Section 6. The idea of proving Proposition 3.5 is to reduce the statement to the first order theory of the reals; while for proving Proposition 3.6 we will use the *super Gröbner basis* introduced in the original proof of Einsiedler et al. [13].

We are now ready to prove our main theorem by bridging the remaining gaps.

▶ **Theorem 3.7.** *The Identity Problem and the Group Problem in $\mathbb{Z} \wr \mathbb{Z}$ are decidable.*

Proof. First we show decidability of the Group Problem. Given a finite set $\mathcal{G} = \{(y_a, b_a) \mid a \in A\}$ in $\mathbb{Z} \wr \mathbb{Z}$, define the index sets I, J, K as in (2). If I or J is empty, then Proposition 3.1 shows that the Group Problem for $\mathcal{G}$ is decidable. If I and J are not empty, we enumerate all double-full sets $S \subset I \times J$. For each S we compute a finite basis of $\mathcal{M}$ defined in (14). Corollary 3.3 together with Proposition 3.4 shows that the Group Problem for $\mathcal{G}$ has a positive answer if and only if for some S, the three conditions in Proposition 3.4 are all satisfied. For each S, Condition (i) can be decided using Proposition 3.5; Condition (ii) can be decided using Proposition 3.6 by taking $* = +, a = 1$; Condition (iii) can be decided using Proposition 3.6 by swapping the coordinates S and K and taking $* = -, a = 0$. Therefore the Group Problem in $\mathbb{Z} \wr \mathbb{Z}$ is decidable. By Lemma 2.2, the Identity Problem in $\mathbb{Z} \wr \mathbb{Z}$ is also decidable. ◀

4 From semigroup to polynomial equations

4.1 Definition of $\mathcal{G}$-graphs

Section 4 is dedicated to the proof of Proposition 3.2. In this subsection, we will define the notion of a *$\mathcal{G}$-graph*. Let A be a finite set of indices. Let $\mathcal{G} = \{(y_a, b_a) \mid a \in A\}$ be a finite set of elements in the group $\mathbb{Z} \wr \mathbb{Z}$ or $\mathbb{Q}(X) \rtimes \mathbb{Z}$. We define the following notion of a $\mathcal{G}$-graph.

▶ **Definition 4.1** ($\mathcal{G}$-graphs)**.** A *$\mathcal{G}$-graph* is a directed multigraph G, whose set of vertices $V(G)$ is a finite subset of $\mathbb{Z}$, and its edges are each labeled with an index in A. Furthermore, if an edge from vertex d_1 to vertex d_2 has label a, then $d_2 = d_1 + b_a$.

For a word w over the alphabet $\mathcal{G}$, we associate to it a unique $\mathcal{G}$-graph $G(w)$, defined as follows. Write $w = (y_{a_1}, b_{a_1}) \cdots (y_{a_p}, b_{a_p})$. For each $i = 0, \ldots, p-1$, we add an edge starting at the vertex $b_{a_1} + \cdots + b_{a_i}$, ending at the vertex $b_{a_1} + \cdots + b_{a_{i+1}}$, with the label a_i. (If $i = 0$ then the edge starts at 0 and ends at b_{a_1}.) The graph $G(w)$ is then obtained by taking the connected component of the vertex 0. See Figure 1 for the illustration of an example.

By reading the letters in w one by one and tracing the corresponding edges of $G(w)$, we obtain an Euler path of $G(w)$. Furthermore, if the word w represents the neutral element (or any element of the form $(y, 0)$), then this Euler path is an Euler circuit.

We point out that the element which w represents is uniquely determined by $G(w)$:

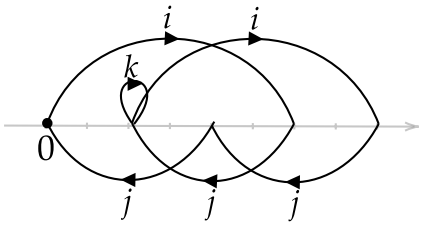

Figure 1 Illustration of $G(w)$. Here, $A = \{i, j, k\}$, $\mathcal{G} = \{(y_i, 6), (y_j, -4), (y_k, 0)\}$, $w = (y_i, 6)(y_j, -4)(y_k, 0)(y_i, 6)(y_j, -4)(y_j, -4)$.

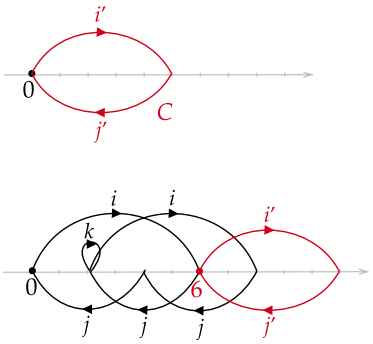

Figure 2 Attaching the circuit C to $G(w)$ at vertex 6.

▶ **Fact 4.2** (Product of associated graph). Let w be a word over the alphabet $\mathcal{G}$, and let $G = G(w)$ be its associated $\mathcal{G}$-graph. For an edge $e \in E(G)$, denote by $\ell(e)$ the label of e, denote by $s(e) \in \mathbb{Z}$ the starting vertex of e, then w represents the element

$$\left(\sum_{e \in E(G)} X^{s(e)} \cdot y_{\ell(e)}, \sum_{e \in E(G)} b_{\ell(e)} \right). \tag{20}$$

For an arbitrary $\mathcal{G}$-graph G, the element in Expression (20) will be called the *product* of the graph G. It is easy to see that, if G contains an Eulerian path, then by following this path we obtain a word w that represents the product of G.

Let C be a another Eulerian $\mathcal{G}$-graph (seen as a circuit). We define the following action of *attaching C to G at vertex v*: For each edge e of C, starting at vertex $s(e)$ with label $\ell(e)$, we add an edge e' to G, starting at vertex $s(e) + v$ with label $\ell(e)$. See Figure 2 for the illustration of an example. The product of the resulting graph is uniquely determined by G, C as well as v:

▶ **Fact 4.3** (Effect of attaching circuit to a graph). Let G be an arbitrary $\mathcal{G}$-graph and C be an Eulerian $\mathcal{G}$-graph. Denote by (y_G, b_G) the product of G and by $(y_C, 0)$ the product of C. Then attaching C to G at vertex v results in a graph with product $(y_G + X^v \cdot y_C, b_G)$.

4.2 Group Problem implies polynomial equations

In this subsection, we prove the "only if" part of Proposition 3.2. We will show that if $\langle \mathcal{G} \rangle$ is a group then there exists a double-full set $S \subset I \times J$ and polynomials $f_{(i,j)}, f_k \in \mathbb{N}[X^{\pm d}]^*$ for $(i, j) \in S, k \in K$ satisfying (i)-(iii) of Proposition 3.2.

Recall that $d \coloneqq \gcd(\{b_a \mid (y_a, b_a) \in \mathcal{G}\})$. Define the alphabet $\widehat{\mathcal{G}}$ of *radical* elements:

$$\widehat{\mathcal{G}} \coloneqq \left\{ (\widehat{y}_a, \widehat{b}_a) \;\middle|\; (y_a, b_a) \in \mathcal{G} \right\},$$

where

$$(\widehat{y}_a, \widehat{b}_a) \coloneqq \begin{cases} \left(\frac{y_a}{1 + X^d + \cdots + X^{b_a - d}}, d \right) & a \in I \quad \text{(or equivalently, } b_a > 0\text{)}, \\ \left(\frac{y_a}{1 + X^{-d} + \cdots + X^{-(|b_a| - d)}}, -d \right) & a \in J \quad \text{(or equivalently, } b_a < 0\text{)}, \\ (y_a, 0) & a \in K \quad \text{(or equivalently, } b_a = 0\text{)}. \end{cases}$$

Note that these elements are in $\mathbb{Q}(X) \rtimes \mathbb{Z}$ instead of $\mathbb{Z} \wr \mathbb{Z}$. Direct computation shows that

$$(\widehat{y}_a, \widehat{b}_a)^{|b_a|/d} = (y_a, b_a) \tag{21}$$

for $a \in I \cup J$. Equation (21) can also be taken as the definition of $(\widehat{y}_a, \widehat{b}_a)$.

Since $\langle \mathcal{G} \rangle$ is a group, by Lemma 2.1 there exists a full-image word $w \in \mathcal{G}^*$ that represents the neutral element. Replacing the letters (y_a, b_a) in w by the words $\underbrace{(\widehat{y}_a, \widehat{b}_a) \cdots (\widehat{y}_a, \widehat{b}_a)}_{|b_a|/d \text{ times}}$ for every $a \in I \cup J$, we obtain a word $\widehat{w} \in \widehat{\mathcal{G}}^*$. By Equation (21), $\widehat{w}$ also represents the neutral element. To the word $\widehat{w}$ we associate a $\widehat{\mathcal{G}}$-graph $G(\widehat{w})$. See Figure 3 for the illustration of an example of $G(\widehat{w})$; one can compare it with Figure 1 which illustrates $G(w)$ for the same w.

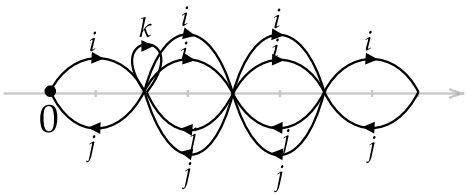

Figure 3 Decomposition of $G(\widehat{w})$. Here $\mathcal{G}$ and w are the same as in Figure 1.

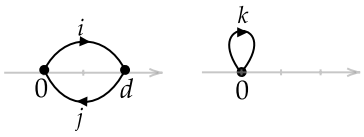

Figure 4 Primitive circuits of type (i, j) and k.

Since $\widehat{w}$ represents the neutral element, the graph $G(\widehat{w})$ is Eulerian. Since $\widehat{b}_a = \pm d$ or 0 for all indices $a \in I \cup J \cup K$, the graph $G(\widehat{w})$ can be decomposed into two classes of smaller circuits. The first class of circuits is an edge with some label $i \in I$ (edge directed to the right) followed by an edge with some label $j \in J$ (edge directed to the left); we call such a circuit *of the type* (i, j). The second class is a loop with label $k \in K$; we call such a circuit *of the type* k. We call these two classes of circuits *primitive*. See Figure 4 for an illustration.

▶ **Lemma 4.4.** *The graph $G(\widehat{w})$ can be constructed by starting with an edgeless graph with a single vertex 0 and gradually attaching primitive circuits.*

Recall the definition of $h_{(i,j)}$ in Equation (3). In fact, $h_{(i,j)}$ is the product of a primitive circuit of type (i, j), meaning $(\widehat{y}_i, \widehat{b}_i) \cdot (\widehat{y}_j, \widehat{b}_j) = (h_{(i,j)}, 0)$. Similarly, the product of a circuit of type k is $(h_k, 0) \coloneqq (y_k, 0)$. By Lemma 4.4, $G(\widehat{w})$ can be decomposed into primitive circuits. For each primitive circuit C in the decomposition, denote by $s(C) \in d\mathbb{Z}$ the vertex where C is attached, and by $type(C)$ the type of C. Denote by $\mathcal{C}$ the set of circuits in the decomposition of $G(\widehat{w})$ into primitive circuits. By Fact 4.3, the product of $G(\widehat{w})$ can be written as

$$\left(\sum_{C \in \mathcal{C}} X^{s(C)} \cdot h_{type(C)}, 0 \right) = (0, 0). \tag{22}$$

For each $(i, j) \in I \times J$ and $k \in K$, define the following polynomials in $\mathbb{N}[X^{\pm d}]$:

$$f_{(i,j)} \coloneqq \sum_{C \in \mathcal{C} \text{ of type } (i,j)} \left(X^d\right)^{\frac{s(C)}{d}}, \quad f_k \coloneqq \sum_{C \in \mathcal{C} \text{ of type } k} \left(X^d\right)^{\frac{s(C)}{d}}. \tag{23}$$

Let $S \coloneqq \{(i, j) \in I \times J \mid f_{(i,j)} \neq 0\}$. We point out that $f_k \neq 0$ for all $k \in K$, because $\widehat{w}$ is full-image, meaning $G(\widehat{w})$ contains a loop of label k for each $k \in K$. Equation (22) becomes

$$\sum_{(i,j) \in S} f_{(i,j)} \cdot h_{(i,j)} + \sum_{k \in K} f_k \cdot y_k = 0. \tag{24}$$

This is exactly Condition (i) of Proposition 3.2. It suffices to show the following to complete the proof of the first implication of Proposition 3.2.

▶ **Lemma 4.5.** *Let $f_{(i,j)}, f_k \in \mathbb{N}[X^{\pm d}]$ and $S \subset I \times J$ be defined as above, then:*

(i) *S is double-full.*

(ii) $\deg_+\left(\sum_{(i,j)\in S} f_{(i,j)}\right) + d \geq \deg_+\left(\sum_{k\in K} f_k\right)$.

(iii) $\deg_-\left(\sum_{(i,j)\in S} f_{(i,j)}\right) \leq \deg_-\left(\sum_{k\in K} f_k\right)$.

Sketch of proof. For (i), S is double full since $G(\widehat{w})$ contains edges of each type of labels. For (ii) and (iii), it suffices to notice that $G(\widehat{w})$ must be connected while $\max(V(G(\widehat{w}))) = \deg_+\left(\sum_{(i,j)\in S} f_{(i,j)}\right) + d$ and $\min(V(G(\widehat{w}))) = \deg_-\left(\sum_{(i,j)\in S} f_{(i,j)}\right)$. ◀

Proof of "only if" part of Proposition 3.2. If $\langle \mathcal{G} \rangle$ is a group, then there exists a full-image word $w \in \mathcal{G}^*$ that represents the neutral element. Consider $G(\widehat{w})$ and let $f_{(i,j)}, f_k \in \mathbb{N}[X^{\pm d}]^*, (i,j) \in S, k \in K$, be as defined in (23). The Conditions (i)-(iii) of Proposition 3.2 follow directly from Equation (24) and Lemma 4.5. ◀

4.3 Polynomial equation implies Group Problem

In this subsection, we prove the "if" part of Proposition 3.2. Given a double-full set $S \subset I \times J$ and positive polynomials $f_{(i,j)}, f_k \in \mathbb{N}[X^{\pm d}]^*$ for $(i,j) \in S, k \in K$ that satisfy Conditions (i)-(iii) of Proposition 3.2, we will construct an Eulerian $\mathcal{G}$-graph G with product zero. The main difficulty here is that the length of the edges of a $\mathcal{G}$-graph are no longer identical, as opposed to $\widehat{\mathcal{G}}$-graphs. Therefore one can no longer decompose $\mathcal{G}$-graphs into primitive circuits. The key idea is a work-around that simulates primitive circuits using longer circuits.

For $(i,j) \in I \times J$, we define an *elementary circuit of the type* (i,j) to be a circuit that starts with $|b_j|$ edges of label i, followed by b_i edges of label j. See Figure 5 for an example.

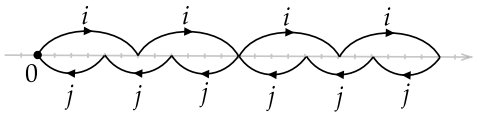

Figure 5 An elementary circuit of type (i,j). Here, $b_i = 6, b_j = -4$.

▶ **Lemma 4.6.** *Suppose $S \subset I \times J$ be double-full. There exists an Eulerian $\mathcal{G}$-graph A with $d \in V(A)$, obtained by attaching together elementary circuits of types in S.*

The idea of constructing A is illustrated in Figure 6, with a detailed proof given in Appendix A. We now characterize the product of A. An elementary circuit of type (i,j) attached at vertex dv contributes $X^{dv}(1 + X^d + \cdots + X^{b_i|b_j|-d}) \cdot h_{(i,j)}$ to the product (see Equation (4)). Since A is a combination of elementary circuits, the product of A can written as $\sum_{(i,j)\in S} a_{(i,j)} h_{(i,j)}$ for some $a_{(i,j)} \in \mathbb{N}[X^{\pm d}]$.

Let $N \coloneqq \prod_{i\in I\cup J} |b_i|$. Note that simultaneously multiplying all $f_{(i,j)}$ and f_k by any polynomial $g \in \mathbb{N}[X^{\pm d}]^*$ does not change the fact that $f_{(i,j)}, f_k \in \mathbb{N}[X^{\pm d}]^*$, and they still satisfy Conditions (i)-(iii) of Proposition 3.2. Also note that $1 + X^d + \cdots + X^{b_i|b_j|-d} \mid 1 + X^d + \cdots + X^{N-d}$. Therefore, by simultaneously multiplying all $f_{(i,j)}$ and f_k by $p \cdot (X^{-d} + 1 + \cdots + X^{N-2d})^q$ for large enough $p, q \in \mathbb{N}$, we can suppose that for all $(i,j) \in S$,

$$g_{(i,j)} \coloneqq \frac{f_{(i,j)} - a_{(i,j)} \cdot (1 + X^d + \cdots + X^{N-d})}{1 + X^d + \cdots + X^{b_i|b_j|-d}} \in \mathbb{N}[X^{\pm d}]^* \quad \text{is gap-free,} \tag{25}$$

and

$$\deg_+\left(f_{(i,j)}\right) > \deg_+(a_{(i,j)}) + N - d, \qquad \deg_-\left(f_{(i,j)}\right) < \deg_-(a_{(i,j)}). \tag{26}$$

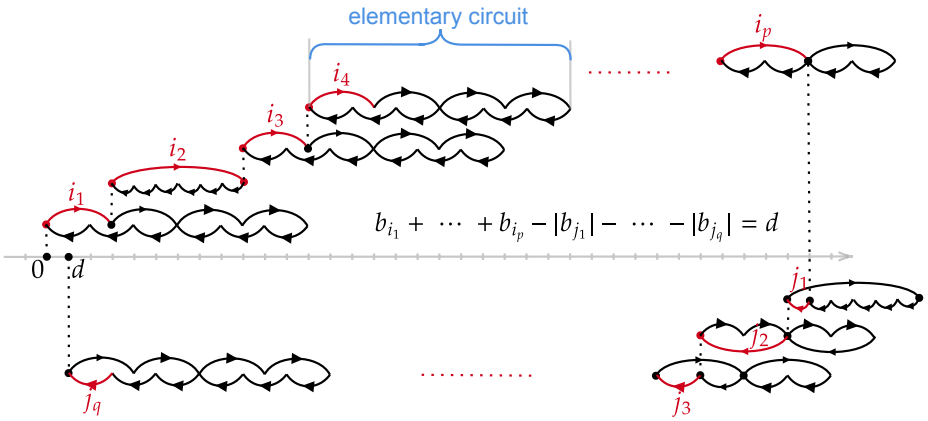

Figure 6 Graph A from Lemma 4.6.

▶ **Proposition 4.7.** *Suppose S is double-full and $f_{(i,j)}, f_k \in \mathbb{N}[X^{\pm d}]^*, (i,j) \in S, k \in K$, satisfy Equations (25), (26) and Conditions (ii)-(iii) of Proposition 3.2, then there exists an Eulerian $\mathcal{G}$-graph G whose product is $\sum_{(i,j)\in S} f_{(i,j)} \cdot h_{(i,j)} + \sum_{k\in K} f_k \cdot y_k$.*

Proof. We construct G in three steps. See Figure 7 for an illustration.

Step 1: Constructing the foundation A'. We start with the $\mathcal{G}$-graph A constructed in Lemma 4.6. We then attach to it another $N/d - 1$ copies of A, where the k-th copy is attached at vertex dk. The resulting graph is still Eulerian because $d \in V(A)$. We denote by A' the $\mathcal{G}$-graph obtained by this attachment. Then we have $0, d, \cdots, N - d \in V(A')$.

Step 2: Attaching elementary circuits of type $(i,j) \in S$. For each pair $(i,j) \in S$, we want to attach elementary circuits of type (i,j) to the graph A', such that the total contribution of these circuits to the product is $g_{(i,j)} \cdot \left(1 + X^d + \cdots + X^{b_i|b_j|-d}\right) \cdot h_{(i,j)}$, where $g_{(i,j)}$ is defined in (25). Write $g_{(i,j)} = \sum_{t=p}^{q} \gamma_t X^{dt}$. We attach a total of $\sum_{t=p}^{q} \gamma_t$ elementary circuits of type (i,j) to A', where for $t = p, p+1, \ldots, q$, exactly γ_t of these circuits are attached at the vertex dt. The resulting graph is connected (and Eulerian) because $g_{(i,j)}$ is gap-free. In fact, for each $t \in [\deg_-(g_{(i,j)})/d, \left(\deg_+(g_{(i,j)}) + b_i|b_j|\right)/d] \cap \mathbb{Z}$ and $u \in [0, N)$, such that $dt \equiv du \mod b_i|b_j|$, the vertex dt is connected to $du \in V(A')$ by a chain of circuits of type (i,j). Denote by A'' the resulting graph after doing the above attachments for all $(i,j) \in S$. Then

$$dt \in V(A'') \text{ for all } t \in [\deg_-(g_{(i,j)})/d, \left(\deg_+(g_{(i,j)}) + b_i|b_j|\right)/d] \cap \mathbb{Z},\ (i,j) \in S. \tag{27}$$

Step 3: Attaching loops of type $k \in K$. For each $k \in K$, we want to attach loops of label $k \in K$ to A'', such that the total contribution of these loops to the product is $f_k \cdot y_k$. Write $f_k = \sum_{t=p}^{q} \beta_t X^{dt}$, we attach a total of $\sum_{t=p}^{q} \beta_t$ loops of label k to A'', where for $t = p, p+1, \ldots, q$, exactly β_t of these loops are attached at the vertex dt.

We need to prove that the resulting graph G is still connected (and hence Eulerian). In view of Property (27) of the graph A'', it suffices to prove $\deg_-(f_k) \geq \min_{(i,j)\in S}\left\{\deg_-(g_{(i,j)})\right\}$ and $\deg_+(f_k) \leq \max_{(i,j)\in S}\left\{\deg_+(g_{(i,j)}) + b_i|b_j|\right\}$ for all $k \in K$. By Equations (25) and (26), we have $\deg_-(g_{(i,j)}) = \deg_-(f_{(i,j)})$ and $\deg_+(g_{(i,j)}) + b_i|b_j| - d = \deg_+(f_{(i,j)})$ for all $(i,j) \in S$. Then, by Conditions (ii) and (iii) of Proposition 3.2, we have

$$\deg_-(f_k) \geq \deg_-\left(\sum\nolimits_{k\in K} f_k\right) \geq \min_{(i,j)\in S}\{\deg_-(f_{(i,j)})\} = \min_{(i,j)\in S}\{\deg_-(g_{(i,j)})\},$$
$$\deg_+(f_k) \leq \deg_+\left(\sum\nolimits_{k\in K} f_k\right) \leq \max_{(i,j)\in S}\{\deg_+(f_{(i,j)})\} + d = \max_{(i,j)\in S}\{\deg_-(g_{(i,j)}) + b_i|b_j|\},$$

for all $k \in K$. Therefore, the resulting graph G is still connected.

Finally, we count the product of G. The product of A' is $(1 + X^d + \cdots + X^{N-d}) \cdot \sum_{(i,j)\in S} a_{(i,j)}h_{(i,j)}$. The total contribution of elementary circuits in Step 2 is $\sum_{(i,j)\in S} g_{(i,j)} \cdot \left(1 + X^d + \cdots + X^{b_i|b_j|-d}\right) \cdot h_{(i,j)}$. The total contribution of loops in Step 3 is $\sum_{k\in K} f_k \cdot y_k$. Thus, by Equation (25), the product of G is $\sum_{(i,j)\in S} f_{(i,j)} \cdot h_{(i,j)} + \sum_{k\in K} f_k \cdot y_k$. ◀

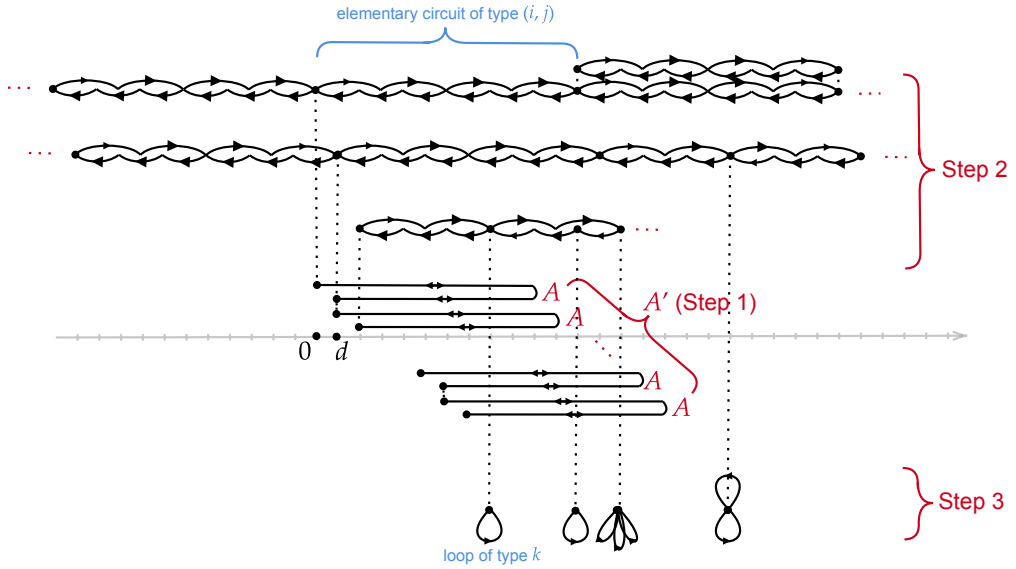

Figure 7 Graph G from Proposition 4.7.

Proof of "if" part of Proposition 3.2. We use Proposition 4.7 to prove the "if" part of Proposition 3.2. Suppose there exist a double-full set $S \subset I \times J$ and polynomials $f_{(i,j)}, f_k \in \mathbb{N}[X^{\pm d}]^*$ for $(i,j) \in S, k \in K$ that satisfy Conditions (i)-(iii). Recall that by simultaneously multiplying all $f_{(i,j)}$ and f_k by $p \cdot (X^{-d} + 1 + X^d + \cdots + X^{N-2d})^q$ for large enough $p, q \in \mathbb{N}$, we can suppose Equations (25) and (26) to be satisfied. Then Proposition 4.7 gives an Eulerian $\mathcal{G}$-graph G whose product is $\left(\sum_{(i,j)\in S} f_{(i,j)} \cdot h_{(i,j)} + \sum_{k\in K} f_k \cdot y_k, 0\right)$. This product is equal to the neutral element due to Conditions (i) of Proposition 3.2. By following an Eulerian cycle of G, we obtain a word w representing the neutral element. The word w is full-image because G contains elementary circuits of all types $(i,j) \in S$ and loops of all types $k \in K$, and because S is double-full. Therefore $\langle \mathcal{G} \rangle$ is a group by Lemma 2.1. ◀

5 A local-global principle for polynomial equations

In this section we prove Proposition 3.4. We follow the line of proof for the original result of Einsiedler et al. [13], while introducing new elements concerning the degree constraints. See Figure 8 in Appendix A for an illustration of the proof.

▶ **Lemma 5.1.** *Suppose Conditions (ii) and (iii) of Proposition 3.4 hold. Then there exists* $\boldsymbol{f}_{end} = (f_{end,S}, f_{end,K}, \cdots) \in \mathcal{M}$ *such that*

$$\mathrm{lc}_+(\boldsymbol{f}_{end}) \in \mathbb{R}^n_{>0}, \quad \deg_+(f_{end,S}) + 1 \geq \deg_+(f_{end,K}), \text{ and} \tag{28}$$

$$\mathrm{lc}_-(\boldsymbol{f}_{end}) \in \mathbb{R}^n_{>0}, \quad \deg_-(f_{end,S}) \leq \deg_-(f_{end,K}). \tag{29}$$

Since $\mathrm{lc}_\pm(\boldsymbol{f}_{end}) \in \mathbb{R}^n_{>0}$, there exists $c > 1$, such that $\boldsymbol{f}_{end}(x) \in \mathbb{R}^n_{>0}$ for all $x \in \mathbb{R}_{>0} \backslash [1/c, c]$. Define the compact set $C := [1/4c, 4c]$.

▶ **Lemma 5.2.** *Suppose Condition (i) of Proposition 3.4 hold. Let* $C \subset \mathbb{R}_{>0}$ *be a compact set, then there exists* $\boldsymbol{f}_C = (f_{C,S}, f_{C,K}, \cdots) \in \mathcal{M}$ *such that* $\boldsymbol{f}_C(x) \in \mathbb{R}^n_{>0}$ *for all* $x \in C$.

The key ingredient for finding an element in $(\mathbb{A}^+)^n$ is the following corollary of Handelman's Theorem.

▶ **Theorem 5.3** (Corollary of Handelman's Theorem [10, 15])**.** *Let* $\boldsymbol{f} \in \mathbb{A}^n$. *There exists* $g \in \mathbb{A}^+$ *such that* $g \cdot \boldsymbol{f} \in (\mathbb{A}^+)^n$ *if and only if the two following conditions are satisfied:*

(i) *For all* $r \in \mathbb{R}_{>0}$, *we have* $\boldsymbol{f}(r) \in \mathbb{R}^n_{>0}$.

(ii) *We have* $\mathrm{lc}_+(\boldsymbol{f}) \in \mathbb{R}^n_{>0}$ *and* $\mathrm{lc}_-(\boldsymbol{f}) \in \mathbb{R}^n_{>0}$.

We now sketch a proof of Proposition 3.4 by "gluing" the two elements $\boldsymbol{f}_{end}$ and $\boldsymbol{f}_C$ obtained respectively in Lemma 5.1 and 5.2, then applying Theorem 5.3. For an illustration of the proof, see Figure 8.

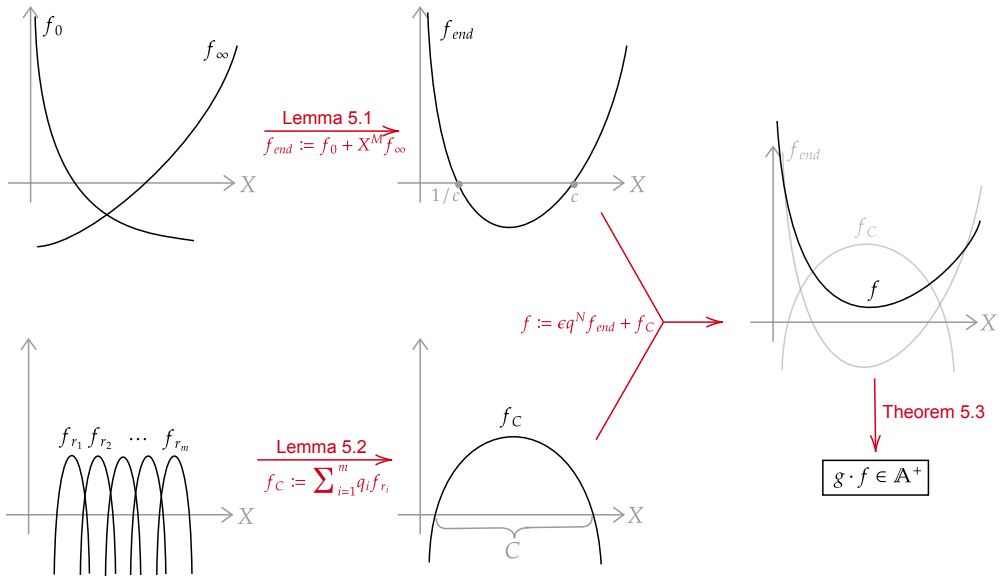

Figure 8 Proof of Proposition 3.4, illustrated at dimension $n = 1$.

Sketch of proof of Proposition 3.4. If $\mathcal{M}$ contains an element $\boldsymbol{f} = (f_S, f_K, \cdots) \in (\mathbb{A}^+)^n$ with $\deg_+(f_S) + 1 \geq \deg_+(f_K)$ and $\deg_-(f_S) \leq \deg_-(f_K)$, then simply take $\boldsymbol{f}_r = \boldsymbol{f}_\infty = \boldsymbol{f}_0 = \boldsymbol{f}$ for all $r \in \mathbb{R}_{>0}$: Equation (16) is satisfied for all r as well as (17) and (18).

Consider the non-trivial direction of implication. Let $\boldsymbol{f}_{end}, \boldsymbol{f}_C \in \mathcal{M}$ be the elements obtained respectively in Lemma 5.1 and 5.2. Define the polynomial $q := \frac{1}{2c}(X + X^{-1})$. Let $\epsilon > 0$ be such that $\epsilon \cdot \boldsymbol{f}_{end}(x) + \boldsymbol{f}_C(x) \in \mathbb{R}^n_{>0}$ for all $x \in C$. Such an ϵ exists by the compactness of C. We claim that there exists $N \in \mathbb{N}$ such that $\boldsymbol{f} := \epsilon q^N \cdot \boldsymbol{f}_{end} + \boldsymbol{f}_C$ satisfies Conditions (i) and (ii) in Theorem 5.3 simultaneously.

Let $M \in \mathbb{N}$ be such that $\deg_+(f_{end,i}) + M > \deg_+(f_{C,i})$ and $\deg_-(f_{end,i}) - M < \deg_-(f_{C,i})$ for every coordinate $i = S, K, \cdots, n$. Let $\boldsymbol{g} \coloneqq \epsilon q^M \cdot \boldsymbol{f}_{end} + \boldsymbol{f}_C$. Then we have $\mathrm{lc}_+(\boldsymbol{g}) = \mathrm{lc}_+(\boldsymbol{f}_{end}) \in \mathbb{R}^n_{>0}$ and $\mathrm{lc}_-(\boldsymbol{g}) = \mathrm{lc}_-(\boldsymbol{f}_{end}) \in \mathbb{R}^n_{>0}$, as well as

$$\deg_+(g_S) + 1 = \deg_+(f_{end,S}) + M + 1 \geq \deg_+(f_{end,K}) + M = \deg_+(g_K),$$
$$\deg_-(g_S) = \deg_-(f_{end,S}) - M \leq \deg_-(f_{end,K}) - M = \deg_-(g_K).$$

Therefore, there exists a compact set $[1/d, d] \supset C$ such that $\boldsymbol{g}(x) \in \mathbb{R}^n_{>0}$ for all $x \in \mathbb{R}_{>0} \setminus [1/d, d]$. Since $[1/d, d]$ is compact, there exists $N > M$ such that $\epsilon f_{end,i}(x) \cdot 2^N + f_{C,i}(x) > 0$ for all $i = S, K, \cdots, n$, and all $x \in [1/d, d]$.

For this N, the vector $\boldsymbol{f} \coloneqq \epsilon q^N \cdot \boldsymbol{f}_{end} + \boldsymbol{f}_C$ satisfies both Conditions (i) and (ii) in Theorem 5.3 (see the full proof in Appendix A). Therefore, we can find $g \in \mathbb{A}^+$ such that $g\boldsymbol{f} \in (\mathbb{A}^+)^n$. We have at the same time $g\boldsymbol{f} \in \mathcal{M}$ as well as $\deg_+(gf_S) + 1 \geq \deg_+(gf_K)$ and $\deg_-(gf_S) \leq \deg_-(gf_K)$. We have thus found the required element $g\boldsymbol{f}$. ◀

6 Decidability of local conditions

In this section we prove Proposition 3.5 and 3.6. Let $\mathcal{M}$ be an $\mathbb{A}$-submodule of $\mathbb{A}^n$.

▶ **Lemma 6.1.** *Let $\boldsymbol{g}_1, \ldots, \boldsymbol{g}_m$ be a basis of $\mathcal{M}$ and $r \in \mathbb{R}_{>0}$. There exists $\boldsymbol{f} \in \mathcal{M}$ with $\boldsymbol{f}(r) \in \mathbb{R}^n_{>0}$ if and only if there exist $r_1, \ldots, r_m \in \mathbb{R}$ such that $r_1\boldsymbol{g}_1(r) + \cdots + r_m\boldsymbol{g}_m(r) \in \mathbb{R}^n_{>0}$.*

▶ **Proposition 3.5.** *Let $\mathcal{M}$ be an $\mathbb{A}$-submodule of $\mathbb{A}^n$. Given as input a finite basis of $\mathcal{M}$, it is decidable whether for every $r \in \mathbb{R}_{>0}$ there exists $\boldsymbol{f}_r \in \mathcal{M}$ with $\boldsymbol{f}_r(r) \in \mathbb{R}^n_{>0}$.*

Proof. By Lemma 6.1, the statement to be decided is equivalent to the following sentence in the first order theory of the reals:

$$\forall r, r > 0 \implies (\exists r_1 \exists r_2 \cdots \exists r_m, r_1\boldsymbol{g}_1(r) + \cdots + r_m\boldsymbol{g}_m(r) \in \mathbb{R}^n_{>0}). \tag{30}$$

Its truth is decidable by Tarski's Theorem [28]. ◀

For Proposition 3.6, we start by the following definitions.

▶ **Definition 6.2.**

(i) Suppose $f = \sum_{i=p}^{q} a_i X^i \in \mathbb{A} \setminus \{0\}$, where $a_p a_q \neq 0$. Define $\mathrm{in}_+(f) \coloneqq a_q X^q$ and $\mathrm{in}_-(f) \coloneqq a_p X^p$. Additionally define $\mathrm{in}_+(0) = \mathrm{in}_-(0) = 0$.

(ii) Given $* \in \{+, -\}$, $\boldsymbol{\alpha} = (\alpha_S, \alpha_K, \ldots) \in \mathbb{Z}^n$ and $\boldsymbol{f} = (f_S, f_K, \ldots) \in \mathbb{A}^n$. Define $\mathrm{sgn}(*) = 1$ when $* = +$, and $\mathrm{sgn}(*) = -1$ when $* = -$. Let

$$m_{*,\boldsymbol{\alpha}}(\boldsymbol{f}) \coloneqq \max\{\mathrm{sgn}(*) \cdot \deg_*(f_S) + \alpha_S, \mathrm{sgn}(*) \cdot \deg_*(f_K) + \alpha_K, \ldots\}.$$

Define $\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{f}) \coloneqq (g_S, g_K, \ldots)$, where for $j = S, K, \ldots$,

$$g_j \coloneqq \begin{cases} \mathrm{in}_*(f_j) & \mathrm{sgn}(*) \cdot \deg_*(f_j) + \alpha_j = m_{*,\boldsymbol{\alpha}}(\boldsymbol{f}), \\ 0 & \deg_*(f_j) + \alpha_j < m_{*,\boldsymbol{\alpha}}(\boldsymbol{f}). \end{cases}$$

For a monomial $f = a_i X^i \in \mathbb{A}$, define $\mathrm{coef}(f) \coloneqq a_i$. In particular, $\mathrm{coef}(0) = 0$. Note that for any $* \in \{+, -\}$, $\boldsymbol{f} \in \mathbb{A}^n$ and $\boldsymbol{\alpha} \in \mathbb{Z}^n$, the above defined $\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{f})$ is an n-tuple of monomials. Writing $\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{f}) = (g_S, g_K, \ldots)$, we then extend the definition of coef() to

$$\mathrm{coef}(\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{f})) \coloneqq (\mathrm{coef}(g_S), \mathrm{coef}(g_K), \ldots) \in \mathbb{R}^n.$$

▶ **Lemma 6.3.** *Fix $* \in \{+,-\}$ and $a \in \mathbb{Z}$. The two following conditions are equivalent:*

(i) *There exists $\boldsymbol{f} = (f_S, f_K, \cdots) \in \mathcal{M}$ such that*

$$\mathrm{lc}_*(\boldsymbol{f}) \in \mathbb{R}^n_{>0} \quad \text{and} \quad \deg_*(f_S) + a \geq \deg_*(f_K). \tag{31}$$

(ii) *There exists $\boldsymbol{\alpha} = (\alpha_S, \alpha_K, \cdots) \in \mathbb{Z}^n$ with $\alpha_S - \alpha_K \leq a$, as well as $\boldsymbol{f} = (f_S, f_K, \cdots) \in \mathcal{M}$, such that $\mathrm{coef}\left(\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{f})\right) \in \mathbb{R}^n_{>0}$.*

We use the notion of a *super Gröbner basis* for $\mathcal{M}$: see [13, Chapter 2] for its exact definition. Readers can simply take the following Lemma 6.4 as its definition, since this will be the only property of the super Gröbner basis that we use in this paper.

▶ **Lemma 6.4** ([13, Lemma 2.1])**.** *Let $* \in \{+,-\}$ and $\boldsymbol{\alpha} \in \mathbb{Z}^n$. Let $\boldsymbol{g}_1, \ldots, \boldsymbol{g}_m$ be a super Gröbner basis for $\mathcal{M}$. For every $\boldsymbol{g} \in \mathcal{M}$, we have $\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{g}) = \sum_{i=1}^m p_i \cdot \mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{g}_i)$ for some $p_1, \ldots, p_m \in \mathbb{A}$.*

By [13, Chapter 2], given a basis for $\mathcal{M}$, a set of super Gröbner basis exists and can be effectively computed. We now fix a set of a super Gröbner basis $\boldsymbol{g}_1, \ldots, \boldsymbol{g}_m$ for $\mathcal{M}$.

▶ **Corollary 6.5.** *Let $* \in \{+,-\}$ and $\boldsymbol{\alpha} \in \mathbb{Z}^n$. Then there exists $\boldsymbol{f} \in \mathcal{M}$ with $\mathrm{coef}\left(\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{f})\right) \in \mathbb{R}^n_{>0}$ if and only if there exist $r_1, \ldots, r_m \in \mathbb{R}$ with $\sum_{i=1}^m r_i \cdot \mathrm{coef}(\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{g}_i)) \in \mathbb{R}^n_{>0}$.*

▶ **Lemma 6.6** (Generalization of [13, Lemma 6.1])**.** *Fix $* \in \{+,-\}$. The initial tuples $\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{g}_1), \ldots, \mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{g}_m)$ can take only a finite number of possible values when $\boldsymbol{\alpha}$ varies in the set $\{\boldsymbol{\alpha} = (\alpha_S, \alpha_K, \cdots) \in \mathbb{Z}^n \mid \alpha_S - \alpha_K \leq a\}$. Furthermore, one can effectively compute representatives $\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_p \in \mathbb{Z}^n$, such that the tuples $\left(\mathrm{in}_{*,\boldsymbol{\alpha}_1}(\boldsymbol{g}_i)\right)_{i=1,\ldots,m}, \ldots, \left(\mathrm{in}_{*,\boldsymbol{\alpha}_p}(\boldsymbol{g}_i)\right)_{i=1,\ldots,m}$ are all the possible tuples $\left(\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{g}_i)\right)_{i=1,\ldots,m}$ when $\boldsymbol{\alpha}$ varies.*

▶ **Proposition 3.6.** *Let $* \in \{+,-\}$, $a \in \mathbb{Z}$ and $\mathcal{M}$ be an $\mathbb{A}$-submodule of $\mathbb{A}^n$. Given as input a finite basis of $\mathcal{M}$, it is decidable whether there exists $\boldsymbol{f} = (f_S, f_K, \cdots) \in \mathcal{M}$ such that*

$$\mathrm{lc}_*(\boldsymbol{f}) \in \mathbb{R}^n_{>0} \quad \text{and} \quad \deg_*(f_S) + a \geq \deg_*(f_K). \tag{19}$$

Proof. First we compute a set of super Gröbner basis $\boldsymbol{g}_1, \ldots, \boldsymbol{g}_m$ for $\mathcal{M}$. Then for each $* \in \{+,-\}$, by Lemma 6.6 we compute $\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_p \in \mathbb{Z}^n$ such that the tuples $\left(\mathrm{in}_{*,\boldsymbol{\alpha}_1}(\boldsymbol{g}_i)\right)_{i=1,\ldots,m}$, $\ldots$, $\left(\mathrm{in}_{*,\boldsymbol{\alpha}_p}(\boldsymbol{g}_i)\right)_{i=1,\ldots,m}$ are all the possible tuples when $\alpha_S - \alpha_K \leq a$. For each of these $\boldsymbol{\alpha} \in \{\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_p\}$, use linear programming to decide whether there exist real numbers $r_1, \ldots, r_m \in \mathbb{R}$ such that $\sum_{i=1}^m r_i \cdot \mathrm{coef}\left(\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{g}_i)\right) \in \mathbb{R}^n_{>0}$. By Corollary 6.5, such $r_1, \ldots, r_m \in \mathbb{R}$ exist if and only if there exists $\boldsymbol{f} \in \mathcal{M}$ with $\mathrm{coef}(\mathrm{in}_{*,\boldsymbol{\alpha}}(\boldsymbol{f})) \in \mathbb{R}^n_{>0}$. By Lemma 6.3, this is true if and only if there exists $\boldsymbol{f} = (f_S, f_K, \cdots) \in \mathcal{M}$ satisfying condition (19). ◀

A Some omitted proofs

This appendix contains some omitted proofs from the main article. Other omitted proofs can be found in the full version of this paper.

▶ **Lemma 2.1.** *Let $\mathcal{G} = \{g_1, \dots, g_a\}$ be a set of elements in a group G. The semigroup $\langle \mathcal{G} \rangle$ is a group if and only if the neutral element I of G is represented by a full-image word over $\mathcal{G}$.*

Proof. Let $w \in \mathcal{G}^*$ be a full-image word with $\pi(w) = I$. Then for every i, the word w can be written as $w = vg_iv'$, so $g_i^{-1} = \pi(v')\pi(v) \in \langle \mathcal{G} \rangle$. Therefore, the semigroup $\langle \mathcal{G} \rangle$ contains all the inverse g_i^{-1}, and is thus a group.

If $\langle \mathcal{G} \rangle$ is a group, then for all i, the inverse g_i^{-1} can be written as $\pi(w_i)$ for some word $w_i \in \mathcal{G}^*$. Then the word $w \coloneqq g_1w_1g_2w_2 \cdots g_aw_a$ is a full-image word with $\pi(w) = \pi(g_1w_1) \cdots \pi(g_aw_a) = I$. ◀

▶ **Proposition 3.1.** *Suppose $I = \emptyset$ or $J = \emptyset$. The semigroup $\langle \mathcal{G} \rangle$ is a group if and only if $I = J = \emptyset$ and $\sum_{k \in K} n_k y_k = 0$ for some positive integers $n_k \in \mathbb{Z}_{>0}$. In particular, this is decidable by integer programming.*

Proof. First suppose $\langle \mathcal{G} \rangle$ is a group. Without loss of generality suppose $I = \emptyset$. Then every element $(y, b) \in \langle \mathcal{G} \rangle$ must satisfy $b \leq 0$. Therefore, for any $(y_j, b_j) \in \mathcal{G}$ with $b_j < 0$, we have $(y_j, b_j)^{-1} = (X^{-b_j} \cdot y_j, -b_j) \notin \langle \mathcal{G} \rangle$ by the positivity of $-b_j$. Hence $J = \emptyset$.

Since $\langle \mathcal{G} \rangle$ is a group, by Lemma 2.1 there exists a full-image word $w \in \mathcal{G}^*$ that represents $(0, 0)$. Let n_k be the number of times the word $(y_k, 0)$ appears in w, then $n_k > 0$ and w represents $\left(\sum_{k \in K} n_k y_k, 0\right) = (0, 0)$. This finishes the first implication.

For the converse implication, suppose $I = J = \emptyset$ and $\sum_{k \in K} n_k y_k = 0$ for some integers $n_k \in \mathbb{Z}_{>0}$. Then the word $\prod_{k \in K} (y_k, 0)^{n_k} = (0, 0)$. Therefore there exists a full-image word that represents $(0, 0)$. Hence $\langle \mathcal{G} \rangle$ is a group.

Let $p = \min_{k \in K}\{\deg_-(y_k)\}$ and $q = \max_{k \in K}\{\deg_+(y_k)\}$. For each $k \in K$, write $y_k = \sum_{t=p}^{q} \beta_{k,t} X^t$, then $\sum_{k \in K} n_k y_k = 0$ is equivalent to the system of linear equations

$$\sum_{k \in K} n_k \beta_{k,t} = 0, \quad t = p, p+1, \dots, q. \tag{32}$$

Deciding whether the system (32) has solution over $\mathbb{Z}_{>0}$ can be decided using integer programming. ◀

▶ **Corollary 3.3.** *The semigroup $\langle \mathcal{G} \rangle$ is a group if and only if there exist a double-full set $S \subset I \times J$ and polynomials $f_S, f_K, f_{(i,j)}, f_k \in \mathbb{R}_{\geq 0}[X^{\pm}]^*$ for $(i, j) \in S, k \in K$ that satisfy the following three conditions.*

(i) ***(System of linear equations)*** *The following linear equations over* $\mathbb{R}(X)$ *are satisfied:*

$$\sum_{(i,j)\in S} f_{(i,j)} h_{(i,j),m} + \sum_{k\in K} f_k y_{k,m} = 0, \quad m = 0,\dots,d-1, \tag{10}$$

$$f_S = \sum_{(i,j)\in S} f_{(i,j)}, \qquad f_K = \sum_{k\in K} f_k. \tag{11}$$

(ii) ***(Positive degree bound)*** *We have:*

$$\deg_+(f_S) + 1 \geq \deg_+(f_K). \tag{12}$$

(iii) ***(Negative degree bound)*** *We have:*

$$\deg_-(f_S) \leq \deg_-(f_K). \tag{13}$$

Proof. We show that Corollary 3.3 is equivalent to Proposition 3.2.

By the definition of $h_{(i,j),m}, y_{k,m}, (i,j) \in S, k \in K, m = 0,\dots,d-1$ in Equation (8) and (9), the Equation (5) in Condition (i) of Proposition 3.2 is equivalent to the following system:

$$\sum_{(i,j)\in S} f'_{(i,j)} h_{(i,j),m} + \sum_{k\in K} f'_k y_{k,m} = 0, \quad m = 0,\dots,d-1. \tag{33}$$

Where $f'_{(i,j)}, f'_k$ are polynomials in $\mathbb{N}[X^{\pm}]^*$ such that $f_{(i,j)} = f'_{(i,j)}(X^d), f_k = f'_k(X^d)$.

On one hand, suppose there exist polynomials $f_{(i,j)}, f_k \in \mathbb{N}[X^{\pm d}]^*$ that satisfy Conditions (i)-(iii) of Proposition 3.2. Then the polynomials $f'_{(i,j)}, f'_k$ satisfying the system (33) are also in $\mathbb{R}_{\geq 0}[X^{\pm}]$. Then let $f'_S = \sum_{(i,j)\in S} f'_{(i,j)}$ and $f'_K = \sum_{k\in K} f'_k$, so Conditions (i)-(iii) of Corollary 3.3 are satisfied for $f'_S, f'_K, f'_{(i,j)}, f'_k \in \mathbb{R}_{>0}[X^{\pm}]^*$.

On the other hand, suppose there exist polynomials $f'_S, f'_K, f'_{(i,j)}, f'_k \in \mathbb{R}_{>0}[X^{\pm}]^*$ that satisfy Conditions (i)-(iii) of Corollary 3.3. We show that there exist $f_S, f_K, f_{(i,j)}, f_k \in \mathbb{N}[X^{\pm}]^*, (i,j) \in S, k \in K$ that satisfy the same Equations (10)-(11), and such that $\deg_\pm f'_{(i,j)} = \deg_\pm f_{(i,j)}$, $\deg_\pm f'_k = \deg_\pm f_k$ for all $(i,j) \in S, k \in K$.

In fact, by the homogeneity of Equations (10)-(11), one can multiply all $h_{(i,j),m}$ and $y_{k,m}$ simultaneously by their common denominator, and suppose $h_{(i,j),m}, y_{k,m} \in \mathbb{Q}[X^{\pm}]$. Then, *fixing the degrees of* $f_{(i,j)}$ *and* f_k, one can rewrite Equations (10)-(11) as a system of homogeneous linear equation where the variables are the coefficients of $f_{(i,j)}$ and f_k. We then add to this system of homogeneous linear equations a boolean combination of homogeneous linear inequalities to guarantee $f_{(i,j)}, f_k \in \mathbb{R}_{>0}[X^{\pm}]^*$ (this can be expressed using inequalities for the coefficients of $f_{(i,j)}, f_k$), as well as to guarantee the degree of $f_{(i,j)}, f_k$. Since this system of homogeneous linear equations plus boolean combination of homogeneous linear inequalities has a solution over $\mathbb{R}$, it also has a solution over $\mathbb{Q}$, and even over $\mathbb{Z}$ by the homogeneity. Therefore, we obtain a solution over $\mathbb{Z}$ for the coefficients of $f_{(i,j)}, f_k$. This gives us a solution $f_{(i,j)}, f_k \in \mathbb{N}[X^{\pm}]^*$ with the same fixed degrees.

Consequently, $f_{(i,j)}, f_k, (i,j) \in S, k \in K$, satisfy the system (33). Thus, $f_{(i,j)}(X^d), f_k(X^d), (i,j) \in S, k \in K$. satisfy Conditions (i)-(iii) of Proposition 3.2. ◀

▶ **Lemma 4.4.** *The graph* $G(\widehat{w})$ *can be constructed by starting with an edgeless graph with a single vertex* 0 *and gradually attaching primitive circuits.*

Proof. Denote by G_0 the edgeless graph with a single vertex 0. We show that every Eulerian $\widehat{\mathcal{G}}$-graph G can be constructed by attaching primitive circuits to G_0. We use induction on the number of edges in G. When there is no edge in G, it is G_0, and we are done.

When there are loops in G, these are loops of some label $k \in K$, and are therefore primitive circuits themselves. Removing them results in another Eulerian graph G' and decreases the number of edges. By the induction hypothesis G' can be constructed by attaching primitive circuits to G_0. Then attaching the loops (primitive circuits of type in K) to G' results in G.

When there are no loops in G, denote $m \coloneqq \max(V(G))$. Then since G is Eulerian, there must be an edge e of label $\ell(e)$ starting from the vertex m, and an edge e' of label $\ell(e')$ ending at the vertex m. Since all the edges in G are of length d, the edge e must end at vertex $m - d$, and e' must start at $m - d$. (The length of an edge of label a is $\widehat{b}_a$.) Therefore the circuit consisting of e and e' is primitive of type $(\ell(e), \ell(e'))$. Removing the circuit (and the vertex m if necessary) results in a graph G'. G' is connected (and Eulerian) since there is no loop at m, and the only possible neighbour of the vertex m is $m - d$. By the induction hypothesis G' can be constructed by attaching primitive circuits to G_0. Then attaching to G' the primitive circuits of type $(\ell(e), \ell(e'))$ at vertex $m - d$ results in G. ◀

Indiscernibles and Flatness in Monadically Stable and Monadically NIP Classes

Abstract

Monadically stable and monadically NIP classes of structures were initially studied in the context of model theory and defined in logical terms. They have recently attracted attention in the area of structural graph theory, as they generalize notions such as nowhere denseness, bounded cliquewidth, and bounded twinwidth.

Our main result is the – to the best of our knowledge first – purely combinatorial characterization of monadically stable classes of graphs, in terms of a property dubbed *flip-flatness*. A class $\mathscr{C}$ of graphs is flip-flat if for every fixed radius r, every sufficiently large set of vertices of a graph $G \in \mathscr{C}$ contains a large subset of vertices with mutual distance larger than r, where the distance is measured in some graph G' that can be obtained from G by performing a bounded number of flips that swap edges and non-edges within a subset of vertices. Flip-flatness generalizes the notion of uniform quasi-wideness, which characterizes nowhere dense classes and had a key impact on the combinatorial and algorithmic treatment of nowhere dense classes. To obtain this result, we develop tools that also apply to the more general monadically NIP classes, based on the notion of indiscernible sequences from model theory. We show that in monadically stable and monadically NIP classes indiscernible sequences impose a strong combinatorial structure on their definable neighborhoods. All our proofs are constructive and yield efficient algorithms.

In particular, we thank Jakub Gajarský and Stephan Kreutzer for suggesting the notion of flip-flatness and providing a proof for the cases $r = 1, 2$.

1 Introduction

An important open problem in structural and algorithmic graph theory is to characterize those hereditary graph classes for which the model checking problem for first-order logic is tractable[1] [23, Section 8.2]. A result of Grohe, Kreutzer, and Siebertz [24] states that for monotone graph classes (that is, classes closed under removing vertices and edges), the limit of tractability is precisely captured by the notion of nowhere denseness, introduced by Nešetřil and Ossona de Mendez [29]. Examples of nowhere dense classes include the class of planar graphs, all classes that exclude a fixed minor, and classes with bounded expansion. Whereas these classes are sparse (for instance, they exclude some fixed biclique as a subgraph), the aforementioned problem seeks to generalize the result of Grohe, Kreutzer, and Siebertz to classes that are not necessarily sparse. Indeed, there are known hereditary graph classes that are not sparse, and for which the model checking problem is tractable, such as transductions of classes of bounded local cliquewidth [5], transductions of nowhere dense classes [16], or classes of ordered graphs (that is, graphs equipped with a total order) of bounded twinwidth [6].

So far, a complete picture is understood in two contexts: for monotone graph classes, where tractability coincides with nowhere denseness, and for hereditary classes of ordered graphs, where tractability coincides with bounded twinwidth. Despite the apparent dissimilarity of the combinatorial definitions of nowhere denseness and bounded twinwidth, those notions can be alternatively characterized in a uniform way in logical terms by the following notion, originating in model theory. Unless mentioned otherwise, all formulas are first-order formulas.

Say that a class $\mathscr{C}$ of graphs *transduces* a class $\mathscr{D}$ of graphs if for every $H \in \mathscr{D}$ there is some $G \in \mathscr{C}$ from which H can be obtained by performing the following steps: (1) coloring the vertices of G arbitrarily (2) interpreting a fixed formula $\varphi(x, y)$ (involving the edge relation and unary relations for the colors), thus yielding a new graph $\varphi(G)$ with the same vertices as G and edges uv such that $\varphi(u, v)$ holds, and finally (3) taking an induced subgraph of $\varphi(G)$. The transducability relation on graph classes is transitive, and classes that *do not* transduce the class of all graphs are called *monadically NIP*. For instance, the class of all bipartite graphs transduces the class of all graphs: to obtain an arbitrary graph G, consider its 1-subdivision, obtained by placing one vertex on each edge of G, thus yielding a bipartite graph H; then the formula $\varphi(x, y)$ expressing that x and y have a common neighbor defines a graph on $V(H)$ containing G as an induced subgraph. Hence, the class of bipartite graphs is not monadically NIP. On the other hand, all the graph classes mentioned earlier – nowhere dense classes and transductions thereof, classes of bounded twinwidth, or transductions of classes with bounded local cliquewidth – are monadically NIP. This suggests that monadic NIP might constitute the limit of tractability of the model checking problem. More precisely, the following has been conjectured[2].

▶ **Conjecture 1** ([1]). *Let $\mathscr{C}$ be a hereditary class of graphs. Then the model checking problem for first-order logic is fixed parameter tractable on $\mathscr{C}$ if and only if $\mathscr{C}$ is monadically NIP.*

Quite remarkably, among monotone graph classes, classes that are monadically NIP correspond precisely to nowhere dense classes [2], and among hereditary graph classes of ordered graphs, classes that are monadically NIP correspond precisely to classes of bounded

[1] more precisely, *fixed parameter-tractable*, that is, solvable in time $f(|\varphi|) \cdot |G|^c$, where φ is the input formula and G is the input graph, for some function $f : \mathbb{N} \to \mathbb{N}$ and constant c

[2] To the best of our knowledge the conjecture was first explicitly discussed during the open problem session of the Algorithms, Logic and Structure Workshop in Warwick, in 2016, see [1].

twinwidth [6]. One may tweak the definition of monadic NIP classes by considering other logics than first-order logic. For instance, for the counting extension CMSO_2 of monadic second-order logic, one recovers precisely the notion of classes of bounded cliquewidth [9], or classes of bounded treewidth if only monotone classes are considered. Thus, variations on the definition of monadic NIP recover important notions from graph theory: nowhere denseness, bounded twinwidth, bounded treewidth, and bounded cliquewidth.

Note that both implications in Conjecture 1 remain open. The conjecture is so far confirmed for monotone graph classes [24] (where monadically NIP classes are exactly the nowhere dense classes) and for hereditary classes of ordered graphs [6], tournaments [22], interval graphs and permutation graphs [7], (where monadically NIP classes are exactly the classes of bounded twinwidth). As a special important case, the conjecture predicts that all *monadically stable* graph classes are tractable. A class $\mathscr{C}$ is monadically stable if it does not transduce the class of all half-graphs, that is, graphs with vertices $a_1, b_1, \ldots, a_n, b_n$ such that a_i is adjacent to b_j if and only if $i \leqslant j$. Although much more restrictive than monadically NIP classes, monadically stable classes include all nowhere dense classes [2], and hence also all classes $\mathscr{D}$ that transduce in a nowhere dense class $\mathscr{C}$ (called structurally nowhere dense classes [19]). Those include dense graph classes, such as for instance squares of planar graphs. In fact, it is conjectured [30] that every monadically stable class of graphs is structurally nowhere dense.

These outlined connections between structural graph theory and model theory have recently triggered the interest to generalize combinatorial and algorithmic results from nowhere dense classes to structurally nowhere dense, monadically stable and monadically NIP classes, and ultimately to efficiently solve the model checking problem for first-order logic on these classes [5, 6, 19, 13, 21, 27, 30, 31, 32]. Logical results on monadically stable and monadically NIP classes in model theory include [3, 34, 8, 4].

Contribution

As discussed above, many central graph classes such as those with bounded cliquewidth, twinwidth or nowhere dense classes can be characterized both from a structural (i.e., graph theoretic) and a logical perspective. While monadically stable and monadically NIP graph classes are naturally defined via logic, structural characterizations have so far been elusive. In this work we take a step towards a structure theory for monadically stable and monadically NIP classes of graphs, which is the basis for their future algorithmic and combinatorial treatment, in particular, a tool for approaching Conjecture 1, as we discuss later.

Flatness. Our main result, Theorem 3, provides a purely combinatorial characterization of monadically stable graph classes in terms of *flip-flatness*. Flip-flatness generalizes *uniform quasi-wideness*[3], introduced by Dawar in [10] in his study of homomorphism preservation properties. Uniform quasi-wideness was proved by Nešetřil and Ossona de Mendez [29] to characterize nowhere dense graph classes and is a key tool in the combinatorial and algorithmic treatment of these classes. To foster the further discussion, let us formally define this notion.

[3] Another reasonable name for flip-flatness would be *flip-wideness*. We avoided this name to prevent confusion with the recently introduced graph parameter *flip-width* [37], which is studied in the same context.

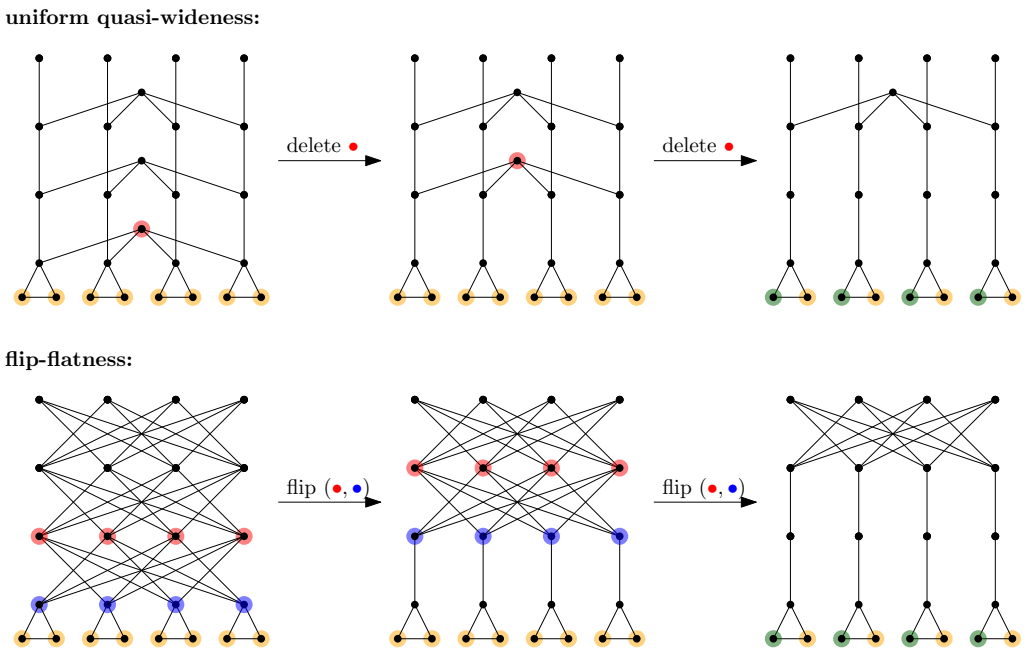

Figure 1 An example of uniform quasi-wideness (flip-flatness). Among the yellow vertices, we find a still large set of green vertices, that is distance-7 independent after deleting a bounded number of red vertices (performing a bounded number of flips between sets of red and blue vertices). Two key properties are illustrated: 1. the higher the desired independence distance, the more operations have to be performed; 2. we cannot hope to make all the yellow vertices distance-r independent with a bounded number of operations.

A set of vertices is *distance-r independent* in a graph if any two vertices in the set are at distance greater than r. A class of graphs $\mathscr{C}$ is *uniformly quasi-wide* if for every $r \in \mathbb{N}$ there exists a function $N_r : \mathbb{N} \to \mathbb{N}$ and a constant $s \in \mathbb{N}$ with the following property. For all $m \in \mathbb{N}$, $G \in \mathscr{C}$, and $A \subseteq V(G)$ with $|A| \geqslant N_r(m)$, there exists $S \subseteq V(G)$ with $|S| \leqslant s$ and $B \subseteq A \setminus S$ with $|B| \geqslant m$ such that B is distance-r independent in $G - S$ (see the top of Figure 1). Intuitively, for uniformly quasi-wide classes, in sufficiently large sets one can find large subsets that are distance-r independent after the deletion of a constant number of vertices. Uniform quasi-wideness is only suitable for the treatment of sparse graphs. Already very simple dense graph classes, such as the class of all cliques, are not uniformly quasi-wide.

Inspired by the notion of uniform quasi-wideness, Jakub Gajarský and Stephan Kreutzer proposed the new notion of *flip-flatness*. Roughly speaking, flip-flatness generalizes uniform quasi-wideness by replacing in its definition the deletion of a bounded size set of vertices by the inversion of the edge relation between a bounded number of (arbitrarily large) vertex sets. Let us make this definition more precise. A *flip* in a graph G is specified by a pair of sets $\mathsf{F} = (A, B)$ with $A, B \subseteq V(G)$. We write $G \oplus \mathsf{F}$ for the graph with the same vertices as G, and edges uv such that $uv \in E(G)$ xor $(u, v) \in (A \times B) \cup (B \times A)$. For a set $F = \{\mathsf{F}_1, \ldots, \mathsf{F}_n\}$ of flips, we write $G \oplus F$ for the graph $G \oplus \mathsf{F}_1 \oplus \cdots \oplus \mathsf{F}_n$.

▶ **Definition 2.** *A class of graphs $\mathscr{C}$ is* flip-flat *if for every $r \in \mathbb{N}$ there exists a function $N_r : \mathbb{N} \to \mathbb{N}$ and a constant $s_r \in \mathbb{N}$ such that for all $m \in \mathbb{N}$, $G \in \mathscr{C}$, and $A \subseteq V(G)$ with $|A| \geqslant N_r(m)$, there exists a set F of at most s_r flips and $B \subseteq A$ with $|B| \geqslant m$ such that B is distance-r independent in $G \oplus F$.*

Intuitively, for flip-flat classes in sufficiently large sets one can find large subsets that are distance-r independent after a constant number of flips (see bottom of Figure 1). For example the class of all cliques is flip-flat, requiring only a single flip to make the whole vertex set distance-∞ independent. Our main result is the following purely combinatorial characterization of monadic stability.

▶ **Theorem 3.** *A class of graphs is monadically stable if and only if it is flip-flat.*

Notably, our proof is algorithmic and yields polynomial bounds in the following sense.

▶ **Theorem 4.** *Every monadically stable class $\mathscr{C}$ of graphs is flip-flat, where for every r, the function N_r is polynomial. Moreover, given an n-vertex graph $G \in \mathscr{C}$, $A \subseteq V(G)$, and $r \in \mathbb{N}$, we can compute a subset $B \subseteq A$ and a set of flips F that makes B distance-r independent in $G \oplus F$ in time $\mathcal{O}(f_{\mathscr{C}}(r) \cdot n^3)$ for some function $f_{\mathscr{C}}$.*

Just as uniform quasi-wideness provided a key tool for the algorithmic treatment of nowhere dense graph classes, in particular for first-order model checking [24], we believe that the characterization by flip-flatness will provide an important step towards the algorithmic treatment of monadically stable classes. We leave as an open question whether a similar characterization of monadically NIP classes exists.

Indiscernible sequences. Our study is based on *indiscernible sequences*, which are a fundamental tool in model theory. An indiscernible sequence is a (finite or infinite) sequence $I = (\bar{a}_1, \bar{a}_2, \ldots)$ of tuples of equal length of elements of a fixed (finite or infinite) structure, such that any two finite subsequences of I that have equal length, satisfy the same formulas. More generally, for a set of formulas Δ, the sequence I is Δ-*indiscernible* if for each formula $\varphi(\bar{x}_1, \ldots, \bar{x}_k)$ from Δ either all subsequences of I of length k satisfy φ, or no subsequence of length k satisfies φ. For example, any enumeration of vertices forming a clique or an independent set in a graph is Δ-indiscernible for $\Delta = \{E(x_1, x_2)\}$ containing only the edge relation. Also, any increasing sequence of rationals in the structure $(\mathbb{Q}, <)$ is Δ-indiscernible for Δ being the set of all formulas. We use indiscernible sequences to obtain new insights about monadically stable and monadically NIP classes.

It was shown by Blumensath [4] that in monadically NIP classes, any fixed element interacts with the tuples of an indiscernible sequence in a very regular way. We give a new finitary proof of Blumensath's result. Building on this, we develop our main technical tool, Theorem 11, where we show that the regular properties of the indiscernible sequences extend to their disjoint definable neighborhoods (see Section 3.2 for details). A result similar to Theorem 11, also for disjoint definable neighborhoods in monadically NIP classes, plays a key role in [6, 35].

Apart from powering our algorithmic proof of flip-flatness, Theorem 11 has already found further applications in monadically stable classes of graphs: it was recently used to obtain improved bounds for Ramsey numbers [14] and to prove an algorithmic game-characterization of these classes, called *Flipper game* [20]. The paper [20] provides two proofs for this game characterization. One is constructive and algorithmic and builds on our work. The other builds on model theoretic tools; it is non-constructive but self-contained and highlights additional properties of monadically stable graph classes, including a second (though non-constructive) proof of Theorem 3. The algorithmic version of the Flipper game plays a crucial role for proving that the first-order model checking problem is fixed parameter tractable for structurally nowhere dense classes of graphs [16]. This suggests that our developed techniques may be an important tool towards resolving Conjecture 1.

2 Preliminaries

We use standard notation from graph theory and model theory and refer to [11] and [25] for extensive background. We write $[m]$ for the set of integers $\{1, \dots, m\}$.

Relational structures and graphs. A *(relational) signature* Σ is a set of relation symbols, each with an associated non-negative integer, called its *arity*. A Σ-*structure* $\mathbb{A}$ consists of a *universe*, which is a non-empty, possibly infinite set, and *interpretations* of the symbols from the signature: each relation symbol of arity k is interpreted as a k-ary relation over the universe. By a slight abuse of notation, we do not differentiate between structures and their universes and between relation symbols and their interpretations. By $\mathscr{C}$ we denote classes of structures over a fixed signature. Unless indicated otherwise, $\mathscr{C}$ may contain finite and infinite structures.

A *monadic extension* Σ^+ of a signature Σ is any extension of Σ by unary predicates. A unary predicate will also be called a *color*. A *monadic expansion* or *coloring* of a Σ-structure $\mathbb{A}$ is a Σ^+-structure $\mathbb{A}^+$, where Σ^+ is a monadic extension of Σ, such that $\mathbb{A}$ is the Σ-*reduct* of $\mathbb{A}^+$, that is, the Σ-structure obtained from $\mathbb{A}^+$ by removing all relations with symbols in $\Sigma^+ \setminus \Sigma$. When $\mathscr{C}$ is a class of Σ-structures and Σ^+ is a monadic extension of Σ, we write $\mathscr{C}[\Sigma^+]$ for the class of all possible Σ^+-expansions of structures from $\mathscr{C}$.

A *graph* is a finite structure over the signature consisting of a binary relation symbol E, interpreted as the symmetric and irreflexive edge relation.

First-order logic. We say that two tuples $\bar{a}, \bar{b}$ of elements are φ-*connected* in a structure $\mathbb{A}$ if $\mathbb{A} \models \varphi(\bar{a}, \bar{b})$. We call the set $N_\varphi^{\mathbb{A}}(\bar{a}) = \{\bar{b} \in \mathbb{A}^{|\bar{y}|} \ : \ \mathbb{A} \models \varphi(\bar{a}, \bar{b})\}$ the φ-*neighborhood* of $\bar{a}$. We simply write $N_\varphi(\bar{a})$ when $\mathbb{A}$ is clear from the context.

Let $\Phi(\bar{x})$ be a finite set of formulas with free variables $\bar{x}$. A Φ-*type* is a conjunction $\tau(\bar{x})$ of formulas in Φ or their negations, such that every formula in Φ occurs in τ either positively or negatively. More precisely, $\tau(\bar{x})$ is a formula of the following form, for some subset $A \subseteq \Phi$:

$$\bigwedge_{\varphi \in A} \varphi(\bar{x}) \wedge \bigwedge_{\varphi \in \Phi \setminus A} \neg\varphi(\bar{x}).$$

Note that for every $|\bar{x}|$-tuple $\bar{a}$ of elements of $\mathbb{A}$, there is exactly one Φ-type $\tau(\bar{x})$ such that $\mathbb{A} \models \tau(\bar{a})$.

Stability and NIP. While we already defined monadic stability and NIP in terms of transductions in the introduction, let us also give the equivalent original definition. A formula $\varphi(\bar{x}, \bar{y})$ has the k-*order property* on a class $\mathscr{C}$ of structures if there are $\mathbb{A} \in \mathscr{C}$ and two sequences $(\bar{a}_i)_{1 \leqslant i \leqslant k}$, $(\bar{b}_i)_{1 \leqslant i \leqslant k}$ of tuples of elements of $\mathbb{A}$, such that for all $i, j \in [k]$

$$\mathbb{A} \models \varphi(\bar{a}_i, \bar{b}_j) \quad \iff \quad i \leqslant j.$$

The formula φ is said to have the *order property* on $\mathscr{C}$ if it has the k-order property for all $k \in \mathbb{N}$. The class $\mathscr{C}$ is called *stable* if no formula has the order-property on $\mathscr{C}$. A class $\mathscr{C}$ of Σ-structures is *monadically stable* if for every monadic extension Σ^+ of Σ the class $\mathscr{C}[\Sigma^+]$ is stable.

Similarly, a formula $\varphi(\bar{x}, \bar{y})$ has the k-*independence property* on a class $\mathscr{C}$ if there are $\mathbb{A} \in \mathscr{C}$, a size k set $A \subseteq \mathbb{A}^{|\bar{x}|}$ and a sequence $(\bar{b}_J)_{J \subseteq A}$ of tuples of elements of $\mathbb{A}$ such that for all $J \subseteq A$ and for all $\bar{a} \in A$

$$\mathbb{A} \models \varphi(\bar{a}, \bar{b}_J) \quad \iff \quad \bar{a} \in J.$$

We then say that A is *shattered* by φ. We define the *independence property* (IP), classes with the *non-independence property* (NIP classes), and *monadically NIP* classes as expected. Note that every (monadically) stable class is (monadically) NIP. Baldwin and Shelah proved that in the definitions of monadic stability and monadic NIP, one can alternatively rely on formulas $\varphi(x,y)$ with just a pair of singleton variables, instead of a pair of tuples of variables [3, Lemma 8.1.3, Theorem 8.1.8].

We call a relation R *definable* on a structure $\mathbb{A}$ if $R = \{\bar{a} \in \mathbb{A}^{|\bar{x}|} : \mathbb{A} \models \varphi(\bar{a})\}$ for some formula $\varphi(\bar{x})$. The following is immediate from the previous definitions.

▶ **Lemma 5.** *Let $\mathscr{C}$ be a monadically stable (monadically NIP) class of Σ-structures, let Σ^+ be a monadic extension of Σ and let $\mathscr{D}$ be the hereditary closure of any expansion of $\mathscr{C}[\Sigma^+]$ by definable relations. Then also $\mathscr{D}$ is monadically stable (monadically NIP).*

A formula $\varphi(x,\bar{y})$ has *pairing index* k on a class $\mathscr{C}$ of structures if there is $\mathbb{A} \in \mathscr{C}$ and two sequences $(a_{ij})_{1 \leqslant i < j \leqslant k}$ and $(\bar{b}_i)_{1 \leqslant i \leqslant k}$ such that for all $1 \leqslant i < j \leqslant k$ and $\ell \in [k]$

$$\mathbb{A} \models \varphi(a_{ij}, \bar{b}_\ell) \quad \iff \quad \ell \in \{i,j\}.$$

We require that x is a single free variable, while $\bar{y}$ is allowed to be a tuple of variables. Intuitively, from a graph theoretic perspective, if a formula has unbounded pairing index on a class $\mathscr{C}$, then it can encode arbitrarily large 1-subdivided cliques in $\mathscr{C}$, where the principal vertices are represented by the tuples $\bar{b}_\ell$ and the subdivision vertices are represented by single elements a_{ij}. As discussed in the introduction, this is sufficient to encode arbitrary graphs in $\mathscr{C}$ by using an additional color predicate. In this case, $\mathscr{C}$ cannot be monadically NIP. The above reasoning is formalized in the following characterization.

▶ **Lemma 6.** *A class $\mathscr{C}$ of Σ-structures is monadically NIP if and only if for every monadic extension Σ^+ of Σ every Σ^+-formula $\varphi(x,\bar{y})$ has bounded pairing index on $\mathscr{C}[\Sigma^+]$.*

Indiscernible sequences. Let $\mathbb{A}$ be a Σ-structure and $\varphi(\bar{x}_1, \ldots, \bar{x}_m)$ a formula. We say a sequence $(\bar{a}_i)_{1 \leqslant i \leqslant n}$ of tuples from $\mathbb{A}$ (where all $\bar{x}_i$ and $\bar{a}_j$ have the same length) is a *φ-indiscernible sequence* of length n, if for every two sequences of indices $i_1 < \cdots < i_m$ and $j_1 < \cdots < j_m$ from $[n]$ we have

$$\mathbb{A} \models \varphi(\bar{a}_{i_1}, \ldots, \bar{a}_{i_m}) \quad \iff \quad \mathbb{A} \models \varphi(\bar{a}_{j_1}, \ldots, \bar{a}_{j_m}).$$

For a set of formulas Δ we call a sequence *Δ-indiscernible* if it is φ-indiscernible for all $\varphi \in \Delta$. For finite Δ, by (iteratively applying) Ramsey's theorem we can extract a Δ-indiscernible sequence from any sequence. In general structures however, in order to extract a large Δ-indiscernible sequence we must initially start with an enormously large sequence. To the best of our knowledge the following theorem goes back to Ehrenfeucht and Mostowski [17].

▶ **Theorem 7.** *Let Δ be a finite set of formulas. There exists a function f such that every sequence of elements of length at least $f(m)$ (in a structure with a signature matching Δ) contains a Δ-indiscernible subsequence of length m.*

In stable classes we can efficiently find polynomially large (that is, $f(m) = m^{O(1)}$) indiscernible sequences of elements (see also [28, Theorem 3.5]). In the full version of the paper we observe that the run time is essentially bounded by the time it takes to evaluate the formulas from Δ on a small polynomial part of the input structure.

3 Technical overview

Our work is organized as follows. Section 3.1 introduces useful combinatorial properties of indiscernibles in monadically NIP classes. We extend those properties in Section 3.2, where we prove our main tool, Theorem 11. We use this tool in Section 3.3 to prove flip-flatness. Due to space constraints, we mostly provide proof sketches, which should convey the key ideas. All missing proofs can be found in the full version of the paper [15].

3.1 Indiscernibles in monadically stable and monadically NIP classes

In classical model theory, instead of classes of finite structures, usually infinite structures are studied. For a single infinite structure $\mathbb{A}$, we say $\mathbb{A}$ is (monadically) stable/NIP, if the class $\{\mathbb{A}\}$ is (monadically) stable/NIP. In this context, an indiscernible sequence is usually assumed to be of infinite length and indiscernible over the set of all first-order formulas. Using Ω to denote the set of all first-order formulas, we will denote the latter property as Ω-*indiscernibility*.

It is well-known that indiscernible sequences can be used to characterize stability and NIP for infinite structures. To characterize NIP, define the *alternation rank* of a formula $\varphi(\bar{x}, \bar{y})$ over a sequence I in a structure $\mathbb{A}$ as the maximum k such that there exists a (possibly non-contiguous) subsequence $(\bar{a}_1, \ldots, \bar{a}_{k+1})$ of I and a tuple $\bar{b} \in \mathbb{A}^{|\bar{x}|}$ such that for all $i \in [k]$ we have $\mathbb{A} \models \varphi(\bar{b}, \bar{a}_i) \iff \mathbb{A} \models \neg\varphi(\bar{b}, \bar{a}_{i+1})$. A structure $\mathbb{A}$ is NIP if and only if every formula has finite alternation rank over every Ω-indiscernible sequence in $\mathbb{A}$ [33, Theorem 12.17]. Stable classes can be characterized in a similar way. We say the *exception rank* of a formula $\varphi(\bar{x}, \bar{y})$ over a sequence I in a structure $\mathbb{A}$ is the maximum k such that there exists a tuple $\bar{b} \in \mathbb{A}^{|\bar{x}|}$ such that for k distinct tuples $\bar{a}_i \in I$ we have $\mathbb{A} \models \varphi(\bar{b}, \bar{a}_i)$ and for k other distinct tuples $\bar{a}_i \in I$ we have $\mathbb{A} \models \neg\varphi(\bar{b}, \bar{a}_i)$. A structure $\mathbb{A}$ is stable if and only if every formula has finite exception rank over every Ω-indiscernible sequence in $\mathbb{A}$ [33, Corollary 12.24].

Hence, NIP and stablility can be characterized by the interaction of tuples of elements with indiscernible sequences. For *monadically* NIP structures, Blumensath [4] shows that the interaction of single elements with indiscernible sequences is even more restricted.

▶ **Theorem 8** ([4, Corollary 4.13]). *In every monadically NIP structure $\mathbb{A}$, for every formula $\varphi(x, \bar{y})$, where x is a single free variable, and Ω-indiscernible sequence $(\bar{a}_i)_{i\in\mathbb{N}}$ of $|\bar{y}|$-tuples the following holds: for every element $b \in \mathbb{A}$ there exists an exceptional index $\mathrm{ex}(b) \in \mathbb{N}$ and two truth values $t_<(b), t_>(b) \in \{0, 1\}$ such that*

$$\begin{aligned} &\text{for all } i < \mathrm{ex(b)} : \mathbb{A} \models \varphi(b, \bar{a}_i) \iff t_<(b) = 1, \text{ and} \\ &\text{for all } i > \mathrm{ex(b)} : \mathbb{A} \models \varphi(b, \bar{a}_i) \iff t_>(b) = 1. \end{aligned}$$

See Figure 2 for examples. In particular, the alternation rank of the formulas $\varphi(x, \bar{y})$ with a single free variable x over every Ω-indiscernible sequence in a monadically NIP structure is at most 2.

Theorem 8 will be a crucial tool for proving flip-flatness. However, as we strive for algorithmic applications, we have to develop an effective, computable version that is suitable for handling classes of finite structures. Instead of requiring Ω-indiscernibility, we will specifically consider Δ-indiscernible sequences with respect to special sets $\Delta = \Delta_k^\Phi$ that we define soon. These sets Δ_k^Φ will strike the right balance of being on the one hand sufficiently rich to allow us to derive structure from them, but on the other hand sufficiently simple such that we can efficiently evaluate formulas from Δ_k^Φ, making our flip-flatness result algorithmic.

Figure 2 Two monadically NIP structures. On the left: the infinite half-graph, where Theorem 8 applies for the edge relation with $t_<(b) = 0$ and $t_>(b) = 1$. On the right: the infinite matching, where we have $t_<(b) = t_>(b) = 0$ but a differing truth value at index $\mathrm{ex}(b) = 3$.

Fix a finite set $\Phi(x, \bar{y})$ of formulas of the form $\varphi(x, \bar{y})$ where x is a single variable. A Φ-*pattern* is a finite sequence $(\varphi_i)_{1 \leqslant i \leqslant k'}$, where each formula $\varphi_i(x, \bar{y})$ is a boolean combination of formulas $\varphi(x, \bar{y}) \in \Phi(x, \bar{y})$. Given a Φ-pattern $(\varphi_i)_{i \in [k']}$, the following formula expresses that, for a given sequence of k' tuples, each of length $|\bar{y}|$, there is some element that realizes that pattern (see Figure 3 for an example):

$$\gamma_{(\varphi_1,\dots,\varphi_{k'})}(\bar{y}_1, \dots, \bar{y}_{k'}) = \exists x. \bigwedge_{i \in [k']} \varphi_i(x, \bar{y}_i).$$

For a finite set of formulas $\Phi(x, \bar{y})$ and an integer k we define Δ_k^Φ to be the set of all formulas $\gamma_{(\varphi_1,\dots,\varphi_{k'})}$, where $(\varphi_1, \dots, \varphi_{k'})$ is a Φ-pattern of length $k' \leqslant k$. Note that the set Δ_k^Φ is finite, as (up to equivalence) there are only finitely many boolean combinations of formulas in Φ. We write Δ_k^φ for $\Delta_k^{\{\varphi\}}$.

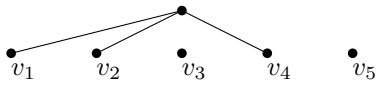

Figure 3 Example of an $\{E\}$-pattern: a graph satisfying $G \models \gamma_{(E,E,\neg E,E,\neg E)}(v_1, v_2, v_3, v_4, v_5)$.

We can now state a finitary version of Theorem 8 as follows. For the convenient use later on, we state the result not for single formulas φ but for Φ-types.

▶ **Theorem 9.** *For every monadically NIP class $\mathscr{C}$ of structures and finite set of formulas $\Phi(x, \bar{y})$ there exist integers n_0 and k, such that for every $\mathbb{A} \in \mathscr{C}$ the following holds. If $I = (\bar{a}_i)_{1 \leqslant i \leqslant n}$ is a Δ_k^Φ-indiscernible sequence of length $n \geqslant n_0$ in $\mathbb{A}$, and $b \in \mathbb{A}$, then there exists an exceptional index $\mathrm{ex}(b) \in [n]$ and Φ-types $\tau_-(x, \bar{y})$ and $\tau_+(x, \bar{y})$ such that*

$\mathbb{A} \models \tau_-(b, \bar{a}_i)$ *holds for all* $1 \leqslant i < \mathrm{ex}(b)$, *and*
$\mathbb{A} \models \tau_+(b, \bar{a}_i)$ *holds for all* $\mathrm{ex}(b) < i \leqslant n$.

Our proof uses different tools than [4]. It is combinatorial, fully constructive, and gives explicit bounds on n_0 and k as well as the required set of formulas Δ_k^Φ. One may alternatively finitize Theorem 8 via compactness, but then we do not obtain these crucial properties.

For the more restricted monadically stable classes we can give even stronger guarantees: for every element $b \in \mathbb{A}$, the types do not alternate and we have $\tau_- = \tau_+$.

▶ **Theorem 10.** *For every monadically stable class $\mathscr{C}$ of structures and finite set of formulas $\Phi(x, \bar{y})$ there exist integers n_0 and k, such that for every $\mathbb{A} \in \mathscr{C}$ the following holds. If $I = (\bar{a}_i)_{1 \leqslant i \leqslant n}$ is a Δ_k^Φ-indiscernible sequence of length $n \geqslant n_0$ in $\mathbb{A}$, and $b \in \mathbb{A}$, then there exists an exceptional index $\mathrm{ex}(b) \in [n]$ and a Φ-type τ, such that*

$\mathbb{A} \models \tau(b, \bar{a}_i)$ *for all* $i \in [n]$ *with* $i \neq \mathrm{ex}(b)$.

Building on Theorem 9, we give a full proof of Theorem 10. In order to give an intuition about the interaction of monadic stability and Δ_k^Φ-indiscernibility, we sketch a standalone proof here.

Proof sketch of Theorem 10. For simplicity, we will focus on the case were Φ is a singleton set $\{\varphi(x,\bar{y})\}$. Let k be the smallest number such that the bound for the pairing index of φ and $\neg\varphi$ on $\mathscr{C}$ is less than k. Such a bound exists since $\mathscr{C}$ is in particular monadically NIP. Assume towards a contradiction that there exists a sufficiently long Δ_k^φ-indiscernible sequence I in a structure $\mathbb{A} \in \mathscr{C}$ and an element $b \in \mathbb{A}$ that is φ-connected to at least two tuples in I and not φ-connected to at least two other tuples in I. By symmetry, we can assume that b is not φ-connected to the majority of I. We therefore find a length-k subsequence $\bar{a}_1, \dots, \bar{a}_k$ of I and two distinct indices $i_0, j_0 \in [k]$, such that b is φ-connected exactly to the i_0th and j_0th element of $\bar{a}_1, \dots, \bar{a}_k$. We say that the i_0th and j_0th element are *φ-paired* by b. Our goal is to derive a contradiction by finding also for every other pair i, j of indices an element that φ-pairs them, witnessing that φ has pairing index at least k in $\mathscr{C}$.

In stable classes, every sufficiently long Δ_k^φ-indiscernible sequence I is also *totally* Δ_k^φ-*indiscernible*: This means that every permutation I' of I is again Δ_k^φ-indiscernible, with the formulas from Δ_k^φ taking the same truth values on I' as on I. Intuitively speaking, if permuting two elements in an indiscernible sequence would change the truth value of a formula, then this formula orders these two elements and by indiscernibility also orders a large part of the sequence, contradicting stability. A proof of the statement for Ω-indiscernibles can be found in [36, Lemma 9.1.1].

The formula $\gamma(\bar{y}_1, \dots, \bar{y}_k) :=$ "$\bar{y}_{i_0}$ and $\bar{y}_{j_0}$ are φ-paired by some element" is contained in Δ_k^φ and holds on $\bar{a}_1, \dots, \bar{a}_k$, as witnessed by b. By total indiscernibility, we may permute $\bar{a}_1, \dots, \bar{a}_k$ and the formula still holds. By swapping a_{i_0} with a_i and a_{j_0} with a_j, we obtain for arbitrary i, j that "$\bar{a}_i$ and $\bar{a}_j$ are φ-paired by some element". This witnesses that φ has pairing index at least k, a contradiction. ◀

For the more general monadically NIP case, we cannot rely on total indiscernibility. Instead, we bound the alternation rank by pairing tuples located around alternation points, leading to a similar but more involved reasoning.

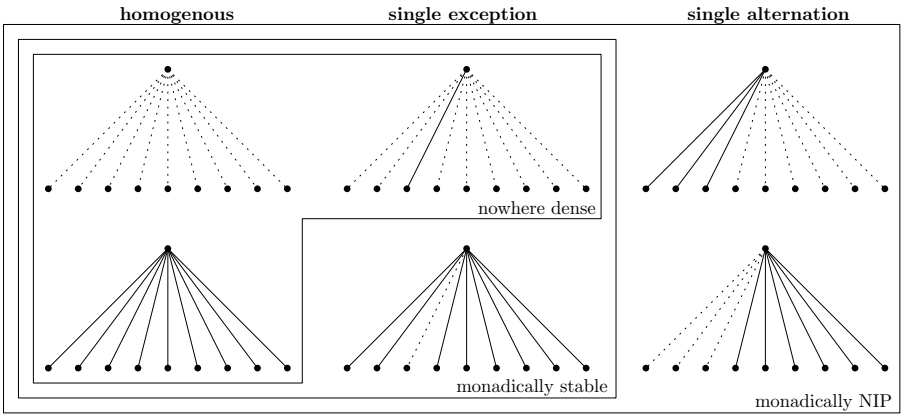

Figure 4 All types of neighborhoods a vertex (top) can have in indiscernible sequences (bottom) in different graph classes.

We conclude this section by mentioning that a behavior similar to Theorem 10 was already observed in [26] for the edge relation in nowhere dense classes. Considering only the edge relation, we depict the different possible behavior of vertices towards indiscernible sequences in different classes of graphs in Figure 4. In monadically NIP (or stable) classes, the same six (or four) patterns apply for connections with respect to any formula $\varphi(x, y)$.

3.2 Disjoint definable neighborhoods

In the previous section we have seen that in monadically stable and monadically NIP classes, every element is very homogeneously connected to all but at most one element of an indiscernible sequence. At a first glance, this exceptional behavior towards one element seems to be erratic and standing in the way of combinatorial and algorithmic applications. However, it turns out that it can be exploited to obtain additional structural properties.

The key observation is that elements that are "exceptionally connected" towards a single element of an indiscernible sequence, inherit some of the good properties of that sequence. We will give a simple example to demonstrate this idea. Let G be a graph containing certain red vertices R and blue vertices B, such that the edges between R and B describe a matching (see Figure 5, left).

Figure 5 Examples of one-to-one and many-to-one connections in a graph. On the left: a matching. On the right: a star forest.

Given a formula $\varphi(x_1, \dots, x_q)$, define

$$\hat{\varphi}(x_1, \dots, x_q) := \exists b_1, \dots, b_q \in B. \varphi(b_1, \dots, b_q) \wedge \bigwedge_{i \in [q]} E(x_i, b_i).$$

Take a $\hat{\varphi}$-indiscernible sequence R' among R. Obviously, every vertex in the blue neighborhood B' of R' has one exceptional connection towards R', that is, towards its unique matching neighbor in R'. It is now easy to see that B' is a φ-indiscernible sequence in G: for every sequence of red vertices $a_1, \dots, a_q \in R'$ and their unique blue matching neighbors $b_1, \dots, b_q \in B'$ we have $G \models \hat{\varphi}(a_1, \dots, a_q)$ if and only if $G \models \varphi(b_1, \dots, b_q)$.

This example sketches how first-order definable one-to-one connections towards elements of an indiscernible sequence preserve indiscernibility. The more general case however is the many-to-one case, where we have a set of elements, each of which is exceptionally connected to a single element of an indiscernible sequence I, while allowing multiple elements to be exceptionally connected to the same element of I (think, for example, of R and B being the centers and leaves of a star-forest as depicted in Figure 5, right). Our notion of such many-to-one connections will be that of *disjoint α-neighborhoods*. Recall, that for a formula $\alpha(\bar{x}, y)$, the α-neighborhood $N_\alpha(\bar{a})$ of a tuple $\bar{a}$ is defined as the set of all b satisfying $\alpha(\bar{a}, b)$. We say a sequence J of $|\bar{x}|$-tuples has *disjoint α-neighborhoods* if $N_\alpha(\bar{a}_1) \cap N_\alpha(\bar{a}_2) = \varnothing$ for all distinct $\bar{a}_1, \bar{a}_2 \in J$.

As the main technical tool of this paper, we prove for monadically NIP classes that every sequence of disjoint α-neighborhoods contains a large subsequence that exerts strong control over its neighborhood. This lifts the strongly regular behaviour of idiscernible sequences to sequences of disjoint α-neighborhoods. The main result of this section, Theorem 11, is the backbone of our flip-flatness proof and states the following. In every large sequence of disjoint α-neighborhoods, we will find a still-large subsequence such that the φ-connections

of every element a towards all α-neighborhoods in the subsequence can be described by a bounded set of sample elements in the following sense. After possibly omitting one exceptional neighborhood at index ex(a) depending on a, the φ-connections are completely homogeneous (in the stable case) or alternate at most once (in the NIP case). A related (but orthogonal) result was also proved in [38, Lemma 64] using tools from model theory.

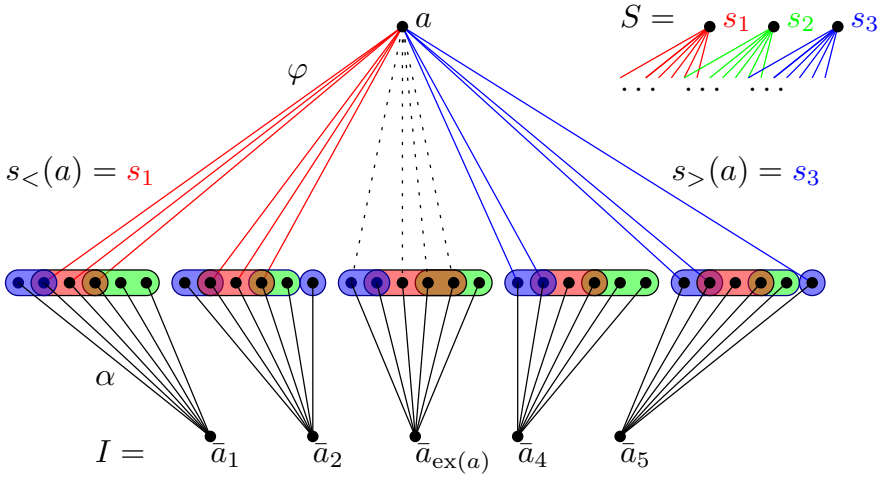

Figure 6 A visualization of Theorem 11. On the bottom: a sequence I with disjoint α-neighborhoods. On the top right: a small set of sample elements S. The φ-neighborhoods of the elements in S in the α-neighborhood of I are colored accordingly. Note that their φ-neighborhoods can overlap. The φ-neighborhood of a in the α-neighborhood of I is equal to the φ-neighborhood of $s_<(a) = s_1$ before the exceptional index $\mathrm{ex}(a)$. After it, it is equal to the φ-neighborhood of $s_>(a) = s_3$. For the α-neighborhood of $\bar{a}_{\mathrm{ex}(a)}$ we make no claims.

▶ **Theorem 11.** *For every monadically NIP class of structures $\mathscr{C}$, and formulas $\varphi(x, y)$ and $\alpha(\bar{x}, y)$, there exists a function $N : \mathbb{N} \to \mathbb{N}$ and an integer k such that for every $m \in \mathbb{N}$ every structure $\mathbb{A} \in \mathscr{C}$ and every finite sequence of tuples $J \subseteq \mathbb{A}^{|\bar{x}|}$ of length $N(m)$ whose α-neighborhoods are disjoint the following holds. There exists a subsequence $I = (\bar{a}_i)_{1 \leqslant i \leqslant m} \subseteq J$ of length m and a set $S \subseteq \mathbb{A}$ of at most k sample elements such that for every element $a \in \mathbb{A}$ there exists an exceptional index $\mathrm{ex}(a) \in [m]$ and a pair $s_<(a), s_>(a) \in S$ such that*

$$\text{for all } 1 \leqslant i < \mathrm{ex(a)} : N_\alpha(\bar{a}_i) \cap N_\varphi(a) = N_\alpha(\bar{a}_i) \cap N_\varphi(s_<(a)), \text{ and}$$
$$\text{for all } \mathrm{ex(a)} < i \leqslant m : N_\alpha(\bar{a}_i) \cap N_\varphi(a) = N_\alpha(\bar{a}_i) \cap N_\varphi(s_>(a)).$$

If $a \in N_\alpha(\bar{a}_i)$ for some $\bar{a}_i \in I$, then $i = \mathrm{ex}(a)$.

If $\mathscr{C}$ is monadically stable, then $s_<(a) = s_>(a)$ for every $a \in \mathbb{A}$.

A visualization of the NIP case of Theorem 11 is provided in Figure 6. An important ingredient of the proof is the following Ramsey-type result due to Ding et al. [12, Corollary 2.4]. We say a bipartite graph with sides $a_1, \ldots, a_\ell$ and $b_1, \ldots, b_\ell$ forms

- a *matching* of order ℓ if a_i and b_j are adjacent if and only if $i = j$ for all $i, j \in [\ell]$,
- a *co-matching* of order ℓ if a_i and b_j are adjacent if and only if $i \neq j$ for all $i, j \in [\ell]$,
- a *ladder* of order ℓ if a_i and b_j are adjacent if and only if $i \leqslant j$ for all $i, j \in [\ell]$.

We call two distinct vertices u and v *twins* in a graph G they have the same neighborhood with regard to the edge relation, i.e. $N_E^G(u) \setminus \{v\} = N_E^G(v) \setminus \{u\}$.

▶ **Theorem 12** ([12, Corollary 2.4]). *There exists a function $Q : \mathbb{N} \to \mathbb{N}$ such that for every $\ell \in \mathbb{N}$ and for every bipartite graph $G = (L, R, E)$ without twins, where L has size at least $Q(\ell)$, contains a matching, co-matching, or ladder of order ℓ as an induced subgraph.*

Equipped with Theorem 10 from the previous subsection and the above Theorem 12, we will now give a proof sketch of the monadically stable case of Theorem 11.

Proof sketch of Theorem 11 (monadically stable case). We will build the sequence I by inductively extracting indiscernible subsequences I_i of J and growing a set of sample elements $S_i = \{s_1, \dots, s_i\}$. During the induction, we maintain the following invariant: every two distinct sample elements from S_i have pairwise different φ-neighborhoods in the α-neighborhood of every tuple of I_i. We start with $I_0 = J$ and $S_0 = \varnothing$ where this trivially holds. Let us now describe the inductive construction of I_{i+1} and S_{i+1}. We first add a constant symbol for every element in S_i to the signature of $\mathbb{A}$. This extended signature will allow us to express for all $j \in [i]$ the formula $\psi_j(x, \bar{y})$ stating that x has the same φ-neighborhood as s_j in the α-neighborhood of $\bar{y}$, i.e., $N_\alpha(\bar{y}) \cap N_\varphi(x) = N_\alpha(\bar{y}) \cap N_\varphi(s_j)$. We collect all these formulas into the set $\Phi = \{\psi_j \ : \ j \in [i]\}$ and build I_{i+1} by extracting a Δ_k^Φ-indiscernible sequence from I_i, for the appropriate value of k given by Theorem 10. Now by Theorem 10, for every element $b \in \mathbb{A}$, there exists a Φ-type $\tau(x, \bar{y})$ such that b is τ-connected to all but at most one tuple from I_{i+1}. Since the Φ-types capture information about the connections relative to vertices in S_i, one of the following two cases applies for every $b \in \mathbb{A}$.

1. The φ-neighborhood of b is different to the φ-neighborhood of every element of S_i in the α-neighborhood around all but at most one tuple of I_{i+1}.
2. For some $j \in [i]$, the φ-neighborhood of b is equal to the φ neighborhood of s_j in the α-neighborhood around all but at most one tuple of I_{i+1} (whose index will $\mathrm{ex}(b)$).

If the first case applies for some $b \in \mathbb{A}$, then we can build S_{i+1} by setting $s_{i+1} := b$, which satisfies our invariant (after we possibly drop one more element from I_{i+1}). If the second case applies for every $b \in \mathbb{A}$, every element is represented by S_i, and the construction stops with $I := I_{i+1}$ and $S := S_i$.

It now remains to show that the construction stops after less than k steps for some k depending only on $\mathscr{C}$, φ, and α. To this end, we show that for every $\ell \in \mathbb{N}$, there exists $k \in \mathbb{N}$ with the following property. If there exists I_k and S_k satisfying the invariant of our construction, then we can derive a formula ψ from φ and α which has pairing index at least ℓ in an expansion of $\mathbb{A}$ with a constant number of colors (in the full proof we use 3 colors). As $\mathscr{C}$ is monadically NIP, the pairing index of ψ is bounded, which also yields a bound for k.

Assume we are given I_k and S_k, such that all the elements from S_k have different φ-neighborhoods, in the α-neighborhoods around the tuples of I_k. By choosing k large enough, repeated application of Theorem 12 and the pigeonhole principle, we find a subset $S' = \{s_1, \dots, s_{\ell^2}\}$ of S_k and a subsequence $I' = \{\bar{a}_1, \dots, \bar{a}_\ell\}$ of I_k with the following property. For each $j \in [\ell]$, there exists a subset N'_j of the α-neighborhood of $\bar{a}_j$, such that the φ-connections from S' to the N'_j all form a matching, all form a co-matching, or all form a ladder. Assume the φ-connections form a matching. Let us now show that the formula

$$\psi(x, \bar{y}) := \exists z \in N_\varphi(x) \cap N_\alpha(\bar{y}).\ R(z)$$

has pairing index at least ℓ in the class $\mathscr{C}$ extended with an additional unary predicate R. The situation is depicted in Figure 7. The formulas φ and α interpret a large 1-subdivided biclique in $\mathbb{A}$ as follows. The tuples from I' and the elements from S' form the principle vertices. The subdivision vertices are formed by $\bigcup_{i \in [\ell]} N'_i$. Due to the assumed matchings, each subdivision element has exactly one incoming φ-connection from S'. Due to the tuples

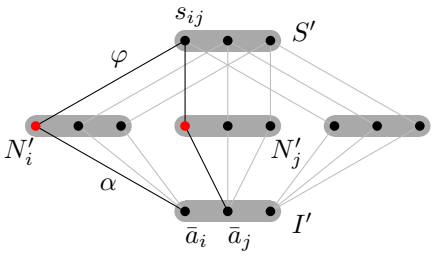

Figure 7 Pairing the elements of I'.

in I' having disjoint α-neighborhoods, each subdivision element has exactly one incoming α-connection from the elements of I'. Since I' has size ℓ and S' has size ℓ^2 we can assign to every pair $\bar{a}_i, \bar{a}_j \in I'$ a unique element $s_{ij} \in S'$. By marking with the predicate R the two unique subdivision elements from $N_\varphi(s_{ij}) \cap N'_i$ and $N_\varphi(s_{ij}) \cap N'_j$, we get that s_{ij} is ψ-connected only to $\bar{a}_i$ and $\bar{a}_j$ among I'. As desired, S' and I' witness that ψ has pairing index at least ℓ.

In case the φ-connections form a co-matching or a ladder, we can replace φ with a derived formula φ', such that the φ'-connections form a matching in a coloring of $\mathbb{A}$, which completes the proof sketch for the size bound of S.

Lastly, in order to ensure that $a \in N_\alpha(\bar{a}_i)$ implies $i = \mathrm{ex}(a)$, we can augment the formula $\psi_j(x, \bar{y})$ in the construction to return false whenever x is contained in $N_\alpha(\bar{y})$. This way, we enforce the single exception given by Theorem 10 to be on a_i. ◀

To prove the more general NIP case, we replace Theorem 10 with Theorem 9, which introduces the possibility for a vertex a to be sampled by two vertices $s_<(a)$ and $s_>(a)$, alternating around $\mathrm{ex}(a)$. We also have to slightly adapt the search for the next sample element s_j using an additional indiscernibility argument.

3.3 Flatness in monadically stable classes of graphs

In this section we use Theorem 11 to characterize monadically stable graph classes in terms of flip-flatness. We start with the forward direction, restated for convenience.

▶ **Theorem 4.** *Every monadically stable class $\mathscr{C}$ of graphs is flip-flat, where for every r, the function N_r is polynomial. Moreover, given an n-vertex graph $G \in \mathscr{C}$, $A \subseteq V(G)$, and $r \in \mathbb{N}$, we can compute a subset $B \subseteq A$ and a set of flips F that makes B distance-r independent in $G \oplus F$ in time $\mathcal{O}(f_{\mathscr{C}}(r) \cdot n^3)$ for some function $f_{\mathscr{C}}$.*

Partial proof. Let $\mathscr{C}$ be a monadically stable class of graphs and $r \in \mathbb{N}$. We want to show that in every graph $G \in \mathscr{C}$, in every set $A \subseteq V(G)$ of size $N_r(m)$ we find a subset $B \subseteq A$ of size at least m and a set F of at most s_r flips such that B is distance-r independent in $G \oplus F$. We will first inductively describe how to obtain the set of vertices B and the set of flips F and bound the runtime and values for N_r and s_r later. In the base case we have $r = 0$. We can pick $B := A$ and $F := \varnothing$ and there is nothing to show.

In the inductive case we assume the result is proved for r and extend it to $r + 1$. Let $r = 2i + p$ for some $i \in \mathbb{N}$ and parity $p \in \{0, 1\}$. Apply the induction hypothesis to obtain s_r flips F_r and a set A_r that is distance-r independent in $G_r := G \oplus F_r$. Note that for every fixed number t of flips, since flips are definable by coloring and a quantifier-free formula, the class $\mathscr{C}_t$ of all graphs obtainable from graphs of $\mathscr{C}$ by at most t flips is monadically stable by Lemma 5. Hence, G_r comes from the monadically stable class $\mathscr{C}_{s_r}$. Our goal is to

find a set of flips F'_{r+1} (of fixed finite size which will determine the number s_{r+1}) together with a set $A_{r+1} \subseteq A_r$, that is distance-$(r+1)$ independent in $G_{r+1} := G_r \oplus F'_{r+1}$. Then $G_r = G \oplus F_{r+1}$ with $F_{r+1} = F_r \cup F'_{r+1}$.

Since the elements in A_r have pairwise disjoint distance-i neighborhoods, we can apply Theorem 11 to A_r with $\varphi(x,y) = E(x,y)$ and $\alpha(x,y) = \mathrm{dist}_{\leqslant i}(x,y)$. Since we are in the monadically stable case, this yields a subset $A_{r+1} \subseteq A_r$ and a small set of sample vertices S such that for every vertex $a \in V(G)$ there exists $s(a) \in S$ and $\mathrm{ex}(a) \in A_{r+1}$ such that a has the same edge-neighborhood as $s(a)$ in the distance-i neighborhoods of all elements from $A_{r+1} \setminus \{\mathrm{ex}(a)\}$. We now do a case distinction depending on whether r is even or odd.

The odd case: $r = 2i+1$. For every $s \in S$ let C_s be the set containing every vertex a for which we have $s(a) = s$ and that is at distance at least $i+1$ from every vertex in A_{r+1}. Let D_s be the set containing every edge-neighbor of s that is at distance exactly i from one of the vertices in A_{r+1}. We now build the set of flips F'_{r+1} by adding for every sample vertex $s \in S$ the flip (C_s, D_s).

Let us now argue that A_{r+1} is distance-$(r+1)$ independent in $G_{r+1} := G_r$. We only flip edges in G_r between pairs of vertices a, b such that a has distance (in G_r) at least $i+1$ and b has distance exactly i to A_{r+1}. It follows that A_{r+1} remains distance-$(2i+1)$ independent in G_{r+1}. Assume towards a contradiction that there exists a path $P = (a, a_1, \ldots, a_i, u, b_i, \ldots, b_1, b)$ of length $r+1 = 2i+2$ between two vertices $a, b \in A_{r+1}$ in G_{r+1}. The distance between a and a_i (resp. b and b_i) is not affected by the flips. Only the connection between a_i (resp. b_i) and u can possibly be impacted. Additionally, note that $u \in C_{s(u)}$.

Since a and b are distinct we have that either $\mathrm{ex}(u) \neq a$ or $\mathrm{ex}(u) \neq b$. By symmetry we can assume the former case. As a_i is in the distance-i neighborhood of a, we have $G_r \models E(u, a_i) \iff G_r \models E(s(u), a_i)$. Observe that if $E(s(u), a_i)$ holds in G_r, then $a_i \in D_{s(u)}$ and therefore the edge (u, a_i) was removed by the flips and is not in G_{r+1}. Similarly, if $E(s(u), a_i)$ does not hold in G_r, then $a_i \notin D_{s(u)}$ and the edge (u, a_i) was not introduced by any flip. We can conclude that P is not a path in G_{r+1}, and that A_{r+1} is distance-$(r+1)$ independent in G_{r+1}.

The even case and runtime analysis. The even distance creates a symmetry that requires additional care to handle, but otherwise proceeds similarly to the odd case. The arguments concerning size bounds and runtimes can be found there as well. The runtime bound crucially uses the fact that we take Δ_k^Φ-indiscernible sequences only with respect to formulas Φ that can be evaluated in polynomial time. ◀

We have shown that for graph classes, monadic stability implies flip-flatness. We now show that the reverse holds as well. We will use the following statement, which is an immediate consequence of Gaifman's locality theorem [18]. For an introduction of the locality theorem see for example [23, Section 4.1].

▶ **Corollary 13** (of [18, Main Theorem]). *Let $\varphi(x,y)$ be a formula. Then there are numbers $r, t \in \mathbb{N}$, where r depends only on the quantifier-rank of φ and t depends only on the signature and quantifier-rank of φ, such that every (colored) graph G can be vertex-colored using t colors in such a way that for any two vertices $u, v \in V(G)$ with distance greater than r in G, $G \models \varphi(u,v)$ depends only on the colors of u and v. We call r the* Gaifman radius *of φ.*

▶ **Lemma 14.** *Every flip-flat class of graphs is monadically stable.*

Proof sketch of Lemma 14. Assume towards a contradiction that there exists a class $\mathscr{C}$ that is not monadically stable but flip-flat. Then there exists a formula $\sigma(x, y)$ and a graph $G \in \mathscr{C}$, such that σ defines an order on a large vertex set A in a coloring G^+. Let r be the Gaifman radius of σ. By flip-flatness there exists a (still large) subset B of A and a bounded size set of flips F, such that B is distance-r independent in $H := G^+ \oplus F$. Let H^+ be the graph where we have marked the flips F with colors in H. We can rewrite σ to a formula σ' of the same quantifier rank such that for all $u, v \in V(G)$ we have $H^+ \models \sigma'(u, v)$ if and only if $G^+ \models \sigma(u, v)$. In particular, σ' orders B in H^+. By Corollary 13 and the pidgeonhole principle, there must be two distinct vertices $u, v \in B$ such that $H^+ \models \sigma'(u, v)$ if and only if $H^+ \models \sigma'(v, u)$. However as σ' orders B, we also have $H^+ \models \sigma'(u, v)$ if and only if $H^+ \not\models \sigma'(v, u)$; a contradiction. ◀

From Theorem 4 and Lemma 14 we conclude the following.

▶ **Theorem 3.** *A class of graphs is monadically stable if and only if it is flip-flat.*

Black-Box Testing Liveness Properties of Partially Observable Stochastic Systems

Javier Esparza
Technische Universiät München, Germany

Vincent P. Grande
RWTH Aachen University, Germany

Abstract

We study black-box testing for stochastic systems and arbitrary ω-regular specifications, explicitly including liveness properties. We are given a finite-state probabilistic system that we can only execute from the initial state. We have no information on the number of reachable states, or on the probabilities; further, we can only partially observe the states. The only action we can take is to restart the system. We design restart strategies guaranteeing that, if the specification is violated with non-zero probability, then w.p.1 the number of restarts is finite, and the infinite run executed after the last restart violates the specification. This improves on previous work that required full observability. We obtain asymptotically optimal upper bounds on the expected number of steps until the last restart. We conduct experiments on a number of benchmarks, and show that our strategies allow one to find violations in Markov chains much larger than the ones considered in previous work.

1 Introduction

Black-box testing is a fundamental analysis technique when the user does not have access to the design or the internal structure of a system [12, 15]. Since it only examines one run of the system at a time, it is computationally cheap, which makes it often the only applicable method for large systems.

We study the black-box testing problem for finite-state probabilistic systems and ω-regular specifications: Given an ω-regular specification, the problem consists of finding a run of the program that violates the property, assuming that such runs have nonzero probability.

Let us describe our assumptions in more detail. We do not have access to the code of the system or its internal structure, and we do not know any upper bound on the size of its state space. We can repeatedly execute the system, restarting it at any time. W.l.o.g. we assume that all runs of the system are infinite. We do not assume full observability of the states of the system, only that we can observe whether the atomic propositions of the property

are currently true or false. For example, if the property states that a system variable, say x, should have a positive value infinitely often, then we only assume that at each state we can observe the sign of x; letting Σ denote the set of possible observations, we have $\Sigma = \{+, -\}$, standing for a positive and a zero or negative value, respectively (in the rest of the introduction we shorten "zero or negative" to "negative"). Every system execution induces an observation, that is, an element of Σ^ω. The violations of the property are the ω-words $V \subseteq \Sigma^\omega$ containing only finitely many occurrences of $+$.

Our goal is to find a *strategy* that decides after each step whether to abort the current run and restart the system, or continue the execution of the current run. The strategy must ensure that some run that violates the property, that is, a run whose observation belongs to V, is eventually executed. The strategy decides depending on the observations made so far. Formally, given Σ and the set of actions $A = \{\mathsf{r}, \mathsf{c}\}$ (for "restart" and "continue") a strategy for V is a mapping from $(\Sigma \times A)^*\Sigma$, the sequence of observations and actions executed so far, to A, the next decision. Our goal is to find a strategy σ satisfying the following property:

> For every finite-state program P over Σ, if $V \subseteq \Sigma^\omega$ has positive probability and the runs of P are restarted according to σ, then w.p.1 the number of restarts is finite, and the observation of the run executed after the last restart belongs to V.

Observe that it is not clear that such strategies exist. They are easy to find for safety properties, where the fact that a run violates the property is witnessed by a *finite* prefix[1], but for liveness properties there is no such prefix in general. We show that these strategies exist for every ω-regular language V. Moreover, the strategies only need to maintain a number of counters that depends only on V, and not on the program. So in order to restart P according to σ one only needs logarithmic memory in the length of the current sequence.

▶ **Example 1.** To give a first idea of why these strategies also exist for liveness properties, consider the property over $\Sigma = \{+, -\}$ stating that a variable x should have a positive value only finitely often. The runs violating the property are those that visit $+$-states infinitely often. Our results show that the following strategy works in detecting a run violating the property (among others):

> After the n-th restart, repeatedly execute blocks of $2n$ steps. If at some point after executing the first block *the second half* of the concatenation of the blocks executed so far contains only negative states, then restart.

For example, assume there have been 4 restarts. Then the strategy repeatedly executes blocks of 8 steps. If after executing $1, 2, 3, \ldots$ of these blocks the last $4, 8, 16, \ldots$ states are negative, then the strategy restarts for the 5th time. If that is never the case, then there are only 4 restarts. Figure 1 shows a family of Markov chains for which naive strategies do not work, but the above strategy does: almost surely the number of restarts is finite and the run after the last restart visits the rightmost state infinitely often. Observe that for every $n \geq 0$ the family exhibits executions that visit $+$ states at least n times, and executions that visit a $+$ state at most once every n steps.

[1] One can choose for σ the strategy "after the n-th reset, execute n steps; if this finite execution is not a witness, restart, otherwise continue forever." Indeed, if the shortest witness has length k, then for every $n \geq k$, after the n-th restart the strategy executes a witness with positive probability, and so it eventually executes one w.p.1.

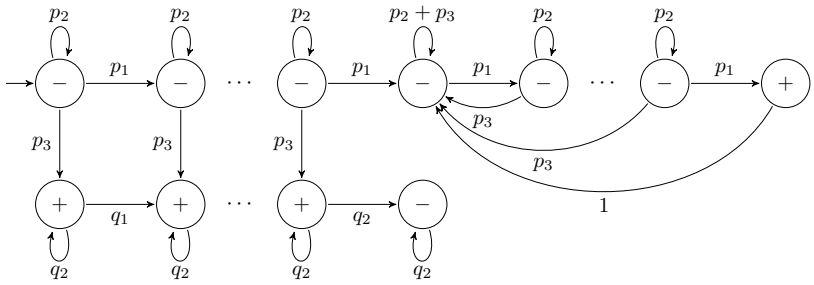

Figure 1 A family of partially observable Markov chains.

We also obtain asymptotically optimal upper bounds on the expected time until the last restart, that is, on the time until the execution of the run violating the property starts. The bounds depend on two parameters of the Markov chain associated to the program, called the *progress radius* and the *progress probability*. An important part of our contribution is the identification of these parameters as the key ones to analyze.

While our results are stated in an abstract setting, they easily translate into practice. In a practical scenario, on top of the values of the atomic propositions, we can also observe useful debugging information, like the values of some variables. We let a computer execute runs of the system for some fixed time t according to the strategy σ. If at time t we observe that the last restart took place a long time ago, then we stop testing and return the run executed since the last restart as candidate for a violation of the property. In the experimental section of our paper we use this scenario to detect errors in *population protocols*, a model of distributed computation, whose state space is too large to find them by other means.

Related work. There is a wealth of literature on black-box testing and black-box checking [12, 15], but the underlying models are not probabilistic and the methods require to know an upper bound on the number of states. Work on probabilistic model-checking assumes that (a model of) the system is known [2]. There are also works on black-box verification of probabilistic systems using statistical model checking of statistical hypothesis testing [22, 17, 18, 20, 21] (see also [11, 13] for surveys on statistical model checking). They consider a different problem: we focus on producing a counterexample run, while the goal of black-box verification is to accept or reject a hypothesis on the probability of the runs that satisfy a property. Our work is also related to the *runtime enforcement problem* [16, 3, 14, 7, 8], which also focus on identifying violations of a property. However, in these works either the setting is not probabilistic, or only a subset of the ω-regular properties close to saftey properties is considered. Finally, the paper closest to ours is [6], which considers the same problem, but for fully observable systems. In particular, in the worst case the strategies introduced in [6] require to store the full sequence of states visited along a run, and so they use linear memory in the length of the current sequence, instead of logarithmic memory, as is the case for our strategy.

Structure of the paper. The paper is organized as follows. Section 2 contains preliminaries. Section 3 introduces the black-box testing problem for arbitrary ω-regular languages with partial observability, and shows that it can be reduced to the problem for canonical languages called the Rabin languages. Section 4 presents our black-box strategies for the Rabin languages, and proves them correct. Section 5 obtains asymptotically optimal upper bounds on the time to the last restart. Section 6 reports some experimental results.

2 Preliminaries

Directed graphs. A directed graph is a pair $G = (V, E)$, where V is the set of nodes and $E \subseteq V \times V$ is the set of edges. A path (infinite path) of G is a finite (infinite) sequence $\pi = v_0, v_1, \ldots$ of nodes such that $(v_i, v_{i+1}) \in E$ for every $i = 0, 1, \ldots$. A path consisting only of one node is *empty*. Given two vertices $v, v' \in V$, the *distance* from v to v' is the length of a shortest path from v to v', and the distance from v to a set $V' \subseteq V$ is the minimum over all $v' \in V'$ of the distance from v to v'.

A graph G is strongly connected if for every two vertices v, v' there is a path leading from v to v'. A graph $G' = (V', E')$ is a subgraph of G, denoted $G' \preceq G$, if $V' \subseteq V$ and $E' \subseteq E \cap (V' \times V')$; we write $G' \prec G$ if $G' \preceq G$ and $G' \neq G$. A graph $G' \preceq G$ is a strongly connected component (SCC) of G if it is strongly connected and no graph G'' satisfying $G' \prec G'' \preceq G$ is strongly connected. An SCC $G' = (V', E')$ of G is a bottom SCC (BSCC) if $v \in V'$ and $(v, v') \in E$ imply $v' \in V'$.

Partially observable Markov chains. Fix a finite set Σ of *observations*. A *partially observable Markov chain* is a tuple $\mathcal{M} = (S, s_{in}, \Sigma, Obs, \mathbf{P})$, where

- Σ is a set of *observations*;
- S is a finite set of *states* and $s_{in} \in S$ is the *initial* state;
- $Obs\colon S \to \Sigma$ is an *observation function* that assigns to every state an observation; and
- $\mathbf{P} : S \times S \to [0, 1]$ is the transition probability matrix, such that for every $s \in S$ it holds $\sum_{s' \in S} \mathbf{P}(s, s') = 1$,

Intuitively, $Obs(s)$ models the information we can observe when the chain visits s. For example, if s is the state of a program, consisting of the value of the program counter and the values of all variables, $Obs(s)$ could be just the values of the program counter, or the values of a subset of public variables. The graph of $\mathcal{M}$ has S as set of nodes and $\{(s, s') \mid \mathbf{P}(s, s') > 0\}$ as set of edges. Abusing language, we also use $\mathcal{M}$ to denote the graph of $\mathcal{M}$. A *run* of $\mathcal{M}$ is an infinite path $\rho = s_0 s_1 \cdots$ of $\mathcal{M}$; we let $\rho[i]$ denote the state s_i. The sequence $Obs(\rho) \coloneqq Obs(s_0)\,Obs(s_1) \cdots$ is the *observation* associated to ρ. Each path π in $\mathcal{M}$ determines the set of runs $\mathsf{Cone}(\pi)$ consisting of all runs that start with π. To $\mathcal{M}$ we assign the probability space $(\mathsf{Runs}, \mathcal{F}, \mathbb{P})$, where Runs is the set of all runs in $\mathcal{M}$, $\mathcal{F}$ is the σ-algebra generated by all $\mathsf{Cone}(\pi)$, and $\mathbb{P}$ is the unique probability measure such that $\mathbb{P}[\mathsf{Cone}(s_0 s_1 \cdots s_k)] = \mu(s_0) \cdot \prod_{i=1}^{k} \mathbf{P}(s_{i-1}, s_i)$, where the empty product equals 1. The expected value of a random variable $f\colon \mathsf{Runs} \to \mathbb{R}$ is $\mathbb{E}[f] = \int_{\mathsf{Runs}} f \; d\mathbb{P}$.

Partially Observable Markov Decision Processes. A Σ-*observable Markov Decision Process* (Σ-MDP) is a tuple $\mathsf{M} = (S, s_{in}, \Sigma, Obs, A, \Delta)$, where S, s_{in}, Σ, Obs are as for Markov chains, A is a finite set of *actions*, and $\Delta\colon S \times A \to \mathcal{D}(S)$ is a *transition function* that for each state s and action $a \in A(s)$ yields a probability distribution over successor states. The probability of state s' in this distribution is denoted $\Delta(s, a, s')$.

Strategies. A *strategy* on Σ-MDPs with A as set of actions is a function $\sigma\colon (\Sigma \times A)^*\Sigma \to A$, which given a finite path $\pi = \ell_0 a_0\, \ell_1\, a_1 \ldots a_{n-1}\, \ell_n \in (\Sigma \times A)^*\Sigma$, yields the action $\sigma(\pi) \in A$ to be taken next. Notice that σ only "observes" $Obs(s)$, not the state s itself. Therefore, it can be applied to any Σ-MDP $\mathsf{M} = (S, s_{in}, \Sigma, Obs, A, \Delta)$, inducing the Markov chain $\mathsf{M}^\sigma = (S^\sigma, s_{in}, \Sigma, Obs, A, \mathbf{P}^\sigma)$ defined as follows: $S^\sigma = (S \times A)^* \times S$; and for every state $\pi \in S^\sigma$ of M^σ ending at a state $s \in S$ of M, the successor distribution is defined by $\mathbf{P}^\sigma(\pi, \pi\, a\, s') \coloneqq \Delta(s, a, s')$ if $\sigma(\pi) = a$ and 0 otherwise.

3 The black-box testing problem

Fix a set Σ of observations, and let r, c (for **r**estart and **c**ontinue) be two actions. We associate to a Σ-observable Markov chain $\mathcal{M} = (S, s_{in}, \Sigma, Obs, \mathbf{P})$ a *restart MDP* $\mathsf{M}_\mathsf{r} = (S, s_{in}, Obs, \{\mathsf{r}, \mathsf{c}\}, \Delta)$, where for every two states $s, s' \in S$ the transition function is given by: $\Delta(s, \mathsf{r}, s') = 1$ if $s' = s_{in}$ and 0 otherwise, and $\Delta(s, \boldsymbol{c}, s') = \mathbf{P}(s, s')$. Intuitively, at every state of M_r we have the choice between restarting the chain $\mathcal{M}$ or continuing.

We consider black-box strategies on Σ and $\{\mathsf{r}, \mathsf{c}\}$. Observe that if a run π of $\mathsf{M}_\mathsf{r}^\sigma$ contains finitely many occurrences of r, then the suffix of π after the last occurrence of r is a run of $\mathcal{M}$ (after dropping the occurrences of the continue action c). More precisely, if $\pi = \pi_0\pi'$, where π' is the longest suffix of π not containing r, then $\pi' = (\pi_0\, s_{in})\,(\pi_0\, s_{in}\, \mathsf{c}\, s_1)\,(\pi_0\, s_{in}\, \mathsf{c}\, s_1\, \mathsf{c}\, s_2)\ldots$, where $s_{in}s_1s_2\ldots$ is a run of $\mathcal{M}$. The sequence of observations of $s_{in}s_1s_2\ldots$ is an infinite word over Σ, called the *tail* of π; formally $tail(\pi) \coloneqq Obs(s_{in})Obs(s_1)Obs(s_2)\cdots$.

▶ **Definition 2** (Black-box testing strategies). *Let $L \subseteq \Sigma^\omega$ be an ω-regular language. A* black-box strategy *σ on Σ and $\{\mathsf{r}, \mathsf{c}\}$ is a* testing strategy for *L if it satisfies the following property: for every Σ-observable Markov chain $\mathcal{M}$, if $\Pr_\mathcal{M}(L) > 0$ then w.p.1 a run of $\mathsf{M}_\mathsf{r}^\sigma$ has a finite number of restarts, and its tail belongs to L. The* black-box testing problem *for L consists of finding a black-box testing strategy for L.*

We denote by $\#\mathsf{r}(\rho) \in \mathbb{N} \cup \{\infty\}$ the number of appearances of the restart action r in ρ. Intuitively, the language L models the set of potential violations of a given liveness specifications. If we sample any finite-state Σ-observable Markov chain $\mathcal{M}$ according to a testing strategy for L, then w.p.1 we eventually stop restarting, and the tail of the run is a violation, or there exist no violations.

3.1 Canonical black-box testing problems

Using standard automata-theoretic techniques, the black-box testing problem for an arbitrary ω-regular language L can be reduced to the black-box testing problem for a canonical language. For this, we need to introduce some standard notions of the theory of automata on infinite words.

A deterministic Rabin automaton (DRA) $\mathcal{A}$ over an alphabet Σ is a tuple $(Q, \Sigma, \gamma, q_0, Acc)$, where Q is a finite set of states, $\gamma\colon Q \times \Sigma \to Q$ is a transition function, $q_0 \in Q$ is the initial state, and $Acc \subseteq 2^Q \times 2^Q$ is the acceptance condition. The elements of Acc are called *Rabin pairs*. A word $w = a_0a_1a_2\ldots \in \Sigma^\omega$ is accepted by $\mathcal{A}$ if the unique run $q_0q_1q_2\ldots$ of $\mathcal{A}$ on w satisfies the following condition: there exists a Rabin pair $(E, F) \in Acc$ such that $a_i \in E$ for infinitely many $i \in \mathbb{N}$ and $a_i \in F$ for finitely many $i \in \mathbb{N}$. It is well known that DRAs recognize exactly the ω-regular languages (see e.g. [2]). The *Rabin index* of an ω-regular language L is the minimal number of Rabin pairs of the DRAs that recognize L.

▶ **Definition 3.** *Let $k \geq 1$, and let $M_k = \{\boldsymbol{e}_1, \ldots, \boldsymbol{e}_k, \boldsymbol{f}_1, \ldots, \boldsymbol{f}_k\}$ be a set of* markers. *The* Rabin language *$\mathcal{R}_k \subseteq (2^{M_k})^\omega$ is the language of all words $w = \alpha_0\alpha_1\cdots \in (2^{M_k})^\omega$ satisfying the following property: there exists $1 \leq j \leq k$ such that $\boldsymbol{e}_j \in \alpha_i$ for infinitely many $i \geq 0$, and $\boldsymbol{f}_j \in \alpha_i$ for at most finitely many $i \geq 0$.*

We show that the black-box testing problem for languages of Rabin index k can be reduced to the black-box testing problem for $\mathcal{R}_k$.

▶ **Lemma 4.** *There is an algorithm that, given an ω-regular language $L \subseteq \Sigma^\omega$ of index k and given a testing strategy σ_k for $\mathcal{R}_k$, effectively constructs a testing strategy σ_L for L.*

Proof. (Sketch, full proof in the Appendix.) Let $\mathcal{A} = (Q, \Sigma, \gamma, q_0, Acc)$ be a DRA recognizing $L \subseteq \Sigma^\omega$ with accepting condition $Acc = \{(E_1, F_1), \dots, (E_k, F_k)\}$, i.e., Acc contains k Rabin pairs. Let σ_k be a black-box strategy for the Rabin language $\mathcal{R}_k$. We construct a black-box strategy σ_L for L.

Let $w = \ell_1 a_1 \ell_2 \cdots \ell_{n-1} a_n \ell_n \in (\Sigma \times \{\mathsf{r}, \mathsf{c}\})^* \Sigma$. We define the action $\sigma_L(w)$ as follows. Let $q_0 q_1 \dots q_n$ be the unique run of $\mathcal{A}$ on the word $\ell_1 \ell_2 \dots \ell_n \in \Sigma^*$. We then define $v = \ell'_1 a_1 \ell'_2 \cdots \ell'_{n-1} a_n \ell'_n \in (2^{M_k} \times \{\mathsf{r}, \mathsf{c}\})^* 2^{M_k}$ as the word given by: $\boldsymbol{e}_j \in \ell'_i$ iff $q_i \in E_j$, and $\boldsymbol{f}_j \in \ell'_i$ iff $q_i \in F_j$. (Intuitively, we mark with $\boldsymbol{e}_j$ the positions in the run at which the DRA visits E_j, and with $\boldsymbol{f}_j$ the positions at which the DRA visits F_j.) We set $\sigma_L(w) \coloneqq \sigma_k(v)$. We show in the Appendix that σ_L is a black-box strategy for L. ◀

4 Black-box strategies for Rabin languages

We describe a family of testing strategies for the Rabin languages $\{\mathcal{R}_k \mid k \geq 1\}$. In Section 4.1 we describe our strategy in detail. In Section 4.2 we introduce the progress radius and the progress probability, two parameters of a chain needed to prove correctness and necessary for quantitative analysis in Section 5. In Section 4.3 we formally prove that our strategy works.

4.1 The strategy

Let $\mathcal{M}$ be a Markov chain with observations in 2^{M_k}, and let $\pi = s_0 s_1 s_2 \cdots s_m$ be a finite path of $\mathcal{M}$. The *length* of π is m, and its last state, denoted $last(\pi)$, is s_m. The *second half* of π is the path $SecondHalf(\pi) \coloneqq s_{\lceil m/2 \rceil} \dots s_m$. The *concatenation* of π and a finite path $\rho = r_0 r_1 \cdots r_l$ of $\mathcal{M}$ such that $s_m = r_0$ is the path $\pi \odot \rho \coloneqq s_0 s_1 s_2 \cdots s_m r_1 \cdots r_l$. A path π is *i-good* if it has length 0 or there are markers $\boldsymbol{e}_i, \boldsymbol{f}_i \in M_k$ such that some state s of π satisfies $\boldsymbol{e}_i \in Obs(s)$ and no state s of π satisfies $\boldsymbol{f}_i \in Obs(s)$. Further, π is *good* if it is i-good for some $1 \leq i \leq k$.

The strategy $\mathfrak{S}[f]$, described in Figure 2, is parametrized by a function $f \colon \mathbb{N} \to \mathbb{N}$. The only requirement on f is $\limsup_{n \to \infty} f(n) = \infty$. In words, after the n-th restart the strategy

$n \coloneqq 0$ ▷ number of restarts
while true **do**
  $\pi \leftarrow s_{in}$ ▷ initial state of the chain
  while $SecondHalf(\pi)$ is good **do**
    sample path ρ from state $last(\pi)$
    of length $2 \cdot f(n)$ ▷ even length for convenience
    $\pi \leftarrow \pi \odot \rho$
  end while ▷ restart
  $n \leftarrow n + 1$
end while

Figure 2 Strategy $\mathfrak{S}[f]$ for the Rabin language $\mathcal{R}_k$ and a function $f \colon \mathbb{N} \to \mathbb{N}$.

keeps sampling in blocks of $2 \cdot f(n)$ steps until the *second half* of the complete path sampled so far is bad, in which case it restarts. For example, after the n-th restart the strategy samples a block $\pi_0 = \pi_{01} \odot \pi_{02}$, where $|\pi_{01}| = |\pi_{02}| = f(n)$, and checks whether π_{02} is good; if not, it restarts, otherwise it samples a block $\pi_1 = \pi_{11} \odot \pi_{12}$ starting from $last(\pi_{02})$, and checks whether $\pi_{11} \odot \pi_{12}$ is good; if not, it restarts; if so it samples a block $\pi_2 = \pi_{21} \odot \pi_{22}$ starting from $last(\pi_{12})$, and checks whether $\pi_{12} \odot \pi_{21} \odot \pi_{22}$ is good, etc. Intuitively, the growth of f controls how the strategy prioritizes deep runs into the chain over quick restarts while the number of restarts increases.

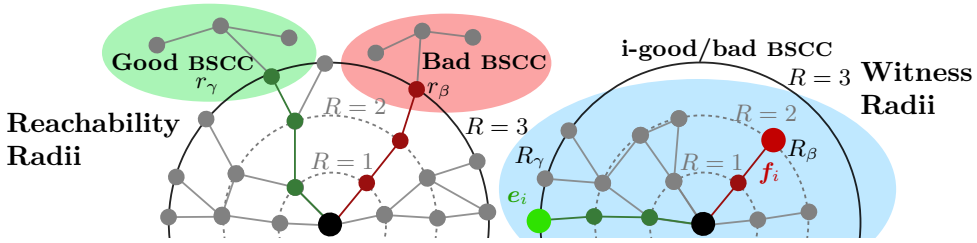

Figure 3 *Left:* Intuitively, r_γ and r_β denote an upper bound of how hard it is to reach a BSCC. *Right:* R_γ and R_β measure how hard it is to reach a state with label $\boldsymbol{e}_i/\boldsymbol{f}_i$ inside the BSCCs.

In the rest of the paper we prove that our strategy is correct, and obtain optimal upper bounds on the number of steps to the last reset. These bounds are given in terms of two parameters of the chain: the progress radius and the progress probability. We introduce the parameters in section 4.2.

4.2 Progress radius and progress probability

We define the notion of progress radius and progress probability for a Markov chain $\mathcal{M}$ with 2^{M_k} as set of observations and such that $\Pr(\mathcal{R}_k) > 0$. Intuitively, the progress radius is the smallest number of steps such that, for any state of the chain, conducting only this number of steps one can "make progress" toward producing a good run or a bad run. The progress probability gives a lower bound for the probability of the paths that make progress.

We define the notions only for the case $k = 1$, which already contains all the important features. The definition for arbitrary k is more technical, and is given in the Appendix.

Good runs and good BSCCs. We extend the definition of good paths to good runs and good BSCCs of a Markov chain. A run $\rho = s_0 s_1 s_2 \dots$ is *good* if $\boldsymbol{e}_1$ appears infinitely often in ρ and $\boldsymbol{f}_1$ finitely often, and *bad* otherwise. So a run ρ is good iff there exists a decomposition of ρ into an infinite concatenation $\rho \coloneqq \pi_0 \odot \pi_1 \odot \pi_2 \odot \cdots$ of non-empty paths such that $\pi_1, \pi_2, \dots$ are good. We let P_{good} denote the probability of the good runs of $\mathcal{M}$.

A BSCC of $\mathcal{M}$ is *good* if it contains at least one state labeled by $\boldsymbol{e}_1$ and no state labeled by $\boldsymbol{f}_1$, and bad otherwise. It is well-known that the runs of any finite-state Markov chain reach a BSCC and visit all its states infinitely often w.p.1 [2, Thm. 10.27]. It follows that good (resp. bad) runs eventually reach a good (resp. bad) BSCC w.p.1.

Progress radius. Intuitively, the progress radius R_{m} is the smallest number of steps such that, for any state s, by conducting R_{m} steps one can "make progress" toward producing a good run – by reaching a good BSCC or, if already in one, by reaching a state with observation $\boldsymbol{e}_1$ – or a bad run.

▶ **Definition 5** (Good-reachability and good-witness radii). *Let B_γ be the set of states of $\mathcal{M}$ that belong to good BSCCs and let S_γ be the set of states from which it is possible to reach B_γ, and let $s \in S_\gamma$. A non-empty path π starting at s is a* good progress path *if*

- *$s \in S_\gamma \setminus B_\gamma$, and π ends at a state of B_γ; or*
- *$s \in B_\gamma$, and π ends at a state with observation $\boldsymbol{e}_1$.*

The good-reachability radius *r_γ is the maximum, taken over every $s \in S_\gamma \setminus B_\gamma$, of the length of a shortest progress path for s. The* good-witness radius *R_γ is the same maximum, but taken over every $s \in B_\gamma$.*

The bad-reachability and bad-witness radii, denoted r_β and R_β are defined analogously. Only the notion of progress path of a state $s \in B_\beta$ needs to be adapted. Loosely speaking, a bad BSCC either contains no states with observation $\boldsymbol{e}_1$, or it contains some state with observation $\boldsymbol{f}_1$. Accordingly, if no state of the BSCC of s has observation $\boldsymbol{e}_1$, then any non-empty path starting at s is a progress path, and otherwise a progress path of s is a non-empty path starting at s and ending at a state with observation $\boldsymbol{f}_1$. We illustrate the definition of the reachability and witness radii in Figure 3. We leave r_β, R_β, p_β, and P_β undefined if the chain does not contain a bad BSCC, and hence runs are good w.p.1.

▶ **Definition 6** (Progress radius). *The* progress radius R_{m} *of* $\mathcal{M}$ *is the maximum of* r_γ, R_γ, r_β, *and* R_β.

Progress probability. From any state of the Markov chain it is possible to "make progress" by executing a progress path of length R_{m}. However, the probability of such paths varies from state to state. Intuitively, the progress probability gives a lower bound on the probability of making progress.

▶ **Definition 7.** *Let* B_γ *be the set of states of* $\mathcal{M}$ *that belong to good BSCCs, let* S_γ *be the set of states from which it is possible to reach* B_γ, *and let* $s \in S_\gamma$. *The* good-reachability probability p_γ *is the minimum, taken over every* $s \in S_\gamma \setminus B_\gamma$, *of the probability that a path with length* r_γ *starting at* s *contains a good progress path. The* good-witness probability P_γ *is the same mininum, but taken over every* $s \in B_\gamma$ *with paths of length* R_γ. *The corresponding bad probabilities are defined analogously. The* progress probability P_{m} *is the minimum of* $p_\gamma, P_\gamma, p_\beta, P_\beta$.

4.3 Correctness proof

We prove that the strategy $\mathfrak{S}[f]$ of section 4.1 is a valid testing strategy $\mathfrak{S}[f]$ for arbitrary Markov chains $\mathcal{M}$. First, we will give an upper bound on the probability that $\mathfrak{S}[f]$ restarts "incorrectly", i.e. at a state $s \in S_\gamma$ from which a good BSCC could still be reached.

▶ **Lemma 8.** *Let* $\mathcal{M}$ *be a Markov chain, and let* $\mathsf{M}_{\mathsf{r}}^{\mathfrak{S}[f]}$ *be its associated Markov chain with* $\mathfrak{S}[f]$ *as restart strategy. Let* NB_n *be the set of paths of* $\mathsf{M}_{\mathsf{r}}^{\mathfrak{S}[f]}$ *that have at least* $n-1$ *restarts and only visit states in* S_γ *after the* $(n-1)$*-th restart. We have:*

$$\Pr[\#\mathsf{r} \geq n \mid NB_n] \leq 3(1 - P_{\mathrm{m}})^{\lfloor f(n)/R_{\mathrm{m}} \rfloor - 1}$$

The technical proof of this lemma is in the Appendix. We give here the proof for a special case that illustrates most ideas. Consider the Markov chain with labels in $2^{\{\boldsymbol{e}_1, \boldsymbol{f}_1\}}$ at the top of Figure 4. The labeling function is $Obs(s_{\mathrm{goal}}) = \{\boldsymbol{e}_1\}$ and $Obs(s) = \emptyset$ for all other states, and $Obs(\rho) \in \mathcal{R}_1$ iff ρ visits s_{goal} infinitely often. The set S_γ contains all states because s_{goal} is reachable from every state. The only BSCC is $\mathcal{B} = \{s_1, s_{\mathrm{goal}}\}$, and it is a good BSCC. From the definitions of the parameters we obtain $r_\gamma = R_\gamma = 1$, $p_\gamma = p$ and $P_\gamma = q$. Further, since there are no bad BSCCs, r_β and R_β are undefined, and so $R_{\mathrm{m}} = 1$. So for this Markov chain Lemma 8 states $\Pr[\#\mathsf{r} \geq n \mid NB_n] \leq 3(1 - P_{\mathrm{m}})^{f(n)-1}$. Let us see why this is the case.

Let ρ be a run of $\mathsf{M}_{\mathsf{r}}^{\mathfrak{S}[f]}$ such that $\#\mathsf{r}(\rho) \geq n$, i.e., ρ has at least n restarts. Since S_γ contains all states, we have $\rho \in NB_n$ iff $\#\mathsf{r}(\rho) \geq n-1$. We consider three cases. In the definition of the cases we start counting steps immediately after the $(n-1)$-th restart, and denote by $\rho[a, b]$ the fragment of ρ that starts immediately before step a, and ends immediately after step b.

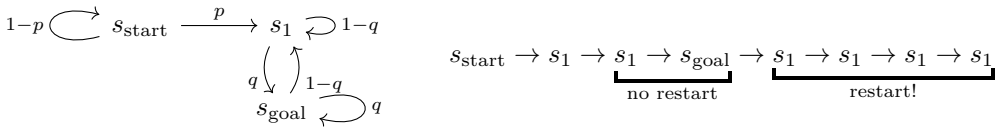

Figure 4 A Markov chain (left), and (a finite prefix of) one of its runs for $n = 2$ and $f(n) = n$ (right). After 2 steps, the run has reached a good BSCC $\mathcal{B}$. After 4 steps, σ checks whether to restart, but decides against it because of s_{goal} in step 4. After 8 steps it checks again, restarting this time. This restart is covered by the third case of the case distinction, with $k = 4$. The run must have visited s_{goal} in step 4, because otherwise the minimal k would be 3 or less.

(a) After $f(n)$ steps, ρ has not yet reached $\mathcal{B}$.
Then ρ has stayed in s_{start} for $f(n)$ consecutive steps, which, since $p = p_\gamma$, happens with probability at most $(1 - p_\gamma)^{f(n)}$.

(b) After $f(n)$ steps, ρ has already reached $\mathcal{B}$. Further, the n-th restart happens immediately after step $2f(n)$.
In this case, by the definition of the strategy, ρ does not visit s_{goal} during the interval $\rho[f(n) + 1, 2f(n)]$ (the second half of $[0, 2f(n)]$). So ρ stays in s_1 during the interval $\rho[f(n) + 1, 2f(n)]$ which, since ρ has already reached $\mathcal{B}$ by step $f(n)$, occurs with probability $(1 - P_\gamma)^{f(n)}$.

(c) After $f(n)$ steps, ρ has already reached $\mathcal{B}$. Further, the n-th restart does not happen before step $2f(n) + 1$.
Since the n-th restart happens at some point, and not before step $2f(n) + 1$, by the definition of the strategy there is a smallest number $k \geq f(n)$ such that ρ does not visit s_{goal} during the interval $\rho[k + 1, 2k]$. Because we assume that the n-th restart happens after step $2f(n)$, we even have $k > f(n)$. By the minimality of k, the run ρ does visit s_{goal} during the interval $\rho[k, 2k - 2]$. So ρ moves to s_{goal} at step k, and then stays in s_1 for k steps. The probability of the runs that eventually move to s_{goal} and then move to stay in s_1 for k steps is $P_\gamma(1 - P_\gamma)^k$.

Figure 4 shows at the bottom an example of a run, and how the stratgy handles it. Since (a)-(c) are mutually exclusive events, $\Pr[\#\mathsf{r} \geq n \mid NB_n]$ is bounded by the sum of their probabilities, where in case (c) we sum over all possible values of k. This yields:

$$Pr[\#\mathsf{r} \geq n \mid NB_n] \leq (1 - p_\gamma)^{f(n)} + (1 - P_\gamma)^{f(n)} + \sum_{k=f(n)+1}^{\infty} P_\gamma(1 - P_\gamma)^k \leq 3(1 - P_{\text{m}})^{f(n)}.$$

The proof for arbitrary Markov chains given in the Appendix has the same structure, and in particular the same split into three different events. Applying Lemma 8 we now easily obtain (see the Appendix for a detailed proof) an upper bound for the probability to restart an n-th time. Note that this bound captures the "correct" as well as the "incorrect" restarts:

▶ **Lemma 9** (Restarting probability). *Let $\mathcal{M}$ be a Markov chain, and let $\mathsf{M}_{\mathsf{r}}^{\mathfrak{S}[f]}$ be its associated Markov chain with $\mathfrak{S}[f]$ as restart strategy. The probability that a run restarts again after $n - 1$ restarts satisfies:*

$$\Pr[\#\mathsf{r} \geq n \mid \#\mathsf{r} \geq n - 1] \leq 1 - P_{good}\left(1 - 3(1 - P_{\text{m}})^{\lfloor f(n)/R_{\text{m}} \rfloor - 1}\right)$$

Proof. Let NB_n be the set of paths of $\mathsf{M}_{\mathsf{r}}^{\mathfrak{S}[f]}$ that have at least $n - 1$ restarts and only visit states in S_γ after the $(n - 1)$-th restart and $\overline{NB_n}$ its complement. We have

$$\Pr[\#\mathsf{r} \geq n \mid \#\mathsf{r} \geq n-1] = \Pr[\#\mathsf{r} \geq n \mid NB_n] \cdot \Pr[NB_n \mid \#\mathsf{r} \geq n-1] + \Pr[\#\mathsf{r} \geq n \mid \overline{NB}_n] \cdot \Pr[\overline{NB}_n \mid \#\mathsf{r} \geq n-1].$$

Applying Lemma 8 and $\Pr[\#\mathsf{r} \geq n \mid \overline{NB}_n] \leq 1$, we get

$$\Pr[\#\mathsf{r} \geq n \mid \#\mathsf{r} \geq n-1] \leq \left(3(1-P_{\mathrm{m}})^{\lfloor f(n)/R_{\mathrm{m}} \rfloor - 1}\right) \Pr[NB_n \mid \#\mathsf{r} \geq n-1] + \Pr[\overline{NB}_n \mid \#\mathsf{r} \geq n-1]$$

W.p.1, good runs of $\mathcal{M}$ only visit states of S_γ and so $\Pr[NB_n \mid \#\mathsf{r} \geq n-1] \geq P_{\mathrm{good}}$ and thus $\Pr[\overline{NB}_n \mid \#\mathsf{r} \geq n-1] \leq 1 - P_{\mathrm{good}}$, which completes the proof. ◀

Finally, we show that $\mathfrak{S}[f]$ is a correct testing strategy. Further, we show that the condition $\limsup_{n\to\infty} f(n) = \infty$ is not ony sufficient, but also necessary. The previous lemma gives an upper bound on the probability for a restart that, for increasing $f(n)$, drops below 1. If $f(n)$ is above that threshold for infinitely many n, it suffices to show that the strategy $\mathfrak{S}[f]$ restarts every bad run:

▶ **Theorem 10.** *$\mathfrak{S}[f]$ is a testing strategy for the Rabin language $\mathcal{R}_k$ iff the function f satisfies $\limsup_{n\to\infty} f(n) = \infty$.*

Proof.
($\Rightarrow$): We prove the contrapositive. If $\limsup_{n\to\infty} f(n) < \infty$ then there is a bound b such that $f(n) \leq b$ for every $n \geq 0$. Consider a Markov chain over 2^{M_1} consisting of a path of $2b+1$ states, with the last state leading to itself with probability 1; the last state is labeled with $\boldsymbol{e}_1$, and no state is labeled with $\boldsymbol{f}_1$. Then the chain has a unique run that goes from the initial to the last state of the path and stays there forever, and its observation is a word of $\mathcal{R}_1$; therefore, $\Pr(\mathcal{R}_1) = 1$. However, since $2f(n) \leq 2b+1$, $\mathfrak{S}[f]$ always restarts the chain before reaching the last state.
($\Leftarrow$): By the previous lemma, we can bound the restart probability after $n-1$ restarts by $1 - \left(1 - 3(1-P_{\mathrm{m}})^{\lfloor f(n)/R_{\mathrm{m}} \rfloor - 1}\right) P_{\mathrm{good}}$. Because $0 < P_{\mathrm{m}} \leq 1$ and and $P_{\mathrm{good}} > 0$, for large enough $f(n)$ this is smaller than $1 - P_{\mathrm{good}}/2 < 1$. Because of $\limsup_{n\to\infty} f(n) = \infty$, we have that the probability to restart the run another time is at most $1 - P_{\mathrm{good}}/2$ for infinitely many n, and hence the total number of restarts is finite with probability 1. A bad run would enter a bad BSCC B w.p.1 and would then go on to visit a set consisting of all the f_i corresponding to B infinitely often. Thus, $\mathfrak{S}[f]$ would restart this run and hence reached a good run when it does not restart. ◀

5 Quantitative analysis

The quality of a testing strategy is given by the expected number of steps until the last restart, because this is the overhead spent until a violation starts to be executed. As in [6], given a labeled Markov chain $\mathcal{M}$ and a testing strategy σ, we define the number of steps to the last restart as random variables over the Markov chain $\mathsf{M}_{\mathsf{r}}^{\sigma}$:

▶ **Definition 11** ($S(\rho)$ and $S_n(\rho)$)**.** *Let ρ be a run of $\mathsf{M}_{\mathsf{r}}^{\sigma}$. We define: $S(\rho)$ is equal to 0 if r does not occur in ρ; it is equal to the length of the longest prefix of ρ ending in r, if r occurs at least once and finitely often in ρ; and it is equal to ∞ otherwise. Further, for every $n \geq 1$ we define $S_n(\rho)$ to be equal to 0 if r occurs less than n times in ρ; and equal to the length of the segment between the $(n-1)$-th (or the beginning of ρ) and the n-th occurrence of r.*

In this section we investigate the dependence of $\mathbb{E}[S]$ on the function $f(n)$. A priori it is unclear whether $f(n)$ should grow fast or slow. Consider the case in which all BSCCs of the chain, good or bad, have size 1, and a run eventually reaches a good BSCC with probability p. In this case the strategy restarts the chain until a sample reaches a good BSCC for the first time. If $f(n)$ grows fast, then after a few restarts, say r, every subsequent run reaches a BSCC of the chain with large probability, and so the expected number of restarts is small, at most $r + (1/p)$. However, the number of steps executed during these few restarts is large, because $f(n)$ grows fast; indeed, only the run after the penultimate restart executes already at least $2f(r + (1/p) - 1)$ steps.

In a first step we show that $\mathbb{E}[S] = \infty$ holds for every function $f(n) \in 2^{\Omega(n)}$.

▶ **Proposition 12.** *Let $f \in 2^{\Omega(n)}$. Then there exists a Markov chain such that the testing strategy of Figure 2 satisfies $\mathbb{E}(S) = \infty$.*

Proof. Let f be in $2^{\Omega(n)}$. Then there exists some $k > 0$ such that we have $\limsup_{n\to\infty} f(n) \cdot (1/2)^{n/k} > 0$. Consider a Markov chain with $P_{\text{good}} = 1 - (1/2)^{1/k}$. Then we have $\mathbb{E}(S) = \sum_{n=0}^{\infty} \mathbb{E}(S_n \mid \#\mathsf{r} \geq n-1)P(\#\mathsf{r} \geq n-1)$. We have that $P(\#\mathsf{r} \geq n-1 \mid \#\mathsf{r} \geq n-2) \geq 1-P_{\text{good}}$ because only good runs will not be restarted. We also have that $\mathbb{E}(S_n \mid \#\mathsf{r} \geq n-1) \geq f(n)(1-P_{\text{good}})$ because of the same reason. Thus

$$\mathbb{E}[S] = \sum_{n=0}^{\infty} \mathbb{E}(S_n \mid \#\mathsf{r} \geq n-1)P(\#\mathsf{r} \geq n-1) \geq \sum_{n=0}^{\infty} f(n)(1-P_{\text{good}}) \cdot (1-P_{\text{good}})^n$$

and hence $\mathbb{E}[S] \geq \sum_{n=0}^{\infty} f(n)(1/2)^{n/k} = \infty$. ◀

It follows that (if we limit ourselves to monotonic functions, which is no restriction in practice), we only need to consider functions $f(n)$ satisfying $f(n) \in \omega(1) \cap 2^{o(n)}$. In the rest of the section we study the strategies corresponding to polynomial functions $f(n) = n^c$ for $c \in \mathbb{N}_+$, and obtain an upper bound as a function of the parameters $R_{\text{m}}/P_{\text{m}}$, P_{good}, and c. The study of subexponential but superpolynomial functions is beyond the scope of this paper.

5.1 Quantitative analysis of strategies with $f(n) = n^c$

We give an upper bound on $\mathbb{E}(S)$, the expected total number of steps before the last restart. Our starting point is Lemma 9, which bounds the probability to restart for the n-th time, if $(n-1)$ restarts have already happened. When the number n of restarts is small, the value of the right-hand-side is above 1, and so the bound is not useful. We first obtain a value X such that after X restarts the right-hand-side drops below 1.

▶ **Lemma 13.** *Let $X = \sqrt[c]{R_{\text{m}}\,(2 + \ln(1/6)/\ln(1-P_{\text{m}}))}$. For all $n \geq X$, we have*

$$\Pr[\#\mathsf{r} \geq n \mid \#\mathsf{r} \geq n-1] \leq 1 - P_{good}/2$$

when restarting according to $\mathfrak{S}[n \mapsto n^c]$.

Proof. Follows immediately from Lemma 9, the fact that the restart probability decreases with n, the definition of X, and some calculations. We recall the statement of Lemma 9:

$$\Pr[\#\mathsf{r} \geq n \mid \#\mathsf{r} \geq n-1] \leq 1 - P_{\text{good}}\left(1 - 3(1-P_{\text{m}})^{\lfloor f(n)/R_{\text{m}} \rfloor - 1}\right)$$

Plugging in an $n \geq X$ validates the claim. ◀

We now try to find a bound for $\mathbb{E}[S]$: By linearity of expectation, we have $\mathbb{E}[S] = \sum_{i=1}^{\infty} \mathbb{E}[S_n]$. We split the sum into two parts: for $n < X$, and for $n \geq X$. For $n < X$ we just approximate $\Pr[\#\mathsf{r} \geq n-1]$ by 1. For $n > X$ we can say more thanks to Lemma 13:

$$\begin{aligned}\Pr[\#\mathsf{r} \geq n-1] &= \Pr[\#\mathsf{r} \geq n-1 | \#\mathsf{r} \geq n-2] \cdots \Pr[\#\mathsf{r} \geq X+1 | \#\mathsf{r} \geq X] \cdot \Pr[\#\mathsf{r} \geq X] \\ &\leq \prod_{k=\lceil X \rceil}^{n} \Pr[\#\mathsf{r} \geq k | R \geq k-1] \leq (1 - P_{\text{good}}/2)^{n-X}\end{aligned}$$

This yields:

$$\begin{aligned}\mathbb{E}[S] &= \sum_{n=0}^{\infty} \mathbb{E}[S_n \mid \#\mathsf{r} \geq n-1] \Pr[\#\mathsf{r} \geq n-1] \\ &\leq \sum_{n=0}^{X} \mathbb{E}[S_n \mid \#\mathsf{r} \geq n-1] + \sum_{n=X}^{\infty} \mathbb{E}[S_n \mid \#\mathsf{r} \geq n-1] \cdot (1 - P_{\text{good}}/2)^{n-X} \qquad (1)\end{aligned}$$

It remains to bound the expected number of steps between two restarts $\mathbb{E}[S_n \mid \#\mathsf{r} \geq n-1]$, which is done in Lemma 14 below. The proof can be found in the Appendix. The proof first observes that the expected number of steps it takes to reach a good or a bad BSCC is r_γ/p_γ resp. r_β/p_β. Then we give a bound on the expected number of steps it takes to perform a progress path inside a bad BSCC for the first time, or to not perform a progress path inside a good BSCC for an entire second half of a run at some point after the $(n-1)$-st restart; the bound is also in terms of $R_{\text{m}}/P_{\text{m}}$ and $R_{\text{m}}/P_{\text{m}}(1-P_\gamma)$. The term $2f(n)$ comes from the fact that the strategy always executes at least $2f(n)$ steps. The term $2R_{\text{m}}$ is an artifact due to the "granularity" of the analysis, where we divide runs in blocks of R_{m} steps.

▶ **Lemma 14** (Expected number of steps in a fragment). *For the strategy $\mathfrak{S}[n \mapsto n^c]$ we have:*

$$\mathbb{E}[S_n \mid \#\mathsf{r} \geq n-1] \leq 2(R_{\text{m}} + f(n)) + 9\left(\frac{R_{\text{m}}}{P_{\text{m}}(1-P_\gamma)}\right). \qquad (1)$$

Plugging Lemma 14 into (1), we finally obtain (see the Appendix):

▶ **Theorem 15** (Expected number of total steps). *For the strategy $\mathfrak{S}[n \mapsto n^c]$ we have:*

$$\mathbb{E}[S] \in \mathbb{O}\left((c+1)! \cdot 2^c \cdot \left(\frac{R_{\text{m}}}{P_{\text{m}}}\right)^{1+1/c} + \frac{2^c(c+1)!}{P_{good}^{c+1}} + (c+1)!(2c)^{c+1}\right).$$

If we fix a value c, we obtain a much simpler statement:

▶ **Corollary 16.** *For a fixed c, the strategy $\mathfrak{S}[n \mapsto n^c]$ satisfies:*

$$\mathbb{E}[S] \in \mathbb{O}\left(\left(\frac{R_{\text{m}}}{P_{\text{m}}}\right)^{1+1/c} + \frac{1}{P_{good}^{c+1}}\right).$$

Thus the bound on the total number of steps depends on two quantities, $R_{\text{m}}/P_{\text{m}}$ and P_{good}. A small c favours the effect of $R_{\text{m}}/P_{\text{m}}$ on the bound, a larger c the effect of P_{good}. In Section 6 we will see that this closely matches the performance of the algorithms for different values of c on synthetic Markov chains and on Markov chains from the PRISM benchmark set.

5.2 Optimality of the Strategy $f(n) = n^c$

We will prove the following optimality guarantee for our strategies.

▶ **Theorem 17.** *For every $c \in \mathbb{N}_+$ there is a family of Markov chains such that our bound of Corollary 16 on $\mathfrak{S}[n \mapsto n^c]$ is asymptotically optimal, i.e., no other black-box testing strategy is in a better asymptotic complexity class.*

This proves two points: first, our bounds cannot be substantially improved. Second, one necessarily needs information on $\frac{R_m}{P_m}$ and P_{good} to pick an optimal value for c; without any information every value is equally good.

Proof. Consider the family of Markov chains at the top of Figure 5. We take an arbitrary $k > 1$ and set $M = k^{c-1}$ and $p = q = 1/k$. With this choice we have $P_{good} = P_m = 1/k$, and $R_m = k^{c-1}$. By Lemma 15, the strategy $\mathfrak{S}[n \mapsto n^c]$. satisfies $\mathbb{E}[S] \in \mathbb{O}((R_m/P_m)^{1+1/c} + (1/P_{good})^{c+1}) = \mathbb{O}(k^{c+1})$

We compare this with the optimal number of expected steps before the final restart. Since runs that visit s_{goal} at least once are good w.p.1, any optimal strategy stops restarting exactly after the visit to s_{goal}. We claim that every such strategy satisfies $\mathbb{E}[S] \geq R_m/(P_{good}P_m)(1 - P_{good})$. For this, we make four observations. First, the probability of a good run is P_{good}. Second, the expected number of steps of a good run until the first visit to s_{goal} is R_m/P_m. Third, the smallest number of steps required to distinguish a bad run, i.e. being in the left BSCC, from a good run is equal to R_m, because until R_m steps are executed, all states visited carry the same label. Hence, every strategy takes $R_m/(P_{good}P_m)$ steps on average before reaching the state s_{goal} for the first time. Fourth, on average $1/P_{good}$ tries are required to have one try result in a good run. Hence, on average at least $\frac{1/P_{good}-1}{1/P_{good}}$ of the $R_m/(P_{good}P_m)$ steps happen before the last restart. Since $\frac{1/P_{good}-1}{1/P_{good}} = (1 - P_{good})$, this proves the claim. Now $R_m/(P_{good}P_m)(1 - P_{good}) = k^{c+1} - k^c \in \Theta(k^{c+1})$ and we are done. ◀

6 Experiments

We report on experiments on three kinds of systems. First, we conduct experiments on two synthetic families of Markov Chains. Second, we repeat the experiments of [6] on models from the standard PRISM Benchmark Suite [10] using our black-box strategies. Finally, we conduct experiments on population protocols from the benchmark suite of the Peregrine tool [4, 5].

Synthetic Experiments. Consider the two (families of) labeled Markov chains at the top of Figure 5. The labels are a and b. In the top chain, state s_{goal} is labeled by a, all others by b. In the bottom chain, the states s_2 to s_M and s_{goal} are labeled by $\{a, s_{start}\}$ and s_{sink} by b. The language L is the set of words containing infinitely many occurrences of a. In the top chain at the initial state we go right or left with probability q and $(1 - q)$, respectively. Runs that go left are bad, and runs that go right are good w.p.1. It follows $P_{good} = q$, $R_m = M$, and $P_m = \min(p, q)$. In our experiments we fix $q = 1/2$. By controlling M and p, we obtain chains with different values of R_m and P_m for fixed $P_{good} = 1/2$. In the bottom chain, $R_\beta = R_\gamma = 1$, $R_m = r_\gamma = M$, $p_\gamma = p^M$, $p_\beta = (1 - p)$ and $P_m = \min(p^M, 1 - p)$ and $P_{good} = p^M$.

Recall that the bound obtained in the last section is $\mathbb{E}[S] \leq f(c)(R_m/P_m)^{1+1/c} + g(c)(1/P_{good})^{c+1}$ where $f(c)$ and $g(c)$ are fast-growing functions of c. If P_{good} and R_m/P_m are small, then $f(c)$ and $g(c)$ dominate the number of steps, and hence strategies with small c should perform better. The data confirms this prediction. Further, for fixed P_{good}, the

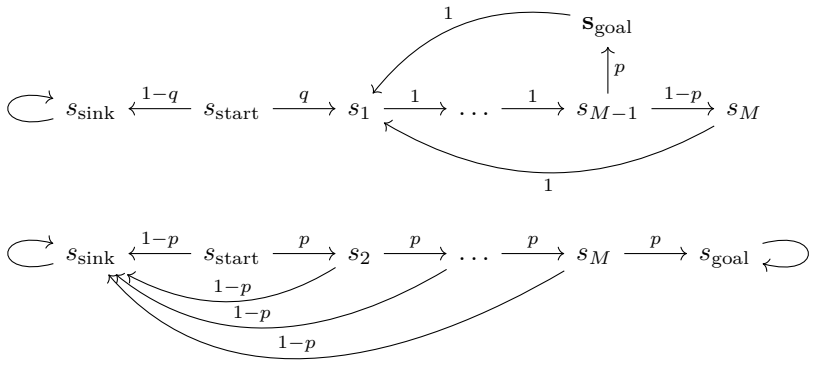

Figure 5 Two families of Markov chains. The initial state is s_{start}. The good runs are those that visit s_{goal} infinitely often. For the top chains, $P_{\text{good}} = q$, $R_{\text{m}} = M$, and $P_{\text{m}} = p$. For the bottom chains, $P_{\text{good}} = p^M$, $R_{\text{m}} = M$, $P_{\text{m}} = p^M$.

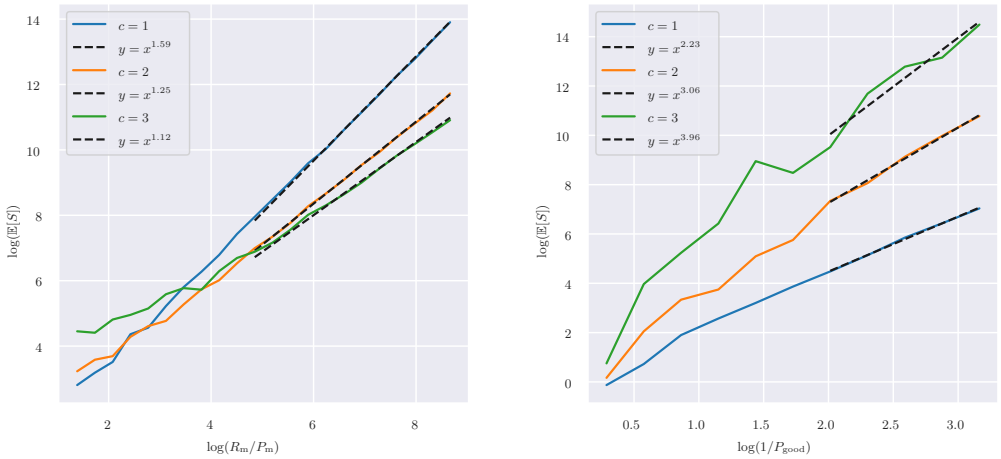

Figure 6 On the left, double-logarithmic plot of the expected total number of steps before the last restart $\mathbb{E}(S)$ for the chain at the top of Figure 5 as a function of $R_{\text{m}}/P_{\text{m}}$ for strategies (2) with $f(n) = n^c$ for varying c. On the right, same for the bottom chain as a function of $1/P_{\text{good}}$. The plots also show linear regressions. The leading exponent can be taken from the legend.

bound predicts $\mathbb{E}[S] \in O((R_{\text{m}}/P_{\text{m}})^{1+1/c})$, and so for growing $R_{\text{m}}/P_{\text{m}}$ strategies with large c should perform better. The left diagram confirms this. Also, the graphs become straight lines in the double logarithmic plot, confirming the predicted polynomial growth. Finally, for $R_{\text{m}}/P_{\text{m}}$ and $1/P_{\text{good}}$ growing roughly at the same speed as in the lower Markov chain, the bound predicts $\mathbb{E}[S] \in O(1/P_{\text{good}}^{c+1})$ for $c = 2, 3$ and $\mathbb{E}[S] \in O(M^2/P_{\text{good}}^{c+1})$ for $c = 1$, and hence for growing P_{good} and $R_{\text{m}}/P_{\text{m}}$, strategies with small c perform better. Again, the right diagram confirms this.

Experiments on the PRISM data set. We evaluate the performance of our black-box testing strategies for different values of c on discrete time Markov chain benchmarks from the PRISM Benchmark suite [10], and compare them with the strategies of [6] for fully observable systems. Table 1 shows the results. The properties checked are of the form $\mathbf{GF}$, $(\mathbf{GF} \to \mathbf{FG})$, or their negations. We add a gridworld example[2] denoted $\overline{\texttt{GW}}$, with larger values of the parameters, to increase the number of states to $\sim 5 \cdot 10^8$. When trying to construct the corresponding Markov chain, Storm experienced a timeout. Runs are sampled using the simulator of the Storm model checker [9] and the python extension Stormpy. We abort a run after 10^6 (Up to $3 \cdot 10^7$ for the gridworld examples gw, $\overline{\texttt{gw}}$, and $\overline{\texttt{GW}}$) steps without a restart. The probability of another restart is negligibly small.

The Cautious$_{10}$- and the Bold$_{0.1}$-strategy of [6] store the complete sequence of states observed, and so need linear memory in the length of the sample. Our strategies use at most a logarithmic amount of memory, at none or little cost in the number of steps to the last restart. Our strategies never timeout and, surprisingly, often require *fewer* steps than fully-observable ones. In particular, the strategies for fully observable systems cannot handle gridworlds, and only the bold strategy handles gridworld. One reason for this difference is our strategies' ability to adapt to the size of the chain automatically by increasing values of $f(n)$ as n grows. In two cases (nand and bluetooth) the fully observing strategies perform better by a factor of ~ 2 to ~ 3. In comparison to the improvement by a factor of ~ 50 in scale$_{10}$ and a factor of ~ 90 in gridworld of the newly presented black-box strategies over the whitebox strategies, this is negligible.

Table 1 Average number of steps before the final restart, averaged over 300 (100 for Herman and $\overline{\texttt{GW}}$) runs. Results for our strategies for $c = 1, 2, 3$, and the bold and cautious strategies of [6].

Experiments on population Protocols. Population protocols are consensus protocols in which a crowd of indistinguishable agents decide a property of their initial configuration by reaching a stable consensus [1, 4]. The specification states that for each initial configuration

[2] Unfortunately, the experimental setup of [6] cannot be applied to this example [19].

the agents eventually reach the right consensus (property holds/does not hold). We have tested our strategies on several protocols from the benchmark suite of Peregrine, the state-of-the-art model checker for population protocols [4, 5]. The first protocol of Table 2 is faulty, but Peregrine cannot prove it; our strategy finds initial configurations for which the protocol exhibits a fault. For the second protocol both our strategies and Peregrine find faulty configurations. The third protocol is correct; Peregrine fails to prove it, and our strategies correctly fail to find counterexamples. The last protocol is correct, but in expectation consensus is reached only after an exponential number of steps in the parameters; we complement the specification, and search for a run that achieves consensus. Thanks to the logarithmic memory requirements, our strategies can run deep into the Markov chain and find the run.

7 Conclusions

We have studied the problem of testing partially observable stochastic systems against ω-regular specifications in a black-box setting where testers can only restart the system, have no information on size or probabilities, and cannot observe the states of the system, only its outputs. We have shown that, despite these limitations, black-box testing strategies exist. We have obtained asymptotically optimal bounds on the number of steps to the last restart. Surprisingly, our strategies never require many more steps than the strategies for fully observable systems of [6], and often even less. Sometimes, the improvement is by a large factor (up to ~ 90 in our experiments) or the black-box strategies are able to solve instances where the strategies of [6] time out.

Abstract

We study the fine-grained complexity of evaluating Boolean Conjunctive Queries and their generalization to sum-of-product problems over an arbitrary semiring. For these problems, we present a general *semiring-oblivious* reduction from the k-clique problem to any query structure (hypergraph). Our reduction uses the notion of *embedding* a graph to a hypergraph, first introduced by Marx [20]. As a consequence of our reduction, we can show tight conditional lower bounds for many classes of hypergraphs, including cycles, Loomis-Whitney joins, some bipartite graphs, and chordal graphs. These lower bounds have a dependence on what we call the *clique embedding power* of a hypergraph H, which we believe is a quantity of independent interest. We show that the clique embedding power is always less than the submodular width of the hypergraph, and present a decidable algorithm for computing it. We conclude with many open problems for future research.

1 Introduction

In a seminal paper, Marx proved the celebrated result that CSP($\mathcal{H}$) is fixed-parameter tractable (FPT) if and only if the hypergraph $\mathcal{H}$ has a bounded submodular width [20]. In the language of database theory, a Boolean Conjunctive Query (BCQ) can be identified as the problem of CSP($\mathcal{H}$) where $\mathcal{H}$ is the hypergraph associated with the query [11]. Thus, Marx's result implies that a class of Boolean Conjunctive Queries is FPT if and only if its submodular width is bounded above by some universal constant. Built on this result, Khamis, Ngo, and Suciu introduced in [17] the PANDA (Proof-Assisted eNtropic Degree-Aware) algorithm, which can evaluate a BCQ[1] in time $\tilde{O}(|I|^{\mathsf{subw}(H)})$, where $|I|$ is the input size and $\mathsf{subw}(\mathcal{H})$ is the submodular width of $\mathcal{H}$ (here $\tilde{O}$ hides polylogarithmic factors). Remarkably, the running time of PANDA achieves the best known running time of *combinatorial algorithm*[2] for *all* BCQs. It is thus an important open question whether there exists a faster combinatorial algorithm than PANDA for some Boolean CQ.

[1] Technically, the PANDA algorithm works for Boolean or full CQs.
[2] Informally speaking, this requires the algorithm does not leverage fast matrix multiplication techniques.

To show that large submodular width implies not being FPT, Marx introduced the notion of an *embedding*, which essentially describes a reduction from one CSP problem to another. Our key insight in this work is that we can apply the notion of an embedding to measure how well *cliques* of different sizes can be embedded to a hypergraph $\mathcal{H}$. By taking the supremum over all possible clique sizes, we arrive at the definition of *clique embedding power*, denoted $\mathsf{emb}(\mathcal{H})$. The use of cliques as the starting problem means that we can use popular lower bound conjectures in fine-grained complexity (the Boolean k-Clique conjecture, the Min-Weight k-Clique conjecture) to obtain (conditional) lower bounds for the evaluation of BCQs that depend on $\mathsf{emb}(\mathcal{H})$.

Equipped with the new notion of the clique embedding power, we can show tight lower bounds for several classes of queries. That is, assuming the Boolean k-Clique Conjecture, we derive (conditional) lower bounds for many queries that meet their submodular width, and therefore the current best algorithm, up to polylogarithmic factors. In particular, we show that for cycles [2], Loomis-Whitney joins [22], and chordal graphs, among others, the current combinatorial algorithms are optimal.

We further extend the embedding reduction to be independent of the underlying (commutative) semiring[3]. It was observed by Green, Karvounarakis, and Tannen [10] that the semantics of CQs can be naturally generalized to sum-of-product operations over a semiring. This point of view unifies a number of database query semantics that seem unrelated. For example, evaluation over set semantics corresponds to evaluation over the Boolean semiring $\sigma_{\mathbb{B}} = (\{0,1\}, \vee, \wedge, 0, 1)$, while bag semantics corresponds to the semiring $(\mathbb{N}, +, \times, 0, 1)$. Interestingly, following this framework, the decision problem of finding a k-clique in a graph can be interpreted as the following sum-of-product operation: consider the input graph $G = (V, E)$ as the edge-weighted graph of the complete graph with $|V|$ vertices where $\mathsf{weight}(e) = \mathbb{1}_{e \in E}$; then the problem is to compute $\bigvee_{V' \subseteq V : |V'| = k} \bigwedge \mathsf{w}(\{v, w\})$. Observe that by changing the underlying semiring to be the tropical semiring $\mathsf{trop} = (\mathbb{R}^{\infty}, \min, +, \infty, 0)$, this formulation computes the min-weight k-clique problem. Indeed, given an edge-weighted graph (where the weight of non-existence edges is 0), the minimum weight of its k-clique is exactly $\min_{V' \subseteq V : |V'| = k} \sum \mathsf{w}(\{v, w\})$. We prove that the clique embedding reduction is *semiring-oblivious*, i.e., the reduction holds for arbitrary underlying semirings. This enables one to transfer the lower bound result independent of the underlying semiring and should be of independent interest.

Recent years have witnessed emerging interests in proving lower bounds for the runtime of database queries (see Durand [8] for a wonderful survey). Casel and Schmid consider the fine-grained complexity of regular path queries over graph databases [7]. Joglekar and Ré prove a full dichotomy for whether a 1-series-parallel graph admits a subquadratic algorithm [13]. Their proof is based on the hardness hypothesis that 3-XOR cannot be solved in subquadratic time. Perhaps the line of work in spirit closest to ours is the characterization of queries which can be enumerated by linear preprocessing time and constant delay [3, 6, 4]. However, their results focus on the enumeration problem and therefore are different from the main subject of our paper. Furthermore, their characterization mainly classifies queries based on the existence of a linear preprocessing time and constant delay algorithm. In contrast, our method can provide a lower bound for *every* query.

[3] A triple $(\mathbf{D}, \oplus, \otimes, \mathbf{0}, \mathbf{1})$ is a commutative semiring if $\oplus$ and $\otimes$ are commutative binary operators over $\mathbf{D}$ with the following properties: (*i*) $(\mathbf{D}, \oplus)$ is a commutative monoid with an additive identity $\mathbf{0}$. (*ii*) $(\mathbf{D}, \otimes)$ is a commutative monoid with a multiplicative identity $\mathbf{1}$. (*iii*) $\otimes$ distributes over $\oplus$. (*iv*) For any element $e \in \mathbf{D}$, we have $e \otimes \mathbf{0} = \mathbf{0} \otimes e = \mathbf{0}$.

Our Contributions. We summarize our contributions as follows:

- We introduce the notion of the *clique embedding power* $\mathsf{emb}(\mathcal{H})$ of a hypergraph $\mathcal{H}$ (Section 3). We show several interesting properties of this notion; most importantly, we show that it is always upper-bounded by the submodular width, $\mathsf{subw}(\mathcal{H})$. This connection can be seen as additional evidence of the plausibility of the lower bound conjectures for the k-clique problem.
- We show how to construct a reduction from the k-clique problem to any hypergraph $\mathcal{H}$ for any semiring, and discuss how the clique embedding power provides a lower bound for its running time (Section 4).
- We study how to compute $\mathsf{emb}(\mathcal{H})$ (Section 5). In particular, we prove that it is a decidable problem, and give a Mixed Integer Linear Program formulation. One interesting consequence of this formulation is that to achieve $\mathsf{emb}(\mathcal{H})$ it suffices to consider clique sizes that depend on the hypergraph size.
- We identify several classes of hypergraphs for which $\mathsf{emb}(\mathcal{H}) = \mathsf{subw}(\mathcal{H})$ (Section 6). For these classes of queries, our lower bounds match the best-known upper bounds if we consider the Boolean semiring with combinatorial algorithms or the tropical semiring. The most interesting class of hypergraphs we consider is the class of *chordal hypergraphs* (which captures chordal graphs).
- Finally, we identify a hypergraph with six vertices for which there is a gap between its clique embedding power and submodular width (Section 7). We believe that the existence of this gap leaves many open questions.

2 Background

In this section, we define the central problem, and notions necessary for our results.

The SumProduct Problem. We define this general problem following the notation in [16, 14]. Consider ℓ variables $x_1, x_2, \ldots, x_\ell$, where each variable x_i takes values in some discrete domain $\mathsf{Dom}(x_i)$. A *valuation* v is a function that maps each x_i to $\mathsf{Dom}(x_i)$. For a subset $S \subseteq [\ell]$, we define the tuple $\mathbf{x}_S = (x_i)_{i \in S}$ and $v(\mathbf{x}_S) = (v(x_i))_{i \in S}$.

The SumProduct Problem is parameterized by:

1. a commutative semiring $\sigma = (\mathbf{D}, \oplus, \otimes, \mathbf{0}, \mathbf{1})$, where $\mathbf{D}$ is a fixed domain.
2. a hypergraph $\mathcal{H} = (V, E)$ where $V = [\ell]$.

The input I specifies for every hyperedge $e \in E$ a function $R_e : \prod_{i \in e} \mathsf{Dom}(x_i) \to \mathbf{D}$. This function is represented in the input as a table of all tuples of the form $(\mathbf{a}_e, R_e(\mathbf{a}_e))$, such that $R_e(\mathbf{a}_e) \neq \mathbf{0}$. This input representation is standard in the CSP and database settings. We use $|I|$ to denote the input size, which is simply the sum of sizes of all tables in the input.

The SumProduct Problem then asks to compute the following function:

$$\bigoplus_{v:\text{valuation}} \bigotimes_{e \in E} R_e(v(\mathbf{x}_e)).$$

We will say that v is a *solution* for the above problem if $\bigotimes_{e \in E} R_e(v(\mathbf{x}_e)) \neq \mathbf{0}$.

Within this framework, we can capture several important problems depending on the choice of the semiring and the hypergraph. If we consider the Boolean semiring $\sigma_{\mathbb{B}} = (\{0, 1\}, \vee, \wedge, 0, 1)$, then each R_e behaves as a relational instance (R_e is 1 if the tuple is in the instance, otherwise 0) and the SumProduct function captures Boolean Conjunctive Query evaluation. If $\sigma = (\mathbb{N}, +, \times, 0, 1)$ and R_e is defined as above, then the SumProduct function computes the number of solutions to a Conjunctive Query. Another important class of

problems is captured when we consider the min-tropical semiring $\mathsf{trop} = (\mathbb{R}^{\infty}, \min, +, \infty, 0)$ and we assign each tuple to a non-negative weight; this computes a minimum weight solution that satisfies the structural properties.

The Complexity for SumProduct Problems. We adopt the *random-access machine (RAM)* as our computation model with $O(\log n)$-bit words, which is standard in fine-grained complexity. The machine has read-only input registers and it contains the database and the query, read-write work memory registers, and write-only output registers. It is assumed that each register can store any tuple, and each tuple is stored in one register. The machine can perform all "standard" [4] operations on one or two registers in constant time.

In this paper, we are interested in the computational complexity of a SumProduct problem for a fixed hypergraph $\mathcal{H}$. (This is typically called *data complexity*). We will consider two different ways of treating semirings when we think about algorithms.

In the first variant, we fix the semiring σ along with the hypergraph $\mathcal{H}$. This means that the representation of the semiring is not part of the input and is known a priori to the algorithm. We denote this problem as $\mathsf{SumProd}\langle\sigma, \mathcal{H}\rangle$. In the second variant, we consider algorithms that access the semiring only via an oracle. In particular, the algorithm does not know the semiring a priori and can only access it during runtime by providing the values for the $\oplus, \otimes$ operations. We assume that each of these operations takes a constant amount of time. We denote this problem as $\mathsf{SumProd}\langle\mathcal{H}\rangle$.

Our goal in this paper is to specify the exact exponent of $|I|$ in the polynomial-time runtime cost of an algorithm that computes $\mathsf{SumProd}\langle\sigma, \mathcal{H}\rangle$ or $\mathsf{SumProd}\langle\mathcal{H}\rangle$.

Tree Decompositions. A *tree decomposition* of a hypergraph $\mathcal{H}$ is a pair $(\mathcal{T}, \chi)$, where $\mathcal{T}$ is a tree and χ maps each node $t \in V(\mathcal{T})$ of the tree to a subset $\chi(t)$ of $V(\mathcal{H})$ such that:

1. every hyperedge $e \in E(\mathcal{H})$ is a subset of $\chi(t)$ for some $t \in V(\mathcal{T})$; and
2. for every vertex $v \in V(\mathcal{H})$, the set $\{t \mid v \in \chi(t)\}$ is a non-empty connected subtree of $\mathcal{T}$.

We say that a hypergraph $\mathcal{H}$ is *acyclic* if it has a tree decomposition such that each bag corresponds to a hyperedge.

Notions of Width. Let $\mathcal{H}$ be a hypergraph and F be a set function over $V(H)$. The F-width of a tree decomposition $(\mathcal{T}, \chi)$ is defined as $\max_t F(\chi(t))$. The F-width of $\mathcal{H}$ is the minimum F-width over all possible tree decompositions of $\mathcal{H}$.

A *fractional independent set* of a hypergraph $\mathcal{H}$ is a mapping $\mu : V(\mathcal{H}) \to [0, 1]$ such that $\sum_{v \in e} \mu(v) \leq 1$ for every $e \in E(\mathcal{H})$. We naturally extend functions on the vertices of $\mathcal{H}$ to subsets of vertices of $\mathcal{H}$ by setting $\mu(X) = \sum_{v \in X} \mu(v)$.

The *adaptive width* $\mathsf{adw}(\mathcal{H})$ of a hypergraph $\mathcal{H}$ is defined as the supreme of F-width$(\mathcal{H})$, where F goes over all fractional independent sets of $\mathcal{H}$. Hence if $\mathsf{adw}(\mathcal{H}) \leq w$, then for every μ, there exists a tree decomposition of $\mathcal{H}$ with μ-width at most w.

A set function F is *submodular* if for any two sets A, B we have $F(A \cup B) + F(A \cap B) \leq F(A) + F(B)$. It is monotone if whenever $A \subseteq B$, then $F(A) \leq F(B)$. The *submodular width* $\mathsf{subw}(\mathcal{H})$ of a hypergraph $\mathcal{H}$ is defined as the supreme of F-width$(\mathcal{H})$, where F now ranges over all non-negative, monotone, and submodular set functions over $V(\mathcal{H})$ such that for every hyperedge $e \in E(\mathcal{H})$, we have $F(e) \leq 1$. A non-negative, monotone, and submodular set function F is *edge-dominated* if $F(e) \leq 1$, for every $e \in E$.

[4] This includes all arithmetic (e.g. $+, -, \div, *$) and logical operations.

The *fractional hypertree width* of a hypergraph $\mathcal{H}$ is $\mathsf{fhw}(\mathcal{H}) = \min_{(\mathcal{T},\chi)} \max_{t \in V(\mathcal{T})} \rho^*(\chi(t))$, where ρ^* is the minimum fractional edge cover number of the set $\chi(t)$. It holds that $\mathsf{adw}(\mathcal{H}) \leq \mathsf{subw}(\mathcal{H}) \leq \mathsf{fhw}(\mathcal{H})$.

It is known that $\mathsf{SumProd}\langle\sigma_{\mathbb{B}}, \mathcal{H}\rangle$ can be computed in time $\tilde{O}(|I|^{\mathsf{subw}(\mathcal{H})})$ using the PANDA algorithm [17]. However, we do not know of a way to achieve the same runtime for the general $\mathsf{SumProd}\langle\mathcal{H}\rangle$ problem. For this, the best known runtime is $\tilde{O}(|I|^{\#\mathsf{subw}(\mathcal{H})})$, where $\mathsf{subw}(\mathcal{H}) \leq \#\mathsf{subw}(\mathcal{H}) \leq \mathsf{fhw}(\mathcal{H})$ [14]. On the other hand, there are hypergraphs for which we can compute $\mathsf{SumProd}\langle\sigma_{\mathbb{B}}, \mathcal{H}\rangle$ with runtime better than $\tilde{O}(|I|^{\mathsf{subw}(\mathcal{H})})$ using non-combinatorial algorithms. For example, if $\mathcal{H}$ is a triangle we can obtain a runtime $\tilde{O}(|I|^{2\omega/(\omega+1)})$, where ω is the matrix multiplication exponent (the submodular width of the triangle is $3/2$).

Conjectures in Fine-Grained Complexity. Our lower bounds will be based on the following popular conjectures in fine-grained complexity. To state the conjectures, it will be helpful to define the *k-clique problem over a semiring σ*: given an undirected graph $G = (V, E)$ where each edge has a weight in the domain of the semiring, we are asked to compute the semiring-product over all the k-cliques in G, where the weight of each clique is the semiring-sum of clique edge weights.

▶ **Definition 1** (Boolean k-Clique Conjecture)**.** *There is no real $\epsilon > 0$ such that computing the k-clique problem (with $k \geq 3$) over the Boolean semiring in an (undirected) n-node graph requires time $O(n^{k-\epsilon})$ using a combinatorial algorithm.*

▶ **Definition 2** (Min-Weight k-Clique Conjecture)**.** *There is no real $\epsilon > 0$ such that computing the k-clique problem (with $k \geq 3$) over the tropical semiring in an (undirected) n-node graph with integer edge weights can be done in time $O(n^{k-\epsilon})$.*

When $k = 3$, min-weight 3-clique is equivalent to the All-Pairs Shortest Path (APSP) problem under subcubic reductions. The Min-Weight Clique Conjecture assumes the Min-Weight k-Clique conjecture for every integer $k \geq 3$ (similarly for the Boolean Clique Conjecture).

3 The Clique Embedding Power

In this section, we define the clique embedding power, a quantity central to this paper.

3.1 Graph Embeddings

We introduce first the definition of embedding a graph G to a hypergraph $\mathcal{H}$, first defined by Marx [20, 19]. We say that two sets of vertices $X, Y \subseteq V(\mathcal{H})$ *touch* in $\mathcal{H}$ if either $X \cap Y \neq \emptyset$ or there is a hyperedge $e \in E(\mathcal{H})$ that intersects both X and Y. We say a hypergraph is connected if its underlying clique graph is connected.

▶ **Definition 3** (Graph Embedding)**.** *Let G be an undirected graph, and $\mathcal{H}$ be a hypergraph. An* embedding *from G to $\mathcal{H}$, denoted $G \mapsto \mathcal{H}$, is a mapping ψ that maps every vertex $v \in V(G)$ to a non-empty subset $\psi(v) \subseteq V(\mathcal{H})$ such that the following hold:*

1. *$\psi(v)$ induces a connected subhypergraph;*
2. *if $u, v \in V(G)$ are adjacent in G, then $\psi(u), \psi(v)$* touch *in $\mathcal{H}$.*

It will often be convenient to describe an embedding ψ by the reverse mapping $\psi^{-1}(x) = \{i \mid x \in \psi(i)\}$, where x is a vertex in $V(\mathcal{H})$. Given an embedding ψ and a vertex $v \in V(\mathcal{H})$, we define its *vertex depth* as $d_\psi(v) = |\psi^{-1}(v)|$. For a hyperedge $e \in E(\mathcal{H})$, we define its *weak edge depth* as $d_\psi(e) = |\{v \in V(G) \mid \psi(v) \cap e \neq \emptyset\}|$, i.e., the number of vertices of G that map to some variable in e. Moreover, we define the *edge depth* of e as $d^+_\psi(e) = \sum_{v \in e} d_\psi(v)$.

The *weak edge depth* of an embedding ψ can then be defined as $\mathsf{wed}(\psi) = \max_e d_\psi(e)$, and the edge depth as $\mathsf{ed}(\psi) = \max_e d^+_\psi(e)$. Additionally, we define as $\mathsf{wed}(G \mapsto \mathcal{H})$ the minimum weak edge depth of any embedding ψ from G to $\mathcal{H}$. Similarly for $\mathsf{ed}(G \mapsto \mathcal{H})$. It is easy to see that $\mathsf{wed}(G \mapsto \mathcal{H}) \leq \mathsf{ed}(G \mapsto \mathcal{H})$.

It will be particularly important for our purposes to think about embedding the k-clique graph C_k to an arbitrary hypergraph $\mathcal{H}$. In this case, it will be simpler to think of the vertices of G as the numbers $1, \ldots, k$ and the embedding ψ as a mapping from the set $\{1, \ldots, k\}$ to a subset of $V(\mathcal{H})$. We can now define the following quantity, which captures how well we can embed a k-clique to H for an integer $k \geq 3$:

$$\mathsf{emb}_k(\mathcal{H}) := \frac{k}{\mathsf{wed}(C_k \mapsto \mathcal{H})}.$$

▶ **Example 4.** Consider the hypergraph $\mathcal{H}$ with the following hyperedges:

$$\{x_1, x_2, x_3\}, \{x_1, y\}, \{x_2, y\}, \{x_3, y\}$$

We can embed the 5-clique into $\mathcal{H}$ as follows:

$$1 \to \{x_1\}, 2 \to \{x_2\}, 3 \to \{x_3\}, 4, 5 \to \{y\}.$$

It is easy to check that this is a valid embedding, since, for example, $1, 4$ touch at the edge $\{x_1, y\}$. Moreover, $\mathsf{wed}(C_5 \mapsto G) = 3$, hence $\mathsf{emb}_5(G) = 5/3$.

3.2 Embedding Properties

In this part, we will explore how $\mathsf{wed}(C_k \mapsto \mathcal{H})$ and $\mathsf{emb}_k(\mathcal{H})$ behave as a function of the size of the clique k. We start with some basic observations.

▶ **Proposition 5.** *For any hypergraph $\mathcal{H}$ and integer $k \geq 3$:*
1. $\mathsf{wed}(C_k \mapsto \mathcal{H}) \leq k$.
2. $\mathsf{wed}(C_k \mapsto \mathcal{H}) \leq \mathsf{wed}(C_{k+1} \mapsto H) \leq \mathsf{wed}(C_k \mapsto \mathcal{H}) + 1$.
3. *If $k = m \cdot n$, where $k, m, n \in \mathbb{Z}_{\geq 0}$, then* $\mathsf{emb}_k(\mathcal{H}) \geq \mathsf{emb}_m(\mathcal{H})$.

Proof. (1) We define an embedding ψ from a k-clique where $\psi(i) = V(\mathcal{H})$ for every $i = 1, \ldots, k$. It is easy to see that ψ is an embedding with weak edge depth k.

(2) For the first inequality, take any ψ_{k+1}, we can construct a ψ_k by only preserving the mapping ψ_{k+1} for $[k]$. Then, for any $e \in E(\mathcal{H})$, we have

$$\{y \in V(C_k) \mid \psi_k(y) \cap e \neq \emptyset\} \subseteq \{y \in V(C_{k+1}) \mid \psi_{k+1}(y) \cap e \neq \emptyset\}$$

Thus,

$$\mathsf{wed}(C_k \mapsto \mathcal{H}) \leq \mathsf{wed}(\psi_k) := \max_{e \in E(\mathcal{H})} d_{\psi_k}(e) \leq \mathsf{wed}(\psi_{k+1}).$$

For the second inequality, take any ψ_k, we construct a ψ_{k+1} by preserving the mapping ψ_k and ψ_{k+1} maps $k+1$ to $V(\mathcal{H})$. Then, for any $e \in E(\mathcal{H})$, we have

$$d_{\psi_{k+1}}(e) = d_{\psi_k}(e) + 1$$

so $\mathsf{wed}(\psi_{k+1}) = \mathsf{wed}(\psi_k) + 1$ and in particular, we can take ψ_k such that

$$\mathsf{wed}(\psi_{k+1}) \leq \mathsf{wed}(C_k \mapsto \mathcal{H}) + 1$$

which implies that

$$\mathsf{wed}(C_{k+1} \mapsto \mathcal{H}) \leq \mathsf{wed}(C_k \mapsto \mathcal{H}) + 1$$

(3) Suppose ψ is the embedding that achieves $\mathsf{emb}_m(\mathcal{H})$ for C_m. It suffices to construct an embedding ψ' for C_k which achieves the same quantity $\mathsf{emb}_m(\mathcal{H})$. To do so, we simply bundle every n vertices in C_k to be a "hypernode". That is, label the bundles as $b_1, \ldots, b_n$. and $\psi'(v) = \psi(i)$ if and only if $v \in B_i$. The embedding power given by ψ' is then

$$\frac{k}{\mathsf{wed}(\psi')} = \frac{mn}{\mathsf{wed}(\psi)n} = \frac{m}{\mathsf{wed}(\psi)} = \mathsf{emb}_m(\mathcal{H}).$$ ◀

The first item of the above proposition tells us that $\mathsf{emb}_k(\mathcal{H}) \geq 1$ for any k. But how does $\mathsf{emb}_k(\mathcal{H})$ behave as k grows? We next show that $\mathsf{emb}_k(\mathcal{H})$ is always upper bounded by the submodular width of $\mathcal{H}$.

▶ **Lemma 6.** *Let $\mathcal{H}$ be a hypergraph. Take an embedding $\psi : C_k \mapsto \mathcal{H}$. Let $(\mathcal{T}, \chi)$ be a tree decomposition of $\mathcal{H}$. Then, there exists a node $t \in T$ such that for every $i = 1, \ldots, k$, $\psi(i) \cap \chi(t) \neq \emptyset$.*

Proof. For $i = 1, \ldots, k$, let $\mathcal{T}_i$ be the subgraph of $\mathcal{T}$ that includes all nodes $t \in V(\mathcal{T})$ such that $\psi(i) \cap \chi(t) \neq \emptyset$.

We first claim that $\mathcal{T}_i$ *forms a tree.* To show this, it suffices to show that $\mathcal{T}_i$ is connected. Indeed, take any two nodes t_1, t_2 in $\mathcal{T}_i$. This means that there exists $x_1 \in \chi(t_1) \cap \psi(i)$ and $x_2 \in \chi(t_2) \cap \psi(i)$. Since $x_1, x_2 \in \psi(i)$ and $\psi(i)$ induces a connected subgraph in $\mathcal{H}$, there exists a sequence of vertices $x_1 = z_1, \ldots, z_k = x_2$, all in $\psi(i)$, such that every two consecutive vertices belong to an edge of $\mathcal{H}$. Let $S_1, \ldots, S_k$ be the trees in $\mathcal{T}$ that contain $z_1, \ldots, z_k$ respectively. Take any two consecutive z_i, z_{i+1}: since they belong to the same edge, there exists a bag that contains both of them, hence S_i, S_{i+1} intersect. This means that there exists a path between t_1, t_2 in $\mathcal{T}$ such that every node is in T_i.

Second, we claim that *any two $\mathcal{T}_i, \mathcal{T}_j$ have at least one common vertex.* Indeed, $\psi(i)$, $\psi(j)$ must touch in $\mathcal{H}$. If there exists a variable $x \in \psi(i) \cap \psi(j)$, then any vertex that contains x is a common vertex between $\mathcal{T}_i, \mathcal{T}_j$. Otherwise, there exists $x \in \psi(i)$, $y \in \psi(j)$ such that x, y occur together in a hyperedge $e \in E(\mathcal{H})$. But this means that some node $t \in \mathcal{T}$ contains both x, y, hence $\mathcal{T}_i, \mathcal{T}_j$ intersect at t.

Finally, we apply the fact that a family of subtrees of a tree satisfies the *Helly property* [12], i.e. *a collection of subtrees of a tree has at least one common node if and only if every pair of subtrees has at least one common node.* Indeed, the trees $\mathcal{T}_1, \ldots, \mathcal{T}_k$ satisfy the latter property, so there is a vertex t common to all of them. Such t has the desired property of the lemma. ◀

We can now state the following Theorem 7 on the embedding power of a hypergraph.

▶ **Theorem 7.** *For any hypergraph $\mathcal{H}$ and integer $k \geq 3$, the following holds:*

$$\mathsf{wed}(C_k \mapsto \mathcal{H}) \geq \frac{k}{\mathsf{subw}(\mathcal{H})}$$

Proof. Let $\mathsf{wed}(C_k \mapsto \mathcal{H}) = \alpha$. Then, there is an embedding $\psi : C_k \mapsto \mathcal{H}$ with weak edge depth α. We will show that $\mathsf{subw}(\mathcal{H}) \geq k/\alpha$.

First, we define the following set function over subsets of $V(\mathcal{H})$: for any $S \subseteq V(\mathcal{H})$, let $\mu(S) = |\{i \mid \psi(i) \cap S \neq \emptyset\}|/\alpha$. This is a coverage function, and hence it is a submodular function. It is also edge-dominated, since for any hyperedge e, we have $\mu(e) = |\{i \mid \psi(i) \cap e \neq \emptyset\}|/\alpha \leq 1$.

Now, consider any decomposition $(\mathcal{T}, B_t)$ of $\mathcal{H}$. From Lemma 6, there is a node $t \in \mathcal{T}$ such that or every $i = 1, \ldots, k$, $\psi(i) \cap B_t \neq \emptyset$. Hence, $\mu(B_t) = |\{i \mid \psi(i) \cap B_t \neq \emptyset\}|/\alpha = k/\alpha$. Thus, the submodular width of the decomposition is at least k/α. ◀

The above result tells us that $\mathsf{emb}_k(\mathcal{H}) \leq \mathsf{subw}(\mathcal{H})$ for any $k \geq 3$. Hence, taking the supremum of $\mathsf{emb}_k(\mathcal{H})$ for $k \geq 3$ is well-defined since the set is bounded. This leads us to the following definition:

▶ **Definition 8** (Clique Embedding Power). *Given a hypergraph $\mathcal{H}$, define the* clique embedding power *of $\mathcal{H}$ as*

$$\mathsf{emb}(\mathcal{H}) := \sup_{k \geq 3} \mathsf{emb}_k(\mathcal{H}) = \sup_{k \geq 3} \frac{k}{\mathsf{wed}(C_k \mapsto \mathcal{H})}.$$

The following is immediate:

▶ **Corollary 9.** *For any hypergraph $\mathcal{H}$, $1 \leq \mathsf{emb}(\mathcal{H}) \leq \mathsf{subw}(\mathcal{H})$.*

For the connection between edge depth width and adaptive width, we have the following theorem analogous to Theorem 7. The proof can be found in [9].

▶ **Theorem 10.** *For any hypergraph $\mathcal{H}$, the following holds:*

$$\mathsf{ed}(C_k \mapsto \mathcal{H}) \geq \frac{k}{\mathsf{adw}(\mathcal{H})}$$

4 Lower Bounds

In this section, we show how to use the clique embedding power to obtain conditional lower bounds for SumProduct problems. Our main reduction follows the reduction used in [20], but also has to account for constructing the appropriate values for the semiring computations.

▶ **Theorem 11.** *For any hypergraph $\mathcal{H}$ and semiring σ, if $\mathsf{SumProd}\langle\sigma, \mathcal{H}\rangle$ can be solved in time $O(|I|^c)$ with input I, then k-Clique over σ can be solved in time $O(n^{c \cdot \mathsf{wed}(C_k \mapsto \mathcal{H})})$ where n is the number of vertices.*

Proof. We will show a reduction from the k-clique problem with n vertices over a semiring σ to $\mathsf{SumProd}\langle\sigma, \mathcal{H}\rangle$. Without loss of generality, we will assume that the input graph G to the k-clique problem is k-partite, with partitions $V_1, \ldots, V_k$. Indeed, given any graph $G = (V, E)$ where $V = \{v_1, v_2, \ldots, v_n\}$, consider the k-partite graph $G^k = (V^k, E^k)$ where $V^k = \{v_i^j \mid 1 \leq i \leq n, 1 \leq j \leq k\}$ and for any two vertices $v_i^j, v_p^q \in V^k$, $\{v_i^j, v_p^q\} \in E^k$ iff $\{v_i, v_p\} \in E$ and $j \neq q$. Then there is a one-to-one mapping from a k-clique in G to a k-clique in G^k.

Let ψ be an embedding from C_k to $\mathcal{H}$ that achieves a weak edge depth $\lambda = k/\mathsf{emb}_k(\mathcal{H})$. As we mentioned before, it is convenient to take $V(C_k) = \{1, \ldots, k\}$. We now construct the input instance I for $\mathsf{SumProd}\langle\sigma, \mathcal{H}\rangle$. More explicitly, the task is to construct the function R_e for each hyperedge $e \in E$.

To this end, we first assign to each pair $\{i, j\} : i \neq j, i, j, \in \{1, 2, \ldots, k\}$ a hyperedge $\theta(\{i, j\}) = e \in E(\mathcal{H})$ satisfying the following conditions: $\psi(i) \cap e \neq \emptyset$ and $\psi(j) \cap e \neq \emptyset$. Such an e must exist by the definition of an embedding. If there is more than one hyperedge satisfying the condition, we arbitrarily choose one.

For every variable $x \in V(\mathcal{H})$, let $\psi^{-1}(x)$ be the subset of $\{1, \ldots, k\}$ mapping to x. Then, we define the domain $\mathsf{Dom}(x_i)$ of each variable x_i in the input instance as vectors over $[n]^{|\psi^{-1}(x_i)|}$. Let $S_e = \{i \in [k] \mid \psi(i) \cap e \neq \emptyset\}$. Note that $|S_e| = d_\psi(e) \leq \lambda$. Also, note

that $\psi^{-1}(x) \subseteq S_e$ for all $x \in e$. Then, we compute all cliques in the graph G between the partitions $V_i, i \in S_e$; these cliques will be of size $|S_e|$ and can be computed in running time $O(n^\lambda)$ by brute force.

For every clique $\{a_i \in V_i \mid i \in S_e\}$, let t be the tuple over $\prod_{i \in S_e} \mathsf{Dom}(x_i)$ such that its value at position x is $\langle a_i \mid i \in \psi^{-1}(x)\rangle$. Then, we set

$$R_e(t) = \mathbf{1} \otimes \bigotimes_{\{i,j\}:\theta(\{i,j\})=e} w(\{i,j\}).$$

In other words, we set the value as the semiring product of all the weights between the edges $\{a_i, a_j\}$ in the clique whenever the pair $\{i,j\}$ is assigned to the hyperedge e. All the other tuples are mapped to $\mathbf{0}$. By construction, the size of the input is $|I| = O(n^\lambda)$.

We now show that the two problems will return exactly the same output. To show this, we first show that there is a bijection between k-cliques in G and the solutions of the SumProduct instance.

$\Leftarrow$ Take a clique $\{a_1, \ldots, a_k\}$ in G. We map the clique to the valuation $v(x) = \langle a_i \mid i \in \psi^{-1}(x)\rangle$. This valuation is a solution to the SumProduct problem, since any subset of $\{a_1, \ldots, a_k\}$ forms a sub-clique. Hence for any hyperedge e, $R_e(v(\mathbf{x}_e)) \neq \mathbf{0}$.

$\Rightarrow$ Take a valuation v. Consider any $i \in \{1, \ldots, k\}$ and consider any two variables $x, y \in \psi(i)$ (recall that $\psi(i)$ must be nonempty). Recall that $x, y \in V(\mathcal{H})$. We claim that the i-th index in the valuation $v(x), v(y)$ must take the same value, which we will denote as a_i; this follows from the connectivity condition of the embedding. Indeed, since $x, y \in \psi(i)$, there exists a sequence of hyperedges $e_1, e_2, \ldots, e_m$ where $m \geq 1$ such that $e_j \cap e_{j+1} \neq \emptyset$ for $1 \leq j \leq m-1$ and $x \in e_1$, $y \in e_m$. By the construction, the i-th index in $v(x)$ will then "propagate" to that in $v(y)$. This proves the claim. It then suffices to show that $\{a_1, \ldots, a_k\}$ is a clique in G. Indeed take any $i, j \in \{1, \ldots, k\}$. Since i and j are adjacent as two vertices in C_k, we know $\psi(i)$ and $\psi(j)$ touch. Therefore, there exists a hyperedge e that contains some $x \in \psi(i)$ and $y \in \psi(j)$. But this means that $\{a_i, a_j\}$ must form an edge in G.

We next show that the semiring product of the weights in the clique has the same value as the semiring product of the corresponding solution. Indeed:

$$\bigotimes_{e \in E} R_e(v(\mathbf{x}_e)) = \mathbf{1} \otimes \bigotimes_{e \in E} \bigotimes_{\{i,j\}:\theta(\{i,j\})=e} w(\{i,j\}) = \bigotimes_{\{i,j\}:i \neq j} w(\{i,j\})$$

where the last equality holds because each edge of the k-clique is assigned to exactly one hyperedge of $\mathcal{H}$.

The above claim together with the bijection show that the output will be the same; indeed, each the semiring sums will go over exactly the same elements with the same values.

To conclude the proof, suppose that $\mathsf{SumProd}\langle\sigma, \mathcal{H}\rangle$ could be answered in time $O(|I|^c)$ for some $c \geq 1$. This means that we can solve the k-clique problem over σ in time $O(n^\lambda + n^{c\lambda}) = O(n^{c \cdot \mathsf{wed}(C_k \mapsto \mathcal{H})})$. ◀

As an immediate consequence of Theorem 11, we can show the following lower bound.

▶ **Proposition 12.** *Under the Min-Weight k-Clique conjecture,* $\mathsf{SumProd}\langle\mathsf{trop}, \mathcal{H}\rangle$ *(and thus* $\mathsf{SumProd}\langle\mathcal{H}\rangle$*) cannot be computed in time $O(|I|^{\mathsf{emb}_k(\mathcal{H})-\epsilon})$ for any constant $\epsilon > 0$.*

Proof. Indeed, if $\mathsf{SumProd}\langle\mathsf{trop}, \mathcal{H}\rangle$ can be computed in time $O(|I|^{\mathsf{emb}_k(\mathcal{H})-\epsilon})$ for some constant $\epsilon > 0$, then by Theorem 11 the k-Clique problem over the tropical semiring can be solved in time $O(n^{(\mathsf{emb}_k(\mathcal{H})-\epsilon)\cdot\mathsf{wed}(C_k \mapsto \mathcal{H})}) = O(n^{k-\delta})$ for some $\delta > 0$. However, this violates the Min-Weight k-Clique conjecture. ◀

Similarly, we can show the following:

▶ **Proposition 13.** *Under the Boolean k-Clique conjecture,* $\mathsf{SumProd}\langle\sigma_{\mathbb{B}}, \mathcal{H}\rangle$ *(and thus* $\mathsf{SumProd}\langle\mathcal{H}\rangle$*) cannot be computed via a combinatorial algorithm in time* $O(|I|^{\mathsf{emb}_k(\mathcal{H})-\epsilon})$ *for any constant* $\epsilon > 0$.

The above two results imply that to obtain the best lower bound, we need to find the clique size with the largest $\mathsf{emb}_k(\mathcal{H})$. However, the function $k \mapsto \mathsf{emb}_k(\mathcal{H})$ is really intriguing. It is not clear whether in the definition supremum is ever needed, i.e., whether there exists a hypergraph where the embedding power is achieved in the limit.

In Section 5, we show that for every hypergraph $\mathcal{H}$, there exists a natural number k such that $\mathsf{emb}(\mathcal{H}) = \mathsf{emb}_k(\mathcal{H})$. We also demonstrate how to compute $\mathsf{emb}(\mathcal{H})$ through a MILP and locate the complexity of computing the embedding power within the class 2-EXPTIME (double exponential time). The insight of our method is that, instead of computing the "integral" embedding power, one can consider the "fractional" embedding power and then recover the "integral" one by letting the clique size k to be sufficiently large.

5 Decidability of the Clique Embedding Power

To illustrate the algorithm for computing $\mathsf{emb}(\mathcal{H})$, it is instructive to first show how to compute $\mathsf{emb}_k(\mathcal{H})$ for a fixed clique size k.

5.1 An Integer Linear Program for $\mathsf{wed}(C_k \mapsto \mathcal{H})$

The following ILP formulation computes the minimum weak edge depth $w = \mathsf{wed}(C_k \mapsto \mathcal{H})$.

$$
\begin{array}{lllll}
\min & w & & & \\
\text{s.t.} & \sum_{S\subseteq V} x_S = k & & & \\
& x_S = 0 & \forall S \subseteq V & \text{where } S \text{ is not connected} & \\
& \min\{x_S, x_T\} = 0 & \forall S, T \subseteq V & \text{where } S, T \text{ do not touch} & \\
& \sum_{S\subseteq V : e\cap S\neq\emptyset} x_S \leq w & \forall e \in \mathcal{E} & & \\
& x_S \in \mathbb{Z}_{\geq 0} & \forall S \subseteq V & &
\end{array}
\tag{1}
$$

Each integer variable x_S, $S \subseteq V$, indicates how many vertices in C_k are assigned to the subset S. For example, if $x_{\{1,2\}} = 3$, this means in the embedding ψ, three vertices are mapped to the subset $\{1, 2\} \subseteq V$. It is sufficient to record only the number of vertices in C_k because of the symmetry of the clique. That is, since any two vertices are connected in C_k, one can arbitrarily permute the vertices in C_k so that the resulting map ψ' is still an embedding (given ψ is). Moreover, since the clique size k is fixed, to compute $\mathsf{emb}_k(\mathcal{H})$ it suffices to minimize w.

Observe that the condition $\min\{x_S, x_T\} = 0$ is not a linear condition. To encode it as such, we perform a standard transformation. We introduce a binary variable y_S for every set $S \subseteq V$. Then, we can write it as

$$
\begin{cases}
x_S + k \cdot y_S \leq k \\
x_T + k \cdot y_T \leq k \\
y_S + y_T \geq 1
\end{cases}
$$

Indeed, since y_S and y_T are binary variables, at least one of them is 1. Without loss of generality assume $y_S = 1$. Then $x_S = 0$ since $x_S \in \mathbb{Z}_{\geq 0}$. Therefore two subsets that do not touch cannot both be chosen in the embedding.

5.2 A Mixed Integer Linear Program for emb($\mathcal{H}$)

The above ILP construction does not directly yield a way to compute the clique embedding power, since the latter is defined to be the supremum for all k.

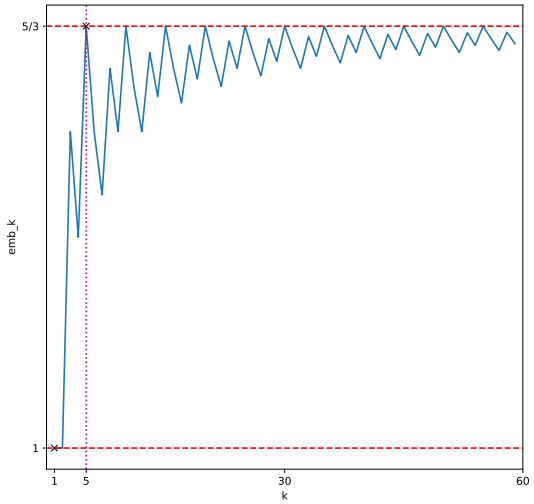

Figure 1 $\mathsf{emb}_k(\mathcal{H})$ for the 6-cycle.

As alluded before, the behavior of $\mathsf{emb}_k(\mathcal{H})$ as a function of k is non-trivial (and certainly not monotone). Figure 1 depicts how the clique embedding power changes with respect to different clique sizes for the 6-cycle, where the horizontal line represents the clique size.

To compute the supremum, the key idea is to change the integer variables x_S to be continuous (so they behave as fractions) and "normalize" the clique size k to 1. Specifically, we can write the following mixed integer linear program (MILP).

$$
\begin{array}{lllll}
\min & w & & & \\
\text{s.t.} & \sum_{S\subseteq V} x_S = 1 & & & \\
& x_S = 0 & \forall S \subseteq V & \text{where } S \text{ is not connected} & \\
& \min\{x_S, x_T\} = 0 & \forall S,T \subseteq V & \text{where } S,T \text{ do not touch} & \\
& \sum_{S\subseteq V: e\cap S\neq\emptyset} x_S \leq w & \forall e \in \mathcal{E} & & \\
& x_S \in \mathbb{R}_{\geq 0} & \forall S \subseteq V & &
\end{array}
\tag{2}
$$

▶ **Proposition 14.** *Let w^* be the optimal solution of MILP (2). Then, $\mathsf{emb}(\mathcal{H}) = 1/w^*$. Additionally, there exists an integer $K \geq 3$ such that $\mathsf{emb}(\mathcal{H}) = \mathsf{emb}_K(\mathcal{H})$.*

Proof. We first show for any k, $\mathsf{emb}_k(\mathcal{H}) \geq 1/w^*$. Indeed, any embedding $\psi : C_k \to \mathcal{H}$ determines the values of the variables x_S in MILP (1). Let $\hat{x_S} = \frac{x_S}{k}$ and $\hat{w} = \frac{w}{k}$ be an assignment of the variables in MILP (2). It is easy to see that this is a feasible assignment. Thus, $w^* \leq \mathsf{wed}(C_k \mapsto \mathcal{H})/k$. Therefore $\mathsf{emb}_k(\mathcal{H}) = k/\mathsf{wed}(C_k \mapsto \mathcal{H}) \leq 1/w^*$.

Next, observe that $\mathsf{emb}(\mathcal{H})$ is a rational number. In fact, the solution w^* for MILP (2) is a rational number, since every constant is a rational number [24]. Let K be the least common multiplier of their denominators of the fractions in the set $\{x_S\}$. Then, the assignment $K \cdot x_S, K \cdot w$ is a feasible solution for MILP (1) for $k = K$. This implies that $K \cdot w^* \geq \mathsf{wed}(C_K \mapsto \mathcal{H})$, so $\mathsf{emb}_K(\mathcal{H}) \geq 1/w^*$.

Table 1 Summary of emb and subw for some classes of queries.

	emb		subw	
Acyclic	1	[Theorem 29]	1	[27]
Chordal	=	[Theorem 24]	=	[22]
ℓ-cycle	$2-1/\lceil \ell/2 \rceil$	[Proposition 18]	$2-1/\lceil \ell/2 \rceil$	[2]
$K_{2,\ell}$	$2-1/\ell$	[Proposition 19]	$2-1/\ell$	[17]
$K_{3,3}$	2	[Proposition 20]	2	[17]
A_ℓ	$(\ell-1)/2$	[Proposition 26]	$(\ell-1)/2$	[22]
$\mathcal{H}_{\ell,k}$	ℓ/k	[Proposition 27]	ℓ/k	[22]
Q_b	17/9		2	[13]
Q_{hb}	7/4		2	[Proposition 30]

Thus, we have shown that $1/w^*$ is an upper bound for $\{\mathsf{emb}_k(\mathcal{H})\}_k$, but also $\mathsf{emb}_K(\mathcal{H}) = 1/w^*$. Hence, $\mathsf{emb}(\mathcal{H}) = \mathsf{emb}_K(\mathcal{H}) = 1/w^*$. ◀

This leads to the following theorem (whose proof can be found in [9]).

▶ **Theorem 15.** *The problem of computing* $\mathsf{emb}(\mathcal{H})$ *for a hypergraph* $\mathcal{H}$ *is in 2-*EXPTIME *and, in particular, is decidable.*

Unfortunately, our method does not yield an upper bound on how large the K in Proposition 14 might be. There is no reason that K cannot be very large, e.g. doubly exponential to the size of $\mathcal{H}$. Some knowledge of that could be very useful in computing the clique embedding power. For example, one can compute all the embeddings from C_k, for k not greater than the upper bound, and output the one with the largest embedding power. The best-known upper bound we have so far is the following. The proof can be found in [9].

▶ **Proposition 16.** *For any hypergraph* $\mathcal{H}$*, there is a constant* $K = O((2^{|V|})!)$ *such that* $\mathsf{emb}(\mathcal{H}) = \mathsf{emb}_K(\mathcal{H})$.

6 Examples of Tightness

In this section, we identify several classes of queries where the clique embedding power coincides with the submodular width. For brevity, we write emb, subw, fhw, and adw when the underlying hypergraph is clear under context. Table 1 summarizes our results.

6.1 Cycles

For the cycle query of length $\ell \geq 3$, we show that $\mathsf{emb} = \mathsf{subw} = 2 - 1/\lceil \ell/2 \rceil$. The best-known algorithm for ℓ-cycle detection (and counting) of Alon, Yuster, and Zwick [2] runs in time $O(|I|^{\mathsf{subw}})$. First, we show the following lemma.

▶ **Lemma 17.** *Consider the cycle query of length* $\ell \geq 3$*. Then* $\mathsf{emb} \geq 2 - 1/\lceil \frac{\ell}{2} \rceil$.

Proof. We start with the case where ℓ is odd and name the variables of the cycle query as $x_1, \ldots, x_\ell$. Then, we define $\lambda = (\ell+1)/2$ and an embedding from a ℓ-clique as follows:

$$\begin{aligned} \psi^{-1}(x_1) &= \{1, 2, \ldots, \lambda - 1\} \\ \psi^{-1}(x_2) &= \{2, 3, \ldots, \lambda\} \\ &\cdots \\ \psi^{-1}(x_\ell) &= \{2\lambda - 1, 1, \ldots, \lambda - 2\} \end{aligned} \tag{3}$$

In other words, ψ maps each $i \in [\ell]$ into a consecutive segment consisting of $\lambda-1$ vertices in the cycle. To see why ψ is an embedding, we observe that for any $i, j \in [\ell]$ such that $\psi(i) \cap \psi(j) = \emptyset$, $|\psi(i) \cup \psi(j)| = 2\lambda - 2 = \ell - 1$, so there is an edge that intersects both $\psi(i)$ and $\psi(j)$. It is easy to see that $\mathsf{wed}(\psi) = \lambda = (\ell+1)/2$. Thus, $\mathsf{emb} \geq \ell/\lambda = 2\ell/(\ell+1) = 2 - 2/(\ell+1)$.

If ℓ is even, we define $\lambda = \ell/2$ and an embedding from a $(\ell-1)$-clique as follows:

$$\begin{aligned}
\psi^{-1}(x_1) &= \{1, 2, \ldots, \lambda - 1\} \\
\psi^{-1}(x_2) &= \{2, 3, \ldots, \lambda\} \\
&\cdots \\
\psi^{-1}(x_{\ell-1}) &= \{2\lambda - 2, 2\lambda - 1, 1, \ldots, \lambda - 3\} \\
\psi^{-1}(x_\ell) &= \psi^{-1}(x_{\ell-1})
\end{aligned}$$

where $\psi^{-1}(x_i), i \in [\ell-1]$ is exactly the embedding we constructed for $(\ell-1)$-cycle. We show that this is a valid embedding. Let $i, j \in [\ell]$ such that $\psi(i) \cap \psi(j) = \emptyset$.

1. If $i \in \psi^{-1}(x_{\ell-1})$ (or $j \in \psi^{-1}(x_{\ell-1})$), then $|\psi(i) \cup \psi(j)| = \ell - 1$, so there is an edge that intersects both $\psi(i)$ and $\psi(j)$.
2. If $i, j \notin \psi^{-1}(x_{\ell-1})$, then $\psi(i)$ and $\psi(j)$ do not contain $x_{\ell-1}$ and x_ℓ. There is an edge that intersects both $\psi(i)$ and $\psi(j)$ since $|\psi(i) \cup \psi(j)| = \ell - 2$.

For this embedding, we have $\mathsf{wed}(\psi) = \lambda = \ell/2$, so $\mathsf{emb} \geq (\ell-1)/\lambda = 2 - 2/\ell$. ◀

Thus, we have the following proposition.

▶ **Proposition 18.** *Consider the cycle query of length $\ell \geq 3$. Then we have*

$$\mathsf{emb} = \mathsf{subw} = 2 - \frac{1}{\lceil \frac{\ell}{2} \rceil}$$

Proof. It can be shown using Example 7.4 in [17] (setting $m = 1$) that $\mathsf{subw} \leq 2 - 1/\lceil \frac{\ell}{2} \rceil$ (technically the Example 7.4 in [17] only deals with cycles of even length, but their argument can be easily adapted to cycles of odd length). We thus conclude by applying Lemma 17 and Theorem 7. ◀

6.2 Complete Bipartite Graphs

We consider a complete bipartite graph $K_{m,n}$ where the two partitions of its vertices are $\{x_1, \ldots, x_m\}$ and $\{y_1, \ldots, y_n\}$. We study two of its special cases, $K_{2,\ell}$ and $K_{3,3}$. The proofs of the following two propositions can be found in [9].

▶ **Proposition 19.** *For the bipartite graph $K_{2,\ell}$, $\mathsf{emb}(K_{2,\ell}) = \mathsf{subw}(K_{2,\ell}) = 2 - 1/\ell$.*

▶ **Proposition 20.** *For $K_{3,3}$, we have $\mathsf{emb}(K_{3,3}) = \mathsf{subw}(K_{3,3}) = 2$.*

Finding $\mathsf{emb}(K_{m,n})$ and $\mathsf{subw}(K_{m,n})$ in the most general case is still an open question.

6.3 Chordal Queries

In this section, we identify a special class of queries, called *choral queries*. We introduce necessary definitions and lemmas to prove that for a chordal query, emb, subw, fhw, and adw all coincide, as stated in Theorem 24.

Let G be a graph. A chord of a cycle C of G is an edge that connects two non-adjacent nodes in C. We say that G is *chordal* if any cycle in G of length greater than 3 has a chord. We can extend chordality to hypergraphs by considering the clique-graph of a hypergraph $\mathcal{H}$, where edges are added between all pairs of vertices contained in the same hyperedge.

Let $(\mathcal{T}, \chi)$ be a tree decomposition of a hypergraph $\mathcal{H}$ and $\mathsf{bags}(\mathcal{T}) \stackrel{\text{def}}{=} \{\chi(t) \mid t \in V(\mathcal{T})\}$. We say that $(\mathcal{T}, \chi)$ is *proper* if there is no tree decomposition $(\mathcal{T}', \chi')$ such that

1. for every bag $b_1 \in \mathsf{bags}(\mathcal{T}')$, there is a bag $b_2 \in \mathsf{bags}(\mathcal{T})$ such that $b_1 \subseteq b_2$;
2. $\mathsf{bags}(\mathcal{T}') \not\supseteq \mathsf{bags}(\mathcal{T})$,

The following important properties hold for chordal graphs.

▶ **Lemma 21** ([5]). *If G is a chordal graph and $(\mathcal{T}, \chi)$ is a proper tree decomposition of G, then the bags of $(\mathcal{T}, \chi)$, i.e. $\mathsf{bags}(\mathcal{T})$, are the maximal cliques in G.*

For chordal hypergraphs, we can show the following lemma:

▶ **Lemma 22.** *Let $\mathcal{H}$ be a hypergraph. Then, $(\mathcal{T}, \chi)$ is a (proper) tree decomposition of $\mathcal{H}$ if and only if it is a (proper) tree decomposition of the clique-graph of $\mathcal{H}$.*

Proof. We first show that $(\mathcal{T}, \chi)$ is a tree decomposition of $\mathcal{H}$ if and only if it is also a tree decomposition of the clique-graph of $\mathcal{H}$. The forward direction is straightforward. For the backward direction, let $(\mathcal{T}, \chi)$ be a decomposition of the clique-graph of $\mathcal{H}$. Then for any hyperedge $e \in \mathcal{H}$ and any pair of vertices $u, v \in e$, we know that $\{t \mid u \in \chi(t)\} \cap \{t \mid v \in \chi(t)\} \neq \emptyset$. By the *Helly Property*, there is a bag that contains all vertices in the hyperedge e. Therefore, $(\mathcal{T}, \chi)$ is a tree decomposition for $\mathcal{H}$. It is easy to extend the proof for proper tree decompositions. ◀

The following corollary is immediate from both Lemma 21 and Lemma 22:

▶ **Corollary 23.** *If $\mathcal{H}$ is a chordal hypergraph and $(\mathcal{T}, \chi)$ is a proper tree decomposition of $\mathcal{H}$, then the bags of $(\mathcal{T}, \chi)$ are the maximal cliques in the clique-graph of $\mathcal{H}$.*

The above corollary tells us that every proper tree decomposition has the same set of bags, with the only difference being the way the bags are connected in the tree. From this, we can easily obtain that $\mathsf{subw} = \mathsf{fhw}$. However, we have an even stronger result:

▶ **Theorem 24.** *If $\mathcal{H}$ is a chordal hypergprah, then* $\mathsf{emb} = \mathsf{adw} = \mathsf{subw} = \mathsf{fhw}$.

Proof. Since $\mathcal{H}$ is chordal, by Corollary 23, the bags of any proper tree decomposition $(\mathcal{T}, \chi)$ of $\mathcal{H}$ are the maximal cliques in the clique-graph of $\mathcal{H}$. Then, there is a node $t \in V(\mathcal{T})$ such that the minimum fractional edge cover (also the maximum fractional vertex packing) of $\chi(t)$ is fhw. In particular, let $\{u_i \mid i \in \chi(t)\}$ be the optimal weights assigned to each vertex in $\chi(t)$ that obtain the maximum fractional vertex packing, so $\sum_{i \in \chi(t)} u_i = \mathsf{fhw}$. We let $\hat{u}_i = u_i / \sum_{i \in \chi(t)} u_i$ and k be the smallest integer such that $k \cdot \hat{u}_i$ is an integer for every $i \in \chi(t)$. Now we construct an embedding ψ from C_k to $\mathcal{H}$ so that every $\psi(j)$, for $j \in [k]$ is a singleton and for each $i \in \chi(t)$, let $d_\psi^{-1}(i) \stackrel{\text{def}}{=} k \cdot \hat{u}_i$. This assignment uses up all k vertices in C_k, since $\sum_{i \in \chi(t)} k \cdot \hat{u}_i = k$. Then,

$$\mathsf{wed}(\psi) = \max_{e \in E(\mathcal{H})} \sum_{i \in e} k \cdot \hat{u}_i = \frac{k}{\sum_{i \in \chi(t)} u_i} \cdot \max_{e \in E(\mathcal{H})} \sum_{i \in e} u_i \leq \frac{k}{\sum_{i \in \chi(t)} u_i}$$

and thus, we get $\mathsf{emb} = \mathsf{fhw}$ since

$$\mathsf{emb} \geq \mathsf{emb}(C_k \mapsto \mathcal{H}) \geq \frac{k}{\mathsf{wed}(\psi)} \geq \sum_{i \in \chi(t)} u_i = \mathsf{fhw}.$$

For adw, we define the following modular function over subsets of $V(\mathcal{H})$: for any $S \subseteq V(\mathcal{H})$, let $\mu(S) \stackrel{\text{def}}{=} \sum_{i \in S} u_i$. It is edge-dominated since for every hyperedge e, $\mu(e) = \sum_{i \in e} u_i \leq 1$. Moreover, we have that $\mu(\chi(t)) = \sum_{i \in \chi(t)} u_i = \mathsf{fhw}$. That is, $\mathsf{adw} \geq \mathsf{fhw}$, so $\mathsf{adw} = \mathsf{fhw}$. As a remark, it is also viable to use Lemma 3.1 in [17] to prove the claim for adaptive width. ◀

Recall that Corollary 23 implies if $\mathcal{H}$ is chordal, then every proper tree decomposition of $\mathcal{H}$ has the same set of bags. We show the converse is also true, which could be of independent interest. The proof is in [9].

▶ **Lemma 25.** *Let $\mathcal{H}$ be a hypergraph. If every proper tree decomposition of $\mathcal{H}$ has the same set of bags, then $\mathcal{H}$ is chordal.*

We identify three classes of hypergraphs (almost-cliques, hypercliques, and acyclic hypergraphs) that are chordal and find their clique embedding powers and submodular widths.

Almost-cliques. Consider the ℓ-clique where one vertex, say x_1, connects to k vertices only, where $1 \leq k < \ell - 1$ (hence it is the missing edges from being a ℓ-clique). We denote such a hypergraph as A_ℓ. To show that A_ℓ is chordal, we observe that for any cycle of length ≥ 4 that contains x_1, the two adjacent vertices of x_1 in the cycle must be connected by an edge in A_ℓ and that edge is a chord to the given cycle. We also show the following proposition.

▶ **Proposition 26.** *For an almost-cliques A_ℓ, $\mathsf{emb} = \mathsf{subw} = \mathsf{fhw} = (\ell - 1)/2$.*

Proof. To prove the claim, suppose WLOG x_i connects only to x_i, where $i \in 2, 3, \ldots, k$. Then, we take the decomposition with two bags: $\{x_1, x_2, \ldots, x_k\}$, $\{x_2, x_3, \ldots, x_\ell\}$, where each bag has an edge cover of at most $(\ell - 1)/2$ since the first bag induces an k-clique and the second bag induces an $(\ell - 1)$-clique. Hence, $\mathsf{fhw} \leq (\ell - 1)/2$.

On the other hand, consider the embedding ψ from the $(\ell - 1)$-clique, where $\psi(i) = x_{i+1}$, $1 \leq i \leq \ell - 1$; it is easy to verify that this is a valid embedding such that $\mathsf{wed}(\psi) = 2$, hence $\mathsf{emb} \geq (\ell - 1)/2$. Therefore, we have shown that $\mathsf{emb} = \mathsf{subw} = (\ell - 1)/2$ by Theorem 7. ◀

Hypercliques. Next, we consider the (ℓ, k)-hyperclique query $\mathcal{H}_{\ell,k}$, where $1 < k \leq \ell$. This query has ℓ variables, and includes as atoms all possible subsets of $\{x_1, \ldots, x_\ell\}$ of size exactly k. When $k = \ell - 1$, the query simply becomes a Loomis-Whitney join [22]. It is easy to see that $\mathcal{H}_{\ell,k}$ is chordal since the clique-graph of $\mathcal{H}_{\ell,k}$ is a ℓ-clique.

▶ **Proposition 27.** *For $\mathcal{H}_{\ell,k}$, we have $\mathsf{emb} = \mathsf{subw} = \mathsf{fhw} = \ell/k$.*

Proof. First, we show that $\mathsf{fhw} \leq \ell/k$. Indeed, there is a fractional edge cover that assigns a weight of $1/k$ to each hyperedge that contains k consecutive vertices in $\{x_1, \ldots, x_\ell\}$ (let the successor of x_ℓ be x_1). The fractional edge cover is then ℓ/k. We show next that this bound coincides with emb.

We simply define the embedding ψ from a ℓ-clique as $\psi(i) = x_i, i \in [\ell]$. Then, $\mathsf{wed}(\psi) = k$ since every hyperedge has exactly k vertices. Therefore, $\mathsf{emb} \geq \ell/k \geq \mathsf{fhw}$ and we conclude by applying Lemma 17 and Theorem 7. ◀

Acyclic Hypergraphs. First, we claim that acyclic queries are indeed chordal queries.

▶ **Lemma 28.** *An acyclic hypergraph $\mathcal{H}$ is chordal.*

Proof. We prove by induction on the number of hyperedges in the hypergraph $\mathcal{H} = (V, E)$. If $|E| = 1$, it is clique-graph is a clique, thus it is chordal. The induction hypothesis assumes the claim for acyclic hypergraphs with $|E| \leq k$ hyperedges. Let $\mathcal{H}$ be an acyclic hypergraph such that $|E| = k+1$. Since $\mathcal{H}$ is acyclic, it has a join forest whose vertices are the hyperedges of $\mathcal{H}$. Let $e_\ell \in E$ be a leaf of the join forest and it is easy to show that $\mathcal{H}' = (V, E \setminus \{e_\ell\})$ is an acyclic hypergraph with k hyperedges. For any cycle in the clique-graph of $\mathcal{H}$ having length ≥ 4, we discuss the following two cases.

If every edge of the cycle is in the clique-graph of $\mathcal{H}'$: by the induction hypothesis, there is a chord for this cycle in the clique-graph of $\mathcal{H}'$ (thus also in $\mathcal{H}$).

Otherwise, there is an edge e in the cycle that is in the clique-graph of $\mathcal{H}$, but not in the clique-graph of $\mathcal{H}'$: therefore, the edge e is only contained by e_ℓ. This implies that there is a vertex u that is only contained by e_ℓ, not by any other edges in E. Let $\{u, v\}$ and $\{u, w\}$ be the edges connecting u in the given cycle, we know that $\{u, v, w\} \subseteq e_\ell$ and thus, $\{v, w\}$ is a chord for the given cycle. ◀

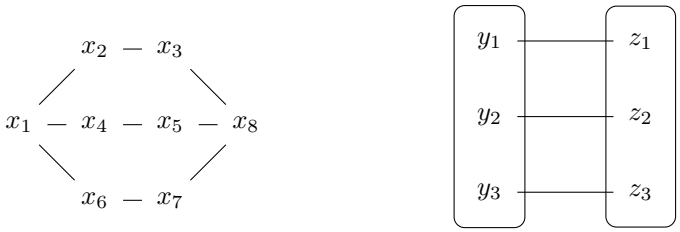
Now we prove the following theorem for acyclic hypergraphs:

▶ **Theorem 29.** *For an acyclic hypergprah $\mathcal{H}$,* $\mathsf{emb} = \mathsf{adw} = \mathsf{subw} = \mathsf{fhw} = 1$.

Proof. From Proposition 5, we know that $\mathsf{emb} \geq 1$. Since it is known that $\mathsf{subw} = \mathsf{fhw} = 1$, the theorem is then a direct result from Lemma 28 and Theorem 24. ◀

7 Gap Between Clique Embedding Power and Submodular Width

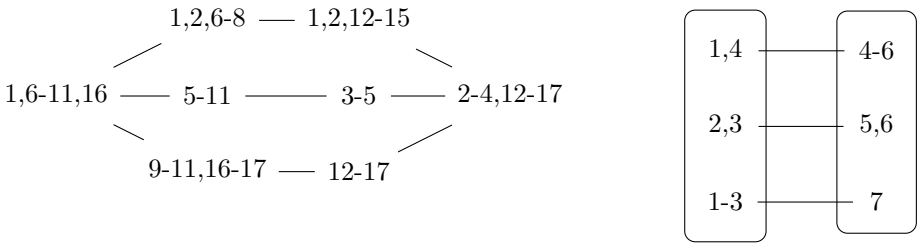
In this section, we discuss the boat query and its variant depicted in Figure 2, where gaps between the clique embedding power and submodular width can be shown.



(a) Boat Query Q_b. **(b)** Hyper-boat Query Q_{hb}.

Figure 2 The Boat query and its variant, the Hyper-boat Query.

7.1 Clique Embedding Power, Submodular Width and Adaptive Width



(a) emb for Q_b. **(b)** emb for Q_{hb}.

Figure 3 Optimal embedding for the boat query and its variants.

Using MILP (2), we find the optimal clique embedding for Q_b and Q_{hb}, as illustrated in Figure 3. The numbers represent the vertices from the clique, and we adopt the shorthand notation, say, 6-8 to refer to the set {6,7,8}. The clique embedding powers for Q_b and Q_{hb} are $\frac{17}{9}$ and $\frac{7}{4}$, respectively. However, [13] proves that for the boat query, $\mathsf{subw}(Q_b) = 2$. This

implies a gap since $\mathsf{emb}(Q_b) = 17/9 < \mathsf{subw}(Q_b) = 2$. We show that for the hyper-boat query Q_{hb}, there is also a gap between the optimal clique embedding power and submodular width. In particular, we show that $\mathsf{subw}(Q_{hb}) = 2$ in the following proposition, which implies the following gap: $\mathsf{emb}(Q_{hb}) = \frac{7}{4} < \mathsf{subw}(Q_{hb}) = 2$. Its proof can be found in [9].

▶ **Proposition 30.** *For Q_{hb}, we have $\mathsf{subw}(Q_{hb}) = 2$.*

7.2 Subquadratic Equivalence Between Boat Queries

In this section, we demonstrate an interesting connection between the two boat queries. To start, let's consider Q_b and Q_{hb}. Both queries admit an algorithm that runs in time $O(|I|^2)$. Informally, we are going to show that either both queries can be executed significantly faster, or neither can. Following the seminal paper by Williams and Williams [25], we define *truly subquadratic algorithm* and *subquadratic equivalence*.

▶ **Definition 31.** *An algorithm is said to be* truly subquadratic *if it runs in time $O(m^{2-\epsilon})$ for some $\epsilon > 0$ (m is the input size).*

Two problems A and B are *subquadratic equivalent* if A admits a truly subquadratic algorithm iff B admits a truly subquadratic algorithm. We show that the two boat queries are subquadratic equivalent.

▶ **Theorem 32.** *Q_b is subquadratic equivalent to Q_{hb}.*

Proof. It's easy to see that a truly subquadratic algorithm for Q_b gives a truly subquadratic algorithm for Q_{hb}. Indeed, given an input instance I_{hb} of Q_{hb}, we can form an input instance I_b of Q_b where the table (x_1, x_2) is the projection of the table (y_1, y_2, y_3) in I_{hb}, and similar for the tables $(x_1, x_4), (x_1, x_6), (x_3, x_8), (x_5, x_8)$ and (x_7, x_8). We then solve I_b by the algorithm for Q_b. It is easy to see that this algorithm is correct and runs in truly quadratic time.

The converse direction needs more work, since if we were to simply create the table (y_1, y_2, y_3) for Q_{hb} by joining the tables $(x_1, x_2), (x_1, x_4)$ and (x_1, x_6) for Q_b, the size of the result might be significantly greater than all previous tables. For example, if the sizes of the tables $(x_1, x_2), (x_1, x_4)$ and (x_1, x_6) are all m, then joining them could result in a table of size $m^{\frac{3}{2}}$ and therefore calling the algorithm for Q_{hb} on this instance does not necessarily yield a truly subquadratic algorithm for Q_b.

We perform our fine-grained reduction based on *heavy-light split*. Our goal is to give a subquadratic algorithm for Q_b assuming there is one such algorithm for Q_{hb}. Suppose the subquadratic algorithm for Q_b runs in time $O(m^{2-\delta})$ for some $\delta > 0$, where m is the size of all tables. Our algorithm for Q_b runs as follows. First, it checks whether there are entries of attribute x_1 that has degree more than $\Delta := m^\epsilon$ in tables $(x_1, x_2), (x_1, x_4)$ and (x_1, x_6) for some $\epsilon > 0$ to be specified later. Those are called *heavy* and there are at most $\frac{m}{\Delta}$ many of them. For those entries, we fix each one so that the remaining query becomes acyclic, and thus can be solved in linear time by Yannakakis algorithm [27]. We do the same procedure for heavy entries of attribute x_8. Therefore, any result of Q_b that contains a heavy entry in attributes x_1 or x_8 will be detected in time $O(m^{2-\epsilon})$. It remains to consider the case where the entries of attributes x_1 and x_8 have degrees less than Δ, which are called *light*. In this case, we loop over all light entries of x_1 in the table (x_1, x_2) and directly join them with the tables (x_1, x_4) and (x_1, x_6) and project the result to build a table (x_2, x_4, x_6). We then do the same procedure for joining x_8. This will cost time $O(m \cdot \Delta \cdot \Delta) = O(m^{1+2\epsilon})$. We then call the $O(m^{2-\delta})$ algorithm for Q_{hb}, which cost time $O(m^{(1+2\epsilon)(2-\delta)})$. By choosing $0 < \epsilon < \frac{\delta}{4-2\delta}$ (note that $\delta < 2$), we observe that the whole algorithm for Q_b takes time $O(m^{2-\epsilon}) + O(m^{(1+2\epsilon)(2-\delta)}) = O(m^{2-\epsilon'})$ for some $\epsilon' > 0$. ◀

We remark that the reduction from Q_{hb} to Q_b is parametrized by the running time of the algorithm for Q_{hb}. That is, the reduction is not uniform in the sense that only after given $\delta > 0$ can we specify a suitable ϵ. Theorem 32 implies that either both boat queries admit a truly subquadratic algorithm or none of them does.

The fact that there is a gap between $\mathsf{subw}(Q_{hb}) = 2$ and $\mathsf{emb}(Q_{hb}) = \frac{7}{4}$ suggests currently our lower bound does not match with the best upper bound, i.e., PANDA. This implies either that PANDA is not universally optimal, or that we are missing the best possible lower bound. We leave this as an open question.

Finally, we note that Theorem 4 in [13], which proves there does not exist a $\tilde{O}(m^{2-\epsilon} + |\text{OUT}|^5)$ algorithm for the boat query unless 3-XOR can be solved in time $\tilde{O}(m^{2-t})$ for a $t > 0$, does not directly translate into the quadratic hardness for the boat query in our case. This is because their reduction uses the output of the boat query in an essential way to "hack back the collision" which is not available in the Boolean case.

8 Related Work

Fine-Grained Complexity. The study of fine-grained complexity aims to show the (conditional) hardness of easy problems. Recent years have witnessed a bloom of development into this fascinating subject, resulting in many tight lower bounds which match exactly, or up to poly log factors, the running time of best-known algorithms [18, 26, 25, 1]. Among many others, popular hardness assumptions include the Strong Exponential Time Hypothesis (SETH), Boolean Matrix Multiplication (BMM), and All-Pairs Shortest Paths (APSP). Our work can be seen as a particular instance under this framework, i.e. using Boolean or Min-Weight k-Clique Conjecture to show conditional lower bounds for BCQs. Interestingly, our reduction of k-cycles essentially mirrors the construction in the proof of Theorem 3.1 in [18].

Conjunctive Queries (CQs) Evaluation. The efficient evaluation of CQs constitutes the core theme of database theory. Khamis, Ngo, and Suciu introduced in [17] the PANDA algorithm that runs in time as predicted by the submodular width of the query hypergraph. This groundbreaking result establishes a profound connection between various lines of work on tree decompositions [19, 20], worst-case optimal join algorithms [23, 22], and the interplay between CQ evaluation and information theory [15, 28, 14].

Functional Aggregate Queries (FAQs). FAQs [16] provides a Sum-of-Product framework that captures the semantics of conjunctive queries over arbitrary semirings. The semiring point-of-view originated from the seminal paper [10]. Khamis, Ngo, and Rudra [16] initiate the study of the efficient evaluation of FAQs. [14] introduces the FAQ version of the submodular width #subw and the #PANDA algorithm (as the FAQ version of the PANDA algorithm) that achieves the runtime as predicated by #subw. We show that the embedding from a k-clique into a hypergraph holds for arbitrary semirings, which enables one to transfer the hardness of k-clique to FAQ independent of the underlying semiring. To the best of our knowledge, this is the first *semiring-oblivious* reduction.

Enumeration and Preprocessing. Bagan, Durand and Grandjean characterized in [3] when a constant delay and linear preprocessing algorithm for self-join-free conjunctive queries is possible. A recent paper [6] makes an initial foray towards the characterization of conjunctive

[5] |OUT| is the size of the output.

queries with self-joins. Also recently, [4] identifies new queries which can be solved with linear preprocessing time and constant delay. Their hardness results are based on the Hyperclique conjecture, the Boolean Matrix Multiplication conjecture, and the 3SUM conjecture.

9 Conclusion

In this paper, we study the fine-grained complexity of BCQs. We give a semiring-oblivious reduction from the k-clique problem to an arbitrary hypergraph. Assuming the Boolean k-Clique Conjecture, we obtain conditional lower bounds for many queries that match the combinatorial upper bound achieved by the best-known algorithms, possibly up to a poly-logarithmic factor.

One attractive future direction is to fully unravel the gap between the clique embedding power and submodular width, where improved lower bounds or upper bounds are possible. The Boolean k-Clique Conjecture states that there is no $O(n^{k-\epsilon})$ *combinatorial* algorithm for detecting k-cliques. One future direction is to base the hardness assumption over Nešetřil and Poljak's algorithm [21], which solves the k-clique problem in $O\left(n^{(\omega/3)k}\right)$ by leveraging fast matrix multiplication techniques and show lower bounds for any algorithm.

Abstract

A class of graphs $\mathcal{C}$ is *monadically stable* if for every unary expansion $\widehat{\mathcal{C}}$ of $\mathcal{C}$, one cannot encode – using first-order transductions – arbitrarily long linear orders in graphs from $\widehat{\mathcal{C}}$. It is known that nowhere dense graph classes are monadically stable; these include classes of bounded maximum degree and classes that exclude a fixed topological minor. On the other hand, monadic stability is a property expressed in purely model-theoretic terms that is also suited for capturing structure in dense graphs.

In this work we provide a characterization of monadic stability in terms of the *Flipper game*: a game on a graph played by *Flipper*, who in each round can complement the edge relation between any pair of vertex subsets, and *Localizer*, who in each round is forced to restrict the game to a ball of bounded radius. This is an analog of the *Splitter game*, which characterizes nowhere dense classes of graphs (Grohe, Kreutzer, and Siebertz, J. ACM '17).

We give two different proofs of our main result. The first proof is based on tools borrowed from model theory, and it exposes an additional property of monadically stable graph classes that is close in spirit to definability of types. Also, as a byproduct, we show that monadic stability for graph classes coincides with monadic stability of existential formulas with two free variables, and we provide another combinatorial characterization of monadic stability via forbidden patterns. The second proof relies on the recently introduced notion of *flip-flatness* (Dreier, Mählmann, Siebertz, and Toruńczyk, arXiv 2206.13765) and provides an efficient algorithm to compute Flipper's moves in a winning strategy.

1 Introduction

Monadic stability is a notion of logical tameness for classes of structures. Introduced by Baldwin and Shelah [3] in the context of model theory[1], it has recently attracted attention in the field of structural graph theory. We recall the definition below. One of the main contributions of this paper is to provide purely combinatorial characterizations of monadically stable classes of graphs via games and via forbidden patterns. Our game characterization is effective, and can be employed in algorithmic applications, as we explain later.

In this paper we focus on (undirected, simple) graphs, rather than arbitrary structures. A graph is modelled as a relational structure with one symmetric binary relation signifying adjacency. By a *class* of graphs we mean any set of graphs. For a class of graphs $\mathcal{C}$, a *unary expansion* of $\mathcal{C}$ is any class $\widehat{\mathcal{C}}$ of structures such that each $\widehat{G} \in \widehat{\mathcal{C}}$ is obtained from some graph in $G \in \mathcal{C}$ by adding some unary predicates. Thus, the elements of $\widehat{\mathcal{C}}$ can be regarded as vertex-colored graphs from $\mathcal{C}$. A class of graphs $\mathcal{C}$ is called *monadically stable* if one cannot interpret, using a fixed formula $\varphi(\bar{x}, \bar{y})$ of first-order logic, arbitrarily long linear orders in any unary expansion $\widehat{\mathcal{C}}$ of $\mathcal{C}$. More precisely, for every unary expansion $\widehat{\mathcal{C}}$ and formula $\varphi(\bar{x}, \bar{y})$ with $|\bar{x}| = |\bar{y}|$ (over the signature of $\widehat{\mathcal{C}}$) there is a bound ℓ such that there is no structure $\widehat{G} \in \widehat{\mathcal{C}}$ and tuples $\bar{a}_1, \ldots, \bar{a}_\ell \in V(\widehat{G})^{\bar{x}}$ such that $\widehat{G} \models \varphi(\bar{a}_i, \bar{a}_j)$ if and only if $i \leqslant j$. More generally, $\mathcal{C}$ is *monadically dependent* (or *monadically NIP*) if one cannot interpret, using a fixed formula $\varphi(\bar{x}, \bar{y})$ of first-order logic, all finite graphs in any unary expansion of $\mathcal{C}$. Thus, from the model-theoretic perspective, the intuition is that being monadically dependent is being non-trivially constrained: for any fixed interpretation, one cannot interpret arbitrarily complicated structures in vertex-colored graphs from the considered class. On the other hand, graphs from monadically stable classes are "orderless", in the sense that one cannot totally order any large part of them using a fixed first-order formula.

Baldwin and Shelah proved that in the definitions, one can alternatively consider only formulas $\varphi(x, y)$ with just a pair of free variables, instead of a pair of tuples of variables [3, Lemma 8.1.3, Theorem 8.1.8]. Moreover, they proved that monadically stable theories are *tree decomposable* [3, Theorem 4.2.17], providing a structure theorem for such theories, although one of a very infinitary nature. A more explicit, combinatorial structure theorem for monadically stable and monadically dependent is desirable for obtaining algorithmic results for the considered classes, as we discuss later.

On the other hand, Braunfeld and Laskowski [6] very recently proved that for *hereditary* classes of structures $\mathcal{C}$ that are not monadically stable or monadically dependent, the required obstructions (total orders or arbitrary graphs) can be exhibited by a boolean combination of existential formulas $\varphi(\bar{x}, \bar{y})$ in the signature of $\mathcal{C}$, without any additional unary predicates. Among other things, this shows that for hereditary classes of structures, the notions of monadic stability coincides with the more well-known notion of stability, and similarly, monadic dependence coincides with dependence (NIP). Furthermore, since the formulas are existential, this result can be seen as a combinatorial non-structure theorem for hereditary classes that are not monadically stable (resp. monadically dependent). Still, they do not provide explicit structural results for classes that are monadically stable or monadically dependent.

[1] Formally, Baldwin and Shelah [3], as well as Braunfeld and Laskowski [6], study monadically dependent and monadically stable *theories*, rather than classes of structures. Some of their results transfer to the more general setting of monadically dependent/stable classes of structures.

Explicit, combinatorial and algorithmic structural results for monadically dependent and monadically stable classes are not only desired, but also expected to exist, based on the known examples of such classes that have been studied in graph theory and computer science. As observed by Adler and Adler [2] based on the work of Podewski and Ziegler [16], all *nowhere dense* graph classes are monadically stable. A class $\mathcal{C}$ is nowhere dense if for every fixed $r \in \mathbb{N}$, one cannot find r-subdivisions of arbitrarily large cliques as subgraphs of graphs in $\mathcal{C}$. In particular, every class excluding a fixed topological minor (so also the class of planar graphs, or the class of subcubic graphs) is monadically stable. In fact, it follows from the results of Adler and Adler [2] and of Dvořák [10] that monadic stability and monadic dependence are both equivalent to nowhere denseness when considering only sparse classes of graphs (formally, classes of graphs that excludes a fixed biclique as a subgraph). However, monadic stability and monadic dependence are not bound to sparsity; they can be used to understand and quantify structure in dense graphs as well.

The pinnacle of the theory of nowhere dense graph classes is the result of Grohe, Kreutzer, and Siebertz [14] that the model-checking problem for first-order logic is fixed-parameter tractable on any nowhere dense class of graphs.

▶ **Theorem 1** ([14]). *For every nowhere dense graph class $\mathcal{C}$, first-order sentence φ, and $\varepsilon > 0$, there exists an algorithm that given an n-vertex graph $G \in \mathcal{C}$ decides whether $G \models \varphi$ in time $\mathcal{O}_{\mathcal{C},\varphi,\varepsilon}(n^{1+\varepsilon})$.*

Here, and in the following, the notation $\mathcal{O}_p(\cdot)$ hides multiplicative factors that depend only on the the parameter p.

Monadically dependent classes include all monadically stable classes, in particular all nowhere dense classes, but also for instance all classes of bounded twin-width [5]. An analogous result, with $1 + \varepsilon$ replaced by 3, holds for all classes $\mathcal{C}$ of *ordered* graphs[2] of bounded twin-width [4].

In light of the discussion above, monadic stability and monadic dependence seem to be well-behaved generalizations of nowhere denseness that are defined in purely model-theoretic terms; hence these concepts may be even better suited for treating the model-checking problem for first-order logic. This motivated the following conjecture [1], which has been a subject of intensive study over the last few years[3].

▶ **Conjecture 2.** *Let $\mathcal{C}$ be a monadically dependent graph class. There exists a constant $c \in \mathbb{N}$ depending only on $\mathcal{C}$ and, for every first-order sentence φ, an algorithm that, given a n-vertex graph $G \in \mathcal{C}$, decides whether $G \models \varphi$ in time $\mathcal{O}_{\mathcal{C},\varphi}(n^c)$.*

Conjecture 2 is not even resolved for monadically stable classes. To approach this conjecture, it is imperative to obtain explicit, combinatorial structure theorems for monadically stable and in monadically dependent graph classes, with a particular focus on finding analogs of the tools used in the proof of Theorem 1. Our work contributes in this direction. We provide certain recursive tree-like decompositions for graphs in monadically stable graph classes, which can be most intuitively explained in terms of games. On the one hand, our decompositions generalize a similar result for nowhere dense classes, recalled below. On the other hand, they are remininiscent of the tree decomposability property proved by Baldwin

[2] *Ordered graphs* are graphs equipped with a total order.
[3] To the best of our knowledge the conjecture was first explicitly discussed during the open problem session of the Algorithms, Logic and Structure Workshop in Warwick, in 2016, see [1].

and Shelah, but are more explicit and finitary in nature. Furthermore, we provide a characterization of monadic stability via forbidden patterns, similar to the known characterization of nowhere denseness.

Splitter game. The cornerstone of the proof of Theorem 1 is a game-theoretic characterization of nowhere denseness, through the *Splitter game*. This game has a fixed radius parameter $r \in \mathbb{N}$ and is played on a graph G between two players, *Splitter* and *Localizer*, who make moves in rounds alternately. In each round, first Splitter chooses any vertex u and removes it from the graph. Next, Localizer selects any other vertex v, and the game gets restricted to the subgraph induced by the ball of radius r with center at v. The game ends with Splitter's victory when there are no vertices left in the graph.

▶ **Theorem 3** ([14]). *A class $\mathcal{C}$ of graphs is nowhere dense if and only if for every $r \in \mathbb{N}$ there exists $k \in \mathbb{N}$ such that for every $G \in \mathcal{C}$, Splitter can win the radius-r Splitter game on G within k rounds.*

Very roughly speaking, Theorem 3 shows that any graph from a nowhere dense class can be hierarchically decomposed into smaller and smaller parts so that the decomposition has height bounded by a constant k depending only on the class and the locality parameter r. This decomposition is used in the algorithm of Theorem 1 to guide model-checking.

Flipper game. In this work we introduce an analog of the Splitter game for monadically stable graph classes: the *Flipper game*. Similarly to before, the game is played on a graph G and there is a fixed radius parameter $r \in \mathbb{N}$. There are two players, *Flipper* and *Localizer*, which make moves in rounds alternately. In each round, first Flipper selects any pair of vertex subsets A, B (possibly non-disjoint) and applies the *flip* between A and B: inverts the adjacency between any pair (a, b) of vertices with $a \in A$ and $b \in B$. Then Localizer, just as in the Splitter game, selects a ball of radius r, and the game is restricted to the subgraph induced by this ball. The game is won by Flipper once there is only one vertex left. See Figure 1 for an illustration.

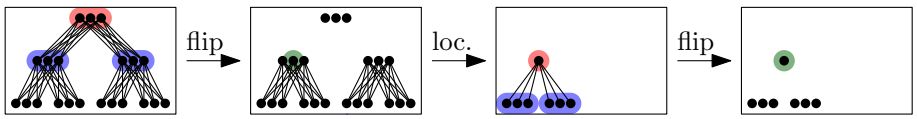

Figure 1 An example play of the radius-1 Flipper game. Taking turns, Flipper flips the red set with the blue set and Localizer restricts to the radius-1 ball centered at the green vertex.

We remark that the Flipper game is a radius-constrained variant of the natural game for graph parameter *SC-depth*, which is functionally equivalent to *shrubdepth*, in the same way that the Splitter game is a radius-constrained variant of the natural game for treedepth. SC-depth and shrubdepth were introduced and studied by Ganian et al. in [13, 12].

Our main result is the following analog of Theorem 3 for monadically stable classes.

▶ **Theorem 4.** *A class $\mathcal{C}$ of graphs is monadically stable if and only if for every $r \in \mathbb{N}$ there exists $k \in \mathbb{N}$ such that for every graph $G \in \mathcal{C}$, Flipper can win the radius-r Flipper game on G within k rounds.*

Let us compare Theorem 4 with another recent characterization of monadic stability, proposed by Gajarský and Kreutzer, and proved by Dreier, Mählmann, Siebertz, and Toruńczyk [9], through the notion of *flip-flatness*. This notion is an analog of *uniform*

quasi-wideness, introduced by Dawar [7]. Without going into technical details, a class of graphs $\mathcal{C}$ is *uniformly quasi-wide* if for any graph $G \in \mathcal{C}$ and any large enough set of vertices A in G, one can find many vertices in A that are pairwise far from each other after the removal of a constant number of vertices from G. As proved by Nešetřil and Ossona de Mendez [15], a class of graphs is uniformly quasi-wide if and only if it is nowhere dense. The definition of flip-flatness is obtained from uniform quasi-wideness similarly as the Flipper game is obtained from the Splitter game: by replacing the concept of deleting a vertex with applying a flip; see Definition 7 for a formal definition. The fact that monadic stability is equivalent to flip-flatness (as proved in [9]) and to the existence of a short winning strategy in the Flipper game (as proved in this paper) suggests the following: the structural theory of monadically stable graph classes mirrors that of nowhere dense graph classes, where the flip operation is the analog of the operation of removing a vertex.

We give two very different proofs of Theorem 4. The first proof is based on elementary model-theoretic techniques, and it provides new insight into the properties of monadically stable graph classes. As a side effect, it gives a new (though non-algorithmic) proof of the main result of [9]: equivalence of monadic stability and flip-flatness. On the other hand, the second proof relies on the combinatorial techniques developed in [9]. It has the advantage of being effective, and provides an efficient algorithm for computing Flipper's moves in a winning strategy.

Forbidden patterns. A class $\mathcal{C}$ of graphs is nowhere dense if for every fixed $r \in \mathbb{N}$ the exact r-subdivision of some clique K_n is not a subgraph of any $G \in \mathcal{C}$, which can be understood as a forbidden pattern characterization. Our model-theoretic proof of Theorem 4 uncovers a similar characterization of monadically stable classes, providing a strong combinatorial non-structure theorem. We prove that a class $\mathcal{C}$ of graphs is monadically stable if and only if there exists a fixed $\ell \in \mathbb{N}$ such that all graphs from $\mathcal{C}$ exclude a ladder of length ℓ as a semi-induced subgraph (see Section 2 for a formal definition), and $\mathcal{C}$ is *pattern-free*. A class $\mathcal{C}$ of graphs is *not* pattern-free if for some $r \geqslant 1, k \in \mathbb{N}$ the exact r-subdivision of every clique K_n can be obtained from an induced subgraph H of some $G \in \mathcal{C}$ by first partitioning $V(H)$ into k parts, and then either flipping the edges, removing all the edges, or inserting all the edges between some pairs of the partition. Equivalently $\mathcal{C}$ is *not* pattern-free if, using a quantifier-free formula $\varphi(x, y)$, one can encode (more formally *transduce*) the class of all r-subdivided cliques for a fixed $r \geqslant 1$.

Model-theoretic proof. The following statement lists properties equivalent to monadic stability uncovered in our model-theoretic proof of Theorem 4. Each condition is shortly explained below the theorem and formally defined in the full version of the paper [11].

▶ **Theorem 5.** *Let $\mathcal{C}$ be a class of graphs. Then the following conditions are equivalent:*

1. *$\mathcal{C}$ is monadically stable.*
2. *$\mathcal{C}$ has a stable edge relation and is monadically dependent with respect to existential formulas $\varphi(x, y)$ with two free variables.*
3. *$\mathcal{C}$ has a stable edge relation and is pattern-free.*
4. *For every $r \in \mathbb{N}$ every model G of the theory of $\mathcal{C}$, every elementary extension H of G, and every vertex $v \in V(H) - V(G)$, there is a finite set $S \subseteq V(G)$ that r-separates v from G.*
5. *For every $r \in \mathbb{N}$ there is $k \in \mathbb{N}$ such that Flipper wins the Flipper Game with qf-definable separation of radius r on every $G \in \mathcal{C}$ in at most k rounds.*

6. *For every $r \in \mathbb{N}$ there is $k \in \mathbb{N}$ such that Flipper wins the Flipper game of radius r on every $G \in \mathcal{C}$ in at most k rounds.*
7. *$\mathcal{C}$ is flip-flat.*

Note that Theorem 4 is the equivalence (1)↔(6). Let us give a brief overview of the presented conditions.

Conditions (1) and (2), respectively, are monadic stability and a weak form of *existential monadic stability*. Recall that Baldwin and Shelah proved that it is sufficient to consider formulas $\varphi(x, y)$ with two free variables in the definition of monadic stability (instead of formulas $\varphi(\bar{x}, \bar{y})$). Braunfeld and Laskowski proved that it is sufficient to consider boolean combinations of existential formulas $\varphi(\bar{x}, \bar{y})$ that do not involve additional unary predicates. The condition (2) lies somewhere in between: it implies that it is sufficient to consider existential formulas $\varphi(x, y)$ with two variables, possibly involving additional unary predicates. In particular, it implies the result of Baldwin and Shelah (in the case of graph classes) and is incomparable with the result of Braunfeld and Laskowski. Our proof uses different techniques.

Condition (3) concerns the combinatorial notion of pattern-freeness discussed earlier.

Condition (4) is phrased in the language of model theory and serves a key role in our proof. It resembles a fundamental property called "definability of types", and in essence it says the following: whenever working with a model G of the theory of $\mathcal{C}$, every element of any elementary extension of G can be robustly "controlled" by a finite subset of G. We believe that the new notion of r-separation used here is of independent interest. It refers to non-existence of short paths after applying some flips governed by S.

Conditions (5) and (6) assert the existence of a short winning strategy in two variants of the Flipper game.

Finally, condition (7) is the notion of flip-flatness, whose equivalence with monadic stability was proved by Dreier et al. [9].

Algorithmic proof. We also give a purely combinatorial proof of the forward implication of Theorem 4, which in particular provides a way to efficiently compute Flipper's moves in a winning strategy. Formally, we show the following.

▶ **Theorem 6.** *Let $\mathcal{C}$ be a monadically stable class of graphs. Then for every radius $r \in \mathbb{N}$ there exist $k \in \mathbb{N}$ and a Flipper strategy* flip* *such that the following holds:*

- *When playing according to* flip* *in the Flipper game of radius r on any graph $G \in \mathcal{C}$, Flipper wins within at most k rounds.*
- *Each move of* flip* *on an n-vertex graph $G \in \mathcal{C}$ can be computed in time $\mathcal{O}_{\mathcal{C},r}(n^2)$.*

The main idea behind the proof of Theorem 6 is to rely on the result of Dreier et al. that monadically stable graph classes are flip-flat [9]. Using the combinatorial tools developed in [9], we strengthen this property: we prove that the set of flips F whose application uncovers a large *scattered set* Y (a set of vertices that are pairwise far from each other) can be selected in a somewhat canonical way, so that knowing any 5-tuple of vertices in Y is enough to uniquely determine F. We can then use such strengthened flip-flatness to provide a winning strategy for Flipper; this roughly resembles the Splitter's strategy used by Grohe et al. in their proof of Theorem 3, which in turn relies on uniform quasi-wideness.

Theorem 6, the algorithmic version of Theorem 4, is the key to algorithmic applications of the Flipper game. In particular, it was very recently used by Dreier, Mählmann, and Siebertz [8] to approach the first-order model checking problem on monadically stable graph classes and prove that it is fixed-parameter tractable on structurally nowhere dense classes, an important subclass of monadically stable classes.

Organization. After introducing monadic stability and the Flipper game in the next section, we give an outline of the model theoretic proof (Section 3) and the algorithmic proof (Section 4). We refer to the appended full version for details.

2 Preliminaries

All graphs in this paper are simple and loopless but not necessarily finite. For a vertex v of a graph G, we write $N(v)$ for the (open) neighborhood of v in G; so $N(v) := \{u \in V(G) \mid uv \in E(G)\}$. For two sets $X, Y \subseteq V(G)$ the bipartite graph *semi-induced* by X and Y in G, denoted $G[X,Y]$, is the bipartite graph with parts X and Y, and edges uv for $u \in X$, $v \in Y$ with $uv \in E(G)$. For vertices $a, b \in V(G)$, an (a,b)-*path* is a path with ends a and b. Similarly, for sets $A, B \subseteq V(G)$, an (A,B)-*path* is a path where one end is in A and the other end is in B.

Model theory. We work with first-order logic over a fixed signature Σ that consists of (possibly infinitely many) constant symbols and of relation symbols. A *model* is a Σ-structure, and is typically denoted $\mathbf{M}, \mathbf{N}$, etc. We usually do not distinguish between a model and its domain, when writing, for instance, $m \in \mathbf{M}$ or $f\colon \mathbf{M} \to X$, or $X \subseteq \mathbf{M}$. A graph G is viewed as a model over the signature consisting of one binary relation denoted E, indicating adjacency between vertices.

A *theory* T (over Σ) is a set of Σ-sentences. A *model of* a theory T is a model $\mathbf{M}$ such that $\mathbf{M} \models \varphi$ for all $\varphi \in T$. When a theory has a model, it is said to be *consistent*. The *theory of* a class of Σ-structures $\mathcal{C}$ is the set of all Σ-sentences φ such that $\mathbf{M} \models \varphi$ for all $\mathbf{M} \in \mathcal{C}$. The *elementary closure* $\overline{\mathcal{C}}$ of $\mathcal{C}$ is the set of all models $\mathbf{M}$ of the theory of $\mathcal{C}$. Thus $\mathcal{C} \subseteq \overline{\mathcal{C}}$, and $\mathcal{C}$ and $\overline{\mathcal{C}}$ have equal theories.

Let $\mathbf{M}$ and $\mathbf{N}$ be two structures with $\mathbf{M} \subseteq \mathbf{N}$, that is, the domain of $\mathbf{M}$ is contained in the domain of $\mathbf{N}$. Then $\mathbf{N}$ is an *elementary extension* of $\mathbf{M}$, written $\mathbf{M} \prec \mathbf{N}$, if for every formula $\varphi(\bar{x})$ (without parameters) and tuple $\bar{m} \in \mathbf{M}^{\bar{x}}$ we have $\mathbf{M} \models \varphi(\bar{m})$ if and only if $\mathbf{N} \models \varphi(\bar{m})$. We also say that $\mathbf{M}$ is an *elementary substructure* of $\mathbf{N}$.

Stability and dependence. A formula $\varphi(\bar{x};\bar{y})$ is *stable* in a class $\mathcal{C}$ of structures if there exists $k \in \mathbb{N}$ such that for every $\mathbf{M} \in \mathcal{C}$, there are no sequences $\bar{a}_1, \dots \bar{a}_k \in \mathbf{M}^{\bar{x}}$ and $\bar{b}_1, \dots, \bar{b}_k \in \mathbf{M}^{\bar{y}}$ such that $\mathbf{M} \models \varphi(\bar{a}_i;\bar{b}_j)$ if and only if $i < j$ for $1 \leqslant i, j \leqslant k$. We say that a class $\mathcal{C}$ of graphs has a *stable edge relation* if the formula $E(x;y)$ is stable in $\mathcal{C}$. Equivalently, $\mathcal{C}$ excludes some ladder as a semi-induced subgraph, where a *ladder* (often called also *half-graph*) of order k is the graph with vertices $a_1, \dots, a_k, b_1, \dots, b_k$ and edges $a_i b_j$ for all $1 \leqslant i < j \leqslant k$. Note that replacing $<$ by $\leqslant$ in the above definitions does not change them.

A formula $\varphi(\bar{x};\bar{y})$ is *dependent*, or *NIP* (standing for "not the independence property") in a class $\mathcal{C}$ if there exists $k \in \mathbb{N}$ such that for every $\mathbf{M} \in \mathcal{C}$, there are no tuples $\bar{a}_1, \dots, \bar{a}_k \in \mathbf{M}^{\bar{x}}$ and $\bar{b}_J \in \mathbf{M}^{\bar{y}}$ for $J \subseteq \{1, \dots, k\}$ such that $\mathbf{M} \models \varphi(\bar{a}_i;\bar{b}_J)$ if and only if $i \in J$ for $1 \leqslant i \leqslant k$ and $J \subseteq \{1, \dots, k\}$. Observe that a formula which is stable is also dependent. A class $\mathcal{C}$ is *stable* (resp. *dependent*) if every formula $\varphi(\bar{x};\bar{y})$ is stable (resp. dependent) in $\mathcal{C}$.

Let Σ be a signature and let $\widehat{\Sigma}$ be a signature extending Σ by (possibly infinitely many) unary relation symbols and constant symbols. A $\widehat{\Sigma}$-structure $\widehat{\mathbf{M}}$ is a *lift* of a Σ-structure $\mathbf{M}$ if $\mathbf{M}$ is obtained from $\widehat{\mathbf{M}}$ by forgetting the symbols from $\widehat{\Sigma} - \Sigma$. A class of $\widehat{\Sigma}$-structures $\widehat{\mathcal{C}}$ is a *unary expansion* of a class of Σ-structures $\mathcal{C}$ if every structure $\widehat{\mathbf{M}} \in \widehat{\mathcal{C}}$ is a lift of some structure $\mathbf{M} \in \mathcal{C}$. A class $\mathcal{C}$ of structures is *monadically stable* if every unary expansion $\widehat{\mathcal{C}}$ of $\mathcal{C}$ is stable. Similarly, $\mathcal{C}$ is *monadically dependent* (or *monadically NIP*) if every unary expansion $\widehat{\mathcal{C}}$ of $\mathcal{C}$ is

dependent. A single structure $\mathbf{M}$ is monadically stable (resp. monadically dependent) if the class $\{\mathbf{M}\}$ is. Note that a class which is monadically stable (resp. monadically dependent) is stable (resp. dependent).

Flips. An *atomic flip* is an operation F specified by a pair (A, B) of (possibly intersecting) vertex sets, which complements the adjacency relation between the sets A and B in a given graph G. Formally, for a graph G, the graph obtained from G by applying the atomic flip F is the graph denoted $G \oplus \mathsf{F}$ with vertex set $V(G)$, where, for distinct vertices u, v in $V(G)$,

$$uv \in E(G \oplus \mathsf{F}) \qquad \iff \qquad \begin{cases} uv \notin E(G), & \text{if } (u,v) \in (A \times B) \cup (B \times A); \\ uv \in E(G), & \text{otherwise.} \end{cases}$$

A set of flips $\{\mathsf{F}_1, \ldots, \mathsf{F}_k\}$ defines an operation F that, given a graph G, results in the graph $G \oplus F := G \oplus \mathsf{F}_1 \oplus \cdots \oplus \mathsf{F}_k$. One can easily show that the order in which we carry out the atomic flips does not matter and that it would be useless to consider multisets. Abusing terminology, we will often just say that the operation F is a set of flips, and write $F = \{\mathsf{F}_1, \ldots, \mathsf{F}_k\}$.

Let $\mathcal{F}$ be a family of vertex sets. Then an $\mathcal{F}$-flip is a set of flips of the form $\{\mathsf{F}_1, \ldots, \mathsf{F}_k\}$, where each flip F_i is a pair (A, B) with $A, B \in \mathcal{F}$. Note that there are at most $2^{|\mathcal{F}|^2}$ different $\mathcal{F}$-flips. In our context, the family $\mathcal{F}$ will usually be a partition of the vertex set of some graph G. An *$\mathcal{F}$-flip* of a graph G, where $\mathcal{F}$ is a family of subsets of $V(G)$, is a graph G' obtained from G after applying an $\mathcal{F}$-flip. Whenever we speak about an $\mathcal{F}$-flip, it will be always clear from the context whether we mean a graph or the family of flips used to obtain it.

Flipper game. Fix a radius r. The Flipper game (or the Flipper/Localizer game) of radius r is played by two players, Flipper and Localizer, on a graph G as follows. At the beginning, set $G_0 := G$. In the ith round, for $i > 0$, the game proceeds as follows.

- If $|G_{i-1}| = 1$ then Flipper wins.
- Localizer chooses a vertex v in G_{i-1} and we set G_{i-1}^{loc} to be the subgraph of G_{i-1} induced by the ball $B^r(v)$ of radius r around v in G_{i-1}.
- Flipper chooses an atomic flip F and applies it to produce G_i, i.e. $G_i = G_{i-1}^{\mathrm{loc}} \oplus \mathsf{F}$.

Variants. It will be convenient to work with different variants of the Flipper game.

- *Batched flipping:* One can consider a variant of the Flipper game where Flipper in the ith move applies a set F of flips to G_{i-1}^{loc} to obtain G_i, where $|F| \leqslant g(i)$ for some function $g\colon \mathbb{N} \to \mathbb{N}$. This does not change the game significantly – if Flipper wins this extended game in m rounds, then Flipper wins the standard Flipper game in $\sum_{i=1}^{m} g(i)$ rounds.
- *Localization modes:* In the definition above, the graph shrinks at each step, and when localizing, distances are computed by only taking into account vertices of the current (shrinked) graph. For this reason, we sometimes call it the *shrinking* variant, or we say that the localization is shrinking. In the *confining* variant, Localizer still remains confined within short distance to his past moves, however Flipper always produces flips of the original graph and distances are measured with respect to the full vertex set.
- *Definability of flips:* We also consider the variant where Flipper is restricted to choosing flips defined using quantifier-free formulas with parameters from the original graph, which we call qf-definable flips.
- *Separation:* Finally, we will also use a variant where distances are measured according to the later defined *separation metric* capturing all possible flips that can be performed over a given (definable) partition of the vertex set.

It will turn out that all these variants are equivalent; for more discussion and formal proofs, see the full version [11]. In particular we will work with the confining Flipper game with qf-definable separation, whose formal definition is deferred to Section 3.

Flip-flatness. The following notion of flip-flatness was introduced in [9] and characterizes monadic stability for graph classes. Given a graph G, a set of vertices $A \subseteq V(G)$ is called *distance-r independent* if all vertices in A are pairwise at distance greater than r in G.

▶ **Definition 7** (Flip-flatness). *A class of graphs $\mathcal{C}$ is* flip-flat *if for every $r \in \mathbb{N}$ there exists a function $N_r \colon \mathbb{N} \to \mathbb{N}$ and a constant $s_r \in \mathbb{N}$ such that for all $m \in \mathbb{N}$, $G \in \mathcal{C}$, and $A \subseteq V(G)$ with $|A| \geqslant N_r(m)$, there exists a set F of flips with $|F| \leqslant s_r$ and $B \subseteq A$ with $|B| \geqslant m$ such that B is distance-r independent in $G \oplus F$.*

▶ **Theorem 8** ([9]). *A class of graphs is monadically stable if and only if it is flip-flat.*

3 Outline of the model-theoretic proof

We prove the implications between the conditions of Theorem 5 as depicted in Figure 2.

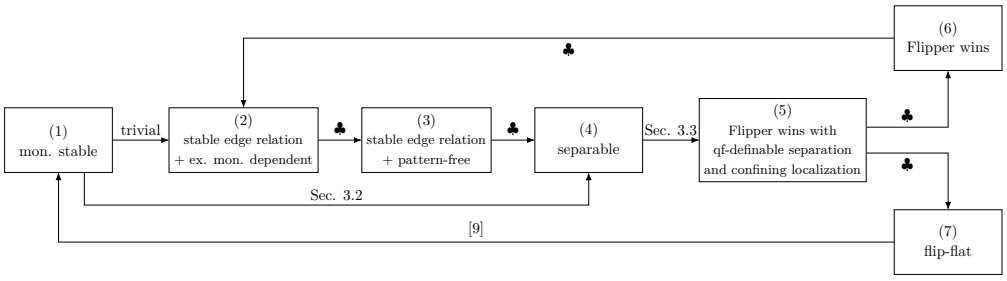

Figure 2 The implications that constitute Theorem 5. Implications marked with ♣ are proved in the full version of the paper.

The implication (1)→(2) is trivial. We prove (2)→(3) by contraposition: using the forbidden patterns, we derive the independence property for some existential formula. The implication (3)→(4) is the core part of our proof; due to space restrictions we will provide a sketch of the implication (1)→(4) (which requires fewer definitions) in Section 3.2. The implication (4)→(5) is proved by proposing a strategy with qf-definable separation in the confining game for Flipper and using compactness combined with (4) to argue that it leads to a victory within a bounded number of rounds. The proof is sketched in Section 3.3. We prove the implication (5)→(7) by (essentially) providing a strategy for Localizer in the confining game with qf-definable separation when the class is not flip-flat. Then we rely on the implication (7)→(1) from [9] to close the circle of implications; this proves the equivalence of (1)-(7) with the exception of (6). We remark that (7)→(1) is the easy implication of [9], hence our reasoning can also serve as an alternative proof of the flip-flatness characterization given in [9].

To put the Flipper game into the picture, we separately prove the implications (5)→(6) and (6)→(2). The implication (5)→(6) relies on a conceptually easy, but technically not-so-trivial translation of the strategies. In the implication (6)→(2) we use obstructions to existential monadic stability to give a strategy for Localizer in the Flipper game that enables her to endure for arbitrarily long.

3.1 Separation

The crucial new ingredient in our model-theoretic proof is the notion of *r-separation*. The definitions provided here are streamlined compared to the full version due to space restrictions.

Let G be a graph, and let $S \subseteq V(G)$ be a finite set of vertices. Consider the equivalence relation $\sim_S$ on $V(G)$, in which two vertices a, b are equivalent if either $a, b \in S$ and $a = b$, or $a, b \notin S$ and $N(a) \cap S = N(b) \cap S$. An *S-class* is an equivalence class of $\sim_S$. In other words, it is a set of vertices either of the form $\{s\}$ for some $s \in S$, or of the form $\{v \in V(G) - S \mid N(v) \cap S = T\}$ for some $T \subseteq S$. The *S-class* of a vertex $v \in V(G)$ is the unique S-class which contains v. Hence, $V(G)$ is partitioned into S-classes, and the number of S-classes is at most $|S| + 2^{|S|}$. An *S-flip* of a graph G is an $\mathcal{F}$-flip G' of G, where $\mathcal{F}$ is the partition of $V(G)$ into S-classes.

▶ **Definition 9** (r-separation). *Let G be a graph, S a finite subset of vertices of G. We say that vertices a and b of G are* r-separated over S, *denoted by*[4] $a \mathop{\downarrow}_S^r b$, *if there exists a S-flip H of G such that* $\mathrm{dist}_H(a, b) > r$.

For any $r \in \mathbb{N}$ and any graph G, finite subset S of $V(G)$, and sets $A, B \in V(G)$, we write $A \mathop{\downarrow}_S^r B$ if there exists an S-flip H of G such that H has no (A, B)-path of length at most r. Note that $A \mathop{\downarrow}_S^r B$ is a stronger condition than $a \mathop{\downarrow}_S^r b$ for all $a \in A$ and $b \in B$, since we require that the same S-flip H is used for all $a \in A$ and $b \in B$. We write $\not\downarrow_S^r$ to denote the negation of the relation $\mathop{\downarrow}_S^r$. If $A \not\downarrow_S^r B$ we say that A and B are *r-connected over S*. If A consists of a single vertex a then we write $a \mathop{\downarrow}_S^r B$ for $A \mathop{\downarrow}_S^r B$.

We now formally introduce the confining Flipper game with qf-definable separation; the most important difference is that we evaluate distances in the original graph G: the localizing ball is always defined with respect to the distance induced by $\mathop{\downarrow}_S^r$ in G, where S is the set of vertices played by Flipper.

Fix a radius $r \in \mathbb{N}$. The game of radius r is played on a graph G as follows. Let $A_0 = V(G)$ and $S_0 = \emptyset$. For $k = 1, 2, \ldots$, the kth round proceeds as follows.

- If $|A_{k-1}| = 1$, then Flipper wins.
- Otherwise, Localizer picks $c_k \in A_{k-1}$ and we set

$$A_k := A_{k-1} - \left\{ w \;\middle|\; w \mathop{\downarrow}_{S_{k-1}}^{r} c_k \right\}$$

  (where separation is evaluated in the graph G).
- Then Flipper picks $s_k \in V(G)$ and we set $S_k := S_{k-1} \cup \{s_k\}$, and proceed to the next round.

As previously, we may allow Flipper to add $g(i)$ vertices to S_{i-1} in the ith round, where $g \colon \mathbb{N} \to \mathbb{N}$ is some fixed function. Again, if Flipper can win this new game in m rounds, then Flipper can also win the original game in $\sum_{i=1}^{m} g(i)$ rounds.

In the full paper [11, Lemma 3.2], we prove that a winning strategy for Flipper in the above game can be adapted by to win in the original Flipper game. The idea is that Flipper carries out all possible S-flips and then flips back to (an induced subgraph of) the original graph.

[4] The symbol $\downarrow$ denotes forking independence in stable theories. Its use here is justified by the relationship of r-separation and forking independence in monadically stable theories, which is briefly explained in the full version of the paper.

▶ **Lemma 10.** *There exists a function $f : \mathbb{N} \to \mathbb{N}$ such that for every radius r and every graph G the following holds. If Flipper wins the confining game with qf-definable separation of radius $2r$ on G in at most k rounds, then Flipper wins the shrinking game with arbitrary flips of radius r on G in at most $f(k)$ rounds.*

Note that the converse direction, allowing to translate a winning strategy of Flipper from the shrinking to the confining variant, is not immediately clear. However, the equivalence of the two games ultimately follows from Theorem 5.

3.2 Finite separators in monadically stable models

In this section, we provide our key model-theoretic characterization of monadically stable graphs. We will use $\mathbf{M}$ to denote a graph that is typically infinite.

▶ **Definition 11.** *A graph $\mathbf{M}$ is* r-separable *if for every elementary extension $\mathbf{N}$ of $\mathbf{M}$, and every $v \in \mathbf{N} - \mathbf{M}$, there is a finite set $S \subseteq \mathbf{M}$ such that $v \downarrow_S^r \mathbf{M}$ in $\mathbf{N}$.*

The main result of this section is the following theorem.

▶ **Theorem 12.** *Every monadically stable graph $\mathbf{M}$ is r-separable, for every $r \in \mathbb{N}$.*

The proof will rely on Lemma 13 and Lemma 14 below. To state them, we will need one more definition. Let $\mathbf{M}$ be a graph and $A, B \subseteq \mathbf{M}$. We say that $a, a' \in A$ have the same *E-type* over B if $N(a) \cap B = N(a') \cap B$; this is clearly an equivalence relation. We denote the set of E-types of A over B by $\mathrm{Types}^E(A/B)$.

▶ **Lemma 13.** *Fix $r \in \mathbb{N}$. Let $\mathbf{M}$ be a monadically stable graph, let $\mathbf{N}$ be an elementary extension of $\mathbf{M}$, and let $v \in \mathbf{N}$ be such that the r-ball $B^r(v)$ around v in $\mathbf{N}$ is disjoint from $\mathbf{M}$. Then $\mathrm{Types}^E(B^r(v)/\mathbf{M})$ is finite.*

We now briefly outline the idea behind the proof of Lemma 13. It is a folklore result that in an infinite bipartite graph with sides L and R there is an infinite induced matching, or an infinite induced co-matching, or an infinite induced ladder, or $\mathrm{Types}^E(L/R)$ is finite. Assume towards a contradiction that the last option (with $L = B^r(v)$ and $R = \mathbf{M}$) does not hold. Since we work with a monadically stable graph, we cannot have an infinite ladder. Therefore, there is an infinite induced matching or co-matching between $B^r(v)$ and $\mathbf{M}$. By symmetry, we can assume the former. From this we obtain, for any k, vertices $a_1, \ldots, a_k$ in $\mathbf{M}$ and $b_1, \ldots, b_k$ in $B^r(v) \subseteq \mathbf{N} - \mathbf{M}$ such that the corresponding pairs a_i, b_i form a semi-induced matching and any b_i, b_j are connected by a path of length at most $2r$ that passes through v. Let H denote the subgraph of N induced by $b_1, \ldots, b_k$ together with the paths connecting them (we pick one such path for each pair). Using the fact that $\mathbf{M}$ is an elementary substructure of $\mathbf{N}$, we can then show that there exist as many disjoint copies of H in $\mathbf{M}$ as we want, and all these copies behave in the same way towards $a_1, \ldots a_k$ as the original H. Consequently, we can for each pair a_i, a_j use one copy of H to create a short path between a_i and a_j, and all these paths can be defined using a single first-order formula, which in turn defines a subdivided clique with k principal vertices. Since k is arbitrary, this means that $\mathbf{M}$ is not monadically dependent, as desired.

▶ **Lemma 14.** *For any graphs $\mathbf{M}$ and $\mathbf{N}$ with $\mathbf{M} \prec \mathbf{N}$ and such that $\mathbf{N}$ is monadically stable and for any set $U \subseteq \mathbf{N} - \mathbf{M}$ such that $\mathrm{Types}^E(U/\mathbf{M})$ is finite, there exists a finite set $S \subseteq \mathbf{M}$ and an S-flip which:*

- *1-separates U from $\mathbf{M}$; and*
- *does not flip the S-class $T := \{v \in \mathbf{N} : \forall s \in S. \neg E(v, s)\}$ with any other S-class (including itself), as long as $T \cap U$ is nonempty.*

The idea behind the proof of Lemma 14 can be briefly summarized as follows. Roughly speaking, we aim to find a finite $S \subseteq \mathbf{M}$ such that if $a, a' \in U$ are in the same S-class, then $N(a) \cap \mathbf{M} = N(a') \cap \mathbf{M}$, and analogously, if $b, b' \in \mathbf{M}$ are in the same S-class, then $N(a) \cap U = N(a') \cap U$. Then we can use these properties to suitably flip between S-classes to obtain the result. First we note that since $\mathrm{Types}^E(U/\mathbf{M})$ is finite, we have that $\mathrm{Types}^E(\mathbf{M}/U)$ is also finite, and so by taking one representative from each class of $\mathrm{Types}^E(\mathbf{M}/U)$ we find a finite subset $S_{\mathbf{M}} \subseteq \mathbf{M}$ such that any two elements in the same $S_{\mathbf{M}}$-class have the same neighborhood in $\mathbf{M}$. Clearly, by the same idea we could find a finite subset set S_U of U such that vertices in the same S_U-class have the same neighborhood in U. However, we need our set S_U to be contained in $\mathbf{M}$. To achieve this, we rely on a fundamental fact about stable formulas known as *definability of types*, which allows us to show that sets $N(u) \cap \mathbf{M}$ (where $u \in U$) can be defined from within $\mathbf{M}$ by looking at S_u-classes, where S_u is a finite subset of $\mathbf{M}$. Since there are only finitely many types of vertices in U with respect to the adjacency towards $\mathbf{M}$, we can list them as $u_1, \ldots, u_k$ and set $S_U := \cup_i S_u$. We can then take $S = S_{\mathbf{M}} \cup S_U$. We remark that the set S defined in the actual proof of Lemma 14 contains more vertices; we refer to the full version of the paper for details.

An inductive proof of Theorem 12 now follows by putting together Lemmas 13 and 14.

Proof sketch of Theorem 12. We proceed by induction on r. Let $\mathbf{M}$ be a monadically stable graph and let $\mathbf{N}$ be an elementary extension of $\mathbf{M}$. For every $v \in \mathbf{N} - \mathbf{M}$, we have to find a finite set $S \subseteq \mathbf{M}$ such that $v \downarrow^r_S \mathbf{M}$ in $\mathbf{N}$. The base case $r = 0$ is immediate as we may take S to be $\varnothing$ since $v \notin \mathbf{M}$. In the inductive step, assume that the result is proved for the distance $r \in \mathbb{N}$. Stated differently, assume there is a finite $S \subseteq \mathbf{M}$ and an S-flip $\mathbf{N}'$ of $\mathbf{N}$ in which the r-ball around v is disjoint from $\mathbf{M}$. It is easily checked that an S-flip of a monadically stable graph is monadically stable, and so $\mathbf{N}'$ is monadically stable. Moreover, one can also show that $\mathbf{N}'$ is an elementary extension of the subgraph of $\mathbf{N}'$ induced by the domain of $\mathbf{M}$. We can therefore apply Lemma 13 to $\mathbf{N}', \mathbf{M}$ and $B^r_{\mathbf{N}'}(v)$. By Lemma 13, $\mathrm{Types}^E(B^r(v)/\mathbf{M})$ is finite. Now Lemma 14 applied to $B^r(v)$ finishes the inductive step and the proof (we are using the fact that we obtain a set S and an S-flip, which doesn't flip the S-class that contains $B^{r-1}(v)$). ◀

Since monadic stability is preserved in the elementary closure[5], we get the following corollary, proving the implication (1)→(4) in Theorem 5.

▶ **Corollary 15.** *If $\mathcal{C}$ is a monadically stable class of graphs and $r \in \mathbb{N}$, then every $\mathbf{M} \in \overline{\mathcal{C}}$ is r-separable.*

3.3 From separability to winning the confining Flipper game

For brevity, in this section we use "Flipper game" to refer to the confining Flipper game with qf-definable separation.

▶ **Theorem 16.** *Fix $r \in \mathbb{N}$, and let $\mathcal{C}$ be a class of graphs such that every $G \in \overline{\mathcal{C}}$ is r-separable. Then there exists $k \in \mathbb{N}$ such that Flipper wins the Flipper game with radius r in k rounds on every $G \in \mathcal{C}$.*

In the proof we will use the Tarski-Vaught test, which we now recall.

[5] The preservation of monadic stability in the elementary closure is true but not obvious (follows from [6]). However, in the full version of the paper, we prove the implication (3)→(4) of Theorem 5 and only require the preservation of edge-stability and pattern-freeness, which we prove easily.

▶ **Theorem 17** (Tarski-Vaught Test). *The following conditions are equivalent for any structures* $\mathbf{M}$ *and* $\mathbf{N}$ *with* $\mathbf{M} \subseteq \mathbf{N}$.

- *The structure* $\mathbf{N}$ *is an elementary extension of* $\mathbf{M}$.
- *For every formula* $\varphi(y; \bar{x})$ *and tuple* $\bar{m} \in \mathbf{M}^{\bar{x}}$, *if* $\mathbf{N} \models \varphi(n; \bar{m})$ *holds for some* $n \in \mathbf{N}$, *then* $\mathbf{N} \models \varphi(n'; \bar{m})$ *holds for some* $n' \in \mathbf{M}$.

In the rest of this section we sketch the proof of Theorem 16. Fix an enumeration $\varphi_1, \varphi_2, \ldots$ of all formulas (in the signature of graphs) of the form $\varphi(y, x_1, \ldots, x_\ell)$, with $\ell \geqslant 0$. We define a strategy of Flipper in any graph G. In the kth round, after Localizer picks $c_k \in A_{k-1}$, Flipper first sets $S := S_{k-1} \cup \{c_k\}$ and marks c_k. Then, for every $i = 1, \ldots, k$, for the formula $\varphi_i(y, \bar{x})$, Flipper does the following.

> For each $\bar{a} \in S^{\bar{x}}$ such that $G \models \exists y.\varphi_i(y, \bar{a})$, Flipper marks any vertex $b \in V(G)$ such that $G \models \varphi_i(b, \bar{a})$.

We say that any strategy of Flipper with this property is *Localizer-complete*. The marked vertices form Flipper response in the kth round, and we set S_k to be the union of S_{k-1} and all the marked vertices. Note that there is a function $f \colon \mathbb{N} \to \mathbb{N}$ such that $|S_k| \leqslant f(k)$ for all $k \in \mathbb{N}$, regardless of which vertices Localizer picks or which of the formulas $\exists y.\varphi_i(y, \bar{a})$ hold.

We prove that there is a number $k \in \mathbb{N}$ such that when Flipper plays according to any Localizer-complete strategy on a graph $G \in \mathcal{C}$, then he wins in at most k rounds. Assume that the conclusion of the theorem does not hold. Then, there exists a sequence of graphs $G_1, G_2, \ldots \in \mathcal{C}$, where in G_n Localizer has a strategy ensuring that Flipper does not win for at least n rounds. We shall now prove that there is some graph G in the elementary closure of $\mathcal{C}$ and a vertex in the graph that survives in the arena indefinitely, when Flipper plays according to a Localizer-complete strategy. We will then use the r-separability of G to derive a contradiction.

▷ Claim 18. There exists a graph $G \in \overline{\mathcal{C}}$, a strategy of Localizer, and a Localizer-complete strategy of Flipper for which the Flipper Game on G lasts indefinitely and the intersection of the arenas $\bigcap_{n<\omega} A_n$ is nonempty.

Proof sketch. For every graph $G_n \in \mathcal{C}$, choose any Localizer-complete strategy of Flipper, and any strategy of Localizer ensuring the game continues for more than n rounds.

In each G_i, use constants to mark moves of Localizer and Flipper in a play in which they play for i moves according to the chosen strategies, and moreover mark by c_ω an arbitrary vertex that remains the arena after i rounds. We then consider, for every $i \in \mathbb{N}$, a sentence ψ_i that is true in a graph if and only if the play encoded by the introduced constants is a valid i move play in the Flipper game and c_ω is in the arena after the ith move. We then have $G_i \models \psi_i$ for each i. By a compactness argument, we can argue that there exists a graph $G \in \overline{\mathcal{C}}$ such that $G \models \psi_i$ for every i. Then we have in G that $c_\omega \in A_i$ for each i, and so $c_\omega \in \bigcap_{n<\omega} A_n$, which means that $\bigcap_{n<\omega} A_n$ is nonempty, as desired. ◁

Let $G \in \overline{\mathcal{C}}$ be the graph produced by Claim 18, along with the strategies of Localizer and Flipper. By assumption, G is r-separable. Recall that $A_0 \supseteq A_1 \supseteq \ldots$ is the sequence of arenas in the play, $c_1, c_2, \ldots$ is the sequence of moves of Localizer, and $S_0 \subseteq S_1 \subseteq \ldots$ is the sequence of sets of vertices marked by Flipper. Denote $A_\omega := \bigcap_{n<\omega} A_n$, and $S_\omega := \bigcup_{n<\omega} S_n$. We will get a contradiction with the previous claim by proving the following claim:

▷ Claim 19. A_ω is empty.

Proof. Observe that for each $k \in \mathbb{N}$, we have $c_k \notin S_{k-1}$: as soon as Localizer plays c_k in S_{k-1}, the arena A_k shrinks to a single vertex and Flipper wins in the following round. Then, A_k is disjoint from S_{k-1}: since Localizer plays c_k outside of S_{k-1}, each vertex of S_{k-1} becomes separated from c_k and thus is removed from the arena. It follows that $A_\omega \cap S_\omega = \emptyset$.

Since Flipper follows a Localizer-complete strategy, S_ω induces an elementary substructure of G by the Tarski-Vaught test (Theorem 17). We also have that $c_1, c_2, \ldots \in S_\omega$ by construction. Now suppose for a contradiction that there exists some $c_\omega \in A_\omega$. We remark that $c_\omega \notin S_\omega$.

By Theorem 12, there exists a finite set $S \subseteq S_\omega$ such that $c_\omega \downarrow^r_S S_\omega$. As S is finite, there is some $n < \omega$ such that $S \subseteq S_n$, so in particular, $c_\omega \downarrow^r_{S_n} S_\omega$. On the other hand, $c_\omega \not\downarrow^r_{S_n} c_{n+1}$, as $c_\omega \in A_{n+1}$. This is a contradiction since $c_{n+1} \in S_\omega$. ◁

However, this means that there exists a graph $G \in \overline{\mathcal{C}}$ and strategies of Localizer and Flipper, for which A_ω is simultaneously nonempty (Claim 18) and empty (Claim 19). This contradicts the existence of the graphs $G_1, G_2, \ldots \in \mathcal{C}$ and completes the proof of Theorem 16.

4 Outline of the algorithmic proof

In this part we outline the proof of Theorem 6 by sketching a winning Flipper strategy whose moves can be computed in time $\mathcal{O}_{\mathcal{C},r}(n^2)$.

Let us first sketch a natural approach to use the flip-flatness characterization of monadic stability (see Definition 7) to derive a winning strategy for Flipper. Consider the radius-r Flipper game on a graph G from a monadically stable class $\mathcal{C}$. For convenience we may assume for now that we work with an extended version of the game where at each round Flipper can apply a bounded (in term of the round's index) number of flips, instead of just one (see the discussion in the preliminaries). As making a vertex isolated requires one flip – between the vertex in question and its neighborhood – we can always assume that the flips applied by Flipper in round i make all the i vertices previously played by Localizer isolated. Hence, Localizer needs to play a new vertex in each round, thus building a growing set X of her moves.

Fix some constant $m \in \mathbb{N}$. According to flip-flatness, there exists some number $N := N_{2r}(m)$ with the property that once X has grown to the size N, we find a set of flips F – whose size is bounded independently of m – and a set Y of m vertices in X that are pairwise at distance greater than $2r$ in $G \oplus F$. It now looks reasonable that Flipper applies the flips from F within his next move. Indeed, since after applying F the vertices of Y are at distance more than $2r$ from each other, the intuition is that F robustly "disconnects" the graph so that the subsequent move of the Localizer will necessarily localize the game to a simpler setting. This intuition is, however, difficult to capture: flip-flatness a priori does not provide any guarantees on the disconnectedness of $G \oplus F$ other than that the vertices of Y are far from each other.

The main idea for circumventing this issue is to revisit the notion of flip-flatness and strengthen it with an additional *predictability* property. Intuitively, predictability says that being given any set of 5 vertices in Y as above is sufficient to uniquely reconstruct the set of flips F. Formally, we prove the following strengthening of the results of [9]. Here and later on, $O(G)$ denotes the set of linear orders on the vertices of G.

▶ **Theorem 20** (Predictable flip-flatness). *Fix a radius $r \in \mathbb{N}$ and a monadically stable class of graphs $\mathcal{C}$. Then there exist the following:*

- *An unbounded non-decreasing function $\alpha_r \colon N \to \mathbb{N}$ and a bound $\lambda_r \in \mathbb{N}$.*

- *A function* FF_r *that maps each triple* $(G \in \mathcal{C}, \preccurlyeq \in O(G), X \subseteq V(G))$ *to a pair* (Y, F) *such that:*
  - F *is a set of at most* λ_r *flips in* G*, and*
  - Y *is a set of* $\alpha_r(|X|)$ *vertices of* X *that is distance-*r *independent in* $G \oplus F$*.*
- *A function* $\mathsf{Predict}_r$ *that maps each triple* $(G \in \mathcal{C}, \preccurlyeq \in O(G), Z \subseteq V(G))$ *with* $|Z| = 5$ *to a set* F *of flips in* G *such that the following holds:*
  - *For every* $X \subseteq V(G)$*, if* $(Y, F) = \mathsf{FF}_r(G, \preccurlyeq, X)$ *and* $Z \subseteq Y$*, then* $F = \mathsf{Predict}_r(G, \preccurlyeq, Z)$*.*

Moreover, given G*,* $\preccurlyeq$*, and* Z*,* $\mathsf{Predict}_r(G, \preccurlyeq, Z)$ *can be computed in time* $\mathcal{O}_{\mathcal{C},r}(|V(G)|^2)$*.*

Let us explain the intuition behind the mappings FF_r and $\mathsf{Predict}_r$ provided by Theorem 20. The existence of bounds α_r and λ_r and of the function FF_r with the properties as above is guaranteed by the standard flip-flatness, see Definition 7 and Theorem 8. However, in the proof we pick the function FF_r in a very specific way, so that the flip set F is defined in a somewhat minimal way with respect to a given vertex ordering $\preccurlyeq$. This enables us to predict what the flip set F should be given any set of 5 vertices from Y. This condition is captured by the function $\mathsf{Predict}_r$.

We remark that the predictability property implies the following condition, which we call *canonicity*, and which may be easier to think about. (We assume the notation from Theorem 20.)

- For every $G \in \mathcal{C}$, $\preccurlyeq \in O(G)$, and $X, X' \subseteq V(G)$, if we denote $(Y, F) = \mathsf{FF}_r(G, \preccurlyeq, X)$ and $(Y', F') = \mathsf{FF}_r(G, \preccurlyeq, X')$, then $|Y \cap Y'| \geqslant 5$ entails $F = F'$.

Indeed, to derive canonicity from predictability note that $F = \mathsf{Predict}_r(G, \preccurlyeq, Z) = F'$, where Z is any 5-element subset of $Y \cap Y'$. Predictability strengthens canonicity by requiring that the mapping from 5-element subsets to flip sets is governed by a single function $\mathsf{Predict}_r$, which is moreover efficiently computable. We prove Theorem 20 in the appended full version of the paper. The proof is based on the combinatorial tools from [9], which were developed to prove the standard flip-flatness. However, the generated sets of flips have to be chosen and analyzed with much greater care.

We now outline how Flipper can use predictable flip-flatness for radius $2r$ to win the radius-r Flipper game in a bounded number of rounds. Suppose the game is played on a graph G; we also fix an arbitrary ordering $\preccurlyeq$ of vertices of G. Flipper will keep track of a growing set X of vertices played by the Localizer. The game proceeds in a number of *eras*, where at the end of each era X will be augmented by one vertex. In an era, Flipper will spend $2 \cdot \binom{|X|}{5}$ rounds trying to robustly disconnect the current set X. To this end, for every 5-element subset Z of X Flipper performs a pair of rounds:

- In the first round, Flipper computes $F := \mathsf{Predict}_{2r}(G, \preccurlyeq, Z)$ and applies the flips from F. Subsequently, Localizer needs to localize the game to a ball of radius r in the F-flip of the current graph.
- In the second round, Flipper reverses the flips by applying F again, and Localizer again localizes.

Thus, after performing a pair of rounds as above, we end with an induced subgraph of the original graph, which moreover is contained in a ball of radius r in the F-flip. Having performed all the $\binom{|X|}{5}$ pairs of rounds as above, Flipper makes the last round of this era: he applies flips that isolates all vertices of X, thus forcing Localizer to play any vertex outside of X that is still available. This adds a new vertex to X and a new era begins.

Let us sketch why this strategy leads to a victory of Flipper within a bounded number of rounds. Suppose the game proceeds for N eras, where N is such that $\alpha_{2r}(N) \geqslant 7$. Then we can apply predictable flip-flatness to the set X built within those eras, thus obtaining a pair $(Y, F) := \mathsf{FF}_{2r}(G, \preccurlyeq, X)$ such that $|Y| = 7$ and F is a set of flips such that Y is

distance-$2r$ independent in $G \oplus F$. Enumerate Y as $\{v_1, \ldots, v_7\}$, according to the order in which they were added to X during the game. Let $Z := \{v_1, \ldots, v_5\}$ and note that $F = \mathsf{Predict}_{2r}(G, \preccurlyeq, Z)$. Observe that in the era following the addition of v_5 to X, Flipper considered Z as one of the 5-element subsets of the (current) set X. Consequently, within one of the pairs of rounds in this era, he applied flips from F and forced Localizer to localize the game subsequently. Since v_6 and v_7 are at distance larger than $2r$ in $G \oplus F$, this necessarily resulted in removing v_6 or v_7 from the graph. This is a contradiction with the assumption that both v_6 and v_7 were played later in the game.

Abstract

The operator precedence languages (OPLs) represent the largest known subclass of the context-free languages which enjoys all desirable closure and decidability properties. This includes the decidability of language inclusion, which is the ultimate verification problem. Operator precedence grammars, automata, and logics have been investigated and used, for example, to verify programs with arithmetic expressions and exceptions (both of which are deterministic pushdown but lie outside the scope of the visibly pushdown languages). In this paper, we complete the picture and give, for the first time, an algebraic characterization of the class of OPLs in the form of a syntactic congruence that has finitely many equivalence classes exactly for the operator precedence languages. This is a generalization of the celebrated Myhill-Nerode theorem for the regular languages to OPLs. As one of the consequences, we show that universality and language inclusion for nondeterministic operator precedence automata can be solved by an antichain algorithm. Antichain algorithms avoid determinization and complementation through an explicit subset construction, by leveraging a quasi-order on words, which allows the pruning of the search space for counterexample words without sacrificing completeness. Antichain algorithms can be implemented symbolically, and these implementations are today the best-performing algorithms in practice for the inclusion of finite automata. We give a generic construction of the quasi-order needed for antichain algorithms from a finite syntactic congruence. This yields the first antichain algorithm for OPLs, an algorithm that solves the ExpTime-hard language inclusion problem for OPLs in exponential time.

1 Introduction

Pushdown automata are a fundamental model of computation and the preferred formalism to parse programs in a deterministic manner. In verification, they are used to encode the behaviors of both systems and specifications that involve, for example, nested procedure calls.

[1] Corresponding author

However, unlike for regular languages specified by finite automata, the inclusion of context-free languages given by pushdown automata is undecidable, even for deterministic machines. This is why expressive subclasses of context-free languages with decidable properties have been studied in the past decades. Prominent among those formalisms is the class of visibly pushdown languages [3], which is strictly contained in the deterministic context-free languages. A visibly pushdown language (VPL) is a context-free language where each word admits a single parse tree, which does not depend on the pushdown automaton that generates (or accepts) the word. More technically, visibly pushdown automata (VPDAs) extend finite automata with a memory stack that is restricted to "push" and "pop" operations on disjoint subsets of the input alphabet. VPDAs have become popular in verification for several reasons. First, they recognize "well-nested" words, which find applications in the analysis of HTML and XML documents. Second, their restricted stack behavior enables desirable closure and decidability properties; in particular, in contrast to deterministic context-free languages, VPDAs can be complemented and their inclusion is decidable. Third, the VPLs admit a generalization of the celebrated Myhill-Nerode theorem for the regular languages [2]: they can be characterized algebraically by a finite syntactic congruence, which not only explains the decidability results, but also leads to symbolic verification algorithms, such as antichain-based universality and inclusion checking for VPDAs [11].

There are, however, important languages that are parsable by deterministic pushdown automata, yet are not visibly pushdown. An important example are the arithmetic expressions with two binary operators, addition and multiplication, where multiplication takes precedence over addition. Most programming languages allow such expressions with implicit precedence relations between operators, instead of insisting on explicit parantheses to disambiguate. For this very purpose, Floyd introduced three elementary precedence relations between letters, namely, *equals in precedence* $\doteq$, *yields precedence* $\lessdot$, and *takes precedence* $\gtrdot$, which provide structure to words. He introduced the *operator precedence languages* (OPLs), a subclass of the context-free languages, where non-conflicting precedence relations between letters can be derived from the context-free grammar [33]. The ability to extract non-conflicting relations from the grammar provides a unique parse tree for each word. However, unlike for VPLs, a letter is not assigned to a unique stack operation, but will trigger "push" and "pop" operations depending on its precedence with respect to the adjacent letters. This allows OPLs to model not only arithmetic expressions, but also languages with exception handling capabilities, where a single closed parenthesis may close several open parentheses [1, 48].

The class of OPLs lies strictly between the VPLs and the deterministic context-free languages. Despite their extra expressive power, the OPLs enjoy the closure and decidability properties of the VPLs, and they even do so at the same cost in computational complexity: the class of OPLs is closed under all boolean and regular operations (union, intersection, complement, concatenation, reverse, and Kleene star) [20, 21]; their emptiness can be solved in PTime (it is PTime-hard for VPDAs), and universality and inclusion in ExpTime (they are ExpTime-hard for VPDAs) [43]. Moreover, OPLs admit a logical characterization in terms of a monadic second-order theory over words, as well as an operational characterization in terms of automata with a stack (called OPAs) [43]. In short, OPLs offer many of the benefits of the VPLs at no extra cost.

In this paper, we complete the picture by showing that OPLs also offer an algebraic characterization in form of a generalized Myhill-Nerode theorem. Specifically, we define a syntactic congruence relation $\equiv_L$ for languages L such that $\equiv_L$ has finitely many equivalence classes if and only if L is an OPL. Finite syntactic congruences provide a formalism-independent (i.e., grammar- and automaton-independent) definition for capturing the algebraic essence of

a class of languages. In addition to the regular languages (Myhill-Nerode) and the VPLs, such congruences have been given also for tree languages [37], for profinite languages [47], for omega-regular languages [4, 44], for sequential and rational transducers [15, 30]. Furthermore, such characterization results through syntactic congruences have been used to design determinization [2, 38], minimization [34, 41], and learning [12, 41, 46] algorithms.

Our contribution in this paper is twofold. Besides giving a finite congruence-based characterization of OPLs, we show how such a characterization can be used to obtain antichain-based verification algorithms, i.e., symbolic algorithms for checking the universality and inclusion of operator precedence automata (OPA). Checking language inclusion is the paradigmatic verification problem for any automaton-based specification formalism, but it is also computationally difficult: PSpace-hard for finite automata, ExpTime-hard for VPDAs, undecidable for pushdown automata. This is why the verification community has devised and implemented symbolic algorithms, which avoid explicit subset constructions for determinization and complementation by manipulating symbolic representations of sets of states. For finite automata, the antichain-based algorithms have proven to be particularly efficient in practice: DWINA [29] outperforms MONA [40] for deciding WS1S formulae, ATC4VPA [11] outperforms VPAchecker [50] for deciding VPDAs inclusion, and Acacia [31] outperforms Lily [39] for LTL synthesis. They leverage a quasi-order on words to prune the search for counterexamples. Intuitively, whenever two words are candidates to contradict the inclusion between two given languages, and the words are related by the quasi-order at hand, the "greater" word can be discarded without compromising the completeness of the search. During symbolic fixpoint iteration, this "quasi-order reduction" yields a succinct representation of intermediate state sets. Based on our syntactic congurence, we show how to systematically compute a quasi-order that enables the antichain approach. Then, we provide the first antichain algorithm for checking language inclusion (and as a special case, universality) between OPAs. In fact, our antichain inclusion algorithm can take any suitable syntactic congruence over structured words (more precisely, any finite equivalence relation that is monotonic for structured words and saturates its language). The instantiation of the antichain algorithm with our syntactic congruence yields an ExpTime algorithm for the inclusion of OPAs, which is optimal in terms of enumeration complexity.

In summary, we generalize two of the most appealing features of the regular languages – the finite characterization by a syntactic congruence, and the antichain inclusion algorithm – to the important context-free subclass of operator precedence languages.

Overview. In Section 2, we define operator precedence alphabets and structured words. We present operator precedence grammars as originally defined by Floyd. We then define the operator precedence languages (OPLs) together with their automaton model (OPAs). Finally, we summarize the known closure and complexity results for OPLs and OPAs. In Section 3, we introduce the syntactic congruence that characterizes the class of OPLs. Subsection 3.1 proves that the syntactic congruence of every OPLs has finitely many equivalence classes, and Subsection 3.2 proves that every language whose syntactic congruence has finitely many equivalence classes is an OPL. In Section 4, we present our antichain inclusion algorithm. First, we introduce the notion of a language abstraction and prove that our syntactic congruence is a language abstraction of OPLs. We also present a quasi-order that relaxes the syntactic congruence while preserving the property of being a language abstraction. Then, we provide an antichain algorithm that decides the inclusion between automata whose languages have finite abstractions. We prove the correctness of our algorithm and establish its complexity on OPAs. In Section 5, we conclude with future directions.

Related Work. Operator precedence grammars and their languages were introduced by Floyd [33] with the motivation to construct efficient parsers. Inspired by Floyd's work, Wirth and Weber [51] defined simple precedence grammars as the basis of an ALGOL-like language. The relation between these two models was studied in [32]. The properties of OPLs were studied in [17, 21]. Later, their relation with the class of VPLs was established in [20], their parallel parsing was explored in [5], and automata-theoretic and logical characterizations were provided in [43]. Recent contributions provide a model-checking algorithm for operator precedence automata [14], a generalization to a weighted model [27], and their application to verifying procedural programs with exceptions [48].

The OPLs form a class of structured context-free languages [45] that sits strictly between deterministic context-free languages and the VPLs [3, 19]. To the best of our knowledge, the OPLs constitute the largest known class that enjoys all desired closure and decidability properties. Several attempts have been made to move beyond this class, however, this often comes at the cost of losing some desirable property. For example, the locally chain-parsable languages are not closed under concatenation and Kleene star [18], and the higher-order OPLs with fixed order are not closed under concatenation [22]. Despite the fact that they are more powerful than the VPLs and enjoy all closure and decidability properties, the class of OPLs is not nearly as well studied. In particular, a finite syntactic congruence characterizing the VPLs was provided in [2]. An analogous result was missing for the OPLs until now.

The antichain algorithm for checking language inclusion was originally introduced for finite automata [52] and later extended to alternating finite automata [53]. The approach has been adapted to solve games with imperfect information [13], the inclusion of tree automata [8], the realizability of linear temporal logic [31], the satisfiability of quantified boolean formulas [9], the inclusion of visibly pushdown automata [11], the inclusion of ω-visibly pushdown automata [24], the satisfiability of weak monadic second-order logic [28], and the inclusion of Büchi automata [25, 26]. The antichain-based approach can be expressed as a complete abstract interpretation as it is captured by the framework introduced in [35, 36]. We provide the first antichain inclusion algorithm for OPLs, and the first generic method to construct an antichain algorithm from a finite syntactic congruence.

2 Operator Precedence Languages

We assume that the reader is familiar with formal language theory.

2.1 Operator Precedence Relations and Structured Words

Let Σ be a finite alphabet. We refer by Σ^* to the set of all words over Σ, by ε to the empty word, and we let $\Sigma^+ = \Sigma^* \setminus \{\varepsilon\}$. Given a word $w \in \Sigma^*$, we denote by $|w|$ its length, by $w^{\triangleleft}$ its first letter, and by $w^{\triangleright}$ its last letter. In particular $|\varepsilon| = 0$, $\varepsilon^{\triangleleft} = \varepsilon$, and $\varepsilon^{\triangleright} = \varepsilon$.

An *operator precedence alphabet* $\widehat{\Sigma}$ is an alphabet Σ equipped with the precedence relations $\lessdot$, $\gtrdot$, $\doteq$, given by a matrix (see Figure 1). Formally, for each ordered pair of letters $(a, b) \in \Sigma^2$, exactly one[1] of the following holds:

- *a yields precedence to b*, denoted $a \lessdot b$,
- *a takes precedence over b*, denoted $a \gtrdot b$,
- *a equals in precedence with b*, denoted $a \doteq b$.

[1] In the literature, operator precedence matrices are defined over sets of precedence relations, leading then to notion of precedence conflict. We use the restriction to singletons because it covers the interesting part of the theory.

	$+$	$\times$	0	1	$(\!\|$	$\|\!)$	ε
$+$	$\gtrdot$	$\lessdot$	$\lessdot$	$\lessdot$	$\lessdot$	$\gtrdot$	$\gtrdot$

Figure 3 (right) Derivation tree of the words $1 + 0 \times (\!|1 + 1|\!) \in L(G_{\text{arith}})$.

For $a, b \in \Sigma$, we write $a \gtrsim b$ iff $a \gtrdot b$ or $a \doteq b$, and similarly $a \lesssim b$ iff $a \lessdot b$ or $a \doteq b$. It is worth emphasizing that, despite their appearance, the operator precedence relations $\lessdot$, $\lesssim$, $\gtrdot$, $\gtrsim$ and $\doteq$ are in general neither reflexive nor transitive. We extend the precedence relations with ε such that $\varepsilon \lessdot a$, $a \gtrdot \varepsilon$, and $\varepsilon \doteq \varepsilon$ for all $a \in \Sigma$.

Every word induces a sequence of precedences. For some words, this sequence corresponds to a *chain* [43], which is a building block of structured words.

▶ **Definition 1** (chain). *Let $a_i \in \widehat{\Sigma}$ and $u_i \in \widehat{\Sigma}^*$ for all $i \in \mathbb{N}$, and let $n \geq 1$. A word $w = a_0 a_1 \dots a_{n+1}$ is a* simple chain *when $a_0, a_{n+1} \in \widehat{\Sigma} \cup \{\varepsilon\}$ and $a_0 \lessdot a_1 \doteq a_2 \doteq \dots \doteq a_n \gtrdot a_{n+1}$. A word $w = a_0 u_0 a_1 u_1 \dots a_n u_n a_{n+1}$ is a* composite chain *when $a_0 a_1 \dots a_{n+1}$ is a simple chain and for all $0 \leq i \leq n$, either $a_i u_i a_{i+1}$ is a (simple or composite) chain or $u_i = \varepsilon$. A word w is a* chain *when w is a simple or a composite chain.*

For all $x, y, z \in \widehat{\Sigma}^*$, the predicate ${}^{x}[y]^{z}$ holds iff $(x^{\triangleright})y(z^{\triangleleft})$ is a chain. Note that, if ${}^{x}[y]^{z}$ then $xyz \neq \varepsilon$.

▶ **Example 2.** Let $\widehat{\Sigma}$ be the operator precedence alphabet in Figure 1 that specifies the precedence relations for generating arithmetic expressions. The word $(\!|(\!|)\!|)$ is a simple chain because $(\!| \lessdot (\!| \doteq |\!) \gtrdot |\!)$. Moreover, the word $(\!|1 + 1|\!)$ is a composite chain because the words $(\!|1+$, $+1|\!)$, and $(\!| + |\!)$ are simple chains.

Next, we define a function that conservatively simplifies the structure of a given word.

▶ **Definition 3** (collapsing function). *For a given operator precedence alphabet $\widehat{\Sigma}$, its* collapsing function $\lambda_{\widehat{\Sigma}} \colon \widehat{\Sigma}^* \to \widehat{\Sigma}^*$ *is defined inductively as follows: $\lambda_{\widehat{\Sigma}}(w) = \lambda_{\widehat{\Sigma}}(xz)$ if $w = xyz$ and ${}^{x}[y]^{z}$ for some $x, y, z \in \widehat{\Sigma}^+$, and $\lambda_{\widehat{\Sigma}}(w) = w$ if there is no such $x, y, z \in \widehat{\Sigma}^+$. When $\widehat{\Sigma}$ is clear from the context, we denote its collapsing function by λ.*

For every $w \in \widehat{\Sigma}$, observe that $\lambda(w)$ is in the following collapsed form: there exist $1 \leq i \leq j \leq n = |\lambda(w)|$ such that $a_1 \gtrsim \dots \gtrsim a_{i-1} \gtrdot a_i \doteq a_{i+1} \doteq \dots \doteq a_j \lessdot a_{j+1} \lesssim \dots \lesssim a_n$.

▶ **Example 4.** Let $\widehat{\Sigma}$ be the operator precedence alphabet in Figure 1. Let $w = (\!|1{+}0|\!) \times (\!|1{+}1|\!)$ and observe that $\lambda(w) = (\!|\,|\!) \times (\!|\,|\!)$ since ${}^{(\!|}[1 + 0]^{|\!)}$ and ${}^{(\!|}[1 + 1]^{|\!)}$. Note also that $(\!| \doteq |\!) \gtrdot \times \lessdot (\!| \doteq |\!)$.

Note that the collapsed form is unique and allows us to generalize classical notions of well-nested words.

▶ **Definition 5** (structured words). *Let $\widehat{\Sigma}$ be an operator precedence alphabet. We define the following sets of words:*

$$\begin{aligned}
\widehat{\Sigma}^*_{\lessdot} &= \{w \in \widehat{\Sigma}^* \mid \lambda(w) = a_1 \dots a_n \text{ where } a_i \lessdot a_{i+1} \text{ for all } i, \text{ or } |\lambda(w)| \leq 1\} \\
\widehat{\Sigma}^*_{\gtrdot} &= \{w \in \widehat{\Sigma}^* \mid \lambda(w) = a_1 \dots a_n \text{ where } a_i \gtrdot a_{i+1} \text{ for all } i, \text{ or } |\lambda(w)| \leq 1\} \\
\widehat{\Sigma}^*_{\doteq} &= \{w \in \widehat{\Sigma}^* \mid \lambda(w) = a_1 \dots a_n \text{ where } a_i \doteq a_{i+1} \text{ for all } i, \text{ or } |\lambda(w)| \leq 1\} = \widehat{\Sigma}^*_{\lessdot} \cap \widehat{\Sigma}^*_{\gtrdot}
\end{aligned}$$

Looking back at the definition of collapsed form, one can verify for every word $w \in \widehat{\Sigma}^*$ that $w \in \widehat{\Sigma}^*_{\lessdot}$ iff $i = 1$, and $w \in \widehat{\Sigma}^*_{\gtrdot}$ iff $j = n$.

▶ **Example 6.** Let $\widehat{\Sigma}$ be the operator precedence alphabet in Figure 1. The word $+ \times (\!|)\!|$ is in $\widehat{\Sigma}^*_{\lessdot}$, the word $(\!|)\!| \times +$ is in $\widehat{\Sigma}^*_{\gtrdot}$, and the word $(\!|)\!|$ is in $\widehat{\Sigma}^*_{\doteq}$. Moreover, note that $+ \lessdot \times \lessdot (\!| \doteq |\!)$ and $(\!| \doteq |\!) \gtrdot \times \gtrdot +$.

2.2 Operator Precedence Grammars

A *context-free grammar* $G = (\Sigma, V, R, S)$ is tuple where Σ is a finite set of terminal symbols, V is a finite set of non-terminal symbols, $R \subseteq V \times (\Sigma \cup V)^*$ is a finite set of derivation rules, and $S \in V$ is the starting symbol. Given $\alpha, \beta \in (\Sigma \cup V)^*$, we write $\alpha \to \beta$ when β can be derived from α with one rule, i.e., when there exists $(\alpha_2, \beta_2) \in R$, $\alpha = \alpha_1\alpha_2\alpha_3$ and $\beta = \alpha_1\beta_2\alpha_3$. Derivations using a sequence of rules are denoted by $\to^*$, the transitive closure of the relation $\to$. The language of G is $L(G) = \{w \in \Sigma^* \mid S \to^* w\}$. A derivation tree for $u \in L(G)$ is a tree over $\Sigma \cup V \cup \{\varepsilon\}$ such that the root is labeled by S, the concatenation of all leaves is u, and if a node is labeled by α and its children labeled by $\beta_1, \dots, \beta_k$ then $(\alpha, \beta_1 \dots \beta_k) \in R$. A grammar is said to be *non-ambiguous* when for all $u \in L(G)$ admits a unique derivation tree.

Intuitively, an *operator precedence grammar* (OPG for short) is an unambiguous context-free grammar whose derivation trees comply with some operator precedence matrix. Formally, let $G = (\Sigma, V, R, S)$ be a context-free grammar and $A \in V$ be a non-terminal, and define the following sets of terminal symbols where $B \in V \cup \{\varepsilon\}$ and $\alpha \in (V \cup \Sigma)^*$:

$$\mathcal{L}_G(A) = \{a \in \Sigma \mid A \to^* Ba\alpha\} \qquad \mathcal{R}_G(A) = \{a \in \Sigma \mid A \to^* \alpha aB\}$$

Given $a, b \in \Sigma$, we define the following operator precedence relations where $\alpha, \beta \in (V \cup \Sigma)^*$:

- $a \lessdot_G b$ iff there exists a rule $A \to \alpha aC\beta$ where $C \in V$ and $b \in \mathcal{L}_G(C)$,
- $a \gtrdot_G b$ iff there exists a rule $A \to \alpha Cb\beta$ where $C \in V$ and $a \in \mathcal{R}_G(C)$,
- $a \doteq_G b$ iff there exists a rule $A \to \alpha aCb\beta$ where $C \in V \cup \{\varepsilon\}$.

Finally, G is an operator precedence grammar if and only if for all $a, b \in \Sigma$, we have that $|\{\odot \in \{\lessdot_G, \doteq_G, \gtrdot_G\} \mid a \odot b\}| \leq 1$.

▶ **Example 7.** Let $G_{\text{arith}} = (\Sigma, V, R, A)$ be a context-free grammar over $\widehat{\Sigma} = \{+, \times, (\!|, |\!), 0, 1\}$ as in Figure 1 where $V = \{A, B, C\}$ and R contains the following rules:

$$A \to A + B \mid B \qquad B \to B \times C \mid C \qquad C \to (\!|A|\!) \mid 0 \mid 1$$

The language $L(G_{\text{arith}})$ consists of valid arithmetic expressions with an implicit relation between terminal symbols: parentheses take precedence over multiplication, which takes precedence over addition [43]. The missing relations, replaced by $\cdot$ in the matrix of Figure 1, denote the precedence relations that cannot be encountered by the given grammar, so the chosen precedence relation does not matter. For example, 00 and $|\!)(\!|$ are not valid arithmetic expressions and cannot be generated by G_{arith}. We remark that the structures of derivation trees and chains share strong similarities as highlighted by Figure 2 and Figure 3.

2.3 Operator Precedence Automata

Intuitively, operator precedence automata are pushdown automata where stack operations are determined by the precedence relations between the next letter and the top of the stack.

▶ **Definition 8** (operator precedence automaton). *An* operator precedence automaton *(OPA for short) over $\widehat{\Sigma}$ is a tuple $\mathcal{A} = (Q, I, F, \Delta)$ where Q is a finite set of states, $I \subseteq Q$ is the set of initial states, $F \subseteq Q$ is a set of accepting states, and $\Delta \subseteq \big(Q \times (\Sigma \cup \{\varepsilon\}) \times (\Gamma^+ \cup \{\bot\})\big)^2$ is the $\widehat{\Sigma}$-driven transition relation where $\Gamma = \Sigma \times Q$ is the stack alphabet and $\bot$ denotes the empty stack, meaning that, when $((s, a, \alpha), (t, b, \beta)) \in \Delta$ the following holds:*

- *If $\alpha = \bot$ or $\alpha = \langle q, a'\rangle\alpha'$ with $a' \lessdot a$, then the input triggers a* push *stack-operation implying that $b = \varepsilon$ and $\beta = \langle s, a\rangle\alpha$. We write $(s, \alpha) \xrightarrow{a} (t, \beta)$.*
- *If $\alpha = \langle q, a'\rangle\alpha'$ with $a' \doteq a$, then the input triggers a* shift *stack-operation implying that $b = \varepsilon$ and $\beta = \langle q, a\rangle\alpha'$. We write $(s, \alpha) \_\xrightarrow{a} (t, \beta)$.*
- *If $\alpha = \langle q, a'\rangle\alpha'$ with $a' \gtrdot a$, then the input triggers a* pop *stack-operation implying that $b = a$ and $\beta = \alpha'$. We write $(s, \alpha) \xRightarrow{a} (t, \beta)$.*

Let $\mathcal{A}$ be an OPA. A *configuration* of $\mathcal{A}$ is a triplet (q, u, θ) where $q \in Q$ is the current state, $u \in \Sigma^*$ is the input suffix left to be read, and $\theta \in \Gamma^+ \cup \{\bot\}$ is the current stack. A *run* of $\mathcal{A}$ is a finite sequence of configurations $((q_i, u_i, \theta_i))_{1 \le i \le n}$ for some $n \in \mathbb{N}$ such that, for all $1 \le i \le n$, the automaton fires (i) a push-transition $(q_{i-1}, \theta_{i-1}) \xrightarrow{a} (q_i, \theta_i)$ where $u_{i-1} = au_i$, (ii) a shift-transition $(q_{i-1}, \theta_{i-1}) \_\xrightarrow{a} (q_i, \theta_i)$ where $u_{i-1} = au_i$, or (iii) a pop-transition $(q_{i-1}, \theta_{i-1}) \xRightarrow{a} (q_i, \theta_i)$ where $u_{i-1} = u_i \in \{au \mid u \in \Sigma^*\}$. We write $(s, u, \alpha) \rightsquigarrow (t, v, \beta)$ when $(s, u, \alpha)(t, v, \beta)$ is a run, and let $(s, u, \alpha) \rightsquigarrow^* (t, v, \beta)$ be its reflexive transitive closure. For all $n \in \mathbb{N}$, we define the predicate $(s, u, \alpha) \rightsquigarrow^n (t, v, \beta)$ inductively by $(s, u, \alpha) = (t, v, \beta)$ when $n = 0$ and by $\exists (q, w, \theta), (s, u, \alpha) \rightsquigarrow (q, w, \theta) \rightsquigarrow^{n-1} (t, v, \beta)$ otherwise. The *language* of $\mathcal{A}$ is defined by $L(\mathcal{A}) = \{w \in \Sigma^* \mid q_0 \in I, q_F \in F, (q_0, w, \bot) \rightsquigarrow^* (q_F, \varepsilon, \bot)\}$. An OPA is *deterministic* when $|I| = 1$ and Δ is a function from $Q \times \Sigma \times (\Gamma^+ \cup \{\bot\})$ to $Q \times (\Sigma \cup \{\varepsilon\}) \times (\Gamma^+ \cup \{\bot\})$, and it is *complete* when from every configuration (s, u, θ) there exists a run that ends in $(t, \varepsilon, \bot)$ for some state $t \in Q$. For a given stack $\theta \in \Gamma^+ \cup \{\bot\}$, we define $\theta^\top$ as the stack symbol at the top of θ if $\theta \in \Gamma^+$, and $\theta^\top = \varepsilon$ if $\theta = \bot$.

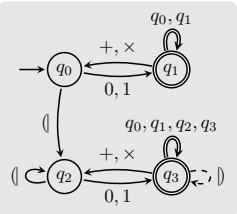
▶ **Definition 9** (operator precedence language). *An* operator precedence language *(OPL for short) is a language recognized by some operator precedence automaton.*

If L is an OPL over the operator precedence alphabet $\widehat{\Sigma}$, we say that L is a $\widehat{\Sigma}$-OPL.

▶ Remark 10. The literature on OPLs often assumes the $\doteq$-acyclicity of operator precedence relations of the alphabet, i.e., that there is no $n \ge 1$ and $a_1, \ldots, a_n \in \Sigma$ with $a_1 \doteq \ldots \doteq a_n \doteq a_1$. This assumption is used to bound the right-hand side of OPG derivation rules, and find a key application for constructing an OPG that recognizes the language of a given OPA [43]. We omit this assumption since it is not needed for establishing the results on OPAs, including the construction of an OPA that recognizes the language of a given OPG.

Now, we present an OPA that recognizes valid arithmetic expressions.

▶ **Example 11.** Recall the OPG of Example 7 generating arithmetic expressions over the operator precedence alphabet of Figure 1. In Figure 4, we show an OPA that recognizes the same language and an example of a computation.



state	input	stack	state	input	stack
q_0	$1 \times \langle 0 + 1 \rangle$	$\bot$	q_2	$1\rangle$	$\langle q_3, + \rangle \langle q_0, \langle \rangle \langle q_1, \times \rangle \bot$
q_1	$\times \langle 0 + 1 \rangle$	$\langle q_0, 1 \rangle \bot$	q_3	$\rangle$	$\langle q_2, 1 \rangle \langle q_3, + \rangle \langle q_0, \langle \rangle \langle q_1, \times \rangle \bot$

2.4 Expressiveness and Decidability of Operator Precedence Languages

In this section, briefly summarize some known results about OPLs. First, we remark that OPLs are context-free languages as they are recognized by a subclass of pushdown automata.

▶ **Theorem 12** (from [20]). *Deterministic context-free languages strictly include OPLs.*

The language $L = \{a^n b a^n \mid n \geq 0\}$, which is a deterministic context-free language, separates the two classes. Indeed, it is not an OPL because while the first segment of a^n must push to the stack (i.e., $a \lessdot a$), the last segment must pop (i.e., $a \gtrdot a$), resulting in conflicting precedence relations. Next, we recall that OPLs enjoy the many closure properties.

▶ **Theorem 13** (from [20, 21]). *OPLs are closed under boolean operations, concatenation, Kleene star, reversal, prefixing, and suffixing.*

The class of VPLs enjoy these closure as well. In fact, every VPL can be expressed as an OPL with an operator precedence alphabet designed as follows: internal characters and returns take precedence over any character; calls equal in precedence with returns, and they yield precedence to calls and internal characters.

▶ **Theorem 14** (from [20]). *OPLs strictly include visibly pushdown languages.*

The language $L = \{a^n b^n \mid n \geq 1\} \cup \{c^n d^n \mid n \geq 1\} \cup \{e^n (bd)^n \mid n \geq 1\}$, which is an OPL due to their closure under union, separate the two classes. Indeed, for L to be a VPL, the first set requires that a is a call and b is a return. Similarly, c is a call and d is a return due to the second set. However, the last set requires that at most one of b and d is a return, resulting in a contradiction. We also note that OPAs support determinization.

▶ **Theorem 15** (from [43]). *Every OPL can be recognized by a deterministic OPA.*

Despite their expressive power, OPL remain decidable for the classical decision problems. In particular, OPAs enjoy the same order of complexity as VPDA for basic decision problems.

▶ **Theorem 16** (from [42, 43]). *The language emptiness is in PTime-C for OPAs. The language inclusion, universality, and equivalence are in PTime for deterministic OPAs and ExpTime-C for nondeterministic OPAs.*

▶ Remark 17. The membership problem is in PTime for OPAs. Determining whether a given word w is accepted by a given OPA $\mathcal{A}$ can be done in polynomial time by constructing an automaton $\mathcal{B}$ that accepts only w, constructing the intersection $\mathcal{C}$ of $\mathcal{A}$ and $\mathcal{B}$, and deciding the non-emptiness of $\mathcal{C}$.

3 A Finite Congruence for Operator Precedence Languages

This section introduces a congruence-based characterization of OPLs, similar to the Myhill-Nerode congruence for regular languages. We let $\widehat{\Sigma}$ be an operator precedence alphabet throughout the section. A relation $\bowtie$ over $\widehat{\Sigma}^*$ is monotonic when $x \bowtie y$ implies $uxv \bowtie uyv$ for all $x, y, u, v \in \widehat{\Sigma}^*$. Intuitively, monotonicity requires two words in relation to stay related while becoming embedded into some context that constructs a larger word. However, such a definition is not well suited for structured words as it does not follow how chains are constructed. Hence, we introduce a more restrictive notion than monotonicity.

▶ **Definition 18** (chain-monotonicity). *A relation $\bowtie$ over $\widehat{\Sigma}^*$ is* chain-monotonic *when $x \bowtie y$ implies $uu_0xv_0v \bowtie uu_0yv_0v$ for all $x, y, u, v, u_0, v_0 \in \widehat{\Sigma}^*$ such that $u_0z^{\lhd} \in \widehat{\Sigma}^*_{\geq}$, $z^{\rhd}v_0 \in \widehat{\Sigma}^*_{\leq}$, and ${}^{u}[u_0zv_0]^{v}$ for each $z \in \{x, y\}$.*

Chain-monotonicity requires two words in relation to stay related while being embedded into some context that construct larger structured words. This leads us to describe when two words agree on whether an embedding into a larger word forms a chain. For this, we introduce a relation that relates words that behave similarly with respect to the chain structure.

▶ **Definition 19** (chain equivalence). *We define the* chain equivalence $\approx$ *over $\widehat{\Sigma}^*$ as follows:*

$$x \approx y \iff \bigwedge \begin{cases} x^{\lhd} = y^{\lhd} \wedge x^{\rhd} = y^{\rhd} \\ \forall u, v, u_0, v_0 \in \widehat{\Sigma}^*, \left(u_0x^{\lhd} \in \widehat{\Sigma}^*_{\geq} \wedge x^{\rhd}v_0 \in \widehat{\Sigma}^*_{\leq}\right) \Rightarrow \left({}^{u}[u_0xv_0]^{v} \Leftrightarrow {}^{u}[u_0yv_0]^{v}\right) \end{cases}$$

We observe that ε is in relation with itself exclusively, i.e., $x = \varepsilon$ iff $\varepsilon \approx x$ iff $x \approx \varepsilon$. Consider a word $w \in \widehat{\Sigma}^+$ for which $\lambda(w)$ is of the form $a_1 \dots a_\ell b_1 \dots b_m c_1 \dots c_n$ for some $\ell, m, n \in \mathbb{N}$ such that $a_1 \geq \dots \geq a_\ell \gtrdot b_1 \doteq \dots \doteq b_m \lessdot c_1 \leq \dots \leq c_n$ where $a_i, b_j, c_k \in \Sigma$ for all i, j, k. We define the *profile* of w as $P_w = (w^{\lhd}, w^{\rhd}, P_w^{\lhd}, P_w^{\rhd})$, where $P_w^{\lhd} = \{a_1, b_1\} \cup \{a_{i+1} \mid a_i \gtrdot a_{i+1}, 1 \leq i < \ell\}$ and $P_w^{\rhd} = \{b_m, c_n\} \cup \{c_k \mid c_k \lessdot c_{k+1}, 1 \leq k < n\}$. There are at most $|\Sigma|^2 \times 2^{2|\Sigma|-2} + 1$ profiles. We can show that two words with the same profile are chain equivalent, leading to the following proposition.

▶ **Proposition 20.** *$\approx$ is a chain-monotonic equivalence relation with finitely many classes.*

Next, we introduce an equivalence relation that characterizes OPLs.

▶ **Definition 21** (syntactic congruence). *Given $L \subseteq \widehat{\Sigma}^*$, we define $\equiv_L$ as the following relation over $\widehat{\Sigma}^*$:*

$$x \equiv_L y \iff x \approx y \wedge \begin{cases} \forall u, v, u_0, v_0 \in \widehat{\Sigma}^*, \left(u_0x^{\lhd} \in \widehat{\Sigma}^*_{\geq} \wedge x^{\rhd}v_0 \in \widehat{\Sigma}^*_{\leq} \wedge {}^{u}[u_0xv_0]^{v}\right) \\ \qquad \Rightarrow \left(uu_0xv_0v \in L \Leftrightarrow uu_0yv_0v \in L\right) \end{cases}$$

Let us demonstrate the syntactic congruence.

▶ **Example 22.** Let $\Sigma = \{a, b\}$ and let $\widehat{\Sigma}$ be the operator precedence alphabet with the relations $a \lessdot a$, $a \doteq b$, $b \gtrdot a$, and $b \gtrdot b$. Consider the language $L = \{a^n b^n \mid n \geq 1\}$.

There are 17 potential profiles for $\widehat{\Sigma}$ in total. Although some of them cannot occur due to the precedence relations of $\widehat{\Sigma}$, the remaining ones correspond to the equivalence classes of $\approx$. For example, $(a, a, \{a\}, \{a, b\})$ cannot occur since $b \gtrdot a$, and $(a, b, \{a\}, \{b\})$ contains exactly the words in L which are of the form $a^n b^n$ for some $n \geq 1$. For brevity, we only show how the syntactic congruence $\equiv_L$ refines the class of $\approx$ corresponding to $(a, a, \{a\}, \{a\})$ by splitting it into four subclasses. The profile $(a, a, \{a\}, \{a\})$ captures exactly the words of the form $w = a$ or $w = aua$ where in each prefix of au there are no more b's than a's. Notice that for such w, $\lambda(w)$ is of the form $(ab)^*a^+$, where $a^+ = \{a^n \mid n > 0\}$.

We first argue that $a \not\equiv_L aa$ but $aa \equiv_L aa^n$ for all $n \geq 1$. Taking $u = v = u_0 = \varepsilon$ and $v_0 = b$, observe that the preconditions for the syntactic congruence are satisfied but $ab \in L$ while $aab \notin L$, therefore $a \not\equiv_L aa$. Now, let $n \geq 2$, and consider the words aa and aa^n. Intuitively, since there is no $x, y \in \widehat{\Sigma}^*$ such that $xaay \in L$ and $xaa^n y \in L$, we show that whenever the preconditions for the congruence are satisfied, both longer words are out of L. Given $u, v, u_0, v_0 \in \widehat{\Sigma}^*$ such that $u_0 a \in \widehat{\Sigma}^*_{\geq}$, $av_0 \in \widehat{\Sigma}^*_{\leq}$, and ${}^u[u_0 aav_0]^v$, we assume towards contradiction that $uu_0 aav_0 v \in L$. Since $uu_0 aav_0 v \in L$ and $u_0 a \in \widehat{\Sigma}^*_{\geq}$, we have $u_0 = \varepsilon$. Moreover, since $av_0 \in \widehat{\Sigma}^*_{\leq}$, we have that v_0 is either of the from a^* or a^*b. Consequently, $\lambda(u_0 aav_0)$ is aaa^* or aaa^*b. This contradicts that ${}^u[u_0 aav_0]^v$ because $a \lessdot a$, and therefore $uu_0 aav_0 v \notin L$. The same argument shows that $uu_0 aa^n v_0 v \notin L$, implying that $aa \equiv_L aa^n$. Similarly as above, we can show that $u \not\equiv_L v$ but $v \equiv_L w$ for all $u, v, w \in \widehat{\Sigma}^*$ such that $\lambda(u) = (ab)^i a$, $\lambda(v) = (ab)^j aa$, and $\lambda(w) = (ab)^k aa^n$, where $n, i, j, k \geq 1$.

We now show that the syntactic congruence is chain-monotonic.

▶ **Theorem 23.** *For every $L \subseteq \widehat{\Sigma}^*$, $\equiv_L$ is a chain-monotonic equivalence relation.*

The main result of this section is the characterization theorem below. We prove each direction separately in Sections 3.1 and 3.2.

▶ **Theorem 24.** *A language L is an OPL iff $\equiv_L$ admits finitely many equivalence classes.*

3.1 Finiteness of the Syntactic Congruence

Let $\widehat{\Sigma}$ be an operator precedence alphabet, $\mathcal{A} = (Q, I, F, \Delta)$ be an OPA over $\widehat{\Sigma}$, and $\star \notin \Sigma$ be a fresh letter for which we extend the precedence relation with $a \lessdot \star$ for all $a \in \Sigma$.

For every word $w \in \widehat{\Sigma}^*$, we define the functions $f_w \colon Q \times (\Gamma \cup \{\bot\}) \to 2^Q$ and $\Phi_w \colon Q \times (\Gamma \cup \{\bot\}) \to 2^{\Gamma^+ \cup \{\bot\}}$ such that for all $q \in Q$ and all $\gamma \in \Gamma \cup \{\bot\}$, we have $f_w(q, \gamma) = \{q_w \in Q \mid \exists \gamma_w \in \Gamma^+ \cup \{\bot\}, (q, w\star, \gamma) \rightsquigarrow^* (q_w, \star, \gamma_w)\}$ and $\Phi_w(q, \gamma) = \{\gamma_w \in \Gamma^+ \cup \{\bot\} \mid \exists q_w \in Q, (q, w\star, \gamma) \rightsquigarrow^* (q_w, \star, \gamma_w)\}$. Intuitively, the states in $f_w(q, \gamma)$ and the stacks in $\Phi_w(q, \gamma)$ come from the configurations that $\mathcal{A}$ can reach after reading w from an initial state in I, but before triggering any pop-transition due to reaching the end of the word w.

Furthermore, for every $w \in \widehat{\Sigma}^*$, we define the function $g_w \colon Q^2 \times (\Gamma \cup \{\bot\}) \to 2^Q$ such that for all $q_1, q_2 \in Q$ and all $\gamma \in \Gamma \cup \{\bot\}$ we have $g_w(q_1, q_2, \gamma) = \{p_w \in Q \mid \exists \gamma_w \in \Phi_w(q_1, \gamma), (q_2, \varepsilon, \gamma_w) \rightsquigarrow^* (p_w, \varepsilon, \bot)\}$. Intuitively, $g_w(q_1, q_2, \gamma)$ is the set of states that $\mathcal{A}$ can reach after triggering from q_2 the pop-transitions that empty the (unique) stack $\gamma_w \in \Phi_w(q_1, \gamma)$ that was generated by reading w while moving from the state q_1 to some state in $f_w(q_1, \gamma)$.

Recall that for a given stack $\theta \in \Gamma^+ \cup \{\bot\}$, we denote by $\theta^\top$ the stack symbol at the top of θ, which is ε when $\theta = \bot$. Moreover, for a given set of stacks $\Theta \subseteq \Gamma^+ \cup \{\bot\}$, let us define $\Theta^\top = \{\theta^\top \mid \theta \in \Theta\}$. For the sequel, we define the following equivalence relation:

▶ **Definition 25** (structural congruence). *Given an OPA $A = (Q, I, F, \Delta)$, we define the relation $\equiv_A$ over $\widehat{\Sigma}^*$ as follows:*

$$x \equiv_{\mathcal{A}} y \iff x \approx y \wedge f_x = f_y \wedge g_x = g_y \wedge \big(\forall q \in Q, \forall \gamma \in \Gamma \cup \{\bot\}, (\Phi_x(q, \gamma))^\top = (\Phi_y(q, \gamma))^\top\big)$$

First, we show that the structural congruence of any OPA has a finite index.

▶ **Lemma 26.** *For every OPA $\mathcal{A}$ with n states and m input letters, the structural congruence $\equiv_{\mathcal{A}}$ has at most $\mathcal{O}(m)^{\mathcal{O}(m \times n)^{\mathcal{O}(1)}}$ equivalence classes.*

Then, we show that for any OPA the syntactic congruence of its language is coarser than its structural congruence, therefore has a finite index as well.

▶ **Lemma 27.** *For every OPA $\mathcal{A}$, the congruence $\equiv_{L(\mathcal{A})}$ is coarser than the congruence $\equiv_{\mathcal{A}}$.*

As a direct result of Lemmas 26 and 27 above, we obtain the following.

▶ **Corollary 28.** *For every $L \subseteq \widehat{\Sigma}^*$, if L is a $\widehat{\Sigma}$-OPL then $\equiv_L$ has finite index.*

3.2 From the Syntactic Congruence to Operator Precedence Automata

Consider a language $L \subseteq \widehat{\Sigma}^*$ such that $\equiv_L$ has finitely many equivalence classes. We construct a deterministic OPA that recognizes L and whose states are based on the equivalence classes of $\equiv_L$. Given $w \in \widehat{\Sigma}^*$, we denote by $[w]$ its equivalence class with respect to $\equiv_L$. We construct $\mathcal{A} = (Q, \{q_0\}, F, \Delta)$ with the set of states $Q = \{([u], [v]) \mid u, v \in \widehat{\Sigma}^*\}$, the initial state $q_0 = ([\varepsilon], [\varepsilon])$, the set of accepting states $F = \{([\varepsilon], [w]) \mid w \in L\}$, and the $\widehat{\Sigma}$-driven transition function $\Delta \colon Q \times \Sigma \times (\Gamma^+ \cup \{\bot\}) \to Q \times (\Sigma \cup \{\varepsilon\}) \times (\Gamma^+ \cup \{\bot\})$, where $\Gamma = \Sigma \times Q$, is defined as follows: Δ maps $(([u], [v]), a, \langle b, ([u'], [v'])\rangle\theta)$ to $(([a], [\varepsilon]), \varepsilon, \langle a, ([u], [v])\rangle\langle b, ([u'], [v'])\rangle\theta)$ if $b \lessdot a$, it returns $(([uva], [\varepsilon]), \varepsilon, \langle a, ([u'], [v'])\rangle\theta)$ if $b \doteq a$, and $(([u'], [v'uv]), a, \theta)$ if $b \gtrdot a$. The soundness of our construction is given by the proof of the following lemma in Appendix.

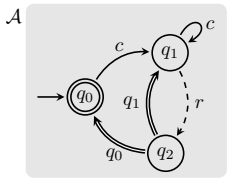
▶ **Lemma 29.** *For every $L \subseteq \widehat{\Sigma}^*$, if $\equiv_L$ has finite index then L is a $\widehat{\Sigma}$-OPL.*

4 Antichain-based Inclusion Checking

Considering two languages L_1 and L_2 given by some automata, the classical approach for deciding whether $L_1 \subseteq L_2$ holds is to first compute the complement $\overline{L}_2$ of L_2, and then decide the emptiness of $L_1 \cap \overline{L}_2$. The major drawback with this approach is that the complementation requires the determinization of the automaton denoting L_2. A way to avoid the determinization is to search among words of L_1 for a counterexample to $L_1 \subseteq L_2$. For this, a breadth-first search can be performed symbolically as a fixpoint iteration. In order to guarantee its termination, the search is equipped with a well quasi-order, and considers only words that are not subsumed, i.e., the minima of L_1 with respect to the quasi-order. It is known that well quasi-orders satisfy the finite basis property, i.e., all sets of words have finitely many minima. Our approach is inspired by [36] which, in the context of unstructured words, presents the antichain approach as a Galois connection, and observes that the upward closure of the quasi-order is a complete abstraction of concatenation according to the standard notion of completeness in abstract interpretation [16]. We identify, in the context of structured words, sufficient conditions on quasi-orders to enable the antichain approach, by defining the class of *language abstraction* quasi-orders (which satisfy the finite basis property). Further, we relax the syntactic congruence into a quasi-order that is a language abstraction of a given OPL. In particular, we prove that the syntactic congruence itself is a language abstraction for its language. Then, we design our inclusion algorithm based on a fixpoint characterization of OPLs, which allows us to iterate breadth-first over all words accepted by a given OPA. Once equipped with a language abstraction quasi-order, this fixpoint is guaranteed to terminate, thus to synthesize a finite set $T \subseteq L_1$ of membership queries for L_2 which suffices to decide whether $L_1 \subseteq L_2$ holds.

4.1 Language Abstraction by Quasi-order

Let E be a set of elements and $\preccurlyeq$ be a binary relation over E. The relation $\preccurlyeq$ is a *quasi-order* when it is reflexive and transitive. A quasi-order $\preccurlyeq$ over E is *decidable* if for all $x, y \in E$, determining whether $x \preccurlyeq y$ holds is computable. Given a subset X of E, we define its *upward closure* with respect to the quasi-order $\preccurlyeq$ by ${}_{\preccurlyeq}\uparrow X = \{e \in E \mid \exists x \in X, x \preccurlyeq e\}$. Given two



$\widehat{\Sigma}_{cr}$	c	r	ε
c	$\lessdot$	$\doteq$	$\gtrdot$
r	$\gtrdot$	$\gtrdot$	$\gtrdot$
ε	$\lessdot$	$\lessdot$	$\doteq$

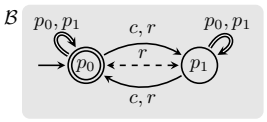


Figure 5 (left) OPA $\mathcal{A}$ over $\widehat{\Sigma}_{cr}$ recognizing the VPL of well-matched *call*/*return* words.

Figure 6 (right) OPA $\mathcal{B}$ over $\widehat{\Sigma}_{cr}$ recognizing the regular language of words of even length.

subsets $X, Y \subseteq E$ the set X is a *basis* for Y with respect to $\preccurlyeq$, denoted $\mathfrak{B}(X \preccurlyeq Y)$, whenever $X \subseteq Y$ and $\preccurlyeq\restriction X = \preccurlyeq\restriction Y$. The quasi-order $\preccurlyeq$ is a *well quasi-order* if and only if for each set $Y \subseteq E$ there exists a finite set $X \subseteq E$ such that $\mathfrak{B}(X \preccurlyeq Y)$. This property on bases is also known as the *finite basis property*. Other equivalent definitions of well quasi-orders can be found in the literature [23], we will use the following two:
(†) For every sequence $\{e_i\}_{i\in\mathbb{N}}$ in E, there exists $i, j \in \mathbb{N}$ with $i < j$ such that $e_i \preccurlyeq e_j$.
(‡) There is no sequence $\{X_i\}_{i\in\mathbb{N}}$ in 2^E such that $\preccurlyeq\restriction X_1 \subsetneq \preccurlyeq\restriction X_2 \subsetneq \dots$ holds.

Let L_1, L_2 be two languages. The main idea behind our inclusion algorithm is to compute a finite subset T of L_1, called a *query-basis*, such that $T \subseteq L_2 \Leftrightarrow L_1 \subseteq L_2$. Then, $L_1 \subseteq L_2$ holds if and only if each word of T belongs to L_2, which is checked via finitely many membership queries. The computation of a query-basis consists of collecting enough words of L_1 to obtain a finite basis T for L_1 with respect to a quasi-order $\preccurlyeq$ that abstracts L_2. When $\preccurlyeq$ is a well quasi-order, some basis is guaranteed to exist thanks to the finite basis property. To ensure the equivalence $L_1 \subseteq L_2 \Leftrightarrow T \subseteq L_2$ for any T such that $\mathfrak{B}(T \preccurlyeq L_1)$, a counterexample $w \in L_1 \setminus L_2$ can be discarded (not included in T), only if it there exists $w_0 \in T$ such that $w_0 \preccurlyeq w$ and w_0 is also a counterexample. Thus, we introduce the *language saturation* property asking a quasi-order $\preccurlyeq$ to satisfy the following: for all $w_0, w \in \widehat{\Sigma}^*$ if $w_0 \preccurlyeq w$ and $w_0 \in L_2$ then $w \in L_2$, or equivalently, $\preccurlyeq\restriction L_2 = L_2$. Intuitively, language saturation ensures the completeness of the language abstraction with respect to the inclusion. Finally, to guarantee that the query-basis T is iteratively constructible with an effective fixpoint computation, the quasi-order $\preccurlyeq$ must be both chain-monotonic and decidable. We now define the notion of *language abstraction* to identify the properties for a quasi-order over structured words that allow an effectively computable query-basis, as was done in [25, 36] in the context of Büchi automata for quasi-orders over unstructured infinite words.

▶ **Definition 30** (language abstraction). *Let $L \subseteq \widehat{\Sigma}^*$. A quasi-order $\preccurlyeq$ over $\widehat{\Sigma}^*$ is a* language abstraction *of L iff (1) it is decidable, (2) it is chain-monotonic, (3) it is a well quasi-order, and (4) it saturates L.*

In the next section, we provide an effective computation of a query-basis for an OPA, thanks to a quasi-order that abstracts its language.

▶ **Example 31.** The operator precedence alphabet $\widehat{\Sigma}_{cr}$ of $\mathcal{A}$ and $\mathcal{B}$ from Figures 5 and 6 induces four families of words: (1) the words of $\widehat{\Sigma}^*_{\doteq}$ where every c matches an r, (2) the words of $\widehat{\Sigma}^*_{\lessdot} = \widehat{\Sigma}^*_{\leqslant} \setminus \widehat{\Sigma}^*_{\doteq}$ where some c is pending for an r on its right, (3) the words of $\widehat{\Sigma}^*_{\gtrdot} = \widehat{\Sigma}^*_{\geqslant} \setminus \widehat{\Sigma}^*_{\doteq}$ where some r is pending for a c on its left, and (4) all other words of $\widehat{\Sigma}^*_{\not\doteq} = \Sigma^* \setminus \left(\widehat{\Sigma}^*_{\leqslant} \cup \widehat{\Sigma}^*_{\geqslant}\right)$.

We focus on deciding whether $L(\mathcal{B})$ is a subset of $L(\mathcal{A})$ and suppose that we are given the quasi-order $\ll$ that is a language abstraction of $L(\mathcal{A})$. Additionally, we have that two words compare with $\ll$ only if they belong to the same family, and we have the following bases: $\mathfrak{B}(\{cr\} \ll \widehat{\Sigma}^*_{=})$, $\mathfrak{B}(\{c\} \ll \widehat{\Sigma}^*_{\lessdot})$, $\mathfrak{B}(\{r\} \ll \widehat{\Sigma}^*_{\gtrdot})$, and $\mathfrak{B}(\{rc\} \ll \widehat{\Sigma}^*_{\neq})$. We observe that $\ll$ saturates $L(\mathcal{A})$ since $\widehat{\Sigma}^*_{=} \subseteq L(A)$ and $\widehat{\Sigma}^*_{\lessdot}, \widehat{\Sigma}^*_{\gtrdot}, \widehat{\Sigma}^*_{\neq} \not\subseteq L(\mathcal{A})$.

Among the representatives cr, c, r, and rc, we can construct the set $T = \{cr, rc\}$ since $c, r \notin L(\mathcal{B})$. The set T is a query-basis for deciding whether $L(\mathcal{B})$ is a subset of $L(\mathcal{A})$. In particular, $rc \in T$ witnesses that $L(\mathcal{B}) \not\subseteq L(\mathcal{A})$.

Note that the syntactic congruence is a natural language abstraction of OPLs.

▶ **Proposition 32.** *For every OPL L, $\equiv_L$ is a language abstraction of L.*

When the language to be abstracted is given by an OPA we are able to define a quasi-order, called *structural quasi-order*, that is based on the underlying structure of the automaton.

▶ **Definition 33** (structural quasi-order). *Given an OPA $\mathcal{A} = (Q, I, F, \Delta)$, we define the relation $\leqslant_{\mathcal{A}}$ over $\widehat{\Sigma}^*$ as follows:*

$$x \leqslant_{\mathcal{A}} y \iff x \approx y \wedge \forall q, q' \in Q, \forall \gamma \in \Gamma \cup \{\bot\} \bigwedge \begin{cases} f_x(q,\gamma) \subseteq f_y(q,\gamma) \\ g_x(q,q',\gamma) \subseteq g_y(q,q',\gamma) \\ (\Phi_x(q,\gamma))^\top \subseteq (\Phi_y(q,\gamma))^\top \end{cases}$$

▶ Remark 34. For every OPA $\mathcal{A}$, the quasi-order $\leqslant_{\mathcal{A}}$ relaxes the congruence $\equiv_A$ from Section 3. For every OPA $\mathcal{A}$, the quasi-order $\leqslant_{\mathcal{A}}$ relaxes the congruence $\equiv_A$ from Section 3.

Note that, for every OPA $\mathcal{A}$, the set $Q \times (\Gamma \cup \{\bot\})$ is finite. Consequently, $\leqslant_{\mathcal{A}}$ is computable, and it is a well quasi-order since there cannot exist an infinite sequence of incomparable elements, i.e., (†) holds.

▶ **Proposition 35.** *For every OPA $\mathcal{A}$, $\leqslant_{\mathcal{A}}$ is a computable chain-monotonic well quasi-order.*

Next, we establish that structural quasi-orders saturate their languages.

▶ **Lemma 36.** *For every OPA $\mathcal{A}$ and $w_1, w_2 \in \widehat{\Sigma}^*$, if $w_1 \leqslant_{\mathcal{A}} w_2$ and $w_1 \in L(\mathcal{A})$ then $w_2 \in L(\mathcal{A})$.*

The following comes as a direct consequence of Proposition 35 and Lemma 36.

▶ **Corollary 37.** *For every OPA $\mathcal{A}$, $\leqslant_{\mathcal{A}}$ is a language abstraction of $L(\mathcal{A})$.*

We continue Example 31, showing that the structural quasi-order agrees with the considered bases above.

▶ **Example 38.** The quasi-order $\ll$ described in Example 31 agrees with the structural quasi-order $\leqslant_{\mathcal{A}}$ of the OPA $\mathcal{A}$ in Figure 5. Indeed, due to the constraint that two comparable words $x, y \in \widehat{\Sigma}^*$ should be chain equivalent, i.e., $x \approx y$, the quasi-order $\leqslant_{\mathcal{A}}$ compares only the words from the same families among $\widehat{\Sigma}^*_{=}, \widehat{\Sigma}^*_{\lessdot}, \widehat{\Sigma}^*_{\gtrdot}$, and $\widehat{\Sigma}^*_{\neq}$. We also note that, for all words, adding a factor in $\widehat{\Sigma}^*_{=}$ cannot change the accessibility in $\mathcal{A}$ since reading such a factor has no effect on the stack or the current state. Additionally, reading several c in a row triggers a self loop and reading several r is not possible in $\mathcal{A}$. As a consequence, the base predicates mentioned in Example 31 hold, that is, $\mathfrak{B}(\{cr\} \leqslant_{\mathcal{A}} \widehat{\Sigma}^*_{=})$, $\mathfrak{B}(\{c\} \leqslant_{\mathcal{A}} \widehat{\Sigma}^*_{\lessdot})$, $\mathfrak{B}(\{r\} \leqslant_{\mathcal{A}} \widehat{\Sigma}^*_{\gtrdot})$, and $\mathfrak{B}(\{rc\} \leqslant_{\mathcal{A}} \widehat{\Sigma}^*_{\neq})$. Yet, we have that $cr \leqslant_{\mathcal{A}} \varepsilon$ because $(q_0, cr, \bot) \rightsquigarrow^* (q_2, \varepsilon, \langle c, q_0 \rangle)$ but $(q_0, \varepsilon, \bot) \not\rightsquigarrow^* (q_2, \varepsilon, \langle c, q_0 \rangle)$.

4.2 Fixpoint Characterization of Languages and Inclusion

In order to formulate our inclusion algorithm, it remains to give an effective computation of a query-basis. We do so through a fixpoint characterization of the languages recognized by OPAs. We introduce the function $\texttt{Cat}$ to construct words that follow the runs of the given OPA. Iterating the $\texttt{Cat}$ function $n \in \mathbb{N}$ times captures all words of length up to n, and the fixpoint of the iteration captures the entire language of a given OPA.

Let $\mathcal{A} = (Q, I, F, \Delta)$ be an OPA. Consider a vector of set of words $\vec{X}$ that accesses its fields with two states $s, t \in Q$, and three letters $a, b, c \in \widehat{\Sigma} \cup \{\varepsilon\}$. Intuitively, we aim at constructing $\vec{X}$ iteratively such that, reading any $w \in \vec{X}_{s,t}^{a,b,c}$ from the configuration (s, wc, α) where $\alpha^\top = a$ allows reaching (t, c, β) where $\beta^\top = b$ in $\mathcal{A}$. We recall that $\bot^\top = \varepsilon$. As the base case, we take $\vec{X}_{s,t}^{a,b,c} = \varepsilon$ when $a = b$ and $s = t$, otherwise $\vec{X}_{s,t}^{a,b,c} = \varnothing$. Then, we introduce operations (more explicitly, functions from sets of words to sets of words) that use the transitivity of $\rightsquigarrow^*$ in $\mathcal{A}$ to extend the sets of $\vec{X}$. We first introduce:

$$\texttt{CatShift}(\vec{X}_{s,t}^{a,b,c}) = \left\{ ub'v \;\middle|\; \begin{array}{l} a', b' \in \Sigma,\ q, s', t' \in Q,\ u \in \vec{X}_{s,s'}^{a,a',b'},\ v \in \vec{X}_{t',t}^{b',b,c}, \\ (s', \langle a', q\rangle \bot) \xrightarrow{b'} (t', \langle b', q\rangle \bot) \end{array} \right\}$$

Essentially, $\texttt{CatShift}$ adds $ub'v$ to $\vec{X}_{s,t}^{a,b,c}$ when some run over u can be appended with b' thanks to a shift-transition, and some run of v requires starting with b' at the top of the stack. Next, we introduce:

$$\texttt{CatChain}(\vec{X}_{s,t}^{a,b,c}) = \left\{ ub'v \;\middle|\; \begin{array}{l} a', b', c' \in \Sigma,\ q, s', t' \in Q,\ u \in \vec{X}_{s,q}^{a,b,b'},\ v \in \vec{X}_{s',t'}^{b',c',c}, \\ b \lessdot b' \wedge (q, \bot) \xrightarrow{b'} (s', \langle b', q\rangle \bot) \wedge (t', \langle c', q\rangle \bot) \Longrightarrow (t, \bot) \end{array} \right\}$$

Intuitively, $\texttt{CatChain}$ adds $ub'v$ to $\vec{X}_{s,t}^{a,b,c}$ when some run over u can be appended with b' thanks to a push-transition, and some run of v requires starting with b' at the top of the stack. Additionally, b' is guaranteed to be removed from the stack thanks to a pop-transition on the incoming letter c. Finally, we define:

$$\texttt{Cat}(\vec{X}_{s,t}^{a,b,c}) = \vec{X}_{s,t}^{a,b,c} \cup \texttt{CatShift}(\vec{X}_{s,t}^{a,b,c}) \cup \texttt{CatChain}(\vec{X}_{s,t}^{a,b,c})$$

Note that the function $\texttt{Cat}$ never removes words from the sets of $\vec{X}$, i.e., $\vec{X}_{s,t}^{a,b,c} \subseteq \texttt{Cat}(\vec{X}_{s,t}^{a,b,c})$. Iterating the $\texttt{Cat}$ function $n \in \mathbb{N}$ times allows us to extend the sets of $\vec{X}$ to words of length at most n that follow some run of $\mathcal{A}$. In particular, $\texttt{Cat}$ characterizes the language of $\mathcal{A}$ by $w \in L(\mathcal{A})$ if and only if $w \in \texttt{Cat}^*(\vec{X}_{q_I,q_F}^{\varepsilon,\varepsilon,\varepsilon})$ for some $q_I \in I$ and $q_F \in F$. This is formalized by the following lemma.

▶ **Lemma 39.** *Let $\mathcal{A} = (Q, I, F, \Delta)$ be an OPA, and let $\Gamma = \Sigma \times Q$. Considering $\vec{U}_{s,t}^{a,b,c} = \varepsilon$ when $a = b$ and $s = t$, otherwise $\vec{U}_{s,t}^{a,b,c} = \varnothing$. The following holds for all $n > 0$:*

$$\texttt{Cat}^n(\vec{U}_{s,t}^{a,b,c}) = \left\{ u \mid (s, uc, \alpha) \rightsquigarrow^* (t, c, \beta), |u| = n, \alpha \in \Theta_a, \beta \in \Theta_b, au \in \widehat{\Sigma}^*_{\lessdot}, uc \in \widehat{\Sigma}^*_{\gtrdot}, u^\triangleright = b \right\}$$

where, for all $a \in \widehat{\Sigma}$, the set of stack symbols $\Theta_a \subseteq \Gamma \cup \{\bot\}$ is defined by $\Theta_a = \{\bot\}$ if $a = \varepsilon$, and $\Theta_a = \{\langle a, q\rangle \mid q \in Q\}$ otherwise.

We continue Example 31, showing that $\texttt{Cat}$ agrees with the considered query-basis.

▶ **Example 40.** Let $\vec{U}_{s,t}^{a,b,c} = \varepsilon$ when $a = b$ and $s = t$, otherwise $\vec{U}_{s,t}^{a,b,c} = \varnothing$. Thanks to Lemma 39, we have that $L(\mathcal{B}) = \texttt{Cat}^*(\vec{U}_{p_0,p_0}^{\varepsilon,\varepsilon,\varepsilon})$. First observe that $c, r \notin \texttt{Cat}^*(\vec{U}_{p_0,p_0}^{\varepsilon,\varepsilon,\varepsilon})$. This comes from Lemma 39 and the fact that there is no run of $\mathcal{B}$ from p_0 to p_0 that reads a single letter. Next, we prove that $cr, rc \in \texttt{Cat}^2(\vec{U}_{p_0,p_0}^{\varepsilon,\varepsilon,\varepsilon})$.

We show that $r \in \texttt{Cat}(\vec{U}^{\varepsilon,\varepsilon,c}_{p_0,p_1})$ by `CatChain`. Indeed, we have $\varepsilon \in \vec{U}^{\varepsilon,\varepsilon,r}_{p_0,p_0}$, $\varepsilon \in \vec{U}^{r,r,c}_{p_1,p_1}$, $\varepsilon \preccurlyeq r$, and $(p_0,\bot) \xrightarrow{r} (p_1,\langle r,p_1\rangle\bot) \xRightarrow{c} (p_1,\bot)$. Then, $rc \in \texttt{Cat}^2(\vec{U}^{\varepsilon,\varepsilon,\varepsilon}_{p_0,p_0})$ by `CatChain` since $r \in \texttt{Cat}(\vec{U}^{\varepsilon,\varepsilon,c}_{p_0,p_1})$, $\varepsilon \in \vec{U}^{c,c,\varepsilon}_{p_0,p_0}$, $\varepsilon \preccurlyeq c$, and $(p_1,\bot) \xrightarrow{c} (p_0,\langle c,p_1\rangle\bot) \xRightarrow{\varepsilon} (p_1,\bot)$.

We show that $r \in \texttt{Cat}(\vec{U}^{c,r,\varepsilon}_{p_1,p_0})$ by `CatShift`. Indeed, we have $\varepsilon \in \vec{U}^{c,c,r}_{p_1,p_1}$, $\varepsilon \in \vec{U}^{r,r,\varepsilon}_{p_0,p_0}$, and $(p_1,\langle c,p\rangle\bot) \xrightarrow{r} (p_0,\langle r,p\rangle\bot)$, for all $p \in \{p_0,p_1\}$. Then, $cr \in \texttt{Cat}^2(\vec{U}^{\varepsilon,\varepsilon,\varepsilon}_{p_0,p_0})$ by `CatChain` since $\varepsilon \in \vec{U}^{\varepsilon,\varepsilon,c}_{p_0,p_0}$, $r \in \texttt{Cat}(\vec{U}^{c,r,\varepsilon}_{p_1,p_0})$, $\varepsilon \preccurlyeq c$, $(p_0,\bot) \xrightarrow{c} (p_1,\langle c,p_0\rangle\bot)$, and $(p_0,\langle r,p_0\rangle) \xRightarrow{\varepsilon} (p_0,\bot)$.

The computation of a query-basis for deciding whether L_1 is a subset of L_2 consists of iterating `Cat` to collect enough words to obtain a vector of finite bases with respect to the quasi-order $\preccurlyeq$ that is a language abstraction of L_2. In other words, we search for $n \in \mathbb{N}$ such that $\texttt{Cat}^n(\vec{X}^{a,b,c}_{s,t})$ is a basis for $\lim_{k\mapsto\infty} \texttt{Cat}^k(\vec{U}^{a,b,c}_{s,t})$ with respect to $\preccurlyeq$. The following lemma shows that when $\mathfrak{B}(\texttt{Cat}^n(\vec{X}^{a,b,c}_{s,t}) \preccurlyeq \texttt{Cat}^{n+1}(\vec{X}^{s,b,c}_{s,t}))$ holds for some $n \in \mathbb{N}$, then $\mathfrak{B}(\texttt{Cat}^n(\vec{X}^{a,b,c}_{s,t}) \preccurlyeq \lim_{k\mapsto\infty} \texttt{Cat}^k(\vec{X}^{a,b,c}_{s,t}))$ holds also, as long as the used quasi-order is chain-monotonic.

▶ **Lemma 41.** *Let $\preccurlyeq$ be a chain-monotonic quasi-order over $\widehat{\Sigma}^*$. For every $A = (Q,I,F,\Delta)$ and $\vec{X},\vec{Y}$ such that $\mathfrak{B}(\vec{X}^{a,b,c}_{s,t} \preccurlyeq \vec{Y}^{a,b,c}_{s,t})$ holds for all $s,t \in Q$ and all $a,b,c \in \Sigma \cup \{\varepsilon\}$, we have $\mathfrak{B}(\texttt{Cat}(\vec{X}^{a,b,c}_{s,t}) \preccurlyeq \texttt{Cat}(\vec{Y}^{a,b,c}_{s,t}))$ holds also for all $s,t \in Q$ and all $a,b,c \in \Sigma \cup \{\varepsilon\}$.*

Input: an OPL L_1 given by the OPA (Q,I,F,Δ)
Input: a language L_2 with a procedure deciding if $w \in L_2$
Input: a quasi-order $\preccurlyeq$ that is a language abstraction of L_2
Output: Returns `ok` if $L_1 \subseteq L_2$ and `ko` otherwise

Figure 7 Antichain inclusion algorithm.

Our inclusion algorithm is given in Figure 7. We can prove that it always terminates thanks to the finite base property of language abstractions. Additionally, its correctness is based on the following: Lemmas 39 and 41 ensure that the repeat-until loop computes a basis of the language L_1 given by an OPA while the language saturation ensures the completeness of this basis with respect to the inclusion problem.

▶ **Theorem 42.** *The algorithm from Figure 7 terminates and decides language inclusion.*

We establish that our inclusion algorithm for OPAs is in ExpTime as a consequence of Lemma 26, Remark 34, the facts that the vector $\vec{X}$ maintains polynomially many sets of words and the membership problem for OPAs is in PTime (Remark 17). We recall that inclusion and universality are ExpTime-C for both OPLs and VPLs [3, 43].

▶ **Theorem 43.** *For all OPAs $\mathcal{A}, \mathcal{B}$ with respectively $n_{\mathcal{A}}, n_{\mathcal{B}}$ states and m input letters, the inclusion algorithm from Figure 7 with $\leqslant_{\mathcal{B}}$ as the language abstraction quasi-order decides if $L(\mathcal{A}) \subseteq L(\mathcal{B})$ in time $\mathcal{O}(m \times n_{\mathcal{A}})^{\mathcal{O}(m \times n_{\mathcal{B}})^{\mathcal{O}(1)}}$.*

5 Conclusion

We provided, for the first time, a syntactic congruence that characterizes operator precedence languages (OPLs) in the following exact sense: for any language L, the syntactic congruence has finitely many equivalence classes if and only if L is an OPL. Second, we gave sufficient conditions for a quasi-order to yield an antichain algorithm for solving the universality and language inclusion problems for nondeterministic automata. These conditions are satisfied by our syntactic congruence, which, like any finite congruence, is monotonic for structured words (i.e., chain-monotonic) and saturates its language. This results in an exponential-time antichain algorithm for the inclusion of operator precedence automata (OPAs), which is the optimal worst-case complexity for the ExpTime-hard problem. This will allow efficient symbolic implementations of antichain algorithms to be extended to OPLs.

The possibility of future research directions regarding OPLs is still vast. One promising direction is to study OPAs from a runtime verification [6] perspective. For example, extending the runtime approaches for visibly pushdown automata [10, 49], one can study the monitor synthesis and right-universality problems for OPAs to establish them as an expressively powerful class of monitors. Also other methods developed for visibly pushdown automata may be generalizable to OPAs based on our syntactic congruence, such as learning algorithms [41].

While OPLs characterize the weakest known restrictions on stack operations which enable decidability of the inclusion problem, one may try to push the frontier of decidability by relaxing the restrictions on stack operations further. Investigating similar restrictions in the context of observability for counter automata can also provide new decidability results. For example, [7] shows that hardcoding the counter operations (increments and decrements) in the input letters yields decidable inclusion for one-counter automata. Another natural direction is to investigate quantitative versions of OPAs, for instance, through the addition of Presburger acceptance constraints, and to identify decidable fragments thereof [27].

Abstract

It is a longstanding open problem whether there is an algorithm to decide the Positivity Problem for linear recurrence sequences (LRS) over the integers, namely whether given such a sequence, all its terms are non-negative. Decidability is known for LRS of order 5 or less, i.e., for those sequences in which every new term depends linearly on the previous five (or fewer) terms. For *simple* LRS (i.e., those sequences whose characteristic polynomials have no repeated roots), decidability of Positivity is known up to order 9.

In this paper, we focus on the important subclass of *reversible* LRS, i.e., those integer LRS $\langle u_n \rangle_{n=0}^{\infty}$ whose bi-infinite completion $\langle u_n \rangle_{n=-\infty}^{\infty}$ also takes exclusively integer values; a typical example is the classical Fibonacci (bi-)sequence $\langle \ldots, 5, -3, 2, -1, 1, 0, 1, 1, 2, 3, 5, \ldots \rangle$. Our main results are that Positivity is decidable for reversible LRS of order 11 or less, and for simple reversible LRS of order 17 or less.

1 Introduction

The Positivity Problem

The class of *threshold problems* considers whether a given loop program's variables remain above a fixed threshold before and after each iteration of the loop. In automated verification, this class of decision problems is relevant to program correctness, and particularly questions regarding termination, persistence, and reachability. The moniker *Positivity* is used when the chosen threshold is zero. In this paper, we shall consider the Positivity Problem (and its variants) for a particular class of integer-valued linear recurrence sequences.

An integer-valued *linear recurrence sequence (LRS)* $\langle u_n \rangle_n$ satisfies a relation of the form

$$u_{n+d} = a_{d-1}u_{n+d-1} + \cdots + a_1 u_{n+1} + a_0 u_n \tag{1}$$

where the coefficients $a_{d-1}, \ldots, a_1, a_0 \in \mathbb{Z}$ and, without loss of generality, we can assume that $a_0 \neq 0$. The sequence $\langle u_n \rangle_n$ is then wholly determined by the recurrence relation and the initial values $u_0, u_1, \ldots, u_{d-1}$. The relation in (1) is said to have *length* d and the *order* of an LRS $\langle u_n \rangle_n$ is equal to the length of the shortest relation that $\langle u_n \rangle_n$ satisfies. The polynomial $f(X) = X^d - a_{d-1}X^{d-1} - \cdots - a_1 X - a_0$ is the *characteristic polynomial* associated with relation (1).

Given an LRS $\langle u_n \rangle_n$, the *Positivity Problem* asks to determine whether $u_n \geq 0$ for each $n \in \mathbb{N}_0$. Positivity is a longstanding open problem and is intimately related to the well-known *Skolem Problem*, which asks to determine whether an LRS vanishes at some term [6, 8]. Indeed, if one could establish decidability of Positivity, then decidability of Skolem would necessarily follow (cf. [13]). One of the motivations to study Positivity lies in its connections to program verification [15]. Take, for example, the following linear loop P with inputs $\underline{w}, \underline{b} \in \mathbb{Z}^d$ and $A \in \mathbb{Z}^{d \times d}$ where

$$P\colon \underline{v} \leftarrow \underline{w};\ \textbf{while}\ \underline{b}^\top \cdot \underline{v} \geq 0\ \textbf{do}\ \underline{v} \leftarrow A\underline{v}. \tag{2}$$

Let $\langle u_n \rangle_n$ be the LRS with terms given by $u_n = \underline{b}^\top A^n \underline{w}$. It is clear that loop P terminates if and only if there exists an $n \in \mathbb{N}_0$ such that $u_n < 0$. Conversely, to each LRS $\langle u_n \rangle_n$ we can associate a linear loop of the form (2): one need only take A to be the transpose of the companion matrix associated with $\langle u_n \rangle_n$ so that

$$A = \begin{pmatrix} a_{d-1} & 1 & \cdots & 0 & 0 \\ \vdots & 0 & \ddots & 0 & 0 \\ a_2 & 0 & \cdots & 1 & 0 \\ a_1 & 0 & \cdots & 0 & 1 \\ a_0 & 0 & \cdots & 0 & 0 \end{pmatrix}, \underline{b}^\top = (u_{d-1}, \ldots, u_1, u_0), \text{ and } \underline{w} = (1, 0, \ldots, 0)^\top$$

in order to recover the terms $u_{n+d-1} = \underline{b}^\top A^n \underline{w}$.

Variants of the Positivity Problem have also garnered attention in the literature. For example, the *Ultimate Positivity Problem* weakens the guard clause: given an LRS $\langle u_n \rangle_n$, determine whether there exists an $N \in \mathbb{N}$ such that $u_n \geq 0$ if $n > N$. By contrast, the *Simple Positivity Problem* restricts the class of sequences under consideration to those that are simple. Here an LRS $\langle u_n \rangle_n$ is *simple* if each of the roots of the associated characteristic polynomial has algebraic multiplicity one. In this paper, we focus on the *Reversible Positivity Problem*, i.e., the restriction of the Positivity Problem to the class of LRS that are reversible (as defined below).

Background and Motivation

Lipton *et al.* [11] coined the term *reversible* to describe the class of LRS that assume exclusively integer values, whether the sequences are expanded forwards or backwards. Equivalently, such LRS can be shown to satisfy relations of the form (1) with the condition $a_0 = \pm 1$ (or, alternatively, the associated characteristic polynomial satisfies $f(0) = \pm 1$). The subclass of while loops (as in (2)) naturally associated with reversible sequences have *unimodular* update matrices. The inverse A^{-1} of a unimodular matrix A is likewise unimodular. Thus the uniquely defined bi-infinite extension $\langle u_n \rangle_{n=-\infty}^{\infty}$ with each $u_n = \underline{b}^\top A^n \underline{w}$ (as above) is integer-valued.

The decidability of Reversible Skolem – where one restricts the Skolem Problem to reversible LRS – was established up to order 7 in a recent paper by Lipton *et al.* [11]. Kenison [9] gave an alternative proof of this decidability result, leveraging a powerful result for algebraic units due to Dubickas and Smyth [5]. In general, the Skolem Problem is only known to be decidable for arbitrary LRS up to order four [12, 22]. The Positivity Problem is decidable for arbitrary LRS of order five or less [16], and for simple LRS of order 9 or less [13]. The Ultimate Positivity Problem is also decidable for arbitrary LRS of order 5 of less, as well as for simple LRS of arbitrary order [14, 16]. Previous work showed that the Positivity Problem is decidable for simple reversible LRS of order 10 or less [9].

Contributions

In this paper, we shall consider Positivity problems for reversible LRS. We will exploit spectral properties of reversible LRS and employ techniques from both Galois theory and Diophantine approximation to establish decidability at higher orders than is currently known for general positivity. Our main contributions are as follows:

▶ **Theorem 1.** *For reversible LRS, the Positivity and Ultimate Positivity Problems are both decidable up to order* 11*.*

▶ **Theorem 2.** *For simple reversible LRS, the Positivity Problem is decidable up to order* 17*.*

Structure

The remainder of this paper is structured as follows. In the next section we review necessary preliminary material. In Section 3, we prove results on the root structures of characteristic polynomials associated with reversible LRS. In Section 4, we prove Theorems 1 and 2. We also consider barriers impeding further progress to the state of the art (i.e., decidability results at higher orders) by exhibiting sequences that are not amenable to standard Diophantine approximation techniques due to certain spectral properties (see Section 5). The calculations involved in preparing these hard instances were performed in SageMath [4].

2 Preliminaries

2.1 Linear Recurrence Sequences

We expand upon the standard terminology for LRS given in the introduction. It is straightforward to see that an LRS $\langle u_n \rangle_n$ is wholly determined by a recurrence relation (as in (1)) and the initial values $u_0, u_1, \ldots, u_{d-1}$.

Let $\langle u_n \rangle_n$ be an LRS with characteristic polynomial f. It is well-known that an LRS admits a closed-form representation as an exponential polynomial; specifically, for each $n \in \mathbb{N}_0$, we have $u_n = A_1(n)\lambda_1^n + \cdots + A_\ell(n)\lambda_\ell^n$. Here the *characteristic roots* $\lambda_1, \ldots, \lambda_\ell$ are the distinct roots of f. Further, the polynomial coefficients $A_j \in \overline{\mathbb{Q}}[X]$ are completely determined by the initial values of $\langle u_n \rangle_n$. The polynomial coefficients for a simple LRS are all constants; that is, if $\langle u_n \rangle_n$ is simple, then $u_n = A_1\lambda_1^n + \cdots + A_\ell\lambda_\ell^n$.

An LRS is *degenerate* when there are two distinct characteristic roots whose quotient is a root of unity. Otherwise, the sequence is said to be *non-degenerate*.

Let $\lambda_1, \ldots, \lambda_\ell$ be the characteristic roots of an LRS $\langle u_n \rangle_n$. A characteristic root λ of $\langle u_n \rangle_n$ is *dominant* if $|\lambda| \geq |\lambda_j|$ for each $j \in \{1, \ldots, \ell\}$. By convention, when we talk about the number of dominant roots *we do not count multiplicity*; e.g., a recurrence sequence that satisfies the relation $u_{n+2} = 2u_{n+1} - u_n$ with characteristic polynomial $(X-1)^2$ has only one dominant root.

In the sequel, we will state and prove technical results for polynomials in $\mathbb{Z}[X]$. Here we say that a polynomial in $\mathbb{Z}[X]$ is *non-degenerate* if no quotient of distinct roots is a root of unity and we say that it is *reversible* if it is monic and has constant term ± 1. Note that our use of these terms for both recurrence sequences and their characteristic polynomials is consistent.

2.2 The Positivity Problem

In this subsection we briefly recall decidability results for the Positivity Problem for LRS. We first recall the standard assumptions that permit us to reduce the problem of deciding positivity to that of deciding positivity for LRS that are both non-degenerate and possess a positive dominant characteristic root.

First, it is well known (cf. [6, 8]) that we can effectively reduce the computational study of LRS to that of non-degenerate LRS. This observation follows because each degenerate LRS can be realised as an interleaving of finitely many non-degenerate LRS of the same order. Thus we need only consider non-degenerate LRS when studying positivity. We note also that this reduction preserves the quality of having simple characteristic roots.

Second, let us recall the following classical consequence of the Vivanti–Pringsheim Theorem from complex analysis [17, 23] (see also [21, Section 7.21]).

▶ **Lemma 3.** *Suppose that a non-zero LRS $\langle u_n \rangle_n$ has no positive dominant characteristic root. Then the sets $\{n \in \mathbb{N} : u_n > 0\}$ and $\{n \in \mathbb{N} : u_n < 0\}$ are both infinite.*

As a consequence of Lemma 3, we can reduce the problem of deciding positivity to LRS that possess a positive dominant characteristic root.

Together, the two preceding assumptions show that the sequences we consider have an odd number of dominant roots: the set of dominant roots comprises complex-conjugate pairs of roots and a single positive dominant root. Note that a second real dominant root would violate non-degeneracy.

Ouaknine and Worrell showed that the Simple Positivity Problem for LRS is decidable up to order nine [13]. The main technical contribution of that paper was the following result, which, in combination with the various observations above, covers all sequences up to order nine.

▶ **Theorem 4.** *Let $\langle u_n \rangle_n$ be a non-degenerate simple LRS with characteristic polynomial $f \in \mathbb{Z}[X]$ and a positive dominant root. If $f \in \mathbb{Z}[X]$ has either at most eight dominant roots or precisely nine roots, then we can determine whether $u_n \geq 0$ for each $n \in \mathbb{N}_0$.*

2.3 Number Theory

An algebraic integer is a *unit* if its multiplicative inverse is also an algebraic integer. It is a basic fact that an algebraic number is a unit if and only if its minimum polynomial in $\mathbb{Z}[X]$ is monic and has constant term ± 1. Thus the characteristic roots of a reversible LRS are all units.

A *number field* K is a field determined by a finite extension of $\mathbb{Q}$. The *splitting field* K for the polynomial $f \in \mathbb{Q}[X]$ is the field extension of $\mathbb{Q}$ with the following two properties. First, the polynomial f can be written as a product of linear factors in $K[X]$ (i.e., f splits completely in K) and second, f does not split completely over any proper subfield of K containing $\mathbb{Q}$.

2.4 Group Theory

A finite group G is said to act *transitively* on a finite set X if for each pair $x, y \in X$ there is a $g \in G$ such that $gx = y$. The *stabilizer* G_x of an element x in X is defined as the set $\{g \in G : gx = x\}$. The Orbit-Stabilizer Theorem (see, for example, [18, Theorem 3.19]) implies that if G acts transitively on X, the cardinality of G_x is the same for each $x \in X$. Further, $\#\{g \in G : gx = y\}$ is the same for all $x, y \in G$ in this scenario.

2.5 Galois Theory

We assume familiarity with basic notions in Galois theory and the theory of number fields. For reference, we recommend standard textbooks such as [3, 20]. The following includes some of the definitions and theory we use in the sequel.

Given a field extension K of $\mathbb{Q}$, we use $\mathrm{Gal}_{\mathbb{Q}}(K)$ to denote the *Galois group of K over $\mathbb{Q}$*; that is, the group of automorphisms of K that fix $\mathbb{Q}$. We shall refer to elements of a Galois group as *Galois automorphisms*. In the sequel, we shall frequently use the following property of irreducible polynomials. Let $f \in \mathbb{Q}[X]$ be an irreducible polynomial and K the splitting field of f. Then the Galois group $\mathrm{Gal}_{\mathbb{Q}}(K)$ acts transitively on the roots of f. Indeed, the *orbit* of a root of f (i.e., the set of images of the root under the group action) is the set of roots of f. In light of the above, for a given algebraic number α we use the term *Galois conjugates* to refer to set of roots of the minimal polynomial of α.

Recall the following theorem due to Kronecker [10].

▶ **Theorem 5.** *Let $f \in \mathbb{Z}[X]$ be a monic polynomial such that $f(0) \neq 0$. Suppose that all the roots of f have absolute value at most 1. Then all the roots of f are roots of unity.*

We deduce the following. If $f \in \mathbb{Z}[X]$ is the characteristic polynomial of a reversible LRS $\langle u_n \rangle_n$ such that the roots of f all lie in the unit disk $\{z \in \mathbb{C} : |z| \leq 1\}$, then the roots of f are all roots of unity and so $\langle u_n \rangle_n$ is of order one or degenerate. In the former case, positivity of $\langle u_n \rangle_n$ is easily determined and in the latter case, determining whether $\langle u_n \rangle_n$ is positive reduces to studying positivity for associated non-degenerate LRS. Thus in the sequel we shall always assume, without loss of generality, that the dominant roots of f lie on a circle with radius strictly larger than 1.

The roots of an irreducible polynomial are necessarily Galois conjugates. We call the quotient of two distinct roots of an irreducible polynomial a *conjugate ratio*.

Key to the technical lemmas we prove in the sequel are results concerning identities between the roots of irreducible polynomials. We employ a powerful result due to Dubickas and Smyth [5], Theorem 6 below, concerning necessary conditions for an algebraic unit and all its Galois conjugates to lie on two concentric circles centred at the origin. (Theorem 6 is a specialisation of the general result [5, Theorem 2.1].)

▶ **Theorem 6.** *Suppose that $f \in \mathbb{Z}[X]$ is an irreducible, reversible polynomial of degree d such that all the roots of f lie on two circles centred at the origin. Let r and R be the radii of the respective circles and, without loss of generality, suppose that at most half of the roots of f lie on the circle of radius r. Then we have the following: either d is even, in which case half of the roots lie on the circle of radius r; or d is a multiple of three and a third of the roots lie on the circle of radius r. In the latter case, we additionally have that for every root β on the circle of radius r there exists $n > 0$ such that $\beta^n \in \mathbb{R}$.*

We shall frequently employ the following lemma, versions of which were proved by Smyth [19] and Ferguson [7].

▶ **Lemma 7.** *Suppose that λ is an algebraic number with Galois conjugates β and γ satisfying $\lambda^2 = \beta\gamma$. Then the conjugate ratio λ/β is a root of unity.*

3 Root Analysis of Reversible Polynomials

The main result of this section is Theorem 14, concerning the number of dominant roots of a reversible polynomial. Essentially the theorem says that, excepting a number of special cases, no more than half of the roots of such a polynomial can be dominant. This is the key technical tool behind our main decidability results for the Positivity Problem for reversible LRS.

Let us begin with two lemmas concerning the dominant roots of reversible polynomials. These can be considered as weak forms of the main result of the section (and are used in the proof thereof).

▶ **Lemma 8.** *Let $f \in \mathbb{Z}[X]$ be an irreducible non-degenerate polynomial with a real dominant root λ. Then f has exactly one dominant root.*

Proof. Let λ be a real dominant root. Suppose β is also a dominant root. Then $\lambda^2 = \beta\overline{\beta}$ and hence λ/β is a root of unity by Lemma 7. Since f is non-degenerate we have $\lambda = \beta$; that is, f has exactly one dominant root. ◀

▶ **Lemma 9.** *Suppose that $f \in \mathbb{Z}[X]$ is irreducible, non-degenerate, and reversible, with $2m$ non-real dominant roots and no real dominant roots. Then $\deg(f) > 3m$ if $m \geq 2$. Further, $\deg(f) \leq 3m$ only if $(\deg(f), m) = (3, 1)$ or f is constant.*

Proof. Since f has at least $2m$ roots, it is clear that $\deg(f) \geq 2m$. The case where $m = 0$ pertains to constant polynomials, thus we need only consider the case when $m \geq 1$.

We will first show that $\deg(f) > 2m$. Assume, for a contradiction, that $\deg(f) = 2m$. Then the roots of f all lie on the circumference of some circle centred at the origin. We make the following two observations. First, f is reversible, and hence monic. Second, by Vieta's formulas, $|f(0)| = 1$ is equal to the absolute value of the product of the roots of f. From these observations, we conclude that the roots of f all lie on the unit circle and, by Theorem 5, are therefore roots of unity. As $m \geq 1$, f has at least two roots, and their conjugate ratio is thus a root of unity. We have reached a contradiction: f is assumed to be non-degenerate. Thus $\deg(f) > 2m$.

Consider the subcase where $m = 1$. Assume that $2m < \deg(f) \leq 3m$, then clearly we have $\deg(f) = 3$. The assertion in the lemma trivially holds. Hereafter we assume that $m \geq 2$.

We now show that under the assumption that $m \geq 2$, we necessarily have $\deg(f) \geq 3m$. Let $\lambda_1, \overline{\lambda_1}, \ldots, \lambda_m, \overline{\lambda_m}$ be the $2m$ dominant roots of f. Thus $\lambda_1\overline{\lambda_1} = \lambda_i\overline{\lambda_i}$ for each $i \in \{1, \ldots, m\}$. Since $2m < \deg(f)$, f has a non-dominant root γ. Further, since f is irreducible, there is a Galois automorphism σ such that $\sigma(\lambda_1) = \gamma$. We claim that for each $i \in \{2, \ldots, m\}$ at least one of $\sigma(\lambda_i)$ and $\sigma(\overline{\lambda_i})$ is a non-dominant root of f. Assume, for a contradiction, that the claim does not hold. Then there is an $i \in \{2, \ldots, m\}$ such that both $\sigma(\lambda_i)$ and $\sigma(\overline{\lambda_i})$ are dominant roots. The map σ necessarily preserves polynomial symmetries between the roots of f and so $\gamma\sigma(\overline{\lambda_1}) = \sigma(\lambda_i)\sigma(\overline{\lambda_i})$. However, since $\sigma(\lambda_1) = \gamma$ is strictly smaller in absolute value than both $\sigma(\lambda_i)$ and $\sigma(\overline{\lambda_i})$, we have $|\gamma\sigma(\overline{\lambda_1})| < |\sigma(\lambda_i)\sigma(\overline{\lambda_i})|$. This last inequality contradicts the aforementioned symmetry between dominant roots. We conclude that the list of non-dominant roots of f includes γ and at least one of $\sigma(\lambda_i)$ and $\sigma(\overline{\lambda_i})$ for each $i \in \{2, \ldots, m\}$. Thus f has at least m non-dominant roots and so $\deg(f) \geq m + 2m = 3m$.

Finally, we eliminate the case that $\deg(f) = 3m$ when $m \geq 2$. Assume, for a contradiction, that $\deg(f) = 3m$. We can apply the preceding argument to the reciprocal polynomial of f to deduce that the m non-dominant roots of f are equal in modulus and so all lie on a circle $\{z \in \mathbb{C} : |z| = r\}$ for some $r > 0$. Thus all roots of the irreducible and reversible polynomial

f lie on two circles centred at the origin: the dominant roots all lie on one circle, and all the non-dominant roots lie on another circle. Thus, by Theorem 6, each non-dominant root of f takes the form $re^{i\theta}$ where $e^{i\theta}$ is a root of unity. Since $m \geq 2$, there are at least two distinct roots of f, say, $re^{i\theta}$ and $re^{i\theta'}$ of the prescribed form. It follows that the conjugate ratio $re^{i\theta}/re^{i\theta'}$ is a root of unity, which contradicts our assumption that f is non-degenerate. Hence $\deg(f) > 3m$ if $m \geq 2$, from which the desired result follows. ◀

In order to improve the bound from from $\deg(f) > 3m$ to $\deg(f) \geq 4m$, we shall introduce new and novel techniques for counting symmetries in the roots of f. Let $\lambda_1, \ldots, \lambda_\ell$ be the roots of f. The interesting case occurs when all the dominant roots of f are non-real. Let us denote the dominant roots of f by $\lambda_1, \overline{\lambda_1}, \ldots, \lambda_m, \overline{\lambda_m}$. Let $\mu_1 := \lambda_1\overline{\lambda_1}$ and g be the minimal polynomial of μ_1 (hereafter we shall refer to g as the *dominating polynomial of* f). Let $\mu_2, \ldots, \mu_n$ be the Galois conjugates of μ_1 (and thus the other roots of g) and $\sigma_1, \ldots, \sigma_n$ the Galois automorphisms associated with g such that $\sigma_j(\mu_1) = \mu_j$.

Set $K = \mathbb{Q}(\mu_1, \ldots, \mu_n)$ and $L = \mathbb{Q}(\lambda_1, \ldots, \lambda_\ell)$. Clearly, $K \subset L$, and so each σ_j can be lifted to an automorphism $\widetilde{\sigma_j}$ in $\mathrm{Gal}_{\mathbb{Q}}(L)$ such that $\widetilde{\sigma_j}|_K = \sigma_j$. Applying these $\widetilde{\sigma_j}$ on $\lambda_1\overline{\lambda_1} = \cdots = \lambda_m\overline{\lambda_m} = \mu_1$ gives rise to the following n equations:

$$\begin{aligned} \alpha_{1,1,1}\alpha_{1,1,2} &= \ldots = \alpha_{m,1,1}\alpha_{m,1,2} &&= \mu_1 \\ \vdots \quad &\quad \vdots \quad &&\quad \vdots \\ \alpha_{1,n,1}\alpha_{1,n,2} &= \ldots = \alpha_{m,n,1}\alpha_{m,n,2} &&= \mu_n \end{aligned} \tag{3}$$

where $\alpha_{i,j,1} = \widetilde{\sigma_j}(\lambda_i)$ and $\alpha_{i,j,2} = \widetilde{\sigma_j}(\overline{\lambda_i})$. Since each $\alpha_{i,j,k}$ is a Galois conjugate of a dominant root of f, we determine that each $\alpha_{i,j,k}$ is also a root f. Given a root λ of f, we define the *equation number*

$$E = \#\{(i,j,k) : \alpha_{i,j,k} = \lambda \text{ for } 1 \leq i \leq m, 1 \leq j \leq n, k = 1,2\}.$$

In Lemma 11, we will show that E is independent of the choice of root λ. It is useful to see the two roots of f in one position in one equation in (3) as a *pair*. In other words, $\alpha_{i,j,1}$ and $\alpha_{i,j,2}$ are *paired* for all $1 \leq i \leq m$ and $1 \leq j \leq n$. Further, for $j = 1, \ldots, n$, let $\mathscr{A}_j := \{\alpha_{1,j,1}, \alpha_{1,j,2}, \ldots, \alpha_{m,j,1}, \alpha_{m,j,2}\}$. Note that $\#\mathscr{A}_j = 2m$, as $\widetilde{\sigma_j}$ is a bijection between the set of dominant roots of f and $\mathscr{A}_j$.

We claim that $\mathscr{A}_j$ is independent of the choice of lift $\widetilde{\sigma_j}$ of σ_j. If λ and λ' are roots of f such that $\lambda\lambda' = \mu_j$, then $\widetilde{\sigma_j}^{-1}(\lambda)\widetilde{\sigma_j}^{-1}(\lambda') = \mu_1$. Because $\widetilde{\sigma_j}^{-1}(\lambda)$ and $\widetilde{\sigma_j}^{-1}(\lambda')$ are roots of f whose product is equal to $\mu_1 = \lambda_1\overline{\lambda_1}$, we easily deduce that both $\widetilde{\sigma_j}^{-1}(\lambda)$ and $\widetilde{\sigma_j}^{-1}(\lambda')$ are dominant roots of f. Further, since $\widetilde{\sigma_j}$ is a bijection, $\lambda = \widetilde{\sigma_j}\big(\widetilde{\sigma_j}^{-1}(\lambda)\big) \in \mathscr{A}_j$ (and similarly $\lambda' \in \mathscr{A}_j$). We make two deductions. First, if μ_j is the product of two distinct roots of f then those roots are two elements of $\mathscr{A}_j$. Second, we infer our claim that $\mathscr{A}_j$ is independent of the choice of $\widetilde{\sigma_j}$.

In the case of one dominant root, the same construction applies: g is defined as the minimum polynomial of λ_1^2, where λ_1 is the sole dominant root of f. By non-degeneracy, the squares of all roots of f are distinct, and so $\deg(f) = \deg(g)$, $\mu_j = \lambda_j^2$ for $j = 1, \ldots, \deg(f)$ and $E = 2$ for all roots of f (it appears once as a square). Only, $\mathscr{A}_j = \{\lambda_j\}$ consists of exactly one root of f.

▶ **Lemma 10.** *Suppose that $f \in \mathbb{Z}[x]$ is reversible, non-degenerate, and irreducible with $2m$ non-real dominant roots and has degree less than $4m$. Write g for the dominating polynomial of f. Then g is also non-degenerate.*

Proof. Assume, for a contradiction, that the conjugate ratio $\mu_j/\mu_{j'}$ of g is a root of unity. Both root sets $\mathscr{A}_j$ and $\mathscr{A}_{j'}$ have cardinality $2m$. Since $\deg(f) < 4m = \#\mathscr{A}_j + \#\mathscr{A}_{j'}$, we deduce that $\mathscr{A}_j \cap \mathscr{A}_{j'}$ is non-empty. Let $\lambda \in \mathscr{A}_j \cap \mathscr{A}_{j'}$ and κ, κ' be roots of f such that $\lambda\kappa = \mu_j$ and $\lambda\kappa' = \mu_{j'}$. Since $\mu_j \neq \mu_{j'}$, we have $\kappa \neq \kappa'$. It follows that f is degenerate because $\kappa/\kappa' = \mu_j/\mu_{j'}$ is a root of unity. From this contradiction, we deduce that g is non-degenerate. ◀

▶ **Lemma 11.** *Suppose that $f \in \mathbb{Z}[X]$ is reversible, non-degenerate, and irreducible with $2m$ non-real dominant roots. Write g for the dominant polynomial of f. Then all the roots of f have the same equation number E and*

$$2m \deg(g) = E \deg(f). \tag{4}$$

Proof. We use the notation of $\lambda_i, \mu_j, \sigma_j, \widetilde{\sigma_j}$, $\alpha_{i,j,k}$, K, L, etc. as above.

Set $H = \mathrm{Gal}_{\mathbb{Q}}(K)$ and $G = \mathrm{Gal}_{\mathbb{Q}}(L)$. By the Orbit-Stabilizer Theorem, the number of $\sigma \in H$ such that $\sigma(\mu_1) = \mu_j$ is independent of the choice of $j \in \{1, \ldots, n\}$. Now each $\sigma \in H$ has the same number of lifts to G, and so the number of elements of G that map μ_1 to each μ_j is independent of $j \in \{1, \ldots, n\}$. Thus the number of elements of G such that the image of $\mathscr{A}_1$ is $\mathscr{A}_j$ is also independent of the choice of j.

We make the following claim whose proof is given immediately below.

▷ Claim 12. In the setting defined above, there is no pair of distinct j_1 and j_2 for which $\mathscr{A}_{j_1} = \mathscr{A}_{j_2}$.

We also make the following observation. By the Orbit-Stabilizer Theorem, for every choice of two roots λ and λ' of f, the number of $\sigma \in G$ such that $\sigma(\lambda) = \sigma(\lambda')$ is equal. Thus for each root λ of f, the number of $\sigma \in G$ such that one of $\widetilde{\sigma}(\lambda_1), \widetilde{\sigma}(\overline{\lambda_1}), \ldots, \widetilde{\sigma}(\lambda_m), \widetilde{\sigma}(\overline{\lambda_m})$ equals λ is independent of the choice of λ. This shows that the equation number E is independent of the choice of the root λ.

The equation $2m \deg(g) = E \deg(f)$ follows from counting the number of $\alpha_{i,j,k}$. On the one hand, there are $\deg(g)$ equations with $2m$ entries (Claim 12). On the other hand, there are $\deg(f)$ roots each appearing E times. ◀

Proof of Claim 12. Let us assume, for a contradiction, that $\mathscr{A}_{j_1} = \mathscr{A}_{j_2}$ for $j_1 \neq j_2$. Then $\mu_{j_1} \neq \mu_{j_2}$ and

$$\mu_{j_1}^m = \prod_{i=1}^{m} \alpha_{i,j_1,1}\alpha_{i,j_1,2} = \prod_{i=1}^{m} \alpha_{i,j_2,1}\alpha_{i,j_2,2} = \mu_{j_2}^m.$$

Thus μ_{j_1}/μ_{j_2} is a root of unity. Since $\alpha_{1,j_1,1} \in \mathscr{A}_{j_2}$, there are $1 \leq i \leq m$ and $k \in \{1, 2\}$ such that $\alpha_{1,j_1,1} = \alpha_{i,j_2,k}$. Then we have that the conjugate ratio $\alpha_{1,j_1,2}/\alpha_{i,j_2,3-k}$ given by

$$1 \neq \frac{\mu_{j_1}}{\mu_{j_2}} = \frac{\alpha_{1,j_1,1}\alpha_{1,j_1,2}}{\alpha_{i,j_2,1}\alpha_{i,j_2,2}} = \frac{\alpha_{1,j_1,2}}{\alpha_{i,j_2,3-k}}$$

is also a root of unity. Since $\alpha_{1,j_1,2}$ and $\alpha_{i,j_2,3-k}$ are distinct roots of f whose quotient is a root of unity, it follows that f is degenerate. We have reached a contradiction to our assumption that f is non-degenerate. Thus we have the claimed result. ◁

The next result increases the bound on the degree of f to $\deg(f) \geq 4m$.

▶ **Theorem 13.** *Let $f \in \mathbb{Z}[X]$ be an irreducible, non-degenerate, and reversible polynomial with $2m$ dominant non-real roots and no real dominant roots, then $(\deg(f), m) = (3, 1)$ or $\deg(f) \geq 4m$.*

Proof. Assume, for a contradiction, that f is a minimal counterexample in the sense that all polynomials of strictly smaller degree satisfy the statement in Theorem 13.

From Lemma 9, we deduce that $\deg(f) > 3m$ if we are not in the exceptional case $(\deg(f), m) = (3, 1)$. As we assume that f is a counterexample to Theorem 13, $\deg(f) < 4m$ as well. We shall employ the preceding notation for the dominating polynomial g, the sets of roots $\mathscr{A}_j$ of f, and the equation number E.

Consider that there are $2m$ distinct roots of f in each equation in (3). Since $\deg(f) < 4m$ and f has $2m$ dominant roots, there is at least one dominant root of f in each such equation. Let γ be a root of f with minimal absolute value, then $|\gamma\lambda_1|$ is the minimal absolute value attained by any root of g. We now show that at least half of the roots of g lie on the circle $\{z \in \mathbb{C} : |z| = |\gamma\lambda_1|\}$. Observe that γ is witnessed in E (and so more than half) of the pairings in (3) and, further, is necessarily paired with a dominant root (for otherwise, a pairing between γ and a non-dominant root breaks the equality in (3)). From (4) and our assumption that $\deg(f) < 4m$, we deduce that $2E > \deg(g)$, and so γ appears in more than half of the equations in (3). Each such equation is in correspondence with a root of g of minimal absolute value.

Consider the polynomial $h(X) := g(0)X^n g(X^{-1})$. The polynomial $X^n g(X^{-1})$ is the reciprocal polynomial of g and so immediately, the roots of h are precisely $\mu_1^{-1}, \ldots, \mu_n^{-1}$ and $n = \deg(g) = \deg(h)$. From the preceding discussion, more than half of the roots of h are dominant. Moreover, we can easily deduce that h is reversible, irreducible, and non-degenerate as g has these properties. Thus h is another counterexample to the statement in Theorem 13. All that remains is to derive a contradiction from our assumption that f has minimal degree. We derive this contradiction by proving that $\deg(h) < \deg(f)$ and h does not belong to either one of the exceptional cases.

Observe that h cannot belong to one of the exceptional cases since (4) has no integer solutions when $n = 1, 2, 3$ and $3m < \deg(f) < 4m$. Thus it remains to show that $n \geq \deg(f)$ is absurd. Let us assume, for a contradiction, that λ_1 appears in a product pair with a dominant root other than $\overline{\lambda_1}$ in the jth equation of (3). Then μ_1 and μ_j have equal absolute value. If μ_j is real, $\mu_1/\mu_j = \pm 1$ contradicting our non-degeneracy assumption (Lemma 10). Similarly, we derive a contradiction to our non-degeneracy assumption if μ_j is non-real by Lemma 7. Thus, we can pair λ_1 with the $\deg(f) - 2m < 2m$ non-dominant roots of f and $\overline{\lambda_1}$. This gives the upper bound $E \leq \deg(f) - 2m + 1 \leq 2m$ on E. We substitute our assumption that $n = \deg(g) \geq \deg(f)$ into (4) to obtain a lower bound $2m \leq E$. Thus, $E = 2m$.

We use the equality $E = 2m$ to deduce that $\deg(f) = 4m - 1$ and make the following observations. Each of the $2m$ dominant roots of f pair with their respective complex conjugate and all of the $2m - 1$ non-dominant roots of f. Thus we can pair each non-dominant root of f with $2m$ dominant roots. Further, every pair of non-dominant roots of f appears in at least one equation in (3). Thus the roots of g and h lie on two concentric circles centred at the origin. The roots of g are distributed so that g has exactly one dominant root and $2m + (2m - 1) - 1 = 4m - 2$ non-dominant roots. By construction, h has exactly one non-dominant root and $4m - 2$ dominant roots. This distribution of roots is not possible by Theorem 6, hence a contradiction.

In summary, f cannot be a counterexample to Theorem 13 of smallest possible degree. We thus deduce that all polynomials that satisfy the hypothesis in the theorem obey the bound $\deg(f) \geq 4m$, as required. ◀

The only superfluous assumption in Theorem 13 is that f is irreducible. We circumvent the irreducibility assumption with a careful case analysis.

▶ **Theorem 14.** *Let f be a non-degenerate reversible polynomial. Suppose that more than half of the roots of f are dominant. Then either f is linear or f is cubic with two dominant roots.*

Proof. Let f be a counterexample of minimal degree, and factor f into irreducible polynomials $f_1, \ldots, f_k$. For $1 \leq i \leq k$, let m_i' be the number of dominant roots of f_i. Call an irreducible factor *sharp* if $2m_i' = \deg(f_i)$ and *special* if $2m_i' > \deg(f_i)$. From Lemma 8 and Theorem 13, it follows that if an irreducible factor is special, then $(\deg(f_i), m_i') = (1,1)$ or $(3,2)$. If $k = 1$, then f is irreducible and the result follows automatically. Thus we can freely assume that $k \geq 2$. Since f is a counterexample of minimal degree, a straightforward proof by contradiction permits us to assume $k = 2$. Thus our argument reduces to the following cases: we need only show that the product of either two special polynomials or a special and a sharp polynomial breaks the hypothesis. By renumbering, we can assume f_1 is special and f_2 is either sharp or special. We observe that under our assumptions the dominant roots of f_1 and f_2 are necessarily equal in absolute value and, as we do not count multiplicity, $f_1 \neq f_2$.

We begin our case analysis. First, consider the case where $(\deg(f_1), m_1') = (1,1)$. Then $f_1(X) = X \pm 1$ as f_1 is reversible. Since the root ∓ 1 of f_1 is a dominant root of f, we deduce that all roots of f lie on the unit circle as the roots of f are algebraic units. When we combine Lemma 8, Theorem 13, and our assumption that at least half of the roots of f are dominant, we deduce that $(\deg(f_2), m_2') = (1,1)$ and so $f_2(X) = X \mp 1$. Thus -1 and 1 are both roots of f, which contradicts our assumption that f is non-degenerate.

Second, let us suppose that $(\deg(f_1), m_1') = (3,2)$. Following the argument in the preceding case, either $(\deg(f_2), m_2') = (3,2)$ or $\deg(f_2) = 2m_2'$. In the former, the non-dominant roots γ_1 and γ_2 of f_1 and f_2 (respectively) are both real and equal in modulus. This is straightforward to see since each f_j is of the form $f_j = (x - \gamma_j)(x - R\mathrm{e}^{\mathrm{i}\theta_j})(x - R\mathrm{e}^{-\mathrm{i}\theta_j})$ for some $R > 1$ and $\gamma_j := \pm R^{-2}$. We cannot have two such irreducible factors since then the ratio $\gamma_1/\gamma_2 = \pm 1$, which breaks either the non-degeneracy assumption on f or the assumption that $f_1 \neq f_2$.

We continue with the latter subcase $(\deg(f_1), m_1') = (3,2)$ and $\deg(f_2) = 2m_2'$. Since the dominant roots of f_1 and f_2 are dominant roots of f, the dominating polynomials of f_1 and f_2 are one and the same, say g. Let E_1 and E_2 be the respective equation numbers of f_1 and f_2. From (4), $2\deg(g) = E_1 \deg(f_1) = 3E_1$. We thus deduce that E_1 is even. Since $1 \leq E_1 \leq \deg(f_1) = 3$ (each pairing is distinct), we have that $E_1 = 2$ and, it follows immediately, $\deg(g) = 3$. We substitute this result and our assumption that $\deg(f_2) = 2m_2'$ into (4) in order to obtain $m_2' \deg(g) = 3m_2' = 2E_2 m_2'$. We have reached a contradiction: $E_2 = 3/2$ is not an integer. We have exhausted the possibilities for constructing a minimal counterexample f and find that no such counterexample exists. We have thus proved Theorem 14. ◀

4 Decidability at Low Orders

In this section we complete the proofs of our two main theorems concerning the Positivity Problem for reversible LRS. We start with Theorem 2, which states that positivity of reversible sequences that are moreover simple is decidable up to order 17.

Proof of Theorem 2. As previously noted, we can reduce the Simple Reversible Positivity Problem to deciding positivity for the subclass of simple reversible LRS that are additionally both non-degenerate and in possession of a positive dominant root.

In light of the preceding paragraph, consider the subclass of non-degenerate, simple, and reversible LRS with a positive dominant root. Let f be the characteristic polynomial associated with a sequence in this class. Without loss of generality, we can additionally

assume that fewer than half of the roots of f are dominant. If $f \in \mathbb{Z}[X]$ has at least nine dominant roots, then, by Theorem 14, we have the bound $\deg(f) \geq 18$. Taking the contrapositive, if f is again the characteristic polynomial of a sequence in this subclass with $\deg(f) \leq 17$, then f has at most eight dominant roots.

Now we invoke Theorem 4 to deduce that, in the aforementioned subclass, positivity is decidable for LRS up to order 17. As noted at the beginning of this proof, this deduction is sufficient to obtain the desired result: simple reversible positivity is decidable up to order 17. ◀

We now turn our attention to general reversible sequences; i.e., we no longer assume that the characteristic roots are simple. Here, as stated in Theorem 1, we have decidability up to order 11.

Proof of Theorem 1. Assume, for a contradiction, that $\langle u_n \rangle_n$ is a reversible LRS and counterexample to the statement; that is to say, $\langle u_n \rangle_n$ is a reversible LRS with order at most 11 for which we cannot determine positivity or ultimate positivity.

From our earlier discussion on the Positivity Problem and Ultimate Positivity Problem in Subsection 2.2, it follows that we can reduce both problems for reversible LRS to deciding (ultimate) positivity for the subclass of reversible LRS that are additionally both non-degenerate and in possession of a positive dominant root.

For the class of reversible LRS with one dominant root, decidability of (ultimate) positivity is considered folklore. Thus we freely assume that $\langle u_n \rangle_n$ has at least three dominant roots (the positive root and a pair of complex conjugate roots). By Theorem 2 for positivity and the earlier mentioned results in [14] for ultimate positivity, we can also assume that $\langle u_n \rangle_n$ has a non-simple characteristic root. Now consider the exponential polynomial representation of $\langle u_n \rangle_n$: deciding (ultimate) positivity for LRS whose dominant characteristic roots are all simple reduces to deciding (ultimate) positivity for simple LRS. So, in addition, we shall assume that $\langle u_n \rangle_n$ has a non-simple dominant characteristic root. We will use the following claims, whose proofs are given immediately below.

▷ Claim 15. Suppose that the real positive dominant root ρ of sequence $\langle u_n \rangle_n$ (as above) is the only non-simple dominant root of $\langle u_n \rangle_n$. Then we can determine whether $\langle u_n \rangle_n$ is (ultimately) positive.

▷ Claim 16. Suppose that sequence $\langle u_n \rangle_n$ (as above) possesses non-real dominant roots that are not simple and, further, that the real dominant root ρ is simple. Then $\langle u_n \rangle_n$ is neither ultimately positive nor positive.

In light of the preceding claims, we freely assume that the counterexample $\langle u_n \rangle_n$ has at least three non-simple dominant characteristic roots and this collection must include the real dominant root ρ as well as a complex conjugate pair λ and $\overline{\lambda}$.

Let f be the monic integer-valued polynomial of the smallest degree with ρ and λ as roots. Then, f is non-degenerate and reversible. By Theorem 14, it follows that at most half of the roots of f are dominant if f is neither linear nor cubic with two dominant roots. As such, f has degree at least 6 and, additionally, as each of these roots is non-simple being a Galois conjugate of either ρ or λ, $\langle u_n \rangle_n$ has order at least 12.

We thus deduce the desired result: positivity and ultimate positivity are decidable for sequences up to order 11. ◀

Proof of Claim 15. Suppose that the real positive dominant root ρ of $\langle u_n \rangle_n$ is the only non-simple dominant root of the sequence. If such a phenomenon were to take place then $u_n = A_\rho(n)\rho^n + O(\rho^n)$ where A_ρ is a non-constant polynomial. It is straightforward to deduce that $\langle u_n \rangle_n$ is (ultimately) positive if and only if $A_\rho(n)$ is (ultimately) positive in this instance. ◁

Proof of Claim 16. We will show that the claim follows from Lemma 17 (cf. [1]).

▶ **Lemma 17.** *Let $\gamma_1, \ldots, \gamma_k \in \{z \in \mathbb{C} : |z| = 1, z \neq 1\}$ be distinct complex numbers, $\alpha_1, \ldots, \alpha_k \in \mathbb{C} \setminus \{0\}$, and $w_n = \sum_{\ell=1}^{k} \alpha_\ell \gamma_\ell^n$. Then there is a $c < 0$ such that $\mathrm{Re}(w_n) < c$ for infinitely many n.*

To prove the claim, let d be the maximum of the degrees of the roots of $\langle u_n \rangle_n$. Note $d \geq 1$ since, by assumption, $\langle u_n \rangle_n$ has a non-real dominant root that is not simple. We consider the normalised sequence $\langle v_n \rangle_n$ with terms given by $v_n = u_n/(\rho^n n^d)$ where ρ is the dominant root of $\langle u_n \rangle_n$. Note it is sufficient to establish that $\langle v_n \rangle_n$ is neither positive nor ultimately positive to obtain the desired result.

An analysis of the exponential polynomial of $\langle u_n \rangle_n$ leads to

$$v_n = \sum_{\ell=1}^{2k} \frac{A_\ell(n)}{n^d} \frac{\lambda_\ell^n}{\rho^n} + O(n^{-d})$$

where $\lambda_1, \ldots, \lambda_{2k}$ are the non-real dominant roots of $\langle u_n \rangle_n$ and the implied constant associated with $O(n^{-d})$ is real-valued. Let α_ℓ be the leading coefficient of $A_\ell(n)$. Then $A_\ell(n)/n^d \to \alpha_\ell$ as $n \to \infty$. Now

$$v_n < r(n) + \sum_{\ell=1}^{2k} \alpha_\ell \frac{\lambda_\ell^n}{\rho^n} =: r(n) + w_n$$

where $r(n) \in O(n^{-1})$ is real-valued and the LRS $\langle w_n \rangle_n$ is both real-valued and simple. In addition, the characteristic roots of $\langle w_n \rangle_n$ are all non-real and lie on the unit circle. For the avoidance of doubt, the exponential polynomial defining $\langle w_n \rangle_n$ is real-valued since the summands $\alpha_\ell \lambda_\ell^n/\rho^n$ for non-real λ_ℓ occur in complex-conjugate pairs. Thus, w_n satisfies the hypothesis in Lemma 17, and so the inequalities $v_n < r(n) + w_n < r(n) + c$ hold for some $c < 0$ and infinitely many n. Since $r(n) \in O(n^{-1})$, we find that for infinitely many n, $v_n < 0$. Hence $\langle u_n \rangle_n$ is neither positive nor ultimately positive. ◁

5 Hard Instances

In this section we discuss obstacles to extending our results for deciding positivity of reversible LRS of higher orders. Specifically, we construct a simple reversible LRS of order 18 and sketch the construction of a reversible LRS of order 12 that, to the best of our knowledge, lie outside the known classes for which the Positivity Problem can be decided. In particular, these examples lie beyond the scope of Theorem 4.

We start with simple reversible LRS of order 18. In order to illustrate the technical arguments and guide our construction of a hard instance, it is useful to recall the techniques employed by Ouaknine and Worrell in their proof of Theorem 4 [13]. For the sake of brevity, we shall give only a brief outline here; we direct the interested reader to the full argument given in [13].

5.1 Sketch proof of Theorem 4

Let $\langle u_n \rangle_n$ be a simple LRS satisfying the assumptions of Theorem 4. We first normalise $\langle u_n \rangle_n$ and so assume that the dominant roots $\lambda_1, \ldots, \lambda_k$ of $\langle u_n \rangle_n$ lie on the unit circle in the complex plane. Then, for each $n \in \mathbb{N}$,

$$u_n = \alpha_1 \lambda_1^n + \cdots + \alpha_k \lambda_k^n + \beta_1 \xi_1^n + \cdots + \beta_{k'} \xi_{k'}^n$$

where $\xi_1, \ldots, \xi_{k'}$ are the non-dominant roots of $\langle u_n \rangle_n$ and $\alpha_1, \ldots, \alpha_k, \beta_1, \ldots, \beta_{k'}$ are algebraic numbers.

We then compute a basis for the multiplicative relations between the dominant roots and consider a maximal subset $\lambda_1, \ldots, \lambda_\ell$ whose elements are multiplicatively independent. By Kronecker's Theorem on simultaneous Diophantine approximation (cf. [2, page 53]), $\{(\lambda_1^n, \ldots, \lambda_\ell^n) : n \in \mathbb{N}\}$ is a dense subset of the torus $T := \{z \in \mathbb{C} : |z| = 1\}^\ell$, which is compact.

Ouaknine and Worrell then construct a continuous function $\tau \colon T \to \mathbb{R}$ given by

$$\tau(\lambda_1^n, \ldots, \lambda_\ell^n) = \alpha_1 \lambda_1^n + \cdots + \alpha_k \lambda_k^n$$

with the following properties. If $\min_T \tau = 0$, the given sequence $\langle u_n \rangle_n$ is ultimately positive. That is to say, there is a number N such that $u_n \geq 0$ for all $n \geq N$. If $\min_T \tau < 0$, the sequence is not ultimately positive (and thus also not positive). Finally, if $\min_T \tau > 0$, then the sequence grows quickly, and deciding positivity is relatively straightforward. Hence the critical case occurs when $\min_T \tau = 0$. Moreover, we can determine which of the three cases occur (that is, compute $\min_T \tau$).

In the critical case where $\min_T \tau = 0$, we can sometimes exploit the set of points $Z = \{(z_1, \ldots, z_\ell) \in T : \tau(z_1, \ldots, z_\ell) = 0\}$ where the minimum is attained. If $(z_1, \ldots, z_\ell) \in Z$, then Baker's Theorem on linear forms shows that λ_1^n cannot get too "close" to z_1 for n greater than a computable bound. As such, if Z is finite, then we can decide whether $\langle u_n \rangle_n$ is positive.

Theorem 4 is now proven as follows. If $\langle u_n \rangle_n$ has at most eight dominant characteristic roots and falls into the critical case, then Z is finite. Likewise, if $\langle u_n \rangle_n$ has exactly nine characteristic roots all of which are dominant, then $\langle u_n \rangle_n$ is positive in the critical case as $u_n \geq \min_T \tau = 0$.

The approach described breaks down when there are nine dominant roots since then Z is possibly infinite. Briefly, in this setting the state of the art cannot show that $(\lambda_1^n, \ldots, \lambda_\ell^n)$ does not approach this infinite set too "closely". Thus we encounter examples of LRS where we cannot currently determine positivity.

5.2 Constructing a hard example of a simple sequence of order 18

Our hard example is constructed from a function τ that assumes its minimum infinitely often on the torus $T = \{(z_1, z_2) \in \mathbb{C} : |z_1| = |z_2| = 1\}$. To this end, we define $\tau : T \to \mathbb{R}$ by

$$\tau(z_1, z_2) = (a z_1 + \overline{a} z_1^{-1} + b z_2 + \overline{b} z_2^{-1})^2 \tag{5}$$

for some non-zero $a, b \in \mathbb{C}$ with $|a| \neq |b|$. Then $\min_T \tau$ is equal to 0 and τ attains its minimum on an infinite subset of T. This property prevents the application of Theorem 4.

▶ **Example 18.** We shall construct a simple reversible LRS sequence of order 18. An analysis of the spectral properties of this sequence shows that it lies beyond the current state-of-the-art techniques for deciding positivity. This hard instance is derived from the irreducible polynomial

$$f(X) = X^8 - 3X^7 + 4X^6 - 4X^5 + 11X^4 - 21X^3 + 19X^2 - 7X + 1,$$

which has eight non-real roots $\lambda_1, \ldots, \overline{\lambda_4}$ such that λ_1 and λ_2 are dominant, λ_3 and λ_4 are both non-dominant, and $1.143 \approx |\lambda_3| > 1 > |\lambda_4|$.

Let $\phi := (1+\sqrt{5})/2$ denote the golden ratio. Then, with a certain labelling of complex conjugates,

$$\lambda_1\overline{\lambda_1} = \lambda_2\overline{\lambda_2} = \phi^2 \quad \text{and} \quad \lambda_3\lambda_4 = \overline{\lambda_3}\,\overline{\lambda_4} = \phi^{-2},$$

which, due to the number of relations, severely limits the possible Galois automorphisms. In particular, the Galois group has the form of a *wreath product* $D_4 \wr C_2$. Thus a dihedral group D_4 acts on $\lambda_1, \overline{\lambda_1}, \lambda_2$, and $\overline{\lambda_2}$ and is generated by the elements (written in cycle notation) $(\lambda_1\ \lambda_2\ \overline{\lambda_1}\ \overline{\lambda_2})$ and $(\lambda_1\ \overline{\lambda_1})$. A second dihedral group D_4 acts on $\lambda_3, \overline{\lambda_3}, \lambda_4, \overline{\lambda_4}$ and is generated by $(\lambda_3\ \overline{\lambda_3}\ \lambda_4\ \overline{\lambda_4})$ and $(\lambda_3\ \lambda_4)$. Lastly, there is a cyclic C_2 group acting on these two sets of four roots generated by the permutation $(\lambda_1\ \lambda_3)(\overline{\lambda_1}\ \lambda_4)(\lambda_2\ \overline{\lambda_3})(\overline{\lambda_2}\ \overline{\lambda_4})$.

The terms in the sequence $\langle u_n \rangle_n$ are given as follows:

$$u_n = \frac{1}{\sqrt{5}}\Big((1+\lambda_1)\lambda_1^n + (1+\overline{\lambda_1})\overline{\lambda_1}^n + (1+\lambda_2)\lambda_2^n + (1+\overline{\lambda_2})\overline{\lambda_2}^n\Big)^2 \\ - \frac{1}{\sqrt{5}}\Big((1+\lambda_3)\lambda_3^n + (1+\overline{\lambda_3})\overline{\lambda_3}^n + (1+\lambda_4)\lambda_4^n + (1+\overline{\lambda_4})\overline{\lambda_4}^n\Big)^2.$$

By the action of the Galois group, it can be seen that each term u_n is rational and further that $\langle u_n \rangle_n$ is simple, reversible, and has exactly order 18. The initial values $u_0, \ldots, u_{17}$ of $\langle u_n \rangle_n$ are

$$-11, -8, 0, 240, 704, -20, 192, 5508, 46305, 2625, 13425, 73117, \\ 2469800, 536000, 554151, 77287, 108792361, 66461616.$$

The simple LRS $\langle u_n \rangle_n$ satisfies the relation

$$u_{n+18} = u_{n+17} - 10u_{n+16} + 6u_{n+15} + 43u_{n+14} - 93u_{n+13} + 672u_{n+12} - 596u_{n+11} \\ + 120u_{n+10} + 3972u_{n+9} - 15345u_{n+8} + 29654u_{n+7} - 36108u_{n+6} + 23847u_{n+5} \\ - 9572u_{n+4} + 2361u_{n+3} - 325u_{n+2} + 26u_{n+1} - u_n.$$

Observe that u_0, u_1, and u_5 are negative, but up to $n = 10^5$ these are the only negative terms. Thus, the question is to prove that $u_n \geq 0$ for all $n \geq 6$. We reiterate that, as far as the authors are aware, there are no known techniques in the state of the art that can tackle this question.

It remains to show that the torus T associated with $\langle u_n \rangle_n$ has the prescribed "squaring form" (as in (5)) and that $\langle u_n \rangle_n$ is non-degenerate. To start, u_n is positive if and only if $\frac{u_n}{\phi^{2n}}$. Moreover, we observe that $|1+\lambda_1| \neq |1+\lambda_2|$ and that both λ_1/ϕ and λ_2/ϕ lie on the unit circle. For $a = 1+\lambda_1, b = \lambda_2$ and some $0 < r < 1$, we have that

$$\frac{u_n}{\phi^{2n}} = \frac{1}{\phi^{2n}}\Big((1+\lambda_1)\lambda_1^n + (1+\overline{\lambda_1})\overline{\lambda_1}^n + (1+\lambda_2)\lambda_2^n + (1+\overline{\lambda_2})\overline{\lambda_2}^n\Big)^2 + O(r^n) \\ = \left(a\left(\frac{\lambda_1}{\phi}\right)^n + \overline{a}\left(\frac{\lambda_1}{\phi}\right)^{-n} + b\left(\frac{\lambda_2}{\phi}\right)^n + \overline{b}\left(\frac{\lambda_2}{\phi}\right)^{-n}\right)^2 + O(r^n)$$

is close to the "squaring form" discussed at (5). In fact, we have that

$$u_n/\phi^{2n} = \tau((\lambda_1/\phi)^n, (\lambda_2/\phi)^n) + O(r^n).$$

Here, the term $O(r^n)$ decreases exponentially fast and determines how closely the square should approach zero to contradict positivity.

We now show that we cannot apply Theorem 4 in this instance. To this end, we need to show that the points to which we restrict τ are dense on the torus T. That is, we need to show that λ_1/ϕ and λ_2/ϕ are multiplicatively independent. This lack of multiplicative relations also immediately implies that $\langle u_n \rangle_n$ is non-degenerate. We complete the spectral analysis of sequence $\langle u_n \rangle_n$ with the following proposition.

▶ **Proposition 19.** *We have that $\lambda_1/|\lambda_1|$ and $\lambda_2/|\lambda_2|$ are multiplicatively independent.*

Proof. Note that $|\lambda_1| = |\lambda_2| = \phi$ as $\lambda_1\overline{\lambda_1} = \lambda_2\overline{\lambda_2} = \phi^2$. By the earlier described Galois action, we see that there are Galois automorphisms σ and τ such that $\sigma(\lambda_1) = \tau(\lambda_1) = \lambda_3$, $\sigma(\lambda_2) = \lambda_4$ and $\tau(\lambda_2) = \overline{\lambda_3}$. Further, by this choice, $\sigma(\phi) = \tau(\phi) = -\phi^{-1}$.

Assume, for a contradiction, that $\lambda_1/|\lambda_1|$ and $\lambda_2/|\lambda_2|$ are multiplicatively dependent; that is to say, there are $a, b \in \mathbb{Z}$, not both 0, such that $(\lambda_1/|\lambda_1|)^a (\lambda_2/|\lambda_2|)^b = 1$. By applying σ to this identity we obtain

$$1 = \left(\frac{\lambda_3}{-\phi^{-1}}\right)^a \left(\frac{\lambda_4}{-\phi^{-1}}\right)^b = \zeta \left(\frac{|\lambda_3\lambda_4|}{\phi^{-2}}\right)^a \left(\frac{\lambda_4}{-\phi^{-1}}\right)^{b-a} = \zeta \left(\frac{\lambda_4}{-\phi^{-1}}\right)^{b-a}$$

for some ζ on the unit circle. Since $|\lambda_4/-\phi^{-1}| \neq 1$, we conclude that $a = b$. Then when we apply τ to the identity $(\lambda_1/|\lambda_1|)^a (\lambda_2/|\lambda_2|)^b = 1$ we obtain

$$1 = \left(\frac{\lambda_3}{-\phi^{-1}}\right)^a \left(\frac{\overline{\lambda_3}}{-\phi^{-1}}\right)^b = \zeta' \left(\frac{|\lambda_3|}{|\overline{\lambda_3}|}\right)^a \left(\frac{\overline{\lambda_3}}{-\phi^{-1}}\right)^{b+a} = \zeta' \left(\frac{\overline{\lambda_3}}{-\phi^{-1}}\right)^{b+a}$$

for some ζ' on the unit circle. Since $|\overline{\lambda_3}/-\phi^{-1}| \neq 1$, this implies that $a = -b$. Together with $a = b$, we deduce that $a = b = 0$. Thus $\lambda_1/|\lambda_1|$ and $\lambda_2/|\lambda_2|$ are multiplicatively independent. ◀

5.3 Constructing a hard example of a non-simple sequence of order 12

In this subsection, we briefly consider a reversible LRS of order 12 where we cannot decide positivity nor ultimate positivity. Explicit examples are easier to construct than in the simple case and are closely related to the extensive discussion in [16]. Let us recall the following point from Theorem 1: a non-simple LRS that is a hard example of (ultimate) positivity possesses three simple dominant roots of which one is real and positive. One choice, closely resembling Example 4.5 in [11], is to take

$$\rho = \sqrt{2} + 1 \quad \text{and} \quad \lambda = \frac{1 + \sqrt{1 - 4\rho^2}}{2}.$$

Then we have that ρ and λ are units of equal modulus, ρ has one Galois conjugate $\tilde{\rho}$ of smaller modulus, and λ has three Galois conjugates. The three Galois conjugates of λ are its complex conjugate and two real numbers, say, λ_3 and λ_4 of smaller modulus. Lastly, let $q \in \mathbb{Q}_{>0}$. Then define the non-simple reversible rational-valued LRS $\langle u_n^q \rangle_n$ as follows:

$$u_n^q = (n+\rho)\rho^n + (n+\tilde{\rho})\tilde{\rho}^n + q(n+\lambda)\lambda^n + q(n+\overline{\lambda})\overline{\lambda}^n + q(n+\lambda_3)\lambda_3^n + q(n+\lambda_4)\lambda_4^n.$$

For small q, $\langle u_n^q \rangle_n$ is positive and so ultimately positive. For sufficiently large q, $\langle u_n^q \rangle_n$ is neither positive nor ultimately positive. However, given the current state of the art, it is not known how to determine where an arbitrary q falls in this partition. Thus, at the time of writing, we cannot tell whether LRS of the form $\langle u_n^q \rangle_n$ are (ultimately) positive.

Following [11, Section 4.2]), we can construct further LRS (akin to $\langle u_n^q \rangle_n$) where the state of the art is unable to settle positivity and ultimate positivity. In this direction, we may take a real quadratic unit $\rho > 1$ and find a non-real algebraic unit λ of equal modulus such that λ has a minimum polynomial of degree 4.

Abstract

Seminal results establish that the coverability problem for Vector Addition Systems with States (VASS) is in EXPSPACE (Rackoff, '78) and is EXPSPACE-hard already under unary encodings (Lipton, '76). More precisely, Rosier and Yen later utilise Rackoff's bounding technique to show that if coverability holds then there is a run of length at most $n^{2^{\mathcal{O}(d \log d)}}$, where d is the dimension and n is the size of the given unary VASS. Earlier, Lipton showed that there exist instances of coverability in d-dimensional unary VASS that are only witnessed by runs of length at least $n^{2^{\Omega(d)}}$. Our first result closes this gap. We improve the upper bound by removing the twice-exponentiated $\log(d)$ factor, thus matching Lipton's lower bound. This closes the corresponding gap for the exact space required to decide coverability. This also yields a deterministic $n^{2^{\mathcal{O}(d)}}$-time algorithm for coverability. Our second result is a matching lower bound, that there does not exist a deterministic $n^{2^{o(d)}}$-time algorithm, conditioned upon the Exponential Time Hypothesis.

When analysing coverability, a standard proof technique is to consider VASS with bounded counters. Bounded VASS make for an interesting and popular model due to strong connections with timed automata. Withal, we study a natural setting where the counter bound is linear in the size of the VASS. Here the trivial exhaustive search algorithm runs in $\mathcal{O}(n^{d+1})$-time. We give evidence to this being near-optimal. We prove that in dimension one this trivial algorithm is conditionally optimal, by showing that $n^{2-o(1)}$-time is required under the k-cycle hypothesis. In general fixed dimension d, we show that $n^{d-2-o(1)}$-time is required under the 3-uniform hyperclique hypothesis.

1 Introduction

Vector Addition Systems with States (VASS) are a popular model of concurrency with a number of applications in database theory [9], business processes [49], and more (see the survey [47]). A d-dimensional VASS (d-VASS) consists of a finite automaton equipped with d non-negative valued counters that can be updated by transitions. A configuration in a d-VASS consists of a state and a d-dimensional vector over the naturals. One of the central decision problems for VASS is the *coverability problem*, that asks whether there is a run from a given initial configuration to some configuration with at least the counter values of a given target configuration. Coverability finds application in the verification of safety conditions, which often equate to whether or not a particular state can be reached without any precise counter values [13, 24]. Roughly speaking, one can use VASS as a modest model for concurrent systems where the dimension corresponds with the number of locations a process can be in and each counter value corresponds with the number of processes in a particular location [21, 25].

In 1978, Rackoff [45] showed that coverability is in EXPSPACE, by proving that if coverability holds then there exists a run of double-exponential length. Following, Rosier and Yen [46] analysed and discussed Rackoff's ideas in more detail and argued that if a coverability holds then it is witnessed by a run of length at most $n^{2^{\mathcal{O}(d \log d)}}$, where n is the size of the given unary encoded d-VASS. Furthermore, this yields a $2^{\mathcal{O}(d \log d)} \cdot \log(n)$-space algorithm for coverability. Prior to this in 1976, Lipton [37] proved that coverability is EXPSPACE-hard even when VASS is encoded in unary, by constructing an instance of coverability witnessed only by a run of double-exponential length $n^{2^{\Omega(d)}}$. Rosier and Yen [46] also presented a proof that generalises Lipton's constructions to show that $2^{\Omega(d)} \cdot \log(n)$-space is required for coverability. Although this problem is EXPSPACE-complete in terms of classical complexity, a gap was left open for the exact space needed for coverability [46, Section 1]. By using an approach akin to Rackoff's argument, we close this thirty-eight-year-old gap by improving the upper bound to match Lipton's lower bound.

Result 1: If coverability holds then there exists a run of length at most $n^{2^{\mathcal{O}(d)}}$ (Theorem 3.3). Accordingly, we obtain an optimal $2^{\mathcal{O}(d)} \cdot \log(n)$-space algorithm that decides coverability (Corollary 3.4).

Our bound also implies the existence of a deterministic $n^{2^{\mathcal{O}(d)}}$-time algorithm for coverability. We complement this with a matching lower bound on the deterministic running time that is conditioned upon the Exponential Time Hypothesis (ETH).

Result 2: Under ETH, there is no deterministic $n^{2^{o(d)}}$-time algorithm deciding coverability in unary d-VASS (Theorem 4.2).

While our results establish a fast-increasing, conditionally optimal exponent of $2^{\Theta(d)}$ in the time complexity of the coverability problem, they rely on careful constructions that enforce the observation of large counter values. In certain settings, however, it is natural to instead consider a restricted version of coverability, where all counter values remain *bounded*. This yields one of the simplest models, fixed-dimension bounded unary VASS, for which we obtain even tighter results. Decision problems for B-bounded VASS, where B forms part of the input, have been studied due to their strong connections to timed automata [27, 22, 41].

We consider linearly-bounded unary VASS, that is when the maximum counter value is bounded above by a constant multiple of the size of the VASS. Interestingly, coverability and reachability are equivalent in linearly-bounded unary VASS. The trivial algorithm that employs depth-first search on the space of configurations runs in $\mathcal{O}(n^{d+1})$-time for both coverability and reachability. We provide evidence that the trivial algorithm is optimal.

Result 3: Reachability in linearly-bounded unary 1-VASS requires $n^{2-o(1)}$-time, subject to the k-cycle hypothesis (Theorem 5.4).

This effectively demonstrates that the trivial algorithm is optimal in the one-dimensional case. For the case of large dimensions, we show that the trivial algorithm only differs from an optimal deterministic-time algorithm by at most an $n^{3+o(1)}$-time factor.

Result 4: Reachability in linearly-bounded unary d-VASS requires $n^{d-2-o(1)}$-time, subject to the 3-uniform k-hyperclique hypothesis (Theorem 5.8).

Broadly speaking, these results add a time complexity perspective to the already known space complexity, that is for any fixed dimension d, coverability in unary d-VASS is NL-complete [45].

Organisation and Overview. Section 3 contains our first main result, the improved upper bound on the space required for coverability. Most notably, in Theorem 3.3 we show that if coverability holds then there exists a run of length at most $n^{2^{\mathcal{O}(d)}}$. Then, in Corollary 3.4 we are able to obtain a non-deterministic $2^{\mathcal{O}(d)} \cdot \log(n)$-space algorithm and a deterministic $n^{2^{\mathcal{O}(d)}}$-time algorithm for coverability. In much of the same way as Rackoff, we proceed by induction on the dimension. The difference is in the inductive step; Rackoff's inductive hypothesis dealt with a case where all counters are bounded by the same well-chosen value. Intuitively speaking, the configurations are bounded within a d-hypercube. This turns out to be suboptimal. This is due to the fact that the volume of a d-hypercube with sides of length ℓ is ℓ^d; unrolling the induction steps gives a bound of roughly $n^{d\cdot(d-1)\cdot\ldots\cdot 1} = n^{d!} = n^{2^{\mathcal{O}(d \log d)}}$, hence the twice-exponentiated $\log(d)$ factor. The key ingredient in our proof is to replace the d-hypercubes with a collection of objects with greatly reduced volume, thus reducing the number of configurations in a run witnessing coverability.

Section 4 contains our second main result, the matching lower bound on the time required for coverability that is conditioned upon ETH. In Lemma 4.3, we first reduce from finding a k-clique in a graph to an instance of coverability in bounded unary 2-VASS with zero-tests. Then, via Lemma 4.4, we implement the aforementioned technique of Rosier and Yen to, when there is a counter bound, remove the zero-tests at the cost of increasing to a d-dimensional unary VASS. Then, in Theorem 4.2 we are able to conclude, by setting $k = 2^d$, that if ETH holds, then there is no deterministic $n^{2^{o(d)}}$-time algorithms for coverability in unary d-VASS. This is because ETH implies that there is no $f(k) \cdot n^{o(k)}$-time algorithm for finding a k-clique in a graph with n vertices (Theorem 4.1).

Section 5 contains our other results where we study bounded fixed dimension unary VASS. Firstly, Theorem 5.4 states that under the k-cycle hypothesis (Hypothesis 5.2), there does not exist a deterministic $n^{2-o(1)}$-time algorithm deciding reachability in linearly-bounded unary 1-VASS. Further, we conclude in Corollary 5.5, if the k-cycle hypothesis is assumed then there does not exist a deterministic $n^{2-o(1)}$-time algorithm for coverability in (not bounded) unary 2-VASS. Following, we prove Theorem 5.8, that claims there does not exist a deterministic $n^{d-o(1)}$-time algorithm reachability in linearly-bounded unary $(d+2)$-VASS under the 3-uniform k-hyperclique hypothesis (Hypothesis 5.7). We achieve this with two

components. First, in Lemma 5.9, we first reduce from finding a $4d$-hyperclique to an instance of reachability in a bounded unary $(d+1)$-VASS with a fixed number of zero-tests. Second, via Lemma 5.10, we implement the newly developed controlling counter technique of Czerwiński and Orlikowski [16] to remove the fixed number of zero-tests at the cost of increasing the dimension by one.

Related Work. The coverability problem for VASS has plenty of structure that still receives active attention. The set of configurations from which the target can be covered is upwards-closed, meaning that coverability still holds if the initial counter values are increased. An alternative approach, the *backwards algorithm* for coverability, relies on this phenomenon. Starting from the target configuration, one computes the set of configurations from which it can be covered [1]. Thanks to the upwards-closed property, it suffices to maintain the collection of minimal configurations. The backwards algorithm terminates due to Dickson's lemma, however, using Rackoff's bound one can show it runs in double-exponential time [10]. This technique has been deeply analysed for coverability in VASS and some extensions [23, 32]. Despite high complexity, there are many implementations of coverability relying on the backwards algorithm that work well in practice. Intuitively, the idea is to prune the set of configurations, using relaxations that can be efficiently implemented in SMT solvers [21, 7, 8].

Another central decision problem for VASS is the *reachability problem*, asking whether there is a run from a given initial configuration to a given target configuration. Reachability is a provably harder problem. In essence, reachability differs from coverability by allowing one zero-test to each counter. Counter machines, well-known to be equivalent to Turing machines [43], can be seen as VASS with the ability to arbitrarily zero-test counters; coverability and reachability are equivalent here and are undecidable. In 1981, Mayr proved that reachability in VASS is decidable [39], making VASS one of the richest decidable variants of counter machines. Only recently, after decades of work, has the complexity of reachability in VASS been determined to be Ackermann-complete [35, 16, 34]. A widespread technique for obtaining lower bounds for coverability and reachability problems in VASS is to simulate counter machines with some restrictions. Our overall approach to obtaining lower bounds follows suit; we first reduce finding cliques in graphs, finding cycles in graphs, and finding hypercliques in hypergraphs to various intermediate instances of coverability in VASS with extra properties such as bounded counters or a fixed number of zero-tests. These VASS, that are counter machines restricted in some way, are then simulated by standard higher-dimensional VASS. Such simulations are brought about by the two previously developed techniques. Rosier and Yen leverage Lipton's construction to obtain VASS that can simulate counter machines with bounded counters [46]. Czerwiński and Orlikowski have shown that the presence of an additional counter in a VASS, with carefully chosen transition effects and reachability condition, can be used to implicitly perform a limited number of zero-tests [16].

Recently, some work has been dedicated to the coverability problem for low-dimensional VASS [3, 42]. Furthermore, reachability in low-dimensional VASS has been given plenty of attention, in particular for 1-VASS [48, 26] and for 2-VASS [28, 6]. In the restricted class of flat VASS, other fixed dimensions have also been studied [15, 17].

Another studied variant, *bidirected* VASS, has the property that for every transition $(p, \mathbf{x}, q)$, the reverse transition $(q, -\mathbf{x}, p)$ is also present. The reachability problem in bidirected VASS is equivalent to the uniform word problem in commutative semigroups, both of which are EXPSPACE-complete [40]; not to be confused with the reversible reachability problem in general VASS which is also EXPSPACE-complete [33]. In 1982, Meyer and Mayr listed an open problem that stated, in terms of commutative semigroups, the best known upper

bound for coverability in general VASS [45], the best known lower bound for coverability in bidirected VASS [37], and asked for improvements to these bounds [40, Section 8, Problem 3]. Subsequently, Rosier and Yen refined the upper bound for coverability in general VASS to $2^{\mathcal{O}(d \log d)} \cdot \log(n)$-space [46]. Finally, Koppenhagen and Mayr showed that the coverability problem in bidirected VASS can be decided in $2^{\mathcal{O}(n)}$-space [30], matching the lower bound.

2 Preliminaries

We use bold font for vectors. We index the i-th component of a vector $\mathbf{v}$ by writing $\mathbf{v}[i]$. Given two vectors $\mathbf{u}, \mathbf{v} \in \mathbb{Z}^d$ we write $\mathbf{u} \leq \mathbf{v}$ if $\mathbf{u}[i] \leq \mathbf{v}[i]$ for each $1 \leq i \leq d$. For every $1 \leq i \leq d$, we write $\mathbf{e}_i \in \mathbb{Z}^d$ to represent the i-th standard basis vector that has $\mathbf{e}_i[i] = 1$ and $\mathbf{e}_i[j] = 0$ for all $j \neq i$. Given a vector $\mathbf{v} \in \mathbb{Z}^d$ we define $\|\mathbf{v}\| = \max\{1, |\mathbf{v}[1]|, \ldots, |\mathbf{v}[d]|\}$. Throughout, we assume that log has base 2. We use $\mathsf{poly}(n)$ to denote $n^{\mathcal{O}(1)}$.

A *d-dimensional Vector Addition System with States* (d-VASS) $\mathcal{V} = (Q, T)$ consists of a non-empty finite set of states Q and a non-empty set of transitions $T \subseteq Q \times \mathbb{Z}^d \times Q$. A *configuration* of a d-VASS is a pair $(q, \mathbf{v}) \in Q \times \mathbb{N}^d$ consisting of the current state q and current counter values $\mathbf{v}$, denoted $q(\mathbf{v})$. Given two configurations $p(\mathbf{u})$, $q(\mathbf{v})$, we write $p(\mathbf{u}) \to q(\mathbf{v})$ if there exists $t = (p, \mathbf{x}, q) \in T$ where $\mathbf{x} = \mathbf{v} - \mathbf{u}$. We may refer to $\mathbf{x}$ as the *update* of a transition and may also write $p(\mathbf{v}) \xrightarrow{t} q(\mathbf{w})$ to emphasise the transition t taken.

A *path* in a VASS is a (possibly empty) sequence of transitions $((p_1, \mathbf{x}_1, q_1), \ldots, (p_\ell, \mathbf{x}_\ell, q_\ell))$, where $(p_i, \mathbf{x}_i, q_i) \in T$ for all $1 \leq i \leq \ell$ and such that the start and end states of consecutive transitions match $q_i = p_{i+1}$ for all $1 \leq i \leq \ell - 1$. A *run* π in a VASS is a sequence of configurations $\pi = (q_0(\mathbf{v}_0), \ldots, q_\ell(\mathbf{v}_\ell))$ such that $q_i(\mathbf{v}_i) \to q_{i+1}(\mathbf{v}_{i+1})$ for all $1 \leq i \leq \ell - 1$. We denote the length of the run by $\mathrm{len}(\pi) = \ell + 1$. If there is such a run π, we can write $q_0(\mathbf{v}_0) \xrightarrow{\pi} q_\ell(\mathbf{v}_\ell)$. We may also write $p(\mathbf{u}) \xrightarrow{*} q(\mathbf{v})$ if there exists a run from $p(\mathbf{u})$ to $q(\mathbf{v})$. The *underlying path* of a run π is sequence of transitions $(t_1, \ldots, t_\ell)$ taken between each of the configurations in π, so $q_i(\mathbf{v}_i) \xrightarrow{t_{i+1}} q_{i+1}(\mathbf{v}_{i+1})$ for all $0 \leq i \leq \ell - 1$.

A *B-bounded d-VASS*, in short (B, d)-VASS, is given as an integer upper bound on the counter values $B \in \mathbb{N}$ and d-VASS $\mathcal{V}$. A configuration in a (B, d)-VASS is a pair $q(\mathbf{v}) \in Q \times \{0, \ldots, B\}^d$. The notions of paths and runs in bounded VASS remain the same as for VASS, but are accordingly adapted for the appropriate bounded configurations. We note that one should think that B forms part of the problem statement, not the input, as it will be given implicitly by a function depending on the size of the VASS. For example, we later consider *linearly-bounded* d-VASS, that represent occasions where $B = \mathcal{O}(\|\mathcal{V}\|)$.

We do allow for zero-dimensional VASS, that is VASS with no counters, which can be seen as just directed graphs. A *hypergraph* is a generalisation of the graph. Formally, a hypergraph is a tuple $H = (V, E)$ where V is a set of vertices and E is a collection of non-empty subsets of V called *hyperedges*. For an integer μ, a hypergraph is *μ-uniform* if each hyperedge has cardinality μ. Note that a 2-uniform hypergraph is a standard graph.

We study the complexity of the *coverability problem*. An instance $(\mathcal{V}, p(\mathbf{u}), q(\mathbf{v}))$ of coverability asks whether there is a run in the given VASS $\mathcal{V}$ from the given initial configuration $p(\mathbf{u})$ to a configuration $q(\mathbf{v}')$ with at least the counter values $\mathbf{v}' \geq \mathbf{v}$ of the given target configuration $q(\mathbf{v})$. At times, we also consider the *reachability problem* that additionally requires $\mathbf{v}' = \mathbf{v}$ so that the target configuration is reached exactly.

To measure the complexity of these problems we need to discuss the encoding used. In *unary encoding*, a d-VASS $\mathcal{V} = (Q, T)$ has *size* $\|\mathcal{V}\| = |Q| + \sum_{(p,\mathbf{x},q) \in T} \|\mathbf{x}\|$. We define a *unary* d-VASS $\mathcal{U} = (Q', T')$ to have restricted transitions $T' \subseteq Q' \times \{-1, 0, 1\}^d \times Q'$, the size is therefore $\|\mathcal{U}\| = |Q'| + |T'|$. For any unary encoded d-VASS $\mathcal{V}$ there exists an equivalent

unary d-VASS $\mathcal{U}$ such that $\|\mathcal{U}\| = \|\mathcal{V}\|$. An instance $(\mathcal{V}, p(\mathbf{u}), q(\mathbf{v}))$ of coverability has size $n = \|\mathcal{V}\| + \|\mathbf{u}\| + \|\mathbf{v}\|$. An equal in size, equivalent instance $(\mathcal{V}', p'(\mathbf{0}), q'(\mathbf{0}))$ of coverability exists; consider adding an initial transition $(p', \mathbf{s}, p)$ and a final transition $(q, -\mathbf{t}, q')$.

It is well known that for d-VASS, the coverability problem can be reduced to the reachability problem. Indeed, for an instance $(\mathcal{V}, p(\mathbf{u}), q(\mathbf{v}))$ of coverability, define $\mathcal{V}' = (Q, T')$ that has additional decremental transitions at the target states $T' = T \cup \{(q, \mathbf{e}_i, q) : 1 \leq i \leq d\}$. It is clear that $p(\mathbf{u}) \xrightarrow{*} q(\mathbf{v}')$, for some $\mathbf{v}' \geq \mathbf{v}$, in $\mathcal{V}$ if and only if $p(\mathbf{u}) \xrightarrow{*} q(\mathbf{v})$ in $\mathcal{V}'$.

▶ **Lemma 2.1** (folklore). *Let $(\mathcal{V}, p(\mathbf{u}), q(\mathbf{v}))$ be an instance of coverability. It can be reduced to an instance of reachability $(\mathcal{V}', p(\mathbf{u}), q(\mathbf{v}))$ such that $\|\mathcal{V}'\| = \mathcal{O}(\|\mathcal{V}\|)$.*

A *d-dimensional Vector Addition System* (d-VAS) $\mathcal{V}$ is a system without states, consisting only of a non-empty collection of transitions $\mathcal{V} \subseteq \mathbb{Z}^d$. All definitions, notations, and problems carry over for VAS except that, for simplicity, we drop the states across the board. For example, a configuration in a VAS is just a vector $\mathbf{v} \in \mathbb{N}^d$. Another well-known result from the seventies by Hopcroft and Pansiot, one can simulate the states of a VASS at the cost of three extra dimensions in a VAS [28]. For clarity, the VAS obtained has an equivalent reachability relation between configurations; a configuration $q(\mathbf{x})$ in the original VASS corresponds with a configuration $(\mathbf{x}, a, b, c)$ in the VAS, where a, b, and c represent the state q.

▶ **Lemma 2.2** ([28, Lemma 2.1]). *A d-VASS $\mathcal{V}$ can be simulated by $(d+3)$-VAS $\mathcal{V}'$ such that $\|\mathcal{V}'\| = \mathit{poly}(\|\mathcal{V}\|)$.*

3 Improved Bounds on the Maximum Counter Value

This section is devoted to our improvement of the seminal result of Rackoff. Throughout, we fix our attention to the arbitrary instance $(\mathcal{V}, p(\mathbf{s}), q(\mathbf{t}))$ of the coverability problem in a d-VASS $\mathcal{V} = (Q, T)$ from the initial configuration $p(\mathbf{s})$ to a configuration $q(\mathbf{t}')$ with at least the counter values of the target configuration $q(\mathbf{t})$. We denote $n = \|\mathcal{V}\| + \|\mathbf{s}\| + \|\mathbf{t}\|$. Informally, n may as well be the number of states plus the absolute value of the greatest update on any transition, for these differences can be subsumed by the second exponent in our following upper bounds. The following two theorems follow from Rackoff's technique and subsequent work by Rosier and Yen, in particular see [45, Lemma 3.4 and Theorem 3.5] and [46, Theorem 2.1 and Lemma 2.2].

▶ **Theorem 3.1** (Corollary of [45, Lemma 3.4] and [46, Theorem 2.1]). *Suppose $p(\mathbf{s}) \xrightarrow{*} q(\mathbf{t}')$ for some $\mathbf{t}' \geq \mathbf{t}$. Then there exists a run π such that $p(\mathbf{s}) \xrightarrow{\pi} q(\mathbf{t}'')$ for some $\mathbf{t}'' \geq \mathbf{t}$ and $\mathrm{len}(\pi) \leq n^{2^{\mathcal{O}(d \log d)}}$.*

▶ **Theorem 3.2** (cf. [45, Theorem 3.5]). *For a given d-VASS $\mathcal{V}$, integer ℓ, and two configurations $p(\mathbf{s})$ and $q(\mathbf{t})$, there is an algorithm that determines the existence of a run π of length $\mathrm{len}(\pi) \leq \ell$ that witnesses coverability, so $p(\mathbf{s}) \xrightarrow{\pi} q(\mathbf{t}')$ for some $\mathbf{t}' \geq \mathbf{t}$. The algorithm can be implemented to run in non-deterministic $\mathcal{O}(d \log(n \cdot \ell))$-space or deterministic $2^{\mathcal{O}(d \log(n \cdot \ell))}$-time.*

Note that Theorem 3.1 combined with Theorem 3.2, that is proved in the full version [31], yield non-deterministic $2^{\mathcal{O}(d \log d)}$-space and deterministic $n^{2^{\mathcal{O}(d \log(d))}}$-time algorithms for coverability. Our result improves this by a $\mathcal{O}(\log(d))$ factor in the second exponent.

▶ **Theorem 3.3.** *Suppose $p(\mathbf{s}) \xrightarrow{*} q(\mathbf{t}')$ for some $\mathbf{t}' \geq \mathbf{t}$. Then there exists a run π such that $p(\mathbf{s}) \xrightarrow{\pi} q(\mathbf{t}'')$ for some $\mathbf{t}'' \geq \mathbf{t}$ and $\mathrm{len}(\pi) \leq n^{2^{\mathcal{O}(d)}}$.*

This combined with Theorem 3.2 yields the following corollary.

▶ **Corollary 3.4.** *Coverability in d-VASS can be decided by both a non-deterministic $2^{\mathcal{O}(d)} \cdot \log(n)$-space algorithm and a deterministic $n^{2^{\mathcal{O}(d)}}$-time algorithm.*

Note that by Lemma 2.2, we may handle VAS instead of VASS. Recall that, as there are no states, a d-VAS consists only of a set of vectors in $\mathbb{Z}^d$ that we still refer to as transitions. A configuration is just a vector in $\mathbb{N}^d$. Accordingly, we may fix our attention on the instance $(\mathcal{V}, \mathbf{s}, \mathbf{t})$ of the coverability problem in a d-VAS $\mathcal{V} = \{\mathbf{v}_1, \ldots, \mathbf{v}_m\}$ from the initial configuration $\mathbf{s}$ to a configuration $\mathbf{t}'$ that is at least as great as the target configuration $\mathbf{t}$. The rest of this section is dedicated to the proof of Theorem 3.3. Imitating Rackoff's proof, we proceed by induction on the dimension d. Formally, we prove a stronger statement; Theorem 3.3 is a direct corollary of the following lemma.

▶ **Lemma 3.5.** *Define $L_i \coloneqq n^{4^i}$, and let $\mathbf{t} \in \mathbb{N}^d$ such that $\|\mathbf{t}\| \leq n$. For any $\mathbf{s} \in \mathbb{N}^d$, if $\mathbf{s} \xrightarrow{*} \mathbf{t}'$ for some $\mathbf{t}' \geq \mathbf{t}$ then there exists a run π such that $\mathbf{s} \xrightarrow{\pi} \mathbf{t}''$ for some $\mathbf{t}'' \geq \mathbf{t}$ and $\mathrm{len}(\pi) \leq L_d$.*

The base case is $d = 0$. In a 0-dimensional VAS, the only possible configuration is the empty vector $\boldsymbol{\varepsilon}$ and therefore there is only the trivial run $\boldsymbol{\varepsilon} \xrightarrow{*} \boldsymbol{\varepsilon}$. This trivially satisfies the lemma.

For the inductive step, when $d \geq 1$, we assume that Lemma 3.5 holds for all lower dimensions $0, \ldots, d-1$. Let $\pi = (\mathbf{c}_0, \mathbf{c}_1, \ldots, \mathbf{c}_\ell)$ be a run with minimal length such that $\mathbf{s} \xrightarrow{\pi} \mathbf{t}'$ for some $\mathbf{t}' \geq \mathbf{t}$, so in particular, $\mathbf{c}_0 = \mathbf{s}$ and $\mathbf{c}_n = \mathbf{t}'$. Our objective is to prove that $\mathrm{len}(\pi) = \ell + 1 \leq L_d$. Observe that configurations $\mathbf{c}_i$ need to be distinct, else π could be shortened trivially. We introduce the notion of a *thin configuration*.

▶ **Definition 3.6** (Thin Configuration). *In a d-VAS, we say that a configuration $\mathbf{c} \in \mathbb{N}^d$ is* thin *if there exists a permutation σ of $\{1, \ldots, d\}$ such that $\mathbf{c}[\sigma(i)] < M_i$ for every $i \in \{1, \ldots, d\}$, where $M_0 \coloneqq n$ and for $i \geq 1$, $M_i \coloneqq L_{i-1} \cdot n$.*

Recall, from above, the run $\pi = (\mathbf{c}_0, \mathbf{c}_1, \ldots, \mathbf{c}_\ell)$. Let $t \in \{0, \ldots, \ell\}$ be the first index where $\mathbf{c}_t$ is not thin, otherwise let $t = \ell + 1$ if every configuration in π is thin. We decompose the run about the t-th configuration $\pi = \pi_{\text{thin}} \cdot \pi_{\text{tail}}$, where $\pi_{\text{thin}} \coloneqq (\mathbf{c}_0, \ldots, \mathbf{c}_{t-1})$ and $\pi_{\text{tail}} \coloneqq (\mathbf{c}_t, \ldots, \mathbf{c}_\ell)$. Note that π_{thin} or π_{tail} can be empty. Subsequently, we individually analyse the lengths of π_{thin} and π_{tail} (see Figure 1). We will also denote $\mathbf{m} = \mathbf{c}_t$ to be the first configuration that is not thin.

▷ Claim 3.7. $\mathrm{len}(\pi_{\text{thin}}) \leq d! \cdot n^d \cdot L_{d-1} \cdot \ldots \cdot L_0$.

Proof. By definition, every configuration in π_{thin} is thin. Moreover, since π has a minimal length, no configurations in π repeat, let alone in π_{thin}. We now count the number of possible thin configurations. There are $d!$ many permutations of $\{1, \ldots, d\}$. For a given permutation σ and an index $i \in \{1, \ldots, d\}$, we know that for a thin configuration $\mathbf{c}$, $0 \leq \mathbf{c}[\sigma(i)] < M_i$, so there are at most $M_i = L_{i-1} \cdot n$ many possible values on the $\sigma(i)$-th counter. Hence the total number of thin configurations is at most $d! \cdot \prod_{i=1}^{d} (L_{i-1} \cdot n) = d! \cdot n^d \cdot L_{d-1} \cdot \ldots \cdot L_0$. ◁

▷ Claim 3.8. $\mathrm{len}(\pi_{\text{tail}}) \leq L_{d-1}$.

Proof. Consider $\mathbf{m} \in \mathbb{N}^d$, the first configuration of π_{tail}. Let σ be a permutation such that $\mathbf{m}[\sigma(1)] \leq \mathbf{m}[\sigma(2)] \leq \ldots \leq \mathbf{m}[\sigma(d)]$. Given that $\mathbf{m}$ is not thin, for every permutation σ' there exists an $i \in \{1, \ldots, d\}$ such that $\mathbf{m}[\sigma'(i)] \geq M_i$; in particular, this holds for σ. Note that this also implies $M_i \leq \mathbf{m}[\sigma(i+1)] \leq \ldots \leq \mathbf{m}[\sigma(d)]$.

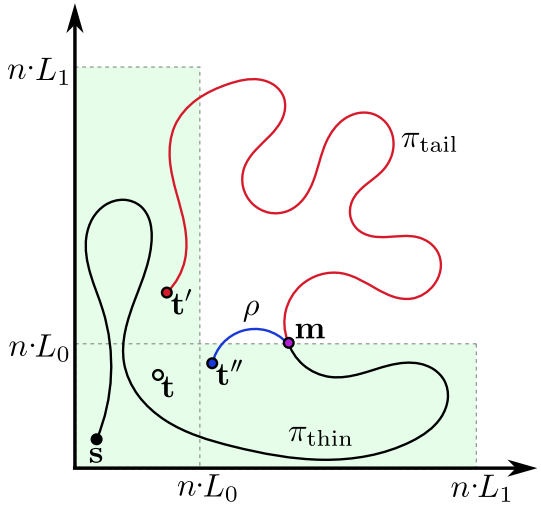

Figure 1 The schematic view of proofs of Claim 3.7 and Claim 3.8, restricted to the two-dimensional case. Note that $\mathbf{s}$ is the initial configuration and $\mathbf{t}$ is the target configuration. Every configuration inside the green shaded polygon is thin, where each rectangular component of the green shaded polygon corresponds to a permutation of the indices. Observe that $\mathbf{m}$ is the first configuration, just outside the green shaded polygon, that is not thin. Claim 3.7 bounds π_{thin}, and therefore its maximum length, by the volume of the green polygon. Claim 3.8 argues that there is an executable run ρ (drawn in blue) from $\mathbf{m}$ to $\mathbf{t}'' \geq \mathbf{t}$ of length at most L_{d-1} that can be used in place of the run π_{tail} (drawn in red) from $\mathbf{m}$ to $\mathbf{t}' \geq \mathbf{t}$.

We construct an $(i-1)$-VAS $\mathcal{U}$ from $\mathcal{V}$ by ignoring the counters $\sigma(i), \ldots, \sigma(d)$. Formally, $\mathbf{u} \in \mathcal{U}$ if there is $\mathbf{v} \in \mathcal{V}$ such that $\mathbf{u}[j] = \mathbf{v}[\sigma(j)]$ for each $1 \leq j \leq i-1$. In such a case we say $\mathbf{u}$ is the *projection* of $\mathbf{v}$ via σ. We will use the inductive hypothesis to show that there is a short path ρ' in $\mathcal{U}$ from (the projection of) $\mathbf{m}$ covering (the projection of) $\mathbf{t}$. We will then show that the remaining components of $\mathbf{m}$ are large enough that the embedding of ρ' into $\mathcal{V}$ maintains its covering status.

Recall that $\mathbf{t}'$ is the final configuration of the run π. Note that the run π_{tail} induces a run π'_{tail} in $\mathcal{U}$ by permuting and projecting every configuration. More precisely, $(\mathbf{m}[\sigma(1)], \ldots, \mathbf{m}[\sigma(i-1)]) \xrightarrow{\pi'_{\text{tail}}} (\mathbf{t}'[\sigma(1)], \ldots, \mathbf{t}'[\sigma(i-1)])$. By the inductive hypothesis there exists a run ρ' in $\mathcal{U}$ such that $(\mathbf{m}[\sigma(1)], \ldots, \mathbf{m}[\sigma(i-1)]) \xrightarrow{\rho'} (\mathbf{t}''[\sigma(1)], \ldots, \mathbf{t}''[\sigma(i-1)])$, such that $(\mathbf{t}''[\sigma(1)], \ldots, \mathbf{t}''[\sigma(i-1)]) \geq (\mathbf{t}[\sigma(1)], \ldots, \mathbf{t}[\sigma(i-1)])$ and $\text{len}(\rho') \leq L_{i-1}$.

Let $(\mathbf{u}_1, \ldots, \mathbf{u}_{\text{len}(\rho')})$ be the underlying path of the run ρ', that is, the sequence of transitions in $\mathcal{U}$ that are sequentially added to form the run ρ'. By construction, each transition vector $\mathbf{u}_i \in \mathcal{U}$ has a corresponding transition vector $\mathbf{v}_i \in \mathcal{V}$ where $\mathbf{u}_i$ is the projection of $\mathbf{v}_i$ via σ. We will now show that the following run witnesses coverability of $\mathbf{t}$.

$$\rho = \left(\mathbf{m},\ \mathbf{m} + \mathbf{v}_1,\ \mathbf{m} + \mathbf{v}_1 + \mathbf{v}_2,\ \ldots,\ \mathbf{m} + \sum_{j=1}^{\text{len}(\rho')} \mathbf{v}_j \right)$$

To this end, we verify that (i) ρ is a run, that is, all configurations lie in $\mathbb{N}^d$, and (ii) the final configuration indeed covers $\mathbf{t}$. For components $\sigma(1), \ldots, \sigma(i-1)$, this follows directly from the inductive hypothesis. For all other components we will show that *all* configurations of ρ are covering $\mathbf{t}$ in these components. This satisfies both (i) and (ii).

Let j be any of the remaining components. Recall that by the choice of $\mathbf{m}$, $\mathbf{m}[j] \geq M_i = n \cdot L_{i-1}$. Since $n > \|\mathcal{V}\| \geq \|\mathbf{v}_j\|$ for every $1 \leq j \leq \mathrm{len}(\rho')$, this means that in a single step, the value of a counter can change by at most n. Given that $\mathrm{len}(\rho) = \mathrm{len}(\rho') \leq L_{i-1}$, the value on each of the remaining components must be at least n for every configuration in ρ. In particular, observing that $\|\mathbf{t}\| \leq n$, the final configuration of ρ satisfies

$$\mathbf{m} + \sum_{j=1}^{\mathrm{len}(\rho')} \mathbf{v}_j \geq \mathbf{t}.$$

Finally, observe that $\mathrm{len}(\rho) = \mathrm{len}(\rho') \leq L_{i-1} \leq L_{d-1}$. ◁

To conclude this section, we show that Lemma 3.5 follows from Claim 3.7 and Claim 3.8.

Proof of Lemma 3.5. From Claim 3.7 and Claim 3.8,

$$\begin{aligned}\mathrm{len}(\pi) \leq \mathrm{len}(\pi_{\mathrm{thin}}) + \mathrm{len}(\pi_{\mathrm{tail}}) &\leq d! \cdot n^d \cdot L_{d-1} \cdot \ldots \cdot L_0 + L_{d-1} \\ &\leq 2 \cdot d! \cdot n^d \cdot L_{d-1} \cdot \ldots \cdot L_0.\end{aligned}$$

Recall that $n \geq 2$ and observe that $2 \cdot d! \cdot n^d \leq n^{2^d}$. Hence,

$$\mathrm{len}(\pi) \leq n^{2^d} \cdot L_{d-1} \cdot \ldots \cdot L_0.$$

Next, we use the definition of $L_i \coloneqq n^{4^i}$ to show

$$\mathrm{len}(\pi) \leq n^{2^d} \cdot \prod_{i=0}^{d-1} n^{4^i} \leq n^{\left(2^d + \sum_{i=0}^{d-1} 4^i\right)}.$$

Finally, when $d \geq 1$, $2^d + \sum_{i=0}^{d-1} 4^i \leq 4^d$ holds, therefore

$$\mathrm{len}(\pi) \leq n^{4^d} = L_d.$$ ◀

4 Conditional Time Lower Bound for Coverability

In this section, we present a conditional lower bound based on the *Exponential Time Hypothesis* (ETH) [29]. Roughly speaking, ETH is a conjecture that an n-variable instance of 3-SAT cannot be solved by a deterministic $2^{o(n)}$-time algorithm (for a modern survey, see [38]). In our reductions, it will be convenient for us to work with the k-clique problem instead. In the k-clique problem we are given a graph $G = (V, E)$ as an input and the task is to decide whether there is a set of k pairwise adjacent vertices in V. The naive algorithm for k-clique runs in $\mathcal{O}(n^k)$ time. Even though the exact constant in the dependence on k can be improved [44], ETH implies that the exponent must have a linear dependence on k.

▶ **Theorem 4.1** ([11, Theorem 4.2], [12, Theorem 4.5], and [14, Theorem 14.21]). *Assuming the Exponential Time Hypothesis, there is no algorithm running in $f(k) \cdot n^{o(k)}$-time for the k-clique problem for any computable function f. Moreover one can assume that G is k-partite, i.e. $G = (V_1 \cup \ldots \cup V_k, E)$ and edges belong to $V_i \times V_j$ for $i \neq j \in \{1, \ldots, k\}$.*

We will use Theorem 4.1 to show the following conditional lower bound for coverability in unary d-VASS, which is proved at the end of this section.

▶ **Theorem 4.2.** *Assuming the Exponential Time Hypothesis, there does not exist an $n^{2^{o(d)}}$-time algorithm deciding coverability in a unary d-VASS with n states.*

We first reduce the k-clique problem to coverability in bounded 2-VASS with the ability to perform a fixed number of zero-tests. We will then leverage a result by Rosier and Yen to construct an equivalent, with respect to coverability, $(\mathcal{O}(\log k))$-VASS without zero-tests.

▶ **Lemma 4.3.** *Given a k-partite graph $G = (V_1 \cup \cdots \cup V_k, E)$ with n vertices, there exists a unary $(\mathcal{O}(n^{2k}), 2)$-VASS $\mathcal{T}$ such that there is a k-clique in G if and only if there exists a run from $q_I(\mathbf{0})$ to $q_F(\mathbf{v})$ in $\mathcal{T}$, for some $\mathbf{v} \geq \mathbf{0}$. Moreover, $\|\mathcal{T}\| \leq \mathsf{poly}(n+k)$ and $\mathcal{T}$ can be constructed in $\mathsf{poly}(n+k)$-time.*

Proof. Without loss of generality, we may assume that each of the k vertex subsets in the graph has the same size $|V_1| = \ldots = |V_k| = \ell$. Thus $n = k \cdot \ell$. For convenience, we denote $V = \{1, \ldots, k\} \times \{1, \ldots, \ell\}$.

We begin by sketching the main ideas behind the reduction before they are implemented. We start by finding the first $n = k \cdot \ell$ primes and associating a distinct prime $p_{i,j}$ to each vertex $(i, j) \in V$. Note that a product of k different primes uniquely corresponds to selecting k vertices. Thus the idea is to guess such a product, and test whether the corresponding verticies form a k-clique. To simplify the presentation we present VASS also as counter programs, inspired by Esparza's presentation of Lipton's lower bound [20, Section 7].

We present an overview of our construction in Algorithm 1. Note that the counter y is used only by subprocedures. Initially both counter values are 0, as in the initial configuration of the coverability instance. The program is non-deterministic and we are interested in the existence of a certain run. One should think that coverability holds if and only if there is a run through the code without getting stuck so to say. In this example a run can be stuck only in the `Edge`$[e]$ subprocedure, that will be explained later. The precise final counter values are not important, as we are simply aiming to cover the target counter values $\mathbf{0}$. The variable i (in the first loop) and variables i and j (in the second loop) are just syntactic sugar for copying similar code multiple times. The variables j (in the first loop) and e (in the second loop) allow us to neatly represent non-determinism in a VASS.

Algorithm 1 A counter program for a VASS with zero tests with two counters x and y.

input : $\mathsf{x} = 0$, $\mathsf{y} = 0$

$\mathsf{x} \mathrel{+}= 1$
for $i \leftarrow 1$ **to** k **do**
  guess $j \in \{1, \ldots, \ell\}$
  `Multiply`$[\mathsf{x}, p_{i,j}]$
end
for $(i, j) \in \{1, \ldots, k\}^2$, $i \neq j$ **do**
  guess $e \in E \cap (V_i \times V_j)$
  `Edge`$[e]$
end

Algorithm 1 uses the `Multiply`$[\mathsf{x}, p]$ and `Edge`$[e]$ subprocedures. These two subprocedures will be implemented later. Note that `Multiply`$[\mathsf{x}, p]$ takes a counter x as input as we later reuse this subprocedure when there is more than one counter subject to multiplication. The intended behaviour of `Multiply`$[\mathsf{x}, p]$ is that it can be performed if and only if as a result we get $\mathsf{x} = \mathsf{x} \cdot p$, despite the fact that VASS can only additively increase and decrease counters. The subprocedure `Edge`$[e]$ can be performed if and only if both vertices of the edge e are encoded in the value of the counter x. Overall, Algorithm 1 is designed so that in the first part the variable x is multiplied by $p_{i,j}$, where for every i one j is guessed. This equates to selecting one vertex from each V_i. Then the second part the algorithm checks whether between every pair of selected vertices from V_i and V_j there is an edge. Clearly there is a run through the program that does not get stuck if and only if there is k-clique in G.

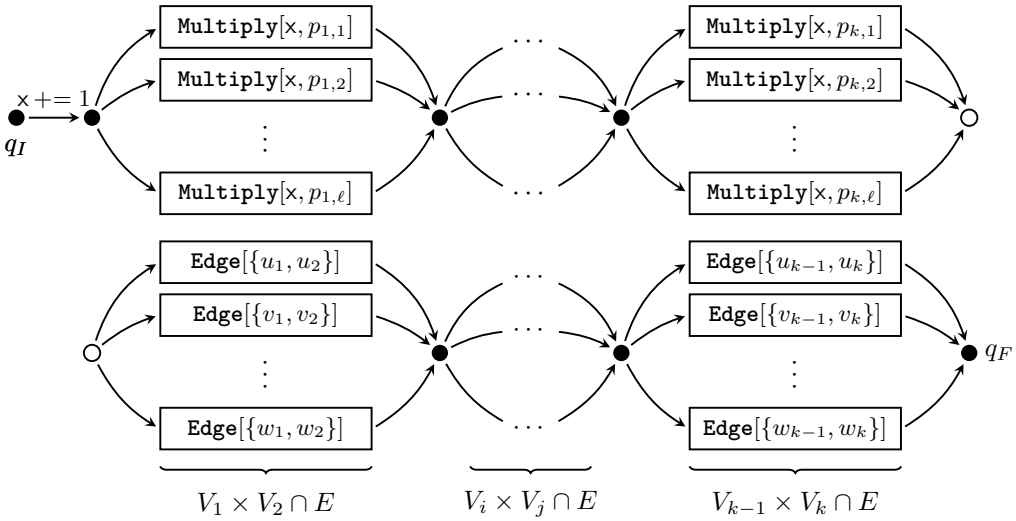

Figure 2 The top part of the VASS implements the first line and the first loop in Algorithm 1. The variable x is multiplied by k non-deterministically chosen primes $p_{i,j}$, each corresponding to a vertex in V_i. The bottom part of the VASS implements the second loop in Algorithm 1. For every pair $i \neq j$ the VASS non-deterministically chooses $e \in V_i \cap V_j$ and invokes the subprocedure **Edge**$[e]$.

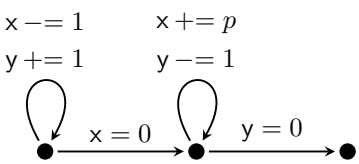
In Figure 2 we present a VASS with zero-tests implementing Algorithm 1. The construction will guarantee that $q_F(\mathbf{0})$ can be covered from $q_I(\mathbf{0})$ if and only if there is a k-clique in G.

It remains to define the subprocedures. One should think that every call of a subprocedure corresponds to a unique part of the VASS, like a gadget of sorts. To enter and leave the subprocedure one needs to add trivial transitions that to do not change the counter values. All subprocedures rely on the invariant $\mathsf{y} = 0$ at the beginning and admit the invariant at the end.

Algorithm 2 The counter program of **Multiply**$[\mathsf{x}, p]$ above its VASS implementation (left) and the counter program of **Divide**$[\mathsf{x}, p]$ above its VASS implementation (right).

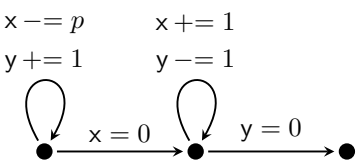
input : $\mathsf{x} = v$, $\mathsf{y} = 0$
output : $\mathsf{x} = v \cdot p$, $\mathsf{y} = 0$

repeat
  $\mathsf{x} -= 1$; $\mathsf{y} += 1$
until $\mathsf{x} = 0$
repeat
  $\mathsf{x} += p$; $\mathsf{y} -= 1$
until $\mathsf{y} = 0$



input : $\mathsf{x} = v \cdot p$, $\mathsf{y} = 0$
output : $\mathsf{x} = v$, $\mathsf{y} = 0$

repeat
  $\mathsf{x} -= p$; $\mathsf{y} += 1$
until $\mathsf{x} = 0$
repeat
  $\mathsf{x} += 1$; $\mathsf{y} -= 1$
until $\mathsf{y} = 0$

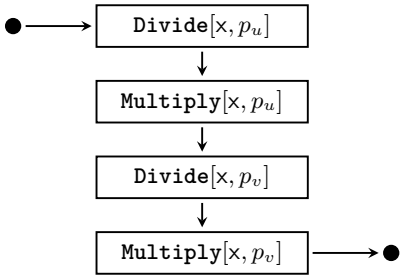


We start with **Multiply**[x, p] and **Divide**[x, p] that indeed multiply and divide x by p, respectively. See Algorithm 2 for the counter program and VASS implementations. Notice that the repeat loops correspond to the self-loops in the VASS. In the **Multiply**[x, p] gadget, it is easy to see that a run passes through the procedure if and only if the counter x is multiplied by p. Similarly, in the **Divide**[x, p] gadget, it is easy to see that a run pass through the procedure if and only if the counter x is divided by p wholly. Indeed, the division procedure would get stuck if $p \nmid$ x because it will be impossible to exit the first loop.

Algorithm 3 The counter program for **Edge**[$\{u, v\}$] and its VASS implementation.

input : x $= v$, y $= 0$
output : x $= v$, y $= 0$

Divide[x, p_u]
Multiply[x, p_u]
Divide[x, p_v]
Multiply[x, p_v]



The procedure **Edge**[$\{u, v\}$] is very simple, it is a sequence of four subprocedures, see Algorithm 3. Indeed, to check if the vertices from edge e are encoded in x we simply check whether x is divisible by the corresponding primes. Afterwards we multiply x with the same primes so that the value does not change and it is ready for future edge checks.

It remains to analyse the size of the VASS and its construction time in this reduction time. In every run from $q_I(\mathbf{0})$ to $q_F(\mathbf{v})$, for some $\mathbf{v} \geq \mathbf{0}$, the greatest counter value observable can be bounded above by p^k where p is the n-th prime. By the Prime Number Theorem (for example, see [51]), we know that $p^k \leq \mathcal{O}((n \log(n))^k) \leq \mathcal{O}(n^{2k})$ is an upper bound on the counter values observed. Hence $\mathcal{T}$ is an $\mathcal{O}(n^{2k})$-bounded unary 2-VASS.

Finally, the **Multiply** and **Divide** subprocedures contain three states and five transitions. Since the n-th prime is bounded above by $\mathcal{O}(n \log(n))$, we also get $\|\mathcal{T}\| = \mathcal{O}(n \log(n))$, hence our VASS can be represented using unary encoding. Analysing Algorithm 1, it is easy to see that overall the number of states is polynomial in n. Finally, the first n primes can be found in $\mathcal{O}(n^{1+o(1)})$-time [2]. Therefore, in total $\mathcal{T}$ has size $\|\mathcal{T}\| = \mathsf{poly}(n + k)$ and can be constructed in $\mathsf{poly}(n + k)$-time. ◀

To attain conditional lower bounds for coverability we must replace the zero-tests. We make use of a technique of Rosier and Yen [46] that relies on the construction of Lipton [37]. They show that a $(2n)^{2^k}$-bounded counter machine with finite state control can be simulated by a unary $(\mathcal{O}(k))$-VASS with n states. As Rosier and Yen detail after their proof, it is possible to apply this technique to multiple counters with zero-tests at once [46]. This accordingly results in the number of VASS counters increasing, but we instantiate this with just two counters. We remark that the VASS constructed in Lemma 4.3 is structurally bounded, so for any initial configuration there is a limit on the largest observable counter, as is the case in the VASS Lipton constructed [37].

▶ **Lemma 4.4** (Corollary of [46, Lemma 4.3]). *Let $\mathcal{T}$ be an n-state unary $(n^{\mathcal{O}(k)}, 2)$-VASS with zero-tests, for some parameter k. Then there exists an $\mathcal{O}(n)$-state $(\mathcal{O}(\log k))$-VASS $\mathcal{V}$, such that there is a run from $q_I(\mathbf{0})$ to $q_F(\mathbf{v})$, for some $\mathbf{v} \geq \mathbf{0}$, in $\mathcal{T}$ if and only if there is a run from $q'_I(\mathbf{0})$ to $q'_F(\mathbf{w})$, for some $\mathbf{w} \geq \mathbf{0}$, in $\mathcal{V}$. Moreover, $\mathcal{V}$ has size $\mathcal{O}(|\mathcal{T}|)$ and can be constructed in the same time.*

Proof of Theorem 4.2. Let $k = 2^d$. We instantiate Lemma 4.3 on k-partite graphs G with n vertices. We therefore obtain a unary $(n^{2^{\mathcal{O}(d)}}, 2)$-VASS with zero tests $\mathcal{T}$ such that G contains a k-clique if and only if there is a run from $q_I(\mathbf{0})$ to $q_F(\mathbf{v})$, for some $\mathbf{v} \geq \mathbf{0}$, in $\mathcal{T}$.

Given the bound on the value of the counters, we can apply Lemma 4.4 to $\mathcal{T}$. This gives us an $\mathcal{O}(n)$-state $(\mathcal{O}(d))$-VASS $\mathcal{V}$ such that G contains a k-clique if and only if there is a run from $q'_I(\mathbf{0})$ to $q'_F(\mathbf{w})$, for some $\mathbf{w} \geq \mathbf{0}$, in $\mathcal{V}$.

By Theorem 4.1 we conclude that under the Exponential Time Hypothesis there does not exist an $n^{2^{o(d)}}$-time algorithm deciding coverability in unary d-VASS. ◀

5 Coverability and Reachability in Bounded Unary VASS

In this section, we give even tighter bounds for coverability in *bounded* fixed dimension unary VASS. Specifically, for a time constructible function $B(n)$, the coverability problem in $(B(n), d)$-VASS asks, for a given $(B(n), d)$-VASS $\mathcal{V} = (Q, T)$ of size n as well as configurations $p(\mathbf{u})$, $q(\mathbf{v})$, whether there is a run in $\mathcal{V}$ from $p(\mathbf{u})$ to $q(\mathbf{v}')$ for some $\mathbf{v}' \geq \mathbf{v}$ such that each counter value remains in $\{0, \ldots, B(n)\}$ throughout. We would like to clarify the fact that the bound is not an input parameter. We focus on the natural setting of linearly-bounded fixed dimension VASS, that is $(\mathcal{O}(n), d)$-VASS. There is a simple algorithm, given in the proof of Observation 5.1 which can be found in the full version [31], that yields an immediate $\mathcal{O}(n^{d+1})$ upper bound for the time needed to decide the coverability problem. We accompany this observation with closely matching lower bounds, see Table 1 for an overview.

Table 1 Conditional lower bounds and upper bounds of the time complexity of coverability and reachability in unary $(\mathcal{O}(n), d)$-VASS. For clarity, we remark that Theorem 5.4 is subject to Hypothesis 5.2 and that Theorem 5.8 is subject to Hypothesis 5.7. Note that the lower bounds for dimensions $d = 2$ and $d = 3$ follow from Theorem 5.4 by just adding components consisting of only zeros. All upper bounds follow from Observation 5.1.

d	Lower Bound	Upper Bound
0	$\Omega(n)$ (trivial)	$\mathcal{O}(n)$
1	$n^{2-o(1)}$ (Theorem 5.4)	$\mathcal{O}(n^2)$
2	$n^{2-o(1)}$ (from above)	$\mathcal{O}(n^3)$
3	$n^{2-o(1)}$ (from above)	$\mathcal{O}(n^4)$

Lower Bounds for Coverability in Linearly-Bounded VASS

Now, we consider lower bounds for the coverability problem in linearly-bounded fixed dimension unary VASS. Firstly, in dimension one, we show that quadratic running time is conditionally optimal under the k-cycle hypothesis. Secondly, in dimensions four and higher, we require a running time at least $n^{d-2-o(1)}$ under the 3-uniform hyperclique hypothesis. Together, this provides evidence that the simple $\mathcal{O}(n^{d+1})$ algorithm for coverability in $(\mathcal{O}(n), d)$-VASS is close to optimal, as summarised in Table 1.

▶ **Hypothesis 5.2** (k-Cycle Hypothesis). *For every $\varepsilon > 0$, there exists a k such that there does not exist a $\mathcal{O}(m^{2-\varepsilon})$-time algorithm for finding a k-cycle in directed graphs with m edges.*

The k-cycle hypothesis arises from the state-of-the-art $\mathcal{O}(m^{2-\frac{c}{k}+o(1)})$-time algorithms, where c is some constant [4, 50, 19]. It has been previously used as an assumption for hardness results, for example, see [36, 5, 18]. It is a standard observation, due to colour-coding arguments, that we may without loss of generality assume that the graph given is a k-circle-layered graph [36, Lemma 2.2]. Specifically, we can assume that the input graph $G = (V, E)$ has vertex partition $V = V_0 \cup \cdots \cup V_{k-1}$ such that each edge $\{u, v\} \in E$ is in $V_i \times V_{i+1 \pmod k}$ for some $0 \leq i < k$. Furthermore, we may assume $|V| \leq |E|$.

The core of the upcoming lower bounds is captured in the following lemma; see Figure 3 for an overview and the full version [31] for the proof.

▶ **Lemma 5.3.** *Given a k-circle-layered graph $G = (V_0 \cup \cdots \cup V_{k-1}, E)$ with m edges, there exists a unary $(\mathcal{O}(n), 1)$-VASS $\mathcal{V}$ such that there is a k-cycle in G if and only if there exists a run from $p(0)$ to $q(0)$ in $\mathcal{V}$. Moreover, $\mathcal{V}$ has size $n \leq \mathcal{O}(m)$ and can be constructed in $\mathcal{O}(m)$-time.*

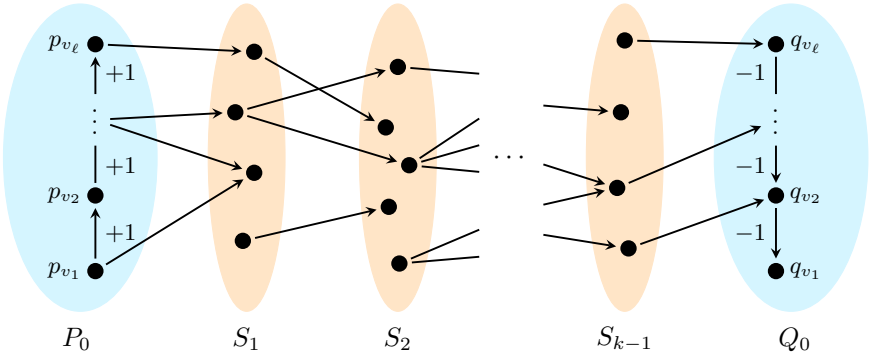

Figure 3 The $(\mathcal{O}(n), 1)$-VASS $\mathcal{V}$ of size $n \leq \mathcal{O}(m)$ for finding k-cycle in a k-circle-layered graphs with m edges. Note that unlabelled transitions have zero effect. Observe that the graph is mostly copied into the states and transitions of the linearly-bounded 1-VASS. Importantly, two copies of V_0 are created. By starting at $p_{v_1}(0)$ in the first copy, a vertex from V_0 belonging to the k-cycle can be selected by loading the sole counter with a value corresponding to that vertex. Then, in the second copy, $q_{v_1}(0)$ can only be reached if the state first arrived at corresponds to the vertex selected in the beginning. Accordingly, there is a run from $p_{v_1}(0)$ to $q_{v_1}(0)$ if and only if there exists a k-cycle, since the states visited in the underlying path of the run correspond to the vertices of the k-cycle.

▶ **Theorem 5.4.** *Assuming the k-cycle hypothesis, coverability and reachability in unary $(\mathcal{O}(n), 1)$-VASS of size n require $n^{2-o(1)}$-time.*

Proof. Assume for contradiction that reachability in a unary $(\mathcal{O}(n), 1)$-VASS of size n can be solved in $\mathcal{O}(n^{2-\varepsilon})$-time for some $\varepsilon > 0$. By the k-cycle hypothesis (Hypothesis 5.2), there exists a k such that the problem of finding a k-cycle in a k-circle layered graph with m vertices cannot be solved in $\mathcal{O}(m^{2-\varepsilon})$-time. Via the reduction presented above in Lemma 5.3, we create a $(\mathcal{O}(n), 1)$-VASS $\mathcal{V}$ of size $n \leq \mathcal{O}(m)$ together with an initial configuration $p(0)$ and a target configuration $q(0)$, such that deciding reachability from $p(0)$ to $q(0)$ in $\mathcal{V}$ determines the existence of a k-cycle in G. Thus the $\mathcal{O}(n^{2-\varepsilon})$ algorithm for reachability would give a $\mathcal{O}(m^{2-\varepsilon})$ algorithm for finding k-cycles, contradicting the k-cycle hypothesis.

By the equivalence of coverability and reachability in unary $(\mathcal{O}(n), 1)$ VASS in Lemma 5.6, the same lower bound holds for coverability. ◀

▶ **Corollary 5.5.** *Assuming the k-cycle hypothesis, coverability in unary 2-VASS of size n requires $n^{2-o(1)}$-time.*

Reachability in $(\mathcal{O}(n), d)$-VASS can be decided in $\mathcal{O}(n(B(n)+1)^d)$-time using the simple algorithm for Observation 5.1 with a trivially modified acceptance condition. It turns out that coverability and reachability are equivalent in unary $(\mathcal{O}(n), d)$-VASS. The following lemma is proved in the full version [31].

▶ **Lemma 5.6.** *For a $(B(n), d)$-VASS, let $C^{B(n)}(n)$ and $R^{B(n)}(n)$ denote the optimal running times for coverability and reachability, respectively. For any $\gamma > 0$, there exists some $\delta > 0$ such that $C^{\gamma \cdot n}(n) \leq \mathcal{O}(R^{\delta \cdot n}(n))$. Conversely, for any $\gamma > 0$, there exists some $\delta > 0$ such that $R^{\gamma \cdot n}(n) \leq \mathcal{O}(C^{\delta \cdot n}(n))$.*

Lower Bounds for Reachability in Linearly-Bounded VASS

To obtain further lower bounds for the coverability problem in $(\mathcal{O}(n), d)$-VASS, by Lemma 5.6, we can equivalently find lower bounds for the reachability problem in $(\mathcal{O}(n), d)$-VASS. In Theorem 5.8, we will assume a well-established hypothesis concerning the time required to find hypercliques in 3-uniform hypergraphs. In fact, Lincoln, Vassilevska Williams, and Williams state and justify an even stronger hypothesis about μ-uniform hypergraphs for every $\mu \geq 3$ [36, Hypothesis 1.4]. We will use this computational complexity hypothesis to expose precise lower bounds on the time complexity of reachability in linearly-bounded fixed dimension unary VASS.

▶ **Hypothesis 5.7** (k-Hyperclique Hypothesis [36, Hypothesis 1.4])**.** *Let $k \geq 3$ be an integer. On Word-RAM with $\mathcal{O}(\log(n))$ bit words, finding an k-hyperclique in a 3-uniform hypergraph on n vertices requires $n^{k-o(1)}$-time.*

▶ **Theorem 5.8.** *Assuming Hypothesis 5.7, reachability in unary $(\mathcal{O}(n), d+2)$-VASS of size n requires $n^{d-o(1)}$-time.*

For the remainder of this section, we focus on the proof of Theorem 5.8. The lower bound is obtained via reduction from finding hyperclique in 3-uniform hypergraphs, hence it is subject to the k-Hyperclique Hypothesis. We present our reduction in two steps. The first step is an intermediate step, in Lemma 5.9 we offer a reduction to an instance of reachability in unary VASS with a limited number of zero-tests (proved in the full version [31]). The second step extends the first, in Lemma 5.10 we modify the reduction by adding a counter so zero-tests are absented. This extension leverages the recently developed *controlling counter technique* of Czerwiński and Orlikowski [16]. This technique allows for implicit zero-tests to be performed in the presence of a dedicated counter whose transition effects and reachability condition ensure the implicit zero-tests were indeed performed correctly.

It has been shown that we may assume that the hypergraph is ℓ-partite for the k-Hyperclique Hypothesis [36, Theorem 3.1]. Thus, we may assume that the vertices can be partitioned into ℓ disjoint subsets $V = V_1 \cup \cdots \cup V_\ell$ and all hyperedges contain three vertices from distinct subsets $\{u, v, w\} \in V_i \times V_j \times V_k$ for some $1 \leq i < j < k \leq \ell$.

▶ **Lemma 5.9.** *Let $d \geq 1$ be a fixed integer. Given a $4d$-partite 3-uniform hypergraph $H = (V_1 \cup \ldots \cup V_{4d}, E)$ with n vertices, there exists a unary $(\mathcal{O}(n^{4+o(1)}), d+1)$-VASS with $\mathcal{O}(d^3)$ zero-tests $\mathcal{T}$ such that there is a $4d$-hyperclique in H if and only if there is a run from $q_I(\mathbf{0})$ to $q_F(\mathbf{v})$, for some $\mathbf{v} \geq \mathbf{0}$, in $\mathcal{T}$. Moreover, $\mathcal{T}$ can be constructed in $\mathsf{poly}(d) \cdot n^{4+o(1)}$-time.*

▶ **Lemma 5.10** ([16, Lemma 10])**.** *Let ρ be a run in a $(d+2)$-VASS such that $q_I(\mathbf{0}) \xrightarrow{\rho} q_F(\mathbf{0})$. Further, let $q_0(\mathbf{v}_0), q_1(\mathbf{v}_1) \ldots, q_r(\mathbf{v}_r)$ be some distinguished configurations observed along the run ρ with $q_0(\mathbf{v}_0) = q_I(\mathbf{0})$ and $q_r(\mathbf{v}_r) = q_F(\mathbf{0})$ and let ρ_j be the segment of ρ that is between $q_{j-1}(\mathbf{v}_{j-1})$ and $q_j(\mathbf{v}_j)$, so ρ can be described as*

$$q_I(\mathbf{0}) = q_0(\mathbf{v}_1) \xrightarrow{\rho_1} q_1(\mathbf{v}_1) \to \cdots \to q_{r-1}(\mathbf{v}_{r-1}) \xrightarrow{\rho_r} q_r(\mathbf{v}_r) = q_F(\mathbf{0}).$$

Let $S_1, \ldots, S_d, S_{d+1} \subseteq \{0, 1, \ldots, r\}$ be the sets of indices of the distinguished configurations where zero-tests could be performed on counters $\mathsf{x}_1, \ldots, \mathsf{x}_d, \mathsf{x}_{d+1}$, respectively. Let $t_{j,i} = |\{s \geq j : s \in S_i\}|$ be the number of zero-test for the counter x_i in the remainder of the run $\rho_{j+1} \cdots \rho_r$. Given that $\mathbf{v}_0 = \mathbf{0}$ and $\mathbf{v}_r = \mathbf{0}$, if

$$\mathrm{eff}(\rho_j)[d+2] = \sum_{i=1}^{d+1} t_{j,i} \cdot \mathrm{eff}(\rho_j)[i], \tag{1}$$

then for every $i \in \{1, \ldots, d, d+1\}$ and $j \in S_i$, we know that $\mathbf{v}_j[i] = 0$.

With Lemma 5.10 in hand, we can ensure that the $\mathcal{O}(d^3)$ zero-tests performed by $\mathcal{T}$, from Lemma 5.9, are executed correctly. We conclude this section with a proof of Theorem 5.8.

Proof of Theorem 5.8. Consider the reduction, presented in Lemma 5.9, from finding a $4d$-hyperclique in a $4d$-partite 3-uniform hypergraph H to reachability in $(\mathcal{O}(n^{4+o(1)}), d+1)$-VASS with $\mathcal{O}(d^3)$ zero-tests. Now, given Lemma 5.10, we will add a controlling counter to $\mathcal{T}$ so that the zero-tests on the $d+1$ counters $\mathsf{x}_1, \ldots, \mathsf{x}_d, \mathsf{y}$ are instead performed implicitly. So we introduce another counter z that receives updates on transitions, consistent with Equation 1, whenever any of the other counters are updated. Note that counters y and z, for the sake of a succinct and consistent description, are respectively referred to as counters x_{d+1} and x_{d+2} in the statement of Lemma 5.10. Moreover, notice that the maximum value of z is bounded by $\mathsf{poly}(d) \cdot \left(\sum_{i=1}^{d+1} \mathsf{x}_i\right) \in \mathsf{poly}(d) \cdot n^{4+o(1)}$.

Therefore, we have constructed a unary $(\mathsf{poly}(d) \cdot n^{4+o(1)}, d+2)$-VASS $\mathcal{V}$ with the property that there H contains a $4d$-hyperclique if and only if there is a run from $q'_I(\mathbf{0})$ to $q'_F(\mathbf{0})$ in $\mathcal{V}$. Such a $(\mathsf{poly}(d) \cdot n^{4+o(1)}, d+2)$-VASS $\mathcal{V}$ has size $\mathcal{O}(t \cdot |\mathcal{T}|)$ where $t \in \mathsf{poly}(d)$ is the number of zero-tests performed on the run from $q_I(\mathbf{0})$ to $q_F(\mathbf{0})$ in $\mathcal{T}$. Moreover, $\mathcal{V}$ can be constructed in $\mathsf{poly}(d) \cdot n^{4+o(1)}$ time. Hence, if reachability in $(\mathcal{O}(n), d+2)$-VASS of size n can be solved faster than $n^{d-o(1)}$, then one can find a $4d$-hyperclique in a 3-uniform hypergraph faster than $n^{4d-o(1)}$, contradicting Hypothesis 5.7. ◀

6 Conclusion

Summary. In this paper, we have revisited a classical problem of coverability in d-VASS. We have closed the gap left by Rosier and Yen [46] on the length of runs witnessing instances of coverability in d-VASS. We have lowered the upper bound of $n^{2^{\mathcal{O}(d \log d)}}$, from Rackoff's technique [45], to $n^{2^{\mathcal{O}(d)}}$ (Theorem 3.3), matching the $n^{2^{\Omega(d)}}$ lower bound from Lipton's construction [37]. This accordingly closes the gap on the exact space required for the coverability problem and yields a deterministic $n^{2^{\mathcal{O}(d)}}$-time algorithm for coverability in d-VASS (Corollary 3.4). We complement this with a matching lower bound conditional on ETH; there does not exist a deterministic $n^{2^{o(d)}}$-time algorithm for coverability (Theorem 4.2). By and large, this settles the exact space and time complexity of coverability in VASS.

In addition, we study linearly-bounded unary d-VASS. Here, coverability and reachability are equivalent and the trivial exhaustive search $\mathcal{O}(n^{d+1})$ algorithm is near-optimal. We prove that reachability in linearly-bounded 1-VASS requires $n^{2-o(1)}$-time under the k-cycle hypothesis (Theorem 5.4), matching the trivial upper bound. We further prove that reachability in linearly-bounded $(d+2)$-VASS requires $n^{d-o(1)}$-time under the 3-uniform hyperclique hypothesis (Theorem 5.8).

Open Problems. The *boundedness problem*, a problem closely related to coverability, asks whether, from a given initial configuration, the set of all reachable configurations is finite. This problem was also studied by Lipton then Rackoff and is EXPSPACE-complete [37, 45].

Boundedness was further analysed by Rosier and Yen [46, Theorem 2.1] and the same gap also exists for the exact space required. We leave the same improvement, to eliminate the same twice-exponentiated $\log(d)$ factor, as an open problem.

Our lower bounds for the time complexity of coverability and reachability in linearly-bounded unary d-VASS, for $d \geq 2$, leave a gap of up to $n^{3+o(1)}$, see Table 1. We leave it as an open problem to either improve upon the upper bound $\mathcal{O}(n^{d+1})$ given by the trivial algorithm, or to raise our conditional lower bounds.

First Order Logic on Pathwidth Revisited Again

Michael Lampis
Université Paris-Dauphine, PSL University, CNRS, LAMSADE, 75016, Paris, France

Abstract

Courcelle's celebrated theorem states that all MSO-expressible properties can be decided in linear time on graphs of bounded treewidth. Unfortunately, the hidden constant implied by this theorem is a tower of exponentials whose height increases with each quantifier alternation in the formula. More devastatingly, this cannot be improved, under standard assumptions, even if we consider the much more restricted problem of deciding FO-expressible properties on trees.

In this paper we revisit this well-studied topic and identify a natural special case where the dependence of Courcelle's theorem can, in fact, be improved. Specifically, we show that all FO-expressible properties can be decided with an elementary dependence on the input formula, if the input graph has bounded pathwidth (rather than treewidth). This is a rare example of treewidth and pathwidth having different complexity behaviors. Our result is also in sharp contrast with MSO logic on graphs of bounded pathwidth, where it is known that the dependence has to be non-elementary, under standard assumptions. Our work builds upon, and generalizes, a corresponding meta-theorem by Gajarský and Hliněný for the more restricted class of graphs of bounded tree-depth.

1 Introduction

Algorithmic meta-theorems are general statements of the form "all problems in a certain class are tractable on a particular class of inputs". Probably the most famous and celebrated result of this type is Courcelle's theorem [5], which states that all graph properties expressible in Monadic Second Order (MSO) logic are solvable in linear time on graphs of bounded treewidth. This result has proved to be of immense importance to parameterized complexity theory, because a vast collection of natural NP-hard problems can be expressed in MSO logic (and its variations that allow optimization objectives [1]) and because treewidth is the most well-studied structural graph parameter. Thanks to Courcelle's theorem, we immediately obtain that all such problems are fixed-parameter tractable (FPT) parameterized by treewidth.

Despite its great success, Courcelle's theorem suffers from a significant weakness: the algorithm it guarantees has a running time that is astronomical for most problems. Indeed, a careful reading of the theorem shows that the running time increases as a tower of exponentials whose height is equal to the number of quantifier alternations of the input MSO formula. Hence, even though Courcelle's theorem shows that any MSO formula ϕ can be decided on n-vertex graphs of treewidth tw in time $f(\phi, \mathrm{tw})n$, the function f is *non-elementary*, that is, it cannot be bounded from above by any tower of exponentials of fixed height.

Table 1 Summary of the state of the art for FO and MSO model checking on graphs of bounded treewidth, pathwidth, and tree-depth. Elementary (green cells) indicates that there is an algorithm which, when the corresponding width is bounded by an absolute constant, decides any formula ϕ in time $f(\phi)n^{O(1)}$, where f is a function that can be bounded above by a finite tower of exponentials. For the remaining cases, this is known to be impossible, under standard assumptions, hence it is inevitable to have an $f(\phi)$ that is a tower of exponentials whose height increases with ϕ.

Parameter	FO	MSO
Treewidth	Non-elementary on Trees [13]	Non-elementary on Trees [13]
Pathwidth	Elementary (Theorem 24)	Non-elementary on Caterpillars [13]
Tree-depth	Elementary [14]	Elementary [14]

One could hope that this terrible dependence on ϕ is an artifact of Courcelle's proof technique. Unfortunately, it was shown in a very influential work by Frick and Grohe [13] that this non-elementary dependence on the number of quantifiers of ϕ is best possible (under standard assumptions), even if one considers the severely restricted special case of model-checking First Order (FO) logic on trees. Recall that FO logic is a basic logic formalism that allows us to express graph properties using quantification over the vertices of the graph, while MSO logic also allows quantification over sets of vertices. Since FO logic is trivially a subset of MSO logic and trees have treewidth 1, this result established that Courcelle's theorem is essentially best possible.

Frick and Grohe's lower bound thus provided the motivation for the search for subclasses of bounded-treewidth graphs where avoiding the non-elementary dependence on ϕ may be possible. The obvious next place to look was naturally, pathwidth, which is the most well-known restriction (and close cousin) of treewidth. Unfortunately, Frick and Grohe's paper provided a negative result for MSO model checking also for this parameter. More precisely, they showed that MSO model checking on strings with a total order relation has a non-elementary dependence on the formula (unless P=NP), but such structures can easily be embedded into caterpillars (which are graphs of pathwidth 1) if one allows quantification over sets. Notice, however, that this does not settle the complexity of FO logic for graphs of counstant pathwidth, as it is not clear how one could implement the total ordering relation of a string without access to set quantifiers (we expand on this question further below).

On the positive side, Frick and Grohe's lower bounds motivated the discovery of several meta-theorems with elementary dependence on the formula for other, more restricted variations of treewidth (we review some such results below). Of all these results, the one that is "closest" to treewidth, is the theorem of Gajarský and Hliněný [14], which states that on graphs of constant tree-depth, MSO (and hence FO) model checking has elementary dependence on the input formula. It is known that for all n-vertex graphs G we have $\mathrm{tw}(G) \leq \mathrm{pw}(G) \leq \mathrm{td}(G) \leq \mathrm{tw}(G) \log n$, where $\mathrm{tw}, \mathrm{pw}, \mathrm{td}$ denote the treewidth, pathwidth and tree-depth. In a sense, this positive result seemed to go as far as one could possibly go towards emulating treewidth, while retaining the elementary dependence on the formula and avoiding the lower bound of Frick and Grohe. This state of the art is summarized in Table 1.

Our result. In this paper we revisit this well-studied topic and address the one remaining case of Table 1 where it is still unknown whether it is possible to obtain an elementary dependence on the formula for model checking. We answer this question positively, showing that if we restrict ourselves to graphs of pathwidth p, where p is an absolute constant, then FO formulas with q quantifiers can be decided in time $f(q)n^{O(1)}$, where f is an elementary function of q. More precisely, the function f is at most a tower of exponentials of height $O(p)$. In other words, our result trades the non-elementary dependence on q which is inherent in Courcelle's theorem, with a non-elementary dependence on p. Though this may seem

disappointing at first, it is known that this is the best one could have hoped for. In fact, the meta-theorem of [14] also has this behavior (its parameter dependence is a tower of exponentials whose height increases with the tree-depth), and it was shown in [24] that this is best possible (under standard assumptions). Since pathwidth is a more general parameter, we cannot evade this lower bound and our algorithm needs to have a non-elementary dependence on pathwidth, if its dependence on the formula is elementary.

The result we obtain is, therefore, in a sense best possible and fills a natural gap in our knowledge regarding FO model checking for a well-studied graph width. Beyond filling this gap, the fact that we are able to give a positive answer to this question and obtain an algorithm with "good" dependence on the formula is interesting, and perhaps even rather striking, for several reasons. First, in many cases in this domain, it is impossible to obtain an elementary dependence on q, no matter how much we are willing to sacrifice on our dependence on the graph width, as demonstrated by the fact that the lower bounds of Table 1 apply for classes with the smallest possible width (trees and caterpillars). Second, even though FO seems much weaker than MSO in general, the complexities of model checking the two logics seem to be similar (that is, at most one level of exponentiation apart) for most parameters (we review some further examples below). Indeed, a main contribution of [14] was to prove that for graphs of bounded tree-depth, the two logics are actually equivalent. It is therefore somewhat unusual (for this context) that for pathwidth FO has quite different complexity from MSO logic. Third, even though treewidth and pathwidth are arguably the two most well-studied graph widths in parameterized complexity, by and large the complexities of the vast majority of problems are the same for both parameters (for more information on this, see [2] which only recently discovered the first example of a natural problem separating the two parameters). It is therefore remarkable that the complexity of FO model checking is so different for pathwidth and treewidth.

Finally, one aspect of our result that makes it more surprising is that it does not seem to generalize to dense graphs. Meta-theorems that give a non-elementary dependence on the formula by using a restriction of treewidth, generally have a dense graph analogue, using a restriction of clique-width (the dense graph analogue of treewidth). Indeed, this is the case for vertex cover [23] (neighborhood diversity [23], twin cover [16]) but also for tree-depth (shrub-depth [17]). One may have expected something similar to hold in our case. However, the natural dense analogue of pathwidth is linear clique-width and it is already known that FO logic has a non-elementary dependence on threshold graphs [24]. Since threshold graphs have linear clique-width 2, we cannot hope to extend our result to this parameter and it appears that the positive result of this paper is an isolated island of "tractability".

High-level proof overview. Our technique extends and builds upon the meta-theorem of [14] which handles the more restricted case of graphs of bounded tree-depth. We recall that the heart of this meta-theorem is the basic observation that FO logic has bounded counting power: if our graph contains $q+1$ identical parts (for some appropriate definition of "identical"), then deleting one cannot affect the validity of any FO formula with q quantifiers. The approach of [14] is to partition the vertices of the graph depending on their height in the tree-depth decomposition, then identify (and delete) identical vertices in the bottom level. This bounds the degree of vertices one level up, which allows us to partition them into a bounded number of types, delete components of the same type if we have too many, hence bound the degree of vertices one level up, and so on until the size of the whole graph is bounded.

Our approach borrows much of this general strategy: we will appropriately rank the vertices of the graph and then move from lower to higher ranks, at each step bounding the maximum degree of any vertex of the current rank. Besides the fact that ranking vertices into levels is less obvious when given a path decomposition, rather than a tree of fixed height,

the main difficulty we encounter is that no matter where we start, we cannot in general easily find identical parts where something can be safely deleted. Intuitively, this is demonstrated by the contrast between the simplest bounded tree-depth graph (a star, where leaves are twins, hence one can easily delete one if we have at least $q+1$) and the simplest bounded pathwidth graph (a path, which contains no twins). In order to handle this more general case, we need to combine the previous approach with arguments that rely on the locality of FO logic.

To understand informally what we mean by this, recall the classical argument which proves that Reachability is not expressible in FO logic. One way this is proved, is to show that a graph G_1 which is a long path (of say, 4^q vertices) and a graph G_2 which is a union of a path and a cycle (of say, $2 \cdot 4^{q-1}$ vertices each) are indistinguishable for FO formulas with q quantifiers. Our strategy is to flip this argument: if we are asked to model check a formula on a long path, we might as well model check the same formula on a simpler (less connected) graph which contains a shorter path and a cycle. Of course, our input graphs will be more complicated than long paths; we will, however, be dealing with long path-like structures, as our graph has small pathwidth. Our strategy is to perform a surgical rewiring operation on the path decomposition, producing the union of a shorter decomposition and a ring-like structure, while still satisfying the same formulas (the reader may skip ahead to Figure 1 to get a feeling for this operation). In other words, the main technical ingredient of our algorithm is inspired by (and exploits) a classical impossibility result on the expressiveness of FO logic. The abstract idea is (in a rough sense) to apply this argument repeatedly, so that if we started with a long path decomposition, we end up with a short path decomposition and many "disconnected rings". Eventually, we will be able to produce some such rings which are identical, delete them, and simplify the graph.

There are, of course, now various technical difficulties we need to overcome in order to turn this intuition into a precise argument. First, when we cut at two points in the path decomposition to extract the part that will form the "ring", we need to make sure that at an appropriate radius around the cut points the decompositions are isomorphic. It is not hard to calculate the appropriate radius we need in the graph (it is known that q-quantifier FO formulas depend on balls of radius roughly 2^q), but a priori two vertices which are close in the graph could be far in the path decomposition. To handle this, we take care when we rank the vertices, so that vertices of lower rank are guaranteed to only appear in a bounded number of bags, hence distances in the path decomposition approximate distances in the graph. Second, we need to calculate how long our decomposition needs to be before we can guarantee that we will be able to find some appropriate cut points. Here we use some counting arguments and pigeonhole principle to show that a path decomposition with length double-exponential in the desired radius is sufficient. Finally, once we find sufficiently many points to rewire and produce sufficiently many "rings", we need to prove that this did not affect the validity of the formula. Then, we are free to delete one, using the same argument as [14] and obtain a smaller equivalent graph. In the end, once we can no longer repeat this process, we obtain a bounded-degree graph, where it is known that FO model checking has an elementary dependence on the formula.

Overall, even though the algorithm we present seems somewhat complicated, the basic ingredients are simple and well-known: the fact that deleting one of many identical parts does not affect the validity of the formula (which is also used in [14]); the fact that FO formulas are not affected if we edit the graph in a way that preserves balls of a small radius around each vertex; and simple counting arguments and the pigeonhole principle.

Paper Organization. We conclude this section below with a short overview of other related work on algorithmic meta-theorems and continue in Section 2 with definitions and notation. The rest of the paper is organized as follows:

1. In Section 3 we present two lemmas, which are standard facts on FO logic, with minor adjustments to our setting. In particular, in Section 3.1 we present the lemma that states that if we have $q+1$ identical parts, it is safe to delete one; and in Section 3.2 we present the lemma that states that if two graphs agree on the local extended neighborhoods around each vertex (for some appropriate radius), then they satisfy the same formulas (that is, FO logic is local). Since these facts are standard, the reader may wish to skip the proofs of Section 3, which are given for the sake of completeness, during a first reading.
2. Then, in Section 4 we present the specific tools we will use to simplify our graph. In Section 4.1 we explain how we rank the vertices of a path decomposition so that each vertex has few neighbors of higher rank (but possibly many neighbors of lower rank). This allows us to process the ranks from lower to higher, simplifying the graph step by step. Then, in Section 4.2 we use some counting arguments to calculate the length of a path decomposition that guarantees the existence of long isomorphic blocks, on which we will apply the rewiring operation. We also show how distances in the graph can be approximated by distances in the path decomposition, if we have bounded the number of occurrences of each vertex in the decomposition. Finally, in Section 4.3 we formally define the rewiring operation and show that if the points where we apply it are in the middle of sufficiently long isomorphic blocks of the decomposition, this operation is safe. We also show that the "rings" it produces can be considered identical, in a sense that will allow us to invoke the lemma of Section 3.1 and delete one.
3. We put everything together in Section 5, where we explain how the lemmas we have presented form parts of an algorithm that ranks the vertices of a graph supplied with a path decomposition and then processes ranks one by one, decreasing the number of occurences of each vertex in the decomposition without affecting the validity of any formula (with q quantifiers). In the end, the processed graph has bounded degree and we invoke known results to decide the formula.

Other related work. Algorithmic meta-theorems are a very well-studied topic in parameterized complexity ([20]) and much work has been devoted in improving and extending Courcelle's theorem. Among such results, we mention the generalization of this theorem to MSO for clique-width, which covers dense graphs [6]. For FO logic, fixed-parameter tractability can be extended to much wider classes of graphs, with the recently introduced notion of twin-width nicely capturing many results in the area [4, 9, 11, 12]. Of course, since all these classes include the class of all trees, the non-elementary dependence on the formula implied by the lower bound of [13] still applies. Meta-theorems have also been given for logics other than FO and MSO, with the goal of either targeting a wider class of problems [18, 21, 22, 28], or achieving better complexity [26]. Kernelization [3, 10, 19] and approximation [8] are also topics where meta-theorems have been studied.

The meta-theorems which are more relevant to the current work are those which explicitly try to improve upon the parameter dependence given by Courcelle, by considering more restricted parameters. We mention here the meta-theorems for vertex cover, max-leaf, and neighborhood diversity [23], twin-cover [16], shrub-depth [17], and vertex integrity [25]. As mentioned, one common aspect of these meta-theorems is that they handle both FO and MSO logic, without a huge difference in complexity (at most one extra level of exponentiation in the parameter dependence), which makes the behavior of FO logic on treewidth somewhat

unusual. The only exception, is the meta-theorem on graphs of bounded max-leaf number of [23] which does not generalize to MSO logic. It was later shown that this is with good reason, as MSO logic has a non-elementary dependence even for unlabeled paths [24], which have the smallest possible max-leaf number. This is therefore the only previous result in the literature which mirrors the situation for pathwidth.

A classical result, incomparable to the parameters mentioned above, is the fact that FO model checking is FPT (with an elementary, triple-exponential dependence on the formula) on graphs of bounded degree [27]. We will use this fact as the last step of our algorithm.

The complexity of model checking FO and MSO formulas on structures other than graphs, such as posets [15] and strings has also been investigated. As mentioned, the case of strings is of particular interest to us, because the standard structure that represents a string over a fixed alphabet (a universe that contains the letters of the string, unary predicates that indicate for each letter which character of the alphabet it corresponds to, and a total ordering relation $\prec$ which indicates the ordering of the letters in the string) allows us to easily translate MSO properties of strings into MSO properties of an appropriate caterpillar. Indeed, to embed a string into a caterpillar, we can start with a path with endpoints s, t, and use one vertex of the path to represent each letter in the string. We can attach an appropriate (constant) number of leaves on each vertex to signify which character it represents. The precedence relation $x \prec y$ of the string now becomes the relation "every connected set that contains s and y, also contains x", which is MSO-expressible. Thanks to this simple transformation, the lower bound result of [13] on model checking MSO (and even FO) logic on strings, immediately carries over to graphs of pathwidth 1. Note, however, that the existence of the ordering relation is crucial, as FO model checking on other models of strings (e.g. with a successor relation) has elementary dependence on the formula, as such structures have bounded degree [13]. Hence, it seems that if we focus on FO (rather than MSO) logic, the similarity between model checking on bounded pathwidth graphs and strings becomes much weaker: FO model checking is easier on graphs of bounded pathwidth than on strings with an ordering relation, but harder than on strings with only a successor relation (as the lower bound of [24] for tree-depth applies to pathwidth, and rules out an algorithm with "only" triple-exponential dependence).

2 Definitions and Preliminaries

We use standard graph-theoretic notation and assume the reader is familiar with the basics of parameterized complexity (see e.g. [7]). For a graph $G = (V, E)$, and $S \subseteq V$, we use $G[S]$ to denote the subgraph of G induced by S. When r is a positive integer, we use $[r]$ to denote the set $\{1, \ldots, r\}$, while for two integers s, t, we use $[s, t]$ to denote the set $\{i \in \mathbb{Z} \mid s \leq i \leq t\}$. Note that if $t < s$ then $[s, t] = \emptyset$. We define $\mathrm{tow}(i, n)$ as follows: $\mathrm{tow}(0, n) = n$ and $\mathrm{tow}(i + 1, n) = 2^{\mathrm{tow}(i,n)}$. A function $f : \mathbb{N} \to \mathbb{N}$ is elementary if there exists a fixed i such that for all n we have $f(n) \leq \mathrm{tow}(i, n)$.

We recall the standard notion of path decomposition: a path decomposition of a graph $G = (V, E)$ is an ordered sequence of bags $B_1, B_2, \ldots, B_\ell$, where each B_i is a subset of V, that satisfies the following: (i) $\bigcup_{j \in [\ell]} B_j = V$ and for all $uv \in E$ there exists $i \in [\ell]$ such that $\{u, v\} \subseteq B_i$ (ii) for all $i_1 < i_2 < i_3$, with $i_1, i_2, i_3 \in [r]$ we have $B_{i_1} \cap B_{i_3} \subseteq B_{i_2}$. The width of a path decomposition is the number of vertices in the largest bag (minus one). The pathwidth of a graph G is the smallest width of any path decomposition of G.

First Order Logic. We use a standard form of First Order (FO) logic on graphs, where quantified variables are allowed to range over vertices. To simplify the presentation of some results, we will allow our formulas to also refer to vertex constants, corresponding to some specific vertices of the graph. More formally, the structures on which we will perform model checking are k-terminal graphs as defined below.

▶ **Definition 1.** *For a positive integer k, a k-terminal graph $G = (V, E)$ is a graph supplied with a function $\mathcal{T} : [k] \to V$, called the terminal labeling function. For $i \in [k]$, we say that $\mathcal{T}(i)$ is the i-th terminal of G. The set of terminals is the set T of images of $\mathcal{T}$ in V. Vertices of $V \setminus T$ are called non-terminals.*

Intuitively, terminals will play two roles: on the one hand, we define FO logic on graphs (below) in a way that allows formulas to refer to the terminal vertices; on the other, in some parts of our algorithm we will use a set of terminals that form a separator of the graph and hence allow us to break down the graph into smaller components. Note, however, that Definition 1 does not require the k terminals to be a separator, or have any other particular property.

A formula of FO logic is made up of the following vocabulary: (i) vertex variables, denoted $x_1, x_2, \ldots$ (ii) vertex constants denoted $\ell_1, \ell_2, \ldots$ (iii) existential quantification $\exists$ (iv) the boolean operations $\neg, \vee$ (v) the binary predicates $\sim$ (for adjacency) and $=$ (for equality). More formally, a First Order formula is a formula produced by the following grammar, where x represents a vertex variable and y represents a vertex variable or constant:

$$\phi \to \exists x.\phi \mid \neg\phi \mid \phi \vee \phi \mid y \sim y \mid y = y$$

A FO formula ϕ is called a sentence if every vertex variable x appearing in ϕ is quantified, that is, x appears within the scope of $\exists x$. A variable that is not quantified is called a free variable. For a formula ϕ that contains a free variable x, we will write $\phi[x/\ell_i]$ to denote the formula obtained by replacing every occurrence of x in ϕ by the constant ℓ_i.

The main problem we are concerned with is model checking: given a k-terminal graph G and a sentence ϕ, decide if G satisfies ϕ. We define the semantics of what this means inductively in a standard way, as follows. We say that a k-terminal graph $G = (V, E)$ with labeling function $\mathcal{T}$ models (or satisfies) a formula ϕ, and write $G, \mathcal{T} \models \phi$ (or simply $G \models \phi$ if $\mathcal{T}$ is clear from the context) if and only if we have one of the following:

1. $\phi := (\ell_i = \ell_j)$, where $i, j \in [k]$ and $\mathcal{T}(i)$ is the same vertex as $\mathcal{T}(j)$.
2. $\phi := (\ell_i \sim \ell_j)$, where $i, j \in [k]$ and $\mathcal{T}(i)\mathcal{T}(j) \in E$.
3. $\phi := (\neg\psi)$ and it is not the case that $G, \mathcal{T} \models \psi$.
4. $\phi := (\psi_1 \vee \psi_2)$ and at least one of $G \models \psi_1$, $G \models \psi_2$ holds.
5. $\phi := (\exists x.\psi)$ and there exists $v \in V$ such that $G, \mathcal{T}' \models \psi[x/\ell_{(k+1)}]$, where $\mathcal{T}'$ is the labeling function that sets $\mathcal{T}'(k+1) = v$ and $\mathcal{T}'(i) = \mathcal{T}(i)$ for $i \in [k]$.

Note that we have not included in our definition universal quantification or other boolean connectives such as $\wedge$. However, this is without loss of generality as $\forall x.\phi$ can be thought of as shorthand for $\neg\exists x.\neg\phi$ and all missing boolean connectives can be simulated using $\neg$ and $\vee$.

Let us also define a kind of isomorphism between labeled graphs that is guaranteed to leave terminal vertices untouched.

▶ **Definition 2.** *A terminal-respecting isomorphism between two k-terminal graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ with terminal labeling functions $\mathcal{T}_1, \mathcal{T}_2$ is a bijective function $f : V_1 \to V_2$ such that (i) for all $u, u' \in V_1$ we have $uu' \in E_1$ if and only if $f(u)f(u') \in E_2$ (ii) for each $i \in [k]$, $f(\mathcal{T}_1(i)) = \mathcal{T}_2(i)$.*

We recall the following basic fact about FO logic which states that isomorphic structures satisfy the same sentences (see e.g. Lemma 9 of [25] for a proof).

▶ **Lemma 3.** *If G_1, G_2 are two k-terminal graphs such there exists a terminal-respecting isomorphism from G_1 to G_2, then, for all FO sentences ϕ we have $G_1 \models \phi$ if and only if $G_2 \models \phi$.*

3 Two Basic Lemmas

The purpose of this section is to establish two basic ingredients that will allow us to simplify the input graph without affecting whether it satisfies any FO formula with at most a given number q of quantified variables. The first lemma (Lemma 5) is rather simple and states that if a graph contains many "identical" components, we can safely remove one. Despite its simplicity, this idea has been sufficient to obtain many of the best currently known meta-theorems with non-elementary dependence in the formula, such as the meta-theorem of [14] for graphs of bounded tree-depth.

The second lemma (Lemma 9) is a variation of standard arguments regarding the locality of FO logic. It states that if we have two graphs which look locally the same, in the sense that for each vertex of one graph there exists a vertex of the other whose r-neighborhood is the same, for some appropriately chosen r, then actually the two graphs are indistinguishable by FO formulas with q quantifiers (even though they are not necessarily isomorphic). As we explained, we intend to use this to allow us to take parts of the graph that resemble "long", low-pathwidth components and cut them up into smaller, disconnected components. The strategy is to eventually produce a large enough number of such components that we can apply Lemma 5 and simplify the graph.

3.1 Identical Parts

We would now like to show that if the given graph contains many (say, at least $q+1$) "identical" parts, then it is safe to delete one without affecting whether the graph satisfies any FO formula with at most q quantifiers. We first define what we mean that two sets of vertices are identical in a k-terminal graph and then prove that if we can find $q+1$ such sets in a graph, we can safely delete one without affecting whether any FO formula with at most q quantifiers is satisfied.

▶ **Definition 4.** *Let $G = (V, E)$ be a k-terminal graph with labeling function $\mathcal{T}$ and terminal set T. We say that two disjoint sets of vertices C_1, C_2 are* identical *if there exists a terminal-respecting isomorphism from G to G that maps all vertices of C_1 to C_2 and all vertices of C_2 to C_1, and maps every vertex of $V \setminus (C_1 \cup C_2)$ to itself.*

Before we proceed, let us make two easy observations. First, if C_1, C_2 are identical, it must be the case that $(C_1 \cup C_2) \cap T = \emptyset$, because C_1, C_2 are disjoint and terminal-respecting isomorphisms must map vertices of T to themselves. Second, the relation of being identical is an equivalence relation on a collection of pairwise disjoint sets of vertices, that is, if C_1, C_2, C_3 are disjoint, C_1 is identical to C_2, and C_2 is identical to C_3, then C_1 is identical to C_3 (the fact that the relation is reflexive and symmetric is easy to see).

▶ **Lemma 5.** *Fix a positive integer q. Let $G = (V, E)$ be a k-terminal graph with labeling function $\mathcal{T}$ and terminal set T and suppose that $C_1, C_2, \ldots, C_{q+1}$ are $q+1$ sets of vertices of G which are pairwise identical. Then, for all FO sentences with at most q quantifiers we have that $G, \mathcal{T} \models \phi$ if and only if $G[V \setminus C_1], \mathcal{T} \models \phi$.*

3.2 Similar Neighborhoods

We now move on to present a lemma that will allow us to claim that two graphs are indistinguishable for FO formulas with q quantifiers if they are locally the same. This is a standard argument in FO logic, going back to Gaifman, though we need to adjust the proof to our purposes to handle terminal vertices appropriately. In particular, we will on the one hand be stricter on the isomorphisms we allow before we consider that the neighborhoods of two vertices are the same (because we only allow terminal-respecting isomorphisms), but on the other, we will only consider the extended neighborhood around a vertex by considering paths that go through non-terminals. This is important, because it allows us to work around the case where, for example, a terminal vertex is connected to everything and hence the diameter of the graph is 2. In such a case, the extended neighborhood of a non-terminal vertex will not trivially contain the whole graph, because we exclude paths that go through the supposed universal terminal.

According to this discussion, we define the notion of a ball of radius r around a vertex v, denoted $B_r(v)$, in a way that only takes into account paths whose internal vertices are non-terminals, as follows.

▶ **Definition 6.** *Let $G = (V, E)$ be a k-terminal graph with terminal labeling function $\mathcal{T}$ and terminal set T, r be a positive integer, and $v \in V$. We define $B_r^G(v)$ (and simply write $B_r(v)$ if G is clear from the context) to be the k-terminal subgraph of G that has labeling function $\mathcal{T}$ and is induced by $T \cup V'$, where V' is the set of all vertices reachable by v via a path of length at most r whose internal vertices are all in $V \setminus T$.*

▶ **Definition 7.** *Let $G_1 = (V_1, E_1), G_2 = (V_2, E_2)$ be two k-terminal graphs, with terminal labeling functions $\mathcal{T}_1, \mathcal{T}_2$ and terminal sets T_1, T_2. For a non-negative integer r, we will say that $v_1 \in V_1$ is* r-similar *to $v_2 \in V_2$, if there exists a terminal-respecting isomorphism from $B_r^{G_1}(v_1)$ to $B_r^{G_2}(v_2)$ that maps v_1 to v_2.*

Note that in the above definition, G_1, G_2 may be the same graph. It is not hard to see that r-similarity is an equivalence relation on the vertices of $V_1 \cup V_2$. Definition 7 allows us to set $r = 0$, in which case we are testing if the graphs induced by $T \cup \{v_1\}$ and $T \cup \{v_2\}$ are isomorphic. Let us also make the following easy observation that decreasing r cannot make two similar vertices dissimilar.

▶ **Observation 8.** *Let G_1, G_2 be two graphs as in Definition 7 and $v_1 \in V(G_1), v_2 \in V(G_2)$ be two vertices which are r-similar. Then, for all non-negative integers $r' \leq r$, v_1 is r'-similar to v_2.*

The main lemma of this section is then the following.

▶ **Lemma 9.** *Let q, k be positive integers and set $r = 2^q - 1$. Let G_1, G_2 be two k-terminal graphs that contain some non-terminal vertices, with labeling functions $\mathcal{T}_1, \mathcal{T}_2$ and terminal sets T_1, T_2. Suppose that there exists a bijective mapping $f : V(G_1) \to V(G_2)$ such that (i) for all $i \in [k]$ we have $f(\mathcal{T}_1(i)) = \mathcal{T}_2(i)$ (ii) for all non-terminal vertices $v \in V(G_1) \setminus T_1$ we have that v is r-similar to $f(v) \in V(G_2) \setminus T_2$. Then, for all FO sentences ϕ with at most q quantifiers we have $G_1 \models \phi$ if and only if $G_2 \models \phi$.*

4 Simplification Operations on Path Decompositions

In this section we present the main technical ingredients of our algorithm. In Section 4.1 we show how we can rank the vertices to bound the number of higher-rank neighbors of any vertex; in Section 4.2 we use the pigeonhole principle to show that for sufficiently long path

decompositions we can always find long isomorphic blocks; and in Section 4.3 we describe the rewiring operation we will use in these blocks and show that it does not affect the validity of any formula and that it produces identical parts, in the sense of Lemma 5.

4.1 Normalized Path Decompositions

▶ **Definition 10.** *A* ranked *path decomposition of a graph $G = (V, E)$ where all bags have size at most p is a path decomposition together with a ranking function $\rho : V \to \mathbb{N}$ that has the property that no bag B_i of the decomposition contains two vertices $u, v \in B_i$ for which $\rho(u) = \rho(v)$.*

▶ **Lemma 11.** *Given a graph $G = (V, E)$ and a path decomposition of G where each bag contains at most p vertices, it is possible in polynomial time to convert it into a ranked path decomposition with a ranking function $\rho : V \to [8p]$ and the property that for each $i < j$ with $i, j \in [8p]$ we have that for every vertex v with $\rho(v) = i$, there exist at most two vertices u_1, u_2 with $\rho(u_1) = \rho(u_2) = j$ that appear in a bag together with v. Furthermore, the produced decomposition has the property that each bag contains at least one vertex that does not appear in the previous bag.*

We will call the ranked path decompositions that satisfy the properties of the decompositions produced by Lemma 11 *normalized* path decompositions. Since such a decomposition can always be obtained without using too many ranks in the ranking function, we will from now on focus on the case where we are given a normalized decomposition. Furthermore, we will usually use p to denote the maximum rank, rather than the pathwidth; this will not have a significant impact as, according to Lemma 11 we can make sure that the two are at most a constant factor apart.

4.2 Finding Isomorphic Bag Intervals

As mentioned, our high-level strategy will be to identify parts of the graph which are locally isomorphic, so that we can apply Lemma 9 to obtain a simpler (less well-connected) graph, and eventually Lemma 5 in order to decrease the size of the graph. In order to identify such parts, we first define what it means for two blocks of bags of a given decomposition to be isomorphic.

▶ **Definition 12.** *Let $G = (V, E)$ be a k-terminal graph with terminal set T, and $B_1, \ldots, B_\ell$ a ranked path decomposition of G with ranking function $\rho : V \to [p]$. Let s_1, t_1, s_2, t_2 be positive integers with $s_1 \leq t_1$ and $t_1 - s_1 = t_2 - s_2$. We define the* block *corresponding to $[s_1, t_1]$ and write $\mathcal{B}(s_1, t_1)$ to be $\{B_j \mid j \in [s_1, t_1]\}$. We say that $\mathcal{B}(s_1, t_1)$ is* block-isomorphic *to $\mathcal{B}(s_2, t_2)$ if*

1. *For each $j \in [s_1, t_1]$ and rank i we have $|\rho^{-1}(i) \cap B_j| = |\rho^{-1}(i) \cap B_{s_2+(j-s_1)}|$.*
2. *For each $j \in [s_1 + 1, t_1]$ and rank i we have that B_j contains a vertex v with $\rho(v) = i$ such that $v \notin B_{j-1}$ if and only if $B_{s_2+(j-s_1)}$ contains a vertex v' with $\rho(v') = i$ such that $v' \notin B_{s_2+(j-s_1)-1}$.*
3. *The following mapping f is a terminal-respecting isomorphism from $G[T \cup (\bigcup_{j\in[s_1,t_1]} B_j)]$ to $G[T \cup (\bigcup_{j\in[s_2,t_2]} B_j)]$. For each $v \in \bigcup_{j\in[s_1,t_1]} B_j$ we let j_v be the minimum index in $[s_1, t_1]$ such that $v \in B_{j_v}$ and define $f(v)$ to be the (unique) vertex of $B_{s_2+(j_v-s_1)}$ such that $\rho(v) = \rho(f(v))$.*

▶ **Definition 13.** *Let $L \geq 0$ and G, k, T, ℓ, ρ as in Definition 12. For positive integers $s_1, s_2 \in [\ell - L]$ we will write $s_1 \approx_L s_2$ to indicate that $\mathcal{B}(s_1, s_1 + L)$ is block-isomorphic to $\mathcal{B}(s_2, s_2 + L)$.*

Note that the isomorphism of Definition 12 is well-defined, because according to the first condition, if B_j contains a vertex of rank i, then so does $B_{s_2+(j_v-s_1)}$, and such a vertex is unique by the definition of ranked path decomposition. According to Definition 12, two blocks of bags are isomorphic only if the subgraphs induced by the bags they contain (and the terminals of G) are isomorphic under the trivial mapping function which maps each vertex of a bag from one block to the vertex of the corresponding bag of the other block that has the same rank. Despite the fact that this restricts the class of isomorphisms we may consider quite a bit, the block-isomorphism relation is an equivalence relation that does not have too many equivalence classes. In particular, we have the following.

▶ **Lemma 14.** *Let $L \geq 0$, $G = (V, E)$ be a k-terminal graph with terminal set T, and $B_1, \ldots, B_\ell$ a ranked path decomposition of G with ranking function $\rho : V \to [p]$. Let t_1, t_2 be integers such that for all $j, j' \in [t_1, t_2]$ we have $B_j \cap T = B_{j'} \cap T$. Then, the relation $\approx_L$ is an equivalence relation on the set $[t_1, t_2 - L]$ with at most $2^{(L+1)(p^2+2p+kp)}$ equivalence classes.*

Proof. The fact that $\approx_L$ is an equivalence relation is easy to see, as terminal-respecting isomorphisms can be composed to show transitivity. The interesting part of the lemma is then the bound on the number of equivalence classes. We prove this by induction on L.

For $L = 0$, we claim there are at most 2^{p+p^2+kp} equivalence classes of bags (in this case, each block consists of a single bag). Indeed, in order to decide if $\mathcal{B}(s_1, s_1) = \{B_{s_1}\}$ and $\mathcal{B}(s_2, s_2) = \{B_{s_2}\}$ are block-isomorphic, we first need to check if B_{s_1}, B_{s_2} contain vertices of the same ranks, and for this there are 2^p equivalence classes. If they do, then we must check, for each $i_1, i_2 \in [p]$ if the vertices of ranks i_1, i_2 in each of B_{s_1}, B_{s_2} are adjacent, and for this we have $2^{\binom{p}{2}} < 2^{p^2}$ equivalence classes. Finally, since the isomorphism has to be terminal-respecting, we have to check for each rank $i \in [p]$ if the vertex of rank i in each of B_{s_1}, B_{s_2} is connected to each of the k terminals, which gives at most kp edges which may or may not exist. (Note that we have to check these edges, even though the two bags contain the same terminals, because terminal-respecting isomorphisms must also preserve the edges towards terminals outside the bag). Overall we have at most $2^{p+p^2+kp} < 2^{p^2+2p+kp}$ choices. If we make the same choices for two bags, the two bags are block-isomorphic, hence we have bounded the number of equivalence classes for $L = 0$.

Suppose now that $L > 0$ and we have shown that the number of equivalence classes of $\approx_{L-1}$ is at most $2^{L(p^2+2p+kp)}$. Consider two indices s_1, s_2 for which we want to check if $s_1 \approx_L s_2$. We claim that for this it is sufficient to have $s_1 \approx_{L-1} s_2$ and to satisfy certain conditions for the bags B_{s_1+L}, B_{s_2+L} for which we have at most $2^{p^2+2p+kp}$ choices. More precisely, for each rank i, we have three possibilities for the bag B_{s_1+L}: either the bag contains no vertex of rank i; or it contains a vertex of rank i that also appears in B_{s_1+L-1}; or it contains a vertex of rank i that appears for the first time in B_{s_1+L} (and hence this vertex is a non-terminal). Suppose now that for each rank i, the bags B_{s_1+L}, B_{s_2+L} agree on the choice of which of these three possibilities holds (there are $3^p < 2^{2p}$ possibilities in total), and furthermore, that the graphs induced by $B_{s_1+L} \cup T$ and $B_{s_2+L} \cup T$ are isomorphic for the natural terminal-respecting isomorphism that matches vertices of the same rank (at most 2^{p^2+kp} possibilities). Then, if $s_1 \approx_{L-1} s_2$, we now have $s_1 \approx_L s_2$. Therefore, each of the $2^{L(p^2+2p+kp)}$ equivalence classes of $\approx_{L-1}$ has been refined into at most 2^{2p+p^2+kp} equivalence classes, giving that the number of equivalence classes of $\approx_L$ is at most $2^{(L+1)(p^2+2p+kp)}$, as desired. ◀

Now that we know that block-isomorphism has a bounded number of equivalence classes (if k, p, L are bounded), we can try to look for "copies" of the same block in our path decomposition. We observe the following lemma.

▶ **Lemma 15.** *Let L be a non-negative integer, $G = (V, E)$ be a k-terminal graph with terminal set T, and $B_1, \ldots, B_\ell$ a ranked path decomposition of G with ranking function $\rho : V \to [p]$. We define $R = (L+1)(2^{(L+1)(p^2+2p+kp)} + 1)$. Let t_1, t_2 be integers such that for all $j, j' \in [t_1, t_2]$ we have $B_j \cap T = B_{j'} \cap T$. Then, for every $s \in [t_1, t_2 - R]$, there exist $s_1, s_2 \in [s, s + R - (L+1)]$ such that $s_1 + L < s_2$ and $s_1 \approx_L s_2$.*

What we have shown so far is that if we take sufficiently many (at least R) consecutive bags in our decomposition, we will find two blocks of length (roughly) L which are block-isomorphic. Let us now move a step further.

▶ **Lemma 16.** *Let L be a non-negative integer, $G = (V, E)$ be a k-terminal graph with terminal set T, $B_1, \ldots, B_\ell$ a ranked path decomposition of G with ranking function $\rho : V \to [p]$, and t_1, t_2 as defined in Lemma 15. Let q, R be positive integers. We define $R^* = (R+1)(q2^{(R+1)(p^2+2p+kp)} + 1)$. Then, for every $s \in [t_1, t_2 - R^*]$ there exist $q+1$ distinct $s_1, s_2, \ldots, s_{q+1} \in [s, s + R^* - (R+1)]$, such that for any two distinct s_i, s_j with $i, j \in [q+1]$ we have $|s_i - s_j| > R$ and $s_i \approx_R s_j$.*

Note that Lemma 15 and Lemma 16 are non-vacuous only if we find a long enough interval where all bags contain the same terminals, that is if $t_2 - t_1 \geq R$ or $t_2 - t_1 \geq R^*$ respectively. We will take this into account when we use these lemmas in the next section.

At this point we are almost done in our search for appropriate isomorphic parts of the graph. What we have proved is that, if we fix some appropriate radius L, there is some larger radius R^* (double-exponential in L), such that if we look at any interval of the path decomposition of length R^*, we will be able to find $q+1$ isomorphic R-blocks, which are long enough to guarantee the existence of two isomorphic L-blocks inside them. What remains is to ask what value of L will be appropriate for our purposes. Ideally, we would like to calculate a value L that will allow us to preserve the balls around vertices for a suitable radius and apply Lemma 9. However, we can only give such a bound if we know that vertices of our path decomposition do not appear in too many bags.

▶ **Lemma 17.** *Let $G = (V, E)$ be a k-terminal graph with terminal set T and $B_1, \ldots, B_\ell$ a ranked path decomposition of G with the additional property that any non-terminal vertex appears in at most Δ bags of the decomposition. Then, for each $r \geq 0$ and for each non-terminal vertex v, if $v \in B_j$, then each non-terminal vertex of $B_r(v)$ is contained in a bag of $\mathcal{B}(j - r\Delta, j + r\Delta)$.*

4.3 Rewiring Operation

The goal of Section 4.2 was to present the basic tools which will allow us to find isomorphic parts of the input graph. Ideally, we would then like to use Lemma 5 and delete one such part. However, this is in general not possible, as the isomorphism guaranteed by the lemmas of Section 4.2 is not sufficient to obtain identical sets, in the sense of Definition 4. What we need to do, then, is to edit the graph in a way that does not affect the validity of any FO formula with q quantifiers but leverages the isomorphic parts we have found to construct $q+1$ identical parts on which Lemma 5 can be applied. We now present the basic edit operation which will allow us to achieve this for appropriate parameters.

▶ **Definition 18** (Rewiring). *Let $G = (V, E)$ be a k-terminal graph for which we are given a ranked path decomposition with ranking function $\rho : V \to [p]$. Let B_{s_1}, B_{s_2} be two bags of this decomposition, for $s_1 < s_2$. We define the* rewiring *operation on (s_1, s_2) as follows: (i) for every non-terminal vertex $v \in B_{s_1}$ which is adjacent to a non-terminal vertex $u \in$*

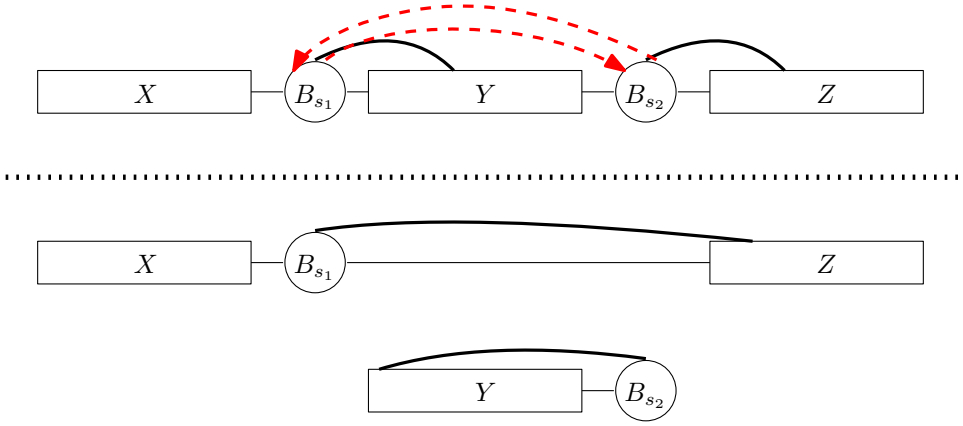

Figure 1 The rewiring operation of Definition 18. Edges from Y to B_{s_1} are rerouted towards B_{s_2}, while edges from Z to B_{s_2} are rerouted towards B_{s_1}. Edges incident on terminals are not modified.

$B_j \setminus (B_{s_1} \cup B_{s_2})$ for some $j \in [s_1 + 1, s_2 - 1]$ we delete the edge uv and add to the graph the edge uv', where $v' \in B_{s_2}$ and $\rho(v) = \rho(v')$, if such a v' exists (ii) for every non-terminal vertex $v \in B_{s_2}$ which is adjacent to a non-terminal vertex $u \in B_j \setminus B_{s_2}$ for some $j > s_2$, we delete the edge uv and add to the graph the edge uv', where $v' \in B_{s_1}$ and $\rho(v) = \rho(v')$, if such a v' exists.

Some explanations are in order regarding the motivation of the rewiring operation. We refer the reader to Figure 1. From standard properties of path decompositions, B_{s_1}, B_{s_2} are separators which break down the graph into three parts, call them X, Y, Z, which are respectively vertices which appear in a bag before B_{s_1}, between B_{s_1} and B_{s_2}, and after B_{s_2}. The rewiring operation leaves all edges incident on terminals and all edges incident on X unchanged. What it does is replace edges from Y to B_{s_1} with edges from Y to B_{s_2} and edges from Z to B_{s_2} with edges from Z to B_{s_1}. Intuitively, what this is meant to achieve is to break down the long path-like structure $X - B_{s_1} - Y - B_{s_2} - Z$ into the shorter path-like structure $X - B_{s_1} - Z$ and the ring-like structure $Y - B_{s_2}$. The idea here is that the $Y - B_{s_2}$ part is "disconnected" from the rest of the graph (more precisely, the k terminals separate this part from the rest of the graph, since terminals are not modified by this operation). Hence if we find many isomorphic such parts, they will also be identical in the sense of Definition 4, allowing us to delete one using Lemma 5. This argument is made precise in Lemma 20.

Before we do all these things, however, we need to be sure that the rewiring operation did not affect the validity of any FO formula of at most q quantifiers. The main claim now is that if s_1, s_2 are sufficiently far apart, we have a bound on the number of occurrences of non-terminal vertices in bags, and a sufficiently large block around B_{s_1} is block-isomorphic to a sufficiently large block around B_{s_2}, then the ball of radius $r = 2^q - 1$ around any vertex has remained unchanged. Hence, we can invoke Lemma 9 to conclude that the rewired graph is indistinguishable from the original graph for FO formulas with q quantifiers. Our main tool in proving this will be the following lemma.

▶ **Lemma 19.** *Let $G = (V, E)$ be a k-terminal graph with terminal set T, $B_1, \ldots, B_\ell$ a ranked path decomposition of G with ranking function $\rho : V \to [p]$ with the additional property that any non-terminal vertex appears in at most Δ bags of the decomposition. Fix an integer $q \geq 0$ and let $L = \Delta(2^q - 1)$. Let s_1, s_2 be such that (i) we have $s_1 > 4L$, $s_2 < \ell - 4L$, $s_2 - s_1 > 6L$ (ii) $\mathcal{B}(s_1 - L, s_1 + L)$ is block-isomorphic to $\mathcal{B}(s_2 - L, s_2 + L)$. Let G' be the graph obtained by applying the rewiring operation on (s_1, s_2). Then, for all FO formulas ϕ with at most q quantifiers we have $G \models \phi$ if and only if $G' \models \phi$.*

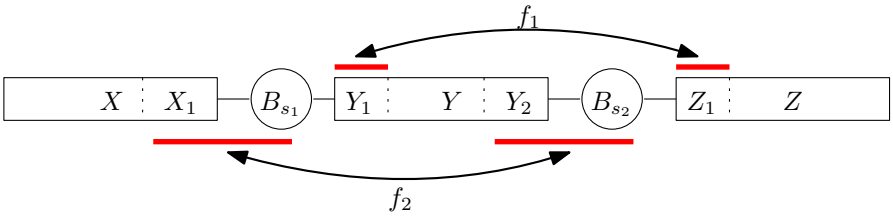

Figure 2 Schematic view of the two mappings of the proof of Lemma 19.

Finally, we argue that if we apply the rewiring operation on two block-isomorphic parts, then we obtain two parts of the graph which are identical in the sense of Definition 4. This will allow us to delete a part of the graph, once we gather sufficiently many identical parts.

▶ **Lemma 20.** *Let R be a positive integer, $G = (V, E)$ be a k-terminal graph with terminal set T, $B_1, \ldots, B_\ell$ a ranked path decomposition of G with ranking function $\rho : V \to [p]$ with the property that no non-terminal vertex appears in more than R bags. Let s_1, s_2 be positive integers such that $s_2 - s_1 > 4R$ and $\mathcal{B}(s_1, s_1 + R)$ is block-isomorphic to $\mathcal{B}(s_2, s_2 + R)$. Let $j_1, j_2 \in [0, R-1]$ with $j_1 < j_2$ and let G' be the graph obtained after applying the rewiring operation on $(s_1 + j_1, s_1 + j_2)$ and also on $(s_2 + j_1, s_2 + j_2)$. Let Y_1 be the set of vertices that appear in a bag with index in $[s_1 + j_1 + 1, s_1 + j_2 - 1]$, but not in $B_{s_1+j_1} \cup B_{s_1+j_2}$. Similarly, let Y_2 be the set of vertices that appear in a bag with index in $[s_2 + j_1 + 1, s_2 + j_2 - 1]$, but not in $B_{s_2+j_1} \cup B_{s_2+j_2}$. Then $(Y_1 \cup B_{s_1+j_2}) \setminus T$ is identical to $(Y_2 \cup B_{s_2+j_2}) \setminus T$.*

5 Putting Everything Together

We are now ready to put everything together to obtain our model checking algorithm for FO logic. We formulate a procedure which can either simplify the graph in a way that does not affect the validity of the given formula (or any formula with the same number of quantifiers), or certify that the graph has bounded degree, and hence we can use known algorithms with an elementary dependence on the formula. On a high level, we take as input a graph G, a path decomposition of G, and a formula ϕ with q quantifiers and we will do the following:

1. Use Lemma 11 to normalize the decomposition and obtain a ranking of the vertices. In this ranking, vertices of rank 1 appear in a constant number of bags. We would like to extend this so that every vertex appears in a bounded number of bags. In the remainder we will use the number of bags a vertex appears in as a proxy bound for its degree.
2. Define a function $\Delta(i)$ which defines an acceptable bound for the number of occurrences in distinct bags for a vertex of rank i. This function will be a tower of exponentials of height roughly $2i$, but this is acceptable, since the maximum rank is upper-bounded by a function of the pathwidth, which we consider to be an absolute constant.
3. Examine the graph and check if any vertex of rank i appears in more than $\Delta(i)$ bags. If this is not the case, we can bound the maximum degree of the graph, and we are done.
4. Otherwise, find a vertex v of minimum rank i that appears more than $\Delta(i)$ times. Find a section of the decomposition where v appears, and where all bags contain the same vertices of rank higher than i (if $\Delta(i)$ is large, we can find such a section that is quite long). We label as terminals the vertices of the first and last bag of the section, and the vertices of rank at least i appearing in the section.
5. Now, the remaining vertices of the section appear a bounded (by $\Delta(i-1)$) number of times, and are separated from the rest of the graph by $k = O(p)$ terminals. However, they are quite numerous, as we assumed that v appears too many times. Therefore,

we can invoke the machinery of Section 4.2 to find some isomorphic parts. Note that it is important that vertices of rank at least i (which are now terminals) are common throughout the section, which allows us to invoke Lemmas 15 and 16.

6. Having found many isomorphic parts, we use the tools of Section 4.3 to perform the rewiring operation that will produce $q+1$ identical parts, of which we can remove one. We then "undo" the operation on the remaining parts, and obtain a smaller graph, where v appears in fewer bags, without changing whether ϕ is satisfied.

▶ **Definition 21.** *Let p, q be positive integers. We define the function $\Delta_{p,q}(i)$ as follows: $\Delta_{p,q}(1) = 3p$ and $\Delta_{p,q}(i+1) = 2^{2^{\Delta_{p,q}(i)\cdot 2^{20qp^2}}}$. When p, q are clear from the context, we will write $\Delta(i)$ to denote $\Delta_{p,q}(i)$.*

▶ **Observation 22.** *For each fixed p, i, the function $\Delta_{p,q}(i)$ is an elementary function of q. Furthermore, $\Delta_{p,q}(i)$ is a strictly increasing function of i.*

▶ **Lemma 23.** *There is an algorithm that takes as input an FO formula ϕ with q quantifiers, an n-vertex graph $G = (V, E)$, a normalized ranked path decomposition of G with ranking function $\rho : V \to [p]$, such that G contains a vertex that appears in at least $3p \cdot \Delta(p)$ bags of the decomposition. Then, the algorithm runs in polynomial time and outputs a smaller graph G' and a normalized ranked path decomposition of G' with the same ranking function ρ, such that $G \models \phi$ if and only if $G' \models \phi$.*

▶ **Theorem 24.** *For every fixed p, model checking a formula ϕ on a graph G with pathwidth p can be performed in time $f(\phi)|G|^{O(1)}$, where f is an elementary function.*

6 Conclusions

We have shown that FO model checking for graphs of bounded pathwidth has a complexity behavior that is in sharp contrast with both MSO logic for the same class of graphs and the complexity of FO logic on graphs of bounded treewidth. It may be interesting to improve upon our result by noting that our algorithm's dependence on the pathwidth is a tower of exponentials whose height is $O(\mathrm{pw})$, where the hidden constant is roughly 16. This is in contrast with the meta-theorem of [14], where the height of the tower is roughly equal to the tree-depth. Can the height of the tower in our case can be made $\mathrm{pw} + O(1)$, or is FO model checking on bounded pathwidth truly harder than for bounded tree-depth?

Another interesting research direction would be to explore parameters which lie between pathwidth and treewidth to attempt to trace the frontier of where the arguments of this paper break down. One idea would be to consider tree decompositions with a bounded number of leaf bags, which would generalize pathwidth, and see if, as long as the number of leaf bag and the width of the decomposition is an absolute constant, we can hope for an elementary dependence on the formula for FO model checking.

Witnessed Symmetric Choice and Interpretations in Fixed-Point Logic with Counting

Moritz Lichter
TU Darmstadt, Germany

Abstract

At the core of the quest for a logic for PTIME is a mismatch between algorithms making arbitrary choices and isomorphism-invariant logics. One approach to tackle this problem is witnessed symmetric choice. It allows for choices from definable orbits certified by definable witnessing automorphisms.

We consider the extension of fixed-point logic with counting (IFPC) with witnessed symmetric choice (IFPC+WSC) and a further extension with an interpretation operator (IFPC+WSC+I). The latter operator evaluates a subformula in the structure defined by an interpretation. When similarly extending pure fixed-point logic (IFP), IFP+WSC+I simulates counting which IFP+WSC fails to do. For IFPC+WSC, it is unknown whether the interpretation operator increases expressiveness and thus allows studying the relation between WSC and interpretations beyond counting.

In this paper, we separate IFPC+WSC from IFPC+WSC+I by showing that IFPC+WSC is not closed under FO-interpretations. By the same argument, we answer an open question of Dawar and Richerby regarding non-witnessed symmetric choice in IFP. Additionally, we prove that nesting WSC-operators increases the expressiveness using the so-called CFI graphs. We show that if IFPC+WSC+I canonizes a particular class of base graphs, then it also canonizes the corresponding CFI graphs. This differs from various other logics, where CFI graphs provide difficult instances.

1 Introduction

The quest for a logic for PTIME is one of the prominent open questions in finite model theory [6, 19]. It asks whether there is a logic defining exactly all polynomial-time decidable properties of finite structures. While Fagin's theorem [14] initiated descriptive complexity theory by showing that there is a logic capturing NPTIME, the question for PTIME is still open. One problem at the core of the question is a mismatch between logics and algorithms. For algorithms, it is common to make arbitrary choices as long as the output is still isomorphism-invariant. In general, it is undecidable whether an algorithm is isomorphism-invariant. Showing this is usually part of the proof that the algorithm is correct. On the other hand, every reasonable logic is required to be isomorphism-invariant by design [22, 13], so in contrast to algorithms we cannot define something non-isomorphism-invariant. That is, a logic has to enforce isomorphism-invariance syntactically and it is generally not clear how algorithms making choices can be implemented in a logic.

For totally ordered structures, inflationary fixed-point logic (IFP) captures Ptime due to the Immerman-Vardi Theorem [27]. On ordered structures, no arbitrary choices are needed and the total order is used to "choose" the unique minimal element. Thus, the lack of making choices is crucial on unordered structures. We therefore would like to support choices in a logic while still guaranteeing isomorphism-invariance. There are logics in which arbitrary choices can be made [2, 10], but for these it is undecidable whether a formula is isomorphism-invariant [2]. In particular, such logics fail to be reasonable in the sense of Gurevich [22]. Similarly, when extending structures by an arbitrary order it is undecidable whether a formula is order-invariant, i.e., it evaluates equally for all such orders (see [16]).

One approach to overcome the lack of choices in logics is to support a restricted form of choice. If only choices from definable orbits (of the automorphism group of the input structure) are allowed, that is, from sets of definable objects related by an automorphism of the input structure, the output is guaranteed to be still isomorphism-invariant [9, 15]. This form of choice is called *symmetric choice* (SC). However, it is unknown whether orbits can be computed in Ptime. So it is unknown whether a logic with symmetric choice can be evaluated in Ptime because during the evaluation we have to verify that the choice-sets are indeed orbits. This is solved by handing over the obligation to check whether the choice-sets are orbits from the evaluation to the formulas themselves. To make a choice, not only a choice-set but also a set of witnessing automorphisms has to be defined. These automorphisms certify that the choice-set is indeed an orbit in the following way: For every pair of elements a and b in the choice-set, an automorphism mapping a to b has to be provided. This condition guarantees evaluation in Ptime. We call this restricted form of choice *witnessed symmetric choice* (WSC).

Besides witnessed symmetric choice, other operators were proposed to extend the expressiveness of logics not capturing Ptime including a counting operator (see [35]) and an operator based on logical interpretations [15]. It was shown that witnessed symmetric choice increases the expressiveness of IFP [15] and that counting operators increase the expressiveness of IFP and the logic of Choiceless Polynomial Time (CPT) [4] (one usually refers with CPT to its extension with counting, which we also do from now). However, for the combination of counting and choices not much is known. In this paper, we investigate the relation of counting, witnessed symmetric choice, and interpretations to better understand their expressive power.

Extending IFP with symmetric and witnessed symmetric choice was first studied by Gire and Hoang [15]. They extend IFP with symmetric choice (which we denote IFP+SC) and which witnessed symmetric choice (which we denote IFP+WSC). The authors show that IFP+WSC distinguishes CFI graphs over ordered base graphs, which IFP (and even fixed-point logic with counting IFPC) fails to do [5]. Afterwards IFP+SC was studied by Dawar and Richerby [9]. They allowed for nested symmetric choice operators, proved that parameters of choice operators increase the expressiveness, showed that nested symmetric choice operators are more expressive than a single one, and conjectured that with additional nesting depth the expressiveness increases.

Recently, extending CPT with witnessed symmetric choice (CPT+WSC) was studied by Lichter and Schweitzer [32]. CPT+WSC has the interesting property that a CPT+WSC-definable isomorphism test on a class of structures implies a CPT+WSC-definable canonization for this class. Canonization is the task of defining an isomorphic but totally ordered copy. The only requirement is that the class is closed under individualization, so under assigning unique colors to vertices. This is often unproblematic [28, 33]. Individualization is natural in the context of choices because a choice is, in some sense, an individualization. The concept of canonization is essential in the quest for a logic for Ptime. It provides the routinely employed

approach to capture Ptime on a class of structures: Define canonization, obtain isomorphic and ordered structures, and apply the Immerman-Vardi Theorem (e.g. [42, 20, 21, 31]). While in CPT+WSC defining isomorphism implies canonization, we do not know whether the same holds for CPT or whether CPT+WSC is more expressive than CPT. Proving this requires separating CPT from Ptime, which has been open for a long time.

(Witnessed) symmetric choice has the drawback that it can only choose from orbits of the input structure. This structure might have complicated orbits that we cannot define or witness in the logic. However, there could be a reduction to a different structure with easier orbits exploitable by witnessed symmetric choice. For logics, the natural concept of a reduction is an interpretation, i.e., defining a structure in terms of another one. Interpretations are in some sense incompatible with (witnessed) symmetric choice because we always have to choose from orbits of the input structure. Orbits of the interpreted structure are always unions of orbits of the input structure, i.e., an interpretation may add more automorphisms but never removes one. To exploit a combination of choices and interpretations, Gire and Hoang proposed an interpretation operator [15]. It evaluates a formula in the image of an interpretation. For logics closed under interpretations (e.g. IFP, IFPC, and CPT) such an interpretation operator does not increase expressiveness. However, for the extension with witnessed symmetric choice this is different: IFP+WSC is less expressive than the extension of IFP+WSC with the interpretation operator. The interpretation operator in combination with WSC simulates counting, which for WSC alone is indicated not to be the case [15].

We are interested in the relation between witnessed symmetric choice and the interpretation operator not specifically for IFP but more generally. Most of the existing results in [15, 9] showing that (witnessed) symmetric choice or the interpretation operator increases in some way the expressiveness of IFP are based on counting. However, counting is not the actual reason for using witnessed symmetric choice. Counting can be achieved more naturally in IFPC. Thus, it is unknown whether the interpretation operator increases expressiveness of IFPC+WSC. In CPT, it is not possible to show that witnessed symmetric choice or the interpretation operator increases expressiveness without separating CPT from Ptime [32].

Overall, a natural base logic for studying the interplay of witnessed symmetric choice and the interpretation operator is IFPC. In IFPC, separation results based on counting are not applicable. But there are known IFPC-undefinable Ptime properties, namely the already mentioned CFI query, which can be used to separate extensions of IFPC. The CFI construction assigns to a connected graph, the so-called base graph, two non-isomorphic CFI graphs: One is called even and the other one is called odd. The CFI query is to define whether a given CFI graph is even.

Results. We define the logics IFPC+WSC and IFPC+WSC+I, which extend IFPC by a fixed-point operator featuring witnessed symmetric choice and the latter additionally by an interpretation operator. We show that the interpretation operator increases expressiveness:

▶ **Theorem 1.** IFPC+WSC $<$ IFPC+WSC+I $\leq$ *Ptime*.

In particular, this separates IFPC+WSC from Ptime. Such a result does not follow from existing techniques because separating IFP+WSC from Ptime is based on counting in [15]. Moreover, we show that both IFPC+WSC and IFP+SC are not even closed under FO-interpretations. This answers an open question of Dawar and Richerby [9]. Proving Theorem 1 relies on the CFI construction and on defining the CFI query for certain classes of base graphs. To show this, we show that IFPC+WSC+I-distinguishable orbits imply an IFPC+WSC+I-definable canonization (similarly to [32]). We apply this to CFI graphs:

▶ **Theorem 2.** *If* IFPC+WSC+I *canonizes a class of colored base graphs $\mathcal{K}$ (closed under individualization), then* IFPC+WSC+I *canonizes the class of CFI graphs* $\mathsf{CFI}(\mathcal{K})$ *over* $\mathcal{K}$.

The conclusion is that for IFPC+WSC+I canonization of a class of CFI graphs is not more difficult than canonization of the corresponding class of base graphs, which is different in many other logics [5, 17, 29, 7]. However, to canonize the CFI graphs in our proof, the nesting depth of WSC-fixed-point operators and interpretation operators increases. We show that this increase is unavoidable: For $L \subseteq$ IFPC+WSC+I, we denote by WSCI(L) the IFPC+WSC+I-fragment which uses IFPC-formula-formation-rules to compose L-formulas and an additional interpretation operator nested inside a WSC-fixed-point operator.

▶ **Theorem 3.** *There is a class of base graphs $\mathcal{K}$, for which* WSCI(IFPC) *defines a canonization but does not define the CFI query for* $\mathsf{CFI}(\mathcal{K})$ *and* WSCI(WSCI(IFPC)) *canonizes* $\mathsf{CFI}(\mathcal{K})$.

Theorem 3 provides a first step towards an operator nesting hierarchy for IFPC+WSC+I.

Our Techniques. We adapt the techniques of [32] from CPT to IFPC to define a WSC-fixed-point operator. It has some small but essential differences to [15, 9]. Similar to [32] for CPT, Gurevich's canonization algorithm [23] is expressible in IFPC+WSC: It suffices to distinguish orbits of a class of individualization-closed structures to define a canonization.

To prove Theorem 2, we use the interpretation operator to show that if IFPC+WSC+I distinguishes orbits of the base graphs, then IFPC+WSC+I distinguishes also orbits of the CFI graphs and thus canonizes the CFI graphs. The CFI-graph-canonizing formula nests one WSC-fixed-point operator (for Gurevich's algorithm) and one interpretation operator (to distinguish orbits) more than the orbit-distinguishing formula of the base graphs. To show that this increase in nesting depth is necessary, we construct double CFI graphs. We start with a class of CFI graphs $\mathsf{CFI}(\mathcal{K}')$ canonized in WSCI(IFPC). We create new base graphs $\mathcal{K}$ from the $\mathsf{CFI}(\mathcal{K}')$-graphs. Applying the CFI construction once more, $\mathsf{CFI}(\mathcal{K})$ is canonized in WSCI(WSCI(IFPC)) but not in WSCI(IFPC): To define orbits of $\mathsf{CFI}(\mathcal{K})$, we have to define orbits of the base graph, for which we need to define the CFI query for $\mathsf{CFI}(\mathcal{K}')$.

To prove IFPC+WSC $<$ IFPC+WSC+I, we construct a class of asymmetric structures, i.e., structures without non-trivial automorphisms, for which isomorphism is not IFPC-definable. Because asymmetric structures have only singleton orbits, witnessed symmetric choice is not beneficial, thus IFPC+WSC = IFPC, and isomorphism is not IFPC+WSC-definable. These structures combine CFI graphs and the so-called multipedes [24], which are asymmetric and for which IFPC fails to distinguish orbits. An interpretation removes the multipedes and reduces the isomorphism problem to the ones of CFI graphs. Thus, isomorphism of this class of structures is IFPC+WSC+I-definable.

Related Work. The logic IFPC was separated from Ptime using the CFI graphs [5]. CFI graphs not only turned out to be difficult for IFPC but variants of them were also used to separate rank logic [29] and the more general linear-algebraic logic [7] from Ptime. CPT was shown to define the so-called CFI query for ordered base graphs [12] and base graphs of maximal logarithmic color class size [37]. Defining the CFI query for these graphs in CPT turned out to be comparatively more complicated than in IFP+WSC for ordered base graphs in [15]. In general, it is still open whether CPT defines the CFI query for all base graphs.

The definitions of the (witnessed) symmetric choice operator in [15, 9] differ at crucial points form the one in [32] and in this paper: The formula defining the witnessing automorphism has access to the obtained fixed-point. This is essential to implement Gurevich's

canonization algorithm but has the drawback to impose (possibly) stronger orbit conditions. Although it is unknown whether these two variants of witnessed symmetric choice have the same expressiveness, existing results [15, 9] transfer to the variant used in this paper. We expect that the results of this paper also hold for the other variant. However, proving Theorem 2 will be more effort because Gurevich's canonization algorithm cannot be used.

CPT+WSC in [32] is a three-valued logic using, beside true and false, an error marker for non-witnessed choices. This is needed for CPT because fixed-point computations in CPT do not necessarily terminate in a polynomial number of steps. Instead, computation is aborted (and orbits cannot be witnessed). For other approaches to integrate choice in first-order logic, but which are no PTIME-logic candidates, see e.g. [3, 36, 10]. We refer to [38] for an overview.

Logical interpretations can also be used to characterize CPT. The logic CPT as the same expressive power as polynomial-time interpretation logic [18]. This logic essentially applies a first-order interpretation (with an appropriate counting extension) iteratively. The iterative application of an interpretation and thereby the ability to iteratively take quotients strictly increases the expressive power. The interpretation operator that we consider evaluates a formula in the interpreted structure, that is, it evaluates an interpretation only once. By nesting this operator, constantly many interpretations can be nested. Hence, for logics closed under interpretations, the interpretation operator does not increase the expressive power.

Multipedes [24] are a class of asymmetric structures not characterized up to isomorphism in k-variable counting logic for every fixed k. Asymmetry turns multipedes to hard examples for graph isomorphism algorithms in the individualization-refinement framework [34, 1]. The size of a multipede not identifiable in k-variable counting logic is large with respect to k. There also exists a class of asymmetric graphs [8] for which the number of variables needed for identification is linear. Both classes are based on the CFI construction.

There is another remarkable but not directly-connected coincidence to lengths of resolution proofs. Resolution proofs for non-isomorphism of CFI-graphs have exponential size [40]. When adding a global symmetry rule (SRC-I), which exploits automorphisms of the formula (so akin to symmetric choice), the length becomes polynomial [39]. For asymmetric multipedes the length in the SRC-I system is still exponential [41]. But when considering the local symmetry rule (SRC-II) exploiting local automorphisms (so somewhat akin to symmetric choice after restricting to a substructure with an interpretation) the length becomes polynomial again [39].

2 Preliminaries

We set $[k] := \{1, \dots, k\}$. The i-th entry of a k-tuple $\bar{t} \in N^k$ is denoted by t_i and its length by $|\bar{t}| = k$. The set of all tuples of length at most k is $N^{\leq k}$ and the set of all finite tuples is N^*.

A *relational signature* τ is a set of relation symbols $\{R_1, \dots, R_\ell\}$ of *arities* $\mathrm{ar}(R_i)$. We use letters τ and σ for signatures. A *τ-structure* is a tuple $\mathfrak{A} = (A, R_1^{\mathfrak{A}}, \dots, R_\ell^{\mathfrak{A}})$ where $R_i^{\mathfrak{A}} \subseteq A^{\mathrm{ar}(R_i)}$. The set A is called *universe* and its elements *vertices*. We use letters $\mathfrak{A}$ and $\mathfrak{B}$ for structures, A and B for their universes, and u, v, and w for vertices. The *reduct* $\mathfrak{A} \restriction \sigma$ is the restriction of $\mathfrak{A}$ to the relations in $\sigma \subseteq \tau$. This paper considers finite structures.

A *colored graph* is an $\{E, \preceq\}$-structure $G = (V, E^G, \preceq^G)$. The relation E is the edge relation and the relation $\preceq$ is a total preorder. Its equivalence classes are the *color classes* or *colors*. We often write $G = (V, E, \preceq)$ for a colored graph. The *neighborhood* of a vertex $u \in V$ is $N_G(u)$. The *induced subgraph* of G by $W \subseteq V$ is $G[W]$. The graph G is *k-connected* if $|V| > k$ and, for every $V' \subseteq V$ of size at most $k-1$, the graph $G \setminus V'$ is connected. The *treewidth* $\mathrm{tw}(G)$ of G measures how close G is to being a tree. We omit a definition (see [11]) and only use the fact that if G is a *minor* of H, i.e., G is obtained from H by deleting vertices or edges and contracting edges, then $\mathrm{tw}(G) \leq \mathrm{tw}(H)$.

Let $\mathfrak{A}$ and $\mathfrak{B}$ be two τ-structures and $\bar{u} \in A^k$ and $\bar{v} \in B^k$. We write $(\mathfrak{A}, \bar{u}) \cong (\mathfrak{B}, \bar{v})$ if there is a *isomorphism* $\varphi\colon \mathfrak{A} \to \mathfrak{B}$ satisfying $\varphi(\bar{u}) = \bar{v}$. An *automorphism* φ of $(\mathfrak{A}, \bar{u})$ is an isomorphism $(\mathfrak{A}, \bar{u}) \to (\mathfrak{A}, \bar{u})$. We say that φ *fixes* $\bar{u}$ and write $\mathsf{Aut}((\mathfrak{A}, \bar{u}))$ for the set of all automorphisms fixing $\bar{u}$. We will use the same notation also for other objects, e.g., for automorphisms fixing relations. A *k-orbit* of $(\mathfrak{A}, \bar{u})$ is a maximal set of k-tuples $O \subseteq A^k$ such that for every $\bar{v}, \bar{w} \in O$, there is an automorphism $\varphi \in \mathsf{Aut}((\mathfrak{A}, \bar{u}))$ satisfying $\varphi(\bar{v}) = \bar{w}$.

Fixed-Point Logic with Counting. We recall fixed-point logic with counting IFPC (proposed in [26], see [35]). Let τ be a signature and $\mathfrak{A} = (A, R_1^{\mathfrak{A}}, \dots, R_\ell^{\mathfrak{A}})$ be a τ-structure. We extend τ and $\mathfrak{A}$ with counting. Set $\tau^{\#} := \tau \uplus \{\cdot, +, 0, 1\}$ and $\mathfrak{A}^{\#} := (A, R_1^{\mathfrak{A}}, \dots, R_\ell^{\mathfrak{A}}, \mathbb{N}, \cdot, +, 0, 1)$ to be the two-sorted $\tau^{\#}$-structure that is the disjoint union of $\mathfrak{A}$ and $\mathbb{N}$. IFPC$[\tau]$ is a two-sorted logic using the signature $\tau^{\#}$. *Element variables* range over vertices and *numeric variables* range over $\mathbb{N}$. The letters x, y, and z are used for element variables, ν and μ for numeric variables, and s and t for numeric terms. IFPC-formulas are built from first-order formulas, a fixed-point operator, and counting terms. The range of numeric variables needs to be bounded to ensure PTIME-evaluation: For an IFPC-formula Φ, a closed numeric IFPC-term s, a numeric variable ν, and a quantifier $Q \in \{\forall, \exists\}$, the formula $Q\nu \leq s.\, \Phi$ is an IFPC-formula. An *inflationary fixed-point operator* defines a relation R. For an IFPC$[\tau, R]$-formula Φ and variables $\bar{x}\bar{\mu}$, the fixed-point operator $[\mathsf{ifp}R\bar{x}\bar{\mu} \leq \bar{s}.\, \Phi]\,(\bar{\nu}\bar{\mu})$ is an IFPC$[\tau]$-formula. The tuple $\bar{s}$ of $|\bar{\mu}|$ closed numeric terms bounds the values of $\bar{\mu}$. The crucial element of IFPC are *counting terms*. For an IFPC-formula Φ, variables $\bar{x}\bar{\nu}$, and $|\bar{\nu}|$ closed numeric IFPC-terms $\bar{s}$, $\#\bar{x}\bar{\nu} \leq \bar{s}.\, \Phi$ is a numeric IFPC-term.

IFPC-formulas (or terms) are evaluated over $\mathfrak{A}^{\#}$. For a numeric term $s(\bar{x}\bar{\nu})$, the function $s^{\mathfrak{A}}\colon A^{|\bar{x}|} \times \mathbb{N}^{|\bar{\nu}|} \to \mathbb{N}$ maps the values for the free variables of s to the value that s takes in $\mathfrak{A}^{\#}$. Likewise, for a formula $\Phi(\bar{x}\bar{\nu})$, we write $\Phi^{\mathfrak{A}} \subseteq A^{|\bar{x}|} \times \mathbb{N}^{|\bar{\nu}|}$ for the set of values for the free variables satisfying Φ. Evaluating a counting term for a formula $\Phi(\bar{y}\bar{x}\bar{\mu}\bar{\nu})$ is defined as follows: $(\#\bar{x}\bar{\nu} \leq s.\, \Phi)^{\mathfrak{A}}(\bar{u}\bar{m}) := |\{\bar{w}\bar{n} \in A^{|\bar{x}|} \times \mathbb{N}^{|\bar{\nu}|} \mid n_i \leq s_i^{\mathfrak{A}} \text{ for all } i \in [|\bar{\nu}|], \bar{u}\bar{w}\bar{m}\bar{n} \in \Phi^{\mathfrak{A}}\}|$.

Finite Variable Counting Logic. The k-variable logic with counting $\mathcal{C}_k$ extends the k-variable fragment of first-order logic (FO) with counting quantifiers $\exists^{\geq j} x.\, \Phi$ ("at least j distinct vertices satisfy Φ"). For every fixed $n \in \mathbb{N}$, every k-variable IFPC-formula is equivalent to a $\mathcal{C}_{\mathcal{O}(k)}$-formula [35] on structures of order up to n. Let $\mathfrak{A}$ and $\mathfrak{B}$ be two τ-structures and $\bar{u} \in A^\ell$ and $\bar{v} \in B^\ell$. A logic L *distinguishes* $(\mathfrak{A}, \bar{u})$ from $(\mathfrak{B}, \bar{v})$ if there is an L-formula Φ with ℓ free variables such that $\bar{u} \in \Phi^{\mathfrak{A}}$ and $\bar{v} \notin \Phi^{\mathfrak{B}}$. Otherwise, the structures are *L-equivalent*. We write $(\mathfrak{A}, \bar{u}) \simeq_{\mathcal{C}}^k (\mathfrak{B}, \bar{v})$ if $(\mathfrak{A}, \bar{u})$ and $(\mathfrak{B}, \bar{v})$ are $\mathcal{C}_k$-equivalent. The logics $\mathcal{C}_k$ are used to prove IFPC-undefinability: Let $(\mathfrak{A}_k, \mathfrak{B}_k)$ be a sequence of finite structures for every $k \in \mathbb{N}$ such that $\mathfrak{A}_k$ has a property P but $\mathfrak{B}_k$ does not. If $\mathfrak{A}_k \simeq_{\mathcal{C}}^k \mathfrak{B}_k$ for every k, then IFPC does not define P. The logic $\mathcal{C}_k$ is characterized by the *bijective k-pebble game* [25]. The game is played on two structures $\mathfrak{A}$ and $\mathfrak{B}$ by two players called Spoiler and Duplicator. There are pebble pairs (p_i, q_i) for every $i \in [k]$. Positions in the game are tuples $(\mathfrak{A}, \bar{u}; \mathfrak{B}, \bar{v})$ for tuples $\bar{u} \in A^{\leq k}$ and $\bar{v} \in B^{\leq k}$ of the same length. A pebble p_j is placed on u_i and q_j is placed on v_i for some $j \in [k]$. No pebbles are placed initially. If $|A| \neq |B|$, then Spoiler wins. If not, Spoiler picks up a pair of pebbles (p_i, q_i). Duplicator answers with a bijection $\lambda\colon A \to B$. Spoiler places p_i on $w \in A$ and q_i on $\lambda(w) \in B$. If in the resulting position $(\mathfrak{A}, \bar{u}; \mathfrak{B}, \bar{v})$ the map $u_i \mapsto v_i$ is not a *pebble-respecting* local isomorphism $(\mathfrak{A}[\bar{u}], \bar{u}) \to (\mathfrak{B}[\bar{v}], \bar{v})$, then Spoiler wins. Otherwise, the game continues with the next round. Duplicator wins if Spoiler never wins. Spoiler/Duplicator has a *winning strategy* in position $(\mathfrak{A}, \bar{u}; \mathfrak{B}, \bar{v})$ if they can always win the game. Spoiler has a winning strategy in position $(\mathfrak{A}, \bar{u}; \mathfrak{B}, \bar{v})$ if and only if $(\mathfrak{A}, \bar{u}) \not\simeq_{\mathcal{C}}^k (\mathfrak{B}, \bar{v})$ [25].

Logical Interpretations. Interpretations define maps between structures via formulas evaluated on tuples containing vertices and numbers. We use $\bar{x}$, $\bar{y}$, and $\bar{z}$ for a tuple of element and numeric variables and $\bar{u}$ and $\bar{v}$ for a tuple of vertices and numbers in the following.

Let $\sigma := \{R_1, \dots, R_\ell\}$. A *$d$-dimensional* IFPC$[\tau,\sigma]$*-interpretation* $\Theta(\bar{z})$ with parameters $\bar{z}$ is a tuple

$$\Theta(\bar{z}) = \big(\Phi_{\mathrm{dom}}(\bar{z}\bar{x}), \Phi_{\cong}(\bar{z}\bar{x}\bar{y}), \Phi_{R_1}(\bar{z}\bar{x}_1 \dots \bar{x}_{\mathrm{ar}(R_1)}), \dots, \Phi_{R_\ell}(\bar{z}\bar{x}_1 \dots \bar{x}_{\mathrm{ar}(R_\ell)}), \bar{s}\big)$$

of IFPC$[\tau]$-formulas and a j-tuple $\bar{s}$ of closed numeric IFPC$[\tau]$-terms, where j is the number of numeric variables in $\bar{x}$. The tuples of variables $\bar{x}$, $\bar{y}$, and the $\bar{x}_i$ are all of length d and agree on whether the k-th variable is an element variable or not. Let $\mathfrak{A}$ be a τ-structure and $\bar{u} \in (A \cup \mathbb{N})^{|\bar{z}|}$ match the parameter variables (element or numeric). Assume that the first j variables in $\bar{x}$ are numeric variables and set $D := \{0, ..., s_1^{\mathfrak{A}}\} \times \cdots \times \{0, ..., s_j^{\mathfrak{A}}\} \times A^{d-j}$. We define the σ-structure $\mathfrak{B} = (B, R_1^{\mathfrak{B}}, \dots, R_\ell^{\mathfrak{B}})$ via

$$B := \big\{\, \bar{v} \in D \;\big|\; \bar{u}\bar{v} \in \Phi_{\mathrm{dom}}^{\mathfrak{A}} \,\big\} \text{ and}$$
$$R_i^{\mathfrak{B}} := \big\{\, (\bar{v}_1, \dots, \bar{v}_{\mathrm{ar}(R_i)}) \in B^{\mathrm{ar}(R_i)} \;\big|\; \bar{u}\bar{v}_1 \dots \bar{v}_{\mathrm{ar}(R_i)} \in \Phi_{R_i}^{\mathfrak{A}} \,\big\}$$

and the relation $E := \{(\bar{v}_1, \bar{v}_2) \in B^2 \mid \bar{u}\bar{v}_1\bar{v}_2 \in \Phi_{\cong}^{\mathfrak{A}}\}$. Set $\Theta(\mathfrak{A}, \bar{u}) := \mathfrak{B}/E$ if E is a congruence relation on $\mathfrak{B}$ and otherwise leave $\Theta(\mathfrak{A}, \bar{u})$ undefined. An interpretation is called *equivalence-free* if $\Phi_{\cong}(\bar{z}\bar{x}\bar{y})$ is the formula $\bar{x} = \bar{y}$. For extensions L of IFPC, the notion of an $L[\tau,\sigma]$-interpretation is defined similarly. For logics without numeric variables like FO or IFP, interpretations are defined analogously omitting the numeric parts.

A property P of τ-structures is *L-reducible* to a property Q of σ-structures if there is a parameter-free $L[\tau,\sigma]$-interpretation Θ such that $\mathfrak{A} \in P$ if and only if $\Theta(\mathfrak{A}) \in Q$ for every τ-structure $\mathfrak{A}$. A logic L' is *closed under L-interpretations* if for every property P that is L-reducible to an L'-definable property Q, the property P itself is L'-definable (cf. [13, 35]).

3 Witnessed Symmetric Choice

We extend IFPC with an inflationary fixed-point operator with witnessed symmetric choice. Let τ be a relational signature and R, R^*, and S be relation symbols not in τ satisfying $k = \mathrm{ar}(R) = \mathrm{ar}(R^*)$. The relation R will be used for stages in the fixed-point computation, R^* for a fixed-point, and S will be a singleton relation containing a chosen tuple.

We define the WSC-fixed-point operator with parameters $\bar{p}\bar{\nu}$. If $\Phi_{\mathrm{step}}(\bar{p}\bar{x}\bar{\nu})$ is an IFPC + WSC$[\tau, R, S]$-formula such that $|\bar{x}| = \mathrm{ar}(R)$, $\Phi_{\mathrm{choice}}(\bar{p}\bar{y}\bar{\nu})$ is a IFPC + WSC$[\tau, R]$-formula such that $|\bar{y}| = \mathrm{ar}(S)$, $\Phi_{\mathrm{wit}}(\bar{p}\bar{y}\bar{y}'z_1z_2\bar{\nu})$ is an IFPC + WSC$[\tau, R, R^*]$-formula where $|\bar{y}| = |\bar{y}'| = \mathrm{ar}(S)$, and $\Phi_{\mathrm{out}}(\bar{p}\bar{\nu})$ is an IFPC + WSC$[\tau, R^*]$-formula, then

$$\Phi(\bar{p}\bar{\nu}) = \mathsf{ifp\text{-}wsc}_{R,\bar{x};R^*;S,\bar{y},\bar{y}';z_1z_2}.\ \big(\Phi_{\mathrm{step}}(\bar{p}\bar{x}\bar{\nu}), \Phi_{\mathrm{choice}}(\bar{p}\bar{y}\bar{\nu}), \Phi_{\mathrm{wit}}(\bar{p}\bar{y}\bar{y}'z_1z_2\bar{\nu}), \Phi_{\mathrm{out}}(\bar{p}\bar{\nu})\big)$$

is an IFPC + WSC$[\tau]$-formula. The formulas Φ_{step}, Φ_{choice}, Φ_{wit}, and Φ_{out} are called *step formula*, *choice formula*, *witnessing formula*, and *output formula* respectively. Note that only element variables are used for defining the fixed-point in the WSC-fixed-point operator. This suffices for our purpose in this paper. We expect that our arguments also work with numeric variables. We omit the free numeric variables $\bar{\nu}$ when defining the semantics of the WSC-fixed-point operator because numeric parameters do not change automorphisms.

Intuitively, Φ is evaluated as follows. The formula Φ defines the set of vertex-tuples $\bar{u}$ that, when interpreting $\bar{p}$ with $\bar{u}$, satisfy the following process: Initialize R as the empty relation. Define a choice-set using the choice formula. Pick an arbitrary tuple of this set and let S

only contain this tuple. Define the next stage from R and S using the step formula. Then set R to be this next stage and repeat until a fixed-point R^* is reached. If the witnessing formula certifies that all choice-set were indeed orbits and the output formula is satisfied by R^*, then $\bar{u}$ satisfies Φ.

We now consider the evaluation in more detail. Let $\mathfrak{A}$ be a τ-structure and $\bar{u} \in A^{|\bar{p}|}$. We define a sequence of relations called *stages* $\emptyset =: R_1^{\mathfrak{A}}, \dots, R_\ell^{\mathfrak{A}} = R_{\ell+1}^{\mathfrak{A}} =: (R^*)^{\mathfrak{A}}$. Given the relation $R_i^{\mathfrak{A}}$, the choice formula defines the choice-set

$$T_{i+1}^{\mathfrak{A}} := \left\{ \bar{v} \;\middle|\; \bar{u}\bar{v} \in \Phi_{\text{choice}}^{\mathfrak{A}, R_i^{\mathfrak{A}}} \right\}.$$

We pick an arbitrary tuple $\bar{v} \in T_{i+1}^{\mathfrak{A}}$ and set $S_{i+1}^{\mathfrak{A}} := \{\bar{v}\}$ or $S_{i+1}^{\mathfrak{A}} := \emptyset$ if $T_{i+1}^{\mathfrak{A}} = \emptyset$. The step formula defines the next stage on the structure $(\mathfrak{A}, R_i^{\mathfrak{A}}, S_{i+1}^{\mathfrak{A}})$:

$$R_{i+1}^{\mathfrak{A}} := R_i^{\mathfrak{A}} \cup \left\{ \bar{w} \;\middle|\; \bar{u}\bar{w} \in \Phi_{\text{step}}^{(\mathfrak{A}, R_i^{\mathfrak{A}}, S_{i+1}^{\mathfrak{A}})} \right\}.$$

We proceed until a fixed-point $(R^*)^{\mathfrak{A}}$ is reached. This fixed-point is in general not isomorphism-invariant, i.e., not invariant under automorphisms of $(\mathfrak{A}, \bar{u})$. Isomorphism-invariance of Φ is ensured as follows: Choices are only allowed from orbits, which is certified by the witnessing formula. A set $N \subseteq \mathsf{Aut}((\mathfrak{A}, \bar{u}))$ *witnesses a relation* $R \subseteq A^k$ *as* $(\mathfrak{A}, \bar{u})$*-orbit*, if for very $\bar{v}, \bar{v}' \in R$ there is a $\varphi \in N$ with $\bar{v} = \varphi(\bar{v}')$. Because we consider isomorphism-invariant sets, the relation R is never a proper subset of an orbit. We require that Φ_{wit} defines a set of automorphisms. For $\bar{v}, \bar{v}' \in T_{i+1}^{\mathfrak{A}}$, a map $\varphi_{\bar{v},\bar{v}'}$ is defined by

$$w \mapsto w' \text{ whenever } \bar{u}\bar{v}\bar{v}'ww' \in \Phi_{\text{wit}}^{(\mathfrak{A}, R_i^{\mathfrak{A}}, (R^*)^{\mathfrak{A}})}.$$

The set $\{\varphi_{\bar{v},\bar{v}'} \mid \bar{v}, \bar{v}' \in T_{i+1}^{\mathfrak{A}}\}$ has to witness $T_{i+1}^{\mathfrak{A}}$ as $(\mathfrak{A}, \bar{u}, R_1^{\mathfrak{A}}, \dots, R_i^{\mathfrak{A}})$-orbit. The witnessing formula always has access to the fixed-point (note that orbits are witnessed after the fixed-point is computed). This is possible because $T_{i+1}^{\mathfrak{A}}$ is an $(\mathfrak{A}, \bar{u}, R_1^{\mathfrak{A}}, \dots, R_i^{\mathfrak{A}})$-orbit and not just an $(\mathfrak{A}, \bar{u}, R_i^{\mathfrak{A}})$-orbit. If some choice is not witnessed, then $\bar{u} \notin \Phi^{\mathfrak{A}}$. Otherwise, the output formula is evaluated on the fixed-point:

$$\Phi^{\mathfrak{A}} := \Phi_{\text{out}}^{(\mathfrak{A}, (R^*)^{\mathfrak{A}})}.$$

Because all choices are witnessed, all possible fixed-points (for different choices) are related by an automorphism of $(\mathfrak{A}, \bar{u})$ and thus either all or none satisfy the output formula.

An Example. We give an illustrating example (an adaption of [32]). We show that the class of threshold graphs (i.e., graphs which can be reduced to the empty graph by iteratively deleting universal or isolated vertices) is IFPC+WSC-definable (it is actually IFP-definable). The set of all isolated or universal vertices of a graph forms a 1-orbit (there cannot be an isolated and a universal vertex in a nontrivial graph). We chose one such vertex, collect it in a unary relation R, and repeat as follows: The choice formula

$$\Phi_{\text{choice}}(y) := \neg R(y) \wedge \big((\forall z.\, \neg R(y) \Rightarrow E(y,z)) \vee (\forall z.\, \neg R(y) \Rightarrow \neg E(y,z))\big)$$

defines the set of all isolated or universal vertices after deleting the vertices in R. The step formula $\Phi_{\text{step}}(x) := R(x) \vee S(x)$ adds the chosen vertex contained in the relation S to R. The output formula $\Phi_{\text{out}} := \forall x.\, R^*(x)$ defines whether it was possible to delete all vertices. Witnessing orbits is easy: To show that two isolated (or universal) vertices y and y' are related by an automorphism, it suffices to define their transposition via

$$\Phi_{\text{wit}}(y, y', z_1, z_2) := (z_1 = y \wedge z_2 = y') \vee (z_2 = y \wedge z_1 = y') \vee (y \neq z_1 = z_2 \neq y').$$

The formula $\mathsf{ifp\text{-}wsc}_{R,x;R^*;S,y,y';z_1 z_2}.\, (\Phi_{\text{step}}, \Phi_{\text{choice}}, \Phi_{\text{wit}}, \Phi_{\text{out}})$ defines the class of threshold graphs.

Reduct Semantics. The semantics is defined formally using the WSC^*-operator from [32]. It formalizes the former evaluation strategy. The WSC-fixed-point operator Φ is evaluated in the structure $\mathfrak{A} \restriction \mathrm{sig}(\Phi)$, where $\mathrm{sig}(\Phi)$ are all relations symbols used in Φ. So adding a relation to $\mathfrak{A}$ that is not mentioned in Φ but possibly changes the orbits of $\mathfrak{A}$ does not change $\Phi^{\mathfrak{A}}$. This is a desirable property of a logic [13]. The *reduct semantics* of a choice operator can also be found in [9].

Extension with an Operator for Logical Interpretations. We extend IFPC+WSC with another operator using interpretations. Every IFPC+WSC-formula is an IFPC+WSC+I-formula. If $\Theta(\bar{p}\bar{\nu})$ is an IFPC+WSC+I$[\tau,\sigma]$-interpretation with parameters $\bar{p}\bar{\nu}$ and Φ is an IFPC+WSC+I$[\sigma]$-sentence, then the *interpretation operator*

$$\Psi(\bar{p}\bar{\nu}) := \mathsf{I}(\Theta(\bar{p}\bar{\nu}); \Phi)$$

is an IFPC+WSC+I$[\tau]$-formula with free variables $\bar{p}\bar{\nu}$. The semantics is defined by

$$\mathsf{I}(\Theta(\bar{p}\bar{\nu}); \Phi)^{\mathfrak{A}} := \left\{ \bar{u}\bar{n} \in A^{|\bar{p}|} \times \mathbb{N}^{|\bar{\nu}|} \;\middle|\; \Phi^{\Theta(\mathfrak{A},\bar{u}\bar{n})} \neq \emptyset \right\}.$$

Note that $\Phi^{\Theta(\mathfrak{A},\bar{u}\bar{n})} = \{()\}$ if Φ is satisfied and $\Phi^{\Theta(\mathfrak{A},\bar{u}\bar{n})} = \emptyset$ otherwise. The interpretation operator evaluates a subformula in the image of an interpretation. For IFPC, such an operator does not increase expressiveness because IFPC is closed under interpretations [35]. For IFPC+WSC this is not clear: Because $\Theta(\mathfrak{A}, \bar{u}\bar{n})$ may have a different automorphism structure, Φ possibly can exploit the WSC-fixed-point operator in a way impossible on $\mathfrak{A}$. Indeed, we will see that IFPC+WSC is not even closed under FO-interpretations. We now study the properties of IFPC+WSC+I and its relation to IFPC+WSC.

4 The CFI Construction

We give an overview of the CFI construction. For more details, we refer to [5]. The *degree-d CFI gadget* consists of d pairs of *edge vertices* $\{a_{i0}, a_{i1}\}$ for every $i \in [d]$ and the set of *gadget vertices* $\{\bar{b} \in \mathbb{F}_2^d \mid b_1 + \cdots + b_d = 0\}$. There is an edge $\{a_{ij}, \bar{b}\}$ if and only if $b_i = j$. If we use d colors to additionally color the vertices $\{a_{i0}, a_{i1}\}$ for every $i \in [d]$, then the CFI gadget realizes precisely the automorphisms exchanging the vertices $\{a_{i0}, a_{i1}\}$ for an even number of $i \in [d]$. We later need a relational variant of the CFI gadgets in which every gadget vertex $\bar{b}$ is replaced by the d-tuple $(a_{1b_1}, \ldots, a_{db_d})$. This gadget has the same automorphisms [24]. A *base graph* is a simple connected graph. Let $G = (V, E, \preceq)$ be a colored base graph. We call V *base vertices* and E *base edges* and use fraktur letters for base vertices or edges. For $f\colon E \to \mathbb{F}_2$, we construct the *CFI graph* $\mathsf{CFI}(G, f)$ as follows: Replace every base vertex by a CFI gadget of the same degree. For every base edge $\{\mathfrak{u}, \mathfrak{v}\} \in E$, we obtain two edge-vertex-pairs $\{a_{i0}, a_{i1}\}$ and $\{a'_{j0}, a'_{j1}\}$. The first one is given by the gadget of $\mathfrak{u}$ and the second one by the gadget of $\mathfrak{v}$. Now add the edges $\{a_{ik}, a'_{j\ell}\}$ satisfying $k + \ell = f(\{\mathfrak{u}, \mathfrak{v}\})$. The gadget vertices of the gadget for a base vertex $\mathfrak{u}$ *originate* from $\mathfrak{u}$, the edge vertices $\{a_{i0}, a_{i1}\}$ originate from $(\mathfrak{u}, \mathfrak{v})$, and the edge vertices $\{a'_{j0}, a'_{j1}\}$ originate from $(\mathfrak{v}, \mathfrak{u})$. The color of edge and gadget vertices is obtained from the color of its origin.

It is known [5] that $\mathsf{CFI}(G, g) \cong \mathsf{CFI}(G, f)$ if and only if $\sum g := \sum_{\mathfrak{e} \in E} g(\mathfrak{e}) = \sum f$. If we are interested in the graph up to isomorphism, we write $\mathsf{CFI}(G, 0)$ and $\mathsf{CFI}(G, 1)$. CFI graphs with $\sum g = 0$ are called *even* and the others *odd*. A base edge $\mathfrak{e} \in E$ is *twisted* by f and g if $g(\mathfrak{e}) \neq f(\mathfrak{e})$. Twisted edges can be moved by path isomorphisms [29]: If $\mathfrak{u}_1, \ldots, \mathfrak{u}_\ell$ is a path in G, then there is an isomorphism $\varphi\colon \mathsf{CFI}(G, g) \to \mathsf{CFI}(G, g')$, where $g'(\mathfrak{e}) = g(\mathfrak{e})$ apart from

$\mathfrak{e}_1 := \{\mathfrak{u}_1, \mathfrak{u}_2\}$ and $\mathfrak{e}_2 := \{\mathfrak{u}_{\ell-1}, \mathfrak{u}_\ell\}$ satisfying $g'(\mathfrak{e}_i) = g(\mathfrak{e}_i) + 1$. If G is totally ordered, then every isomorphism is composed of path-isomorphisms. When considering a cycle instead of a path, we obtain an automorphism of $\mathsf{CFI}(G, g)$.

For a class of base graphs $\mathcal{K}$, set $\mathsf{CFI}(\mathcal{K}) := \{\mathsf{CFI}(G, g) \mid G = (V, E) \in \mathcal{K}, g\colon E \to \mathbb{F}_2\}$. The *CFI query* for $\mathsf{CFI}(\mathcal{K})$ is to decide whether a given CFI graph in $\mathsf{CFI}(\mathcal{K})$ is even.

▶ **Lemma 4** ([11]). *If G is of minimum degree 2 and has treewidth at least k, in particular if G is k-connected, then $\mathsf{CFI}(G, 0) \simeq^k_{\mathcal{C}} \mathsf{CFI}(G, 1)$.*

▶ **Lemma 5.** *Let $G = (V, E, \preceq)$ be $(k+2)$-connected and $\mathfrak{A} = \mathsf{CFI}(G, f)$ for some $f\colon E \to \mathbb{F}_2$. Let $\bar{u} \in A^{\leq k}$ and $\{\mathfrak{u}, \mathfrak{v}\} \in E$ be a base edge such that no vertex in $\bar{u}$ has origin $\mathfrak{u}$, $\mathfrak{v}$, $(\mathfrak{u}, \mathfrak{v})$, or $(\mathfrak{v}, \mathfrak{u})$. Then the two edge vertices with origin $(\mathfrak{u}, \mathfrak{v})$ are contained in the same orbit of $(\mathfrak{A}, \bar{u})$.*

5 Canonization of CFI Graphs in IFPC+WSC+I

We show that canonizing CFI graphs in IFPC+WSC+I is not harder than canonizing the base graphs. We work with a class of base graphs closed under individualization, i.e., intuitively closed under assigning new unique colors to some vertices.

▶ **Definition 6** (Individualization of Vertices). *Let $\mathfrak{A}$ be a τ-structure. A binary relation $\trianglelefteq^{\mathfrak{A}} \subseteq A^2$ is an* individualization of $V \subseteq A$ *if $\trianglelefteq^{\mathfrak{A}}$ is a total order on V and $\trianglelefteq^{\mathfrak{A}} \subseteq V^2$. We say that $\trianglelefteq^{\mathfrak{A}}$ is an individualization if it is an individualization of some $V \subseteq A$ and that a vertex $u \in A$ is* individualized *by $\trianglelefteq^{\mathfrak{A}}$ if $u \in V$.*

The *closure under individualization* of a class of τ-structures $\mathcal{K}$ is the class $\mathcal{K}^{\trianglelefteq}$ of $(\tau \uplus \{\trianglelefteq\})$-structures such that $(\mathfrak{A}, \trianglelefteq^{\mathfrak{A}}) \in \mathcal{K}^{\trianglelefteq}$ for every $\mathfrak{A} \in \mathcal{K}$ and every individualization $\trianglelefteq^{\mathfrak{A}}$. Instead of $(\mathfrak{A}, \trianglelefteq^{\mathfrak{A}})$, one can think of $(\mathfrak{A}, \bar{u})$ where $u_1 \trianglelefteq^{\mathfrak{A}} \cdots \trianglelefteq^{\mathfrak{A}} u_{|\bar{u}|}$ are the $\trianglelefteq^{\mathfrak{A}}$-individualized vertices. In the following, let L be one of the logics IFPC, IFPC+WSC, or IFPC+WSC+I. We adapt some notions related to canonization from [32] to our first-order setting. Note that all definitions that follow implicitly include the closure under individualization.

▶ **Definition 7** (Canonization). *Let $\mathcal{K}$ be a class of τ-structures. An* L-canonization *for $\mathcal{K}$ is an $L[\tau \uplus \{\trianglelefteq\}, \tau \uplus \{\trianglelefteq, \leq\}]$-interpretation Θ such that $\leq^{\Theta(\mathfrak{A})}$ is a total order on $\Theta(\mathfrak{A})$ for every $\mathfrak{A} \in \mathcal{K}^{\trianglelefteq}$, $\mathfrak{A} \cong \Theta(\mathfrak{A}) \restriction (\tau \uplus \{\trianglelefteq\})$ for every $\mathfrak{A} \in \mathcal{K}^{\trianglelefteq}$, and $\Theta(\mathfrak{A}) \cong \Theta(\mathfrak{B})$ if and only if $\mathfrak{A} \cong \mathfrak{B}$ for all $\mathfrak{A}, \mathfrak{B} \in \mathcal{K}^{\trianglelefteq}$. L* canonizes *$\mathcal{K}$ if there is an L-canonization for $\mathcal{K}$.*

▶ **Definition 8** (Distinguishable Orbits). *The logic L* distinguishes k-orbits *for a class of τ-structures $\mathcal{K}$ if some $L[\tau \uplus \{\trianglelefteq\}]$-formula $\Phi(\bar{x}, \bar{y})$ with $|\bar{x}| = |\bar{y}| = k$ defines, for every $\mathfrak{A} \in \mathcal{K}^{\trianglelefteq}$, a total preorder on A^k whose equivalence classes form the k-orbit partition of $\mathfrak{A}$, i.e., Φ orders the k-orbits.*

▶ **Definition 9** (Ready for Individualization). *A class of τ-structures $\mathcal{K}$ is* ready for individualization *in L if there is an $L[\tau \uplus \{\trianglelefteq\}]$-formula $\Phi(x)$ defining for every $\mathfrak{A} \in \mathcal{K}^{\trianglelefteq}$ a set of vertices $O = \Phi^{\mathfrak{A}}$ such that O is a 1-orbit of $\mathfrak{A}$, $|O| > 1$ if $\mathfrak{A}$ has a non-trivial 1-orbit, and if $O = \{u\}$ is a singleton set, then u is not individualized by $\trianglelefteq^{\mathfrak{A}}$ unless $\trianglelefteq^{\mathfrak{A}}$ individualizes A.*

Let L be one logic of IFPC+WSC and IFPC+WSC+I. The following lemma is similar to [32] for CPT+WSC and the proof is analogous (we do not include definable isomorphism):

▶ **Lemma 10.** *Let $\mathcal{K}$ be a class of τ-structures. Then the following are equivalent:*

1. *L defines a canonization for $\mathcal{K}$.*
2. *L distinguishes the k-orbits of $\mathcal{K}$ for every $k \in \mathbb{N}$.*
3. *$\mathcal{K}$ is ready for individualization in L.*

Gurevich's canonization algorithm [23] is used to define the canonization. It requires the WSC-fixed-point operator. When canonizing using Lemma 10, defining witnessing automorphisms is hidden in Gurevich's algorithm and they do not have to be defined explicitly.

▶ **Lemma 11.** *Let $\mathcal{K}$ be a class of colored base graphs. If* IFPC+WSC+I *distinguishes* 2*-orbits of $\mathcal{K}$, then* $\mathsf{CFI}(\mathcal{K})$ *is ready for individualization in* IFPC+WSC+I.

Proof Sketch. For a CFI graph $\mathfrak{A}$ over $G \in \mathcal{K}^{\trianglelefteq}$, the base graph G is definable by an IFPC-interpretation. With an interpretation operator, we evaluate a 2-orbit-defining formula on G.

a) If there is a 2-orbit O of G such that for all edges in O there is a cycle not using the origins of individualized vertices, we define the non-trivial orbit of the CFI graph containing the edge-vertex-pairs with origin in O.

b) Otherwise, we can order each edge-vertex-pair. If there is a non-trivial 2-orbit O of G, we define the non-trivial orbit of the CFI graph containing the greater edge vertex of each edge-vertex-pair (with respect to the edge-vertex-pair-order) with origin in O.

c) Otherwise, the edge-vertex-pair-order extends to a total order. ◀

Proof of Theorem 2. The claim follows immediately from Lemmas 10 and 11. ◀

▶ **Corollary 12.** *If $\mathcal{K}$ is a class of base graphs of bounded degree, then* IFPC+WSC+I *defines canonization for $\mathcal{K}$ if and only if* IFPC+WSC+I *defines canonization for* $\mathsf{CFI}(\mathcal{K})$.

Proof. One direction is by Theorem 2. For the other direction, a base graph G of bounded degree is canonized by defining $\mathsf{CFI}(G, 0)$ (which is possible because G is of bounded degree), canonizing $\mathsf{CFI}(G, 0)$, and defining the base graph of the ordered copy of $\mathsf{CFI}(G, 0)$. ◀

Theorem 2 can be applied iteratively: If IFPC+WSC+I canonizes $\mathcal{K}$, then IFPC+WSC+I canonizes $\mathsf{CFI}(\mathcal{K})$, and so IFPC+WSC+I canonizes $\mathsf{CFI}(\mathsf{CFI}(\mathcal{K}))$. Every iteration adds one WSC-fixed-point operator (Gurevich's algorithm in Lemma 10) and one interpretation operator (define the base graph in Lemma 11), i.e., the nesting depth of these operators increases.

6 The CFI Query and Nesting of Operators

We show that the increased nesting depth of operators in Theorem 2 is unavoidable. If IFPC distinguishes orbits of the base graphs, then the nesting depth of WSC-fixed-point operators has to increase because IFPC does not define the CFI query. To show this for IFPC+WSC+I-distinguishable orbits, we combine non-isomorphic CFI graphs into a new base graph and apply the CFI construction again. To define orbits of these double CFI graphs, one has to define the CFI query for the base CFI graphs, which requires a WSC-fixed-point operator. However, parameters to WSC-fixed-point operators will complicate matters.

Nested WSC-Fixed-Point and Interpretation Operators. Let $\text{IFPC} \subseteq L \subseteq \text{IFPC+WSC+I}$. We write $\text{WSC}(L)$ for formulas composed by IFPC-formula-formation rules from L-formulas and WSC-fixed-point-operators, for which all subformulas are L-formulas. We define $\text{I}(L)$ similarly: One can use interpretation operators $I(\Theta, \Psi)$ where Θ is an L-interpretation and Ψ is an L-formula. We set $\text{WSCI}(L) := \text{WSC}(\text{I}(L))$ and $\text{WSCI}^{k+1}(L) := \text{WSCI}(\text{WSCI}^k(L))$. Note the construction in Lemmas 10 and 11:

▶ **Corollary 13.** *Let $\mathcal{K}$ be a class of base graphs.*

1. *If L distinguishes* 2*-orbits of $\mathcal{K}$, then* $\mathsf{CFI}(\mathcal{K})$ *is ready for individualization in* $\text{I}(L)$.
2. *If* $\mathsf{CFI}(\mathcal{K})$ *is ready for individualization in L, then* $\text{WSC}(L)$ *canonizes* $\mathsf{CFI}(\mathcal{K})$.
3. *If L distinguishes* 2*-orbits of $\mathcal{K}$, then* $\text{WSCI}(L)$ *canonizes* $\mathsf{CFI}(\mathcal{K})$.

Color Class Joins. Let $G_1, \dots, G_\ell$ be connected colored graphs such that all G_i have c colors. The *color class join* $J_{\mathrm{cc}}(G_1, \dots, G_\ell)$ is the following graph: Start with the disjoint union of the G_i and add c additional vertices $u_1, \dots, u_c$. Add, for every $i \in [c]$, edges between u_i and every vertex v in the i-th color class of all G_j. The resulting colored graph $J_{\mathrm{cc}}(G_1, \dots, G_\ell)$ has $2c$ color classes: For every $i \in [c]$, the vertex u_i forms a singleton color class and the union of the i-th color classes of every G_j forms a color class. The G_j are the *parts* of $J_{\mathrm{cc}}(G_1, \dots, G_\ell)$. The u_j are the *join vertices* and the others the *part vertices*. The *part* of a part vertex v is the G_j containing v. Defining orbits of $J_{\mathrm{cc}}(G_1, \dots, G_\ell)$ is at least as hard as defining isomorphism of the G_j.

▶ **Lemma 14.** *If two part vertices v and v' are in the same orbit of $J_{cc}(G_1, \dots, G_\ell)$, then the part of v is isomorphic to the one of v'.*

We set $J^k_{\mathrm{cc}}(G, H, K) := J_{\mathrm{cc}}(G, \dots, G, H, \dots, H, K, \dots, K)$, where G, H, and K are repeated k times. To consider color class joins of CFI graphs, let $\mathcal{K}$ be a class of colored base graphs. For $G \in \mathcal{K}$ and $g \in \mathbb{F}_2$, we set

$$\begin{aligned} \mathsf{CFI}^k(G, g) &:= J^k_{\mathrm{cc}}(\mathsf{CFI}(G, 0), \mathsf{CFI}(G, g), \mathsf{CFI}(G, 1)), \\ \mathsf{CFI}^k(\mathcal{K}) &:= \{\, \mathsf{CFI}^k(G, g) \mid G \in \mathcal{K}, g \in \mathbb{F}_2 \,\}, \\ \mathsf{CFI}^\omega(\mathcal{K}) &:= \bigcup_{k \in \mathbb{N}} \mathsf{CFI}^k(\mathcal{K}). \end{aligned}$$

▶ **Lemma 15.** *If L canonizes $\mathsf{CFI}(\mathcal{K})$, then L canonizes $\mathsf{CFI}^\omega(\mathcal{K})$.*

Let $G_1, \dots, G_\ell$ be colored base graphs and $h \in \mathbb{F}_2$. We transfer the notion of part and join vertices from $H := J_{\mathrm{cc}}(G_1, \dots, G_\ell)$ to $\mathfrak{A} := \mathsf{CFI}(H, h)$. The *$G_i$-part* of $\mathfrak{A}$ is the set of vertices originating from G_i in H. These vertices are called *part vertices of G_i*. A vertex is a part vertex, if it is a part vertex of some G_i. The remaining vertices are the *join vertices*.

We consider a special class of individualizations of $\mathfrak{A}$. Let $\bar{u} \in A^*$. A part of $\mathfrak{A}$ is *pebbled by $\bar{u}$* if the part contains u_i for some i. The set of *$\bar{u}$-pebbled-part vertices* $V_{\bar{u}}(\mathfrak{A})$ is the set of all join vertices and all part vertices of a part pebbled by $\bar{u}$. The set of *$\bar{u}$-pebbled-part individualizations* $P_{\bar{u}}(\mathfrak{A})$ is the set of all individualizations of $V_{\bar{u}}(\mathfrak{A})$.

▶ **Definition 16** (Unpebbled-Part-Distinguishing)**.** *For a tuple $\bar{u} \in A^\ell$, a relation $R \subseteq A^k$ is* $\bar{u}$-unpebbled-part-distinguishing *if there are $m \in [k]$ and $i \neq j \in [\ell]$ such that both the G_i-part and the G_j-part of $\mathfrak{A}$ are $\bar{u}$-unpebbled, there is a $\bar{v} \in R$ such that v_m is a part vertex of G_i, and for every $\bar{w} \in R$, the vertex w_m is not a part vertex of G_j.*

If $G_i \not\cong G_j$ are not $\bar{u}$-pebbled, then every k-orbit O of $(\mathfrak{A}, \bar{u})$ satisfies $O \subseteq V_{\bar{u}}(\mathfrak{A})^k$ or is $\bar{u}$-unpebbled-part-distinguishing because G_i- and G_j-part vertices are not in the same orbit.

Quantifying over Pebbled-Part Individualizations. We now define an extension of $\mathcal{C}_k$ which allows for quantifying over pebbled-part individualizations. This (unnatural) extension can only be evaluated on CFI graphs over color class joins. We use this logic for proving WSCI(IFPC)-undefinability. If $\Phi(\bar{x})$ is a $\mathcal{C}_k[\tau, \trianglelefteq_P]$-formula, then $(\exists^P \trianglelefteq_P . \Phi)(\bar{x})$ is a $\mathcal{P}_k[\tau]$-formula. $\mathcal{P}_k[\tau]$-formulas can be combined as usual in $\mathcal{C}_k$ with Boolean operators and counting quantifiers. Note that $\exists^P$-quantifiers *cannot* be nested. Let $G_1, \dots, G_\ell$ be base graphs, $g \in \mathbb{F}_2$, and $\mathfrak{A} = \mathsf{CFI}(J_{\mathrm{cc}}(G_1, \dots, G_n), g)$. The $\exists^P$-quantifier has the following semantics:

$$(\exists^P \trianglelefteq_P . \Phi)^{\mathfrak{A}} := \{\, \bar{u} \mid \bar{u} \in \Phi^{(\mathfrak{A}, \trianglelefteq_P^{\mathfrak{A}})} \text{ for some } \trianglelefteq_P^{\mathfrak{A}} \in P_{\bar{u}}(\mathfrak{A}) \,\}.$$

▶ **Lemma 17.** *Let $G_1, \dots, G_{k+1}$ be colored base graphs, each with $c > k \geq 3$ color classes, such that $\mathsf{CFI}(G_i, 0) \simeq^k_{\mathcal{C}} \mathsf{CFI}(G_i, 1)$ for every $i \in [k+1]$. Then $\mathsf{CFI}(J_{cc}(G_1, \dots, G_{k+1}), 0)$ and $\mathsf{CFI}(J_{cc}(G_1, \dots, G_{k+1}), 1)$ are $\mathcal{P}_k$-equivalent.*

Proof Sketch. The lemma is proven by a game characterization of $\mathcal{P}_k$. Essentially, because only k of the $k+1$ parts can be pebbled by k pebbles, the twist can always be moved in the pebble-free part, which is not affected by quantifying over pebbled-part individualizations. ◀

Nesting Operators to Define the CFI Query is Necessary. Let $\mathcal{K} := \{G_k \mid k \in \mathbb{N}\}$ be a set of ordered 3-regular base graphs such that G_k has treewidth at least k for every $k \in \mathbb{N}$.

▶ **Lemma 18.** $\mathsf{CFI}(\mathsf{CFI}(G_k, g), 0) \simeq^k_{\mathcal{C}} \mathsf{CFI}(\mathsf{CFI}(G_k, g), 1)$ *for every $k \in \mathbb{N}$ and $g \in \mathbb{F}_2$.*

Proof. The graph G_k is a minor of $\mathsf{CFI}(G_k, g)$ for every $g \in \mathbb{F}_2$ (cf. [11]). Hence, $\mathsf{CFI}(G_k, g)$ has treewidth at least k. The claim follows by Lemma 4. ◀

▶ **Lemma 19.** $\mathrm{WSCI}^2(\mathrm{IFPC})$ *defines the CFI query for* $\mathsf{CFI}(\mathsf{CFI}^\omega(\mathcal{K}))$.

Proof. IFPC distinguishes 2-orbits of $\mathcal{K}$ and so WSCI(IFPC) canonizes $\mathsf{CFI}(\mathcal{K})$ (Corollary 13) and $\mathsf{CFI}^\omega(\mathcal{K})$ (Lemma 15) and so also distinguishes 2-orbits of $\mathsf{CFI}^\omega(\mathcal{K})$. Thus, $\mathrm{WSCI}^2(\mathrm{IFPC})$ canonizes $\mathsf{CFI}(\mathsf{CFI}^\omega(\mathcal{K}))$ (Corollary 13) and hence defines the CFI query for $\mathsf{CFI}(\mathsf{CFI}^\omega(\mathcal{K}))$. ◀

To show WSCI(IFPC)-undefinability, there are two cases: If a choice is made from an orbit of parts not pebbled by parameters, then CFI graphs of $\mathsf{CFI}(\mathcal{K})$ are distinguished. Otherwise, CFI graphs of $\mathsf{CFI}(\mathsf{CFI}^\omega(\mathcal{K}))$ are distinguished only by choices from parameter-pebbled parts, so by (at most) individualizing all pebbled-part vertices, i.e., the graphs are distinguished by $\mathcal{P}_k$. By Lemmas 4 and 17, each case only applies to finitely many $\mathcal{K}$-graphs.

▶ **Lemma 20.** WSCI(IFPC) *does not define the CFI query for* $\mathsf{CFI}(\mathsf{CFI}^\omega(\mathcal{K}))$.

Proof Sketch. Suppose, towards a contradiction, that Φ is a WSCI(IFPC)-formula defining the CFI query for $\mathsf{CFI}(\mathsf{CFI}^\omega(\mathcal{K}))$. Because IFPC is closed under interpretations, we can assume that Φ is a WSC(IFPC)-formula.

Let $\Psi_1(\bar{x}_1), \dots, \Psi_p(\bar{x}_p)$ be all WSC-fixed-point operators in Φ and suppose all $\bar{x}_i$ are element variables (for numeric ones see the full version [30]). Let the number of distinct variables of Φ be k and let $\ell := \ell(k) \geq \max\{k, 3\}$. We consider the subclass $\mathsf{CFI}(\mathsf{CFI}^{\ell+1}(\mathcal{K})) \subseteq \mathsf{CFI}(\mathsf{CFI}^\omega(\mathcal{K}))$ and partition $\mathcal{K}$ as follows: Let $\mathcal{K}_{\mathrm{orb}}$ be the set of all $G \in \mathcal{K}$ such that, for every $g \in \mathbb{F}_2$, there are $h \in \mathbb{F}_2$, $j \in [p]$, and a $|\bar{x}_j|$-tuple $\bar{u}$ of $\mathsf{CFI}(\mathsf{CFI}^{\ell+1}(G, g), h))$ such that
a) all choice-sets during the evaluation of $\Psi_j(\bar{u})$ on $\mathsf{CFI}(\mathsf{CFI}^{\ell+1}(G, g), h)$ are orbits and
b) some choice-set is $\bar{u}$-unpebbled-part-distinguishing.
Set $\mathcal{K}_{\mathrm{cfi}} := \mathcal{K} \setminus \mathcal{K}_{\mathrm{orb}}$. At least one of $\mathcal{K}_{\mathrm{orb}}$ and $\mathcal{K}_{\mathrm{cfi}}$ is infinite. Assume that $\mathcal{K}_{\mathrm{orb}}$ is infinite. We claim that the CFI query for $\mathsf{CFI}(\mathcal{K}_{\mathrm{orb}})$ is IFPC-definable. There is an IFPC-interpretation that for $G \in \mathcal{K}$ maps $\mathsf{CFI}(G, g)$ and $h \in \mathbb{F}_2$ to $(\mathsf{CFI}(\mathsf{CFI}^{\ell+1}(G, g), h), \trianglelefteq)$ such that $\trianglelefteq$ individualizes the vertices of $\ell + 1$ many $\mathsf{CFI}(G, 0)$-parts, $\ell + 1$ many $\mathsf{CFI}(G, 1)$-parts, and all join vertices. For every $\Psi_j(\bar{x}_j)$, we try all $h \in \mathbb{F}_2$ and all tuples $\bar{u}$ of $\trianglelefteq$-individualized vertices for $\bar{x}_j$. We simulate Ψ_j as long as all choices are made from $\bar{u}$-pebbled parts (which are resolved using $\trianglelefteq$). If that is not the case, we check if the choice-set is $\bar{u}$-unpebbled-part distinguishing. If not, the choice-set is not an orbit and we evaluate to false. Otherwise, the choice-set contains vertices of $\mathsf{CFI}(G, g)$-parts and either of $\mathsf{CFI}(G, 0)$-parts or of $\mathsf{CFI}(G, 1)$-parts. At least one $\mathsf{CFI}(G, 0)$-part and one $\mathsf{CFI}(G, 1)$-part is not $\bar{u}$-pebbled because $|\bar{u}| \leq k < \ell + 1$, which is isomorphic to the $\mathsf{CFI}(G, g)$-parts. So we defined the parity of $\mathsf{CFI}(G, g)$ and IFPC defines the CFI query for $\mathsf{CFI}(\mathcal{K}_{\mathrm{orb}})$ contradicting Lemma 4.

So $\mathcal{K}_{\text{cfi}}$ must be infinite. Then there is an $\ell' > \ell$ such that $G := G_{\ell'} \in \mathcal{K}_{\text{cfi}}$. Hence there is a $g \in \mathbb{F}_2$ such that for all $h \in \mathbb{F}_2$, $j \in [p]$, and all $|\bar{x}_j|$-tuples $\bar{u}$ of $\mathsf{CFI}(\mathsf{CFI}^{\ell+1}(G,g),h))$
a) some choice-set during the evaluation of $\Psi_j(\bar{u})$ on $\mathsf{CFI}(\mathsf{CFI}^{\ell+1}(G,g),h)$ is not an orbit or
b) all choice-sets are not $\bar{u}$-unpebbled-part-distinguishing.
We construct a $\mathcal{P}_\ell$-formula equivalent to Φ on $\mathsf{CFI}(\mathsf{CFI}^{\ell+1}(G,g),0)$ and $\mathsf{CFI}(\mathsf{CFI}^{\ell+1}(G,g),1)$. The general idea is that we quantify over all $\bar{u}$-pebbled-part individualizations. Choices from choice-sets using only vertices of the $\bar{u}$-pebbled parts can be resolved deterministically using the individualization. If this is not always the case, one choice-set will not be an orbit and we evaluate to false. So a $\mathcal{P}_\ell$-formula distinguishes $\mathsf{CFI}(\mathsf{CFI}^{\ell+1}(G,g),0)$ and $\mathsf{CFI}(\mathsf{CFI}^{\ell+1}(G,g),1)$. This finally contradicts Lemma 17: The graphs G and $\mathsf{CFI}(G,g')$ have more than ℓ color classes for every $g' \in \mathbb{F}_2$ and we have $\mathsf{CFI}(\mathsf{CFI}(G,g'),0) \simeq^k_{\mathcal{C}} \mathsf{CFI}(\mathsf{CFI}(G,g'),1)$ by Lemma 18. ◀

Proof of Theorem 3. Consider $\mathsf{CFI}^\omega(\mathcal{K})$. The claim follows from Lemmas 15, 19, and 20. ◀

▶ **Corollary 21.** $\mathrm{IFPC} < \mathrm{WSCI}(\mathrm{IFPC}) < \mathrm{WSCI}^2(\mathrm{IFPC})$.

It seems natural that $\mathrm{WSCI}^n(\mathrm{IFPC}) < \mathrm{WSCI}^{n+1}(\mathrm{IFPC})$ for every $n \in \mathbb{N}$. Possibly, this hierarchy can be shown by iterating our construction (e.g., using $\mathsf{CFI}((\mathsf{CFI}^\omega)^n(\mathcal{K}))$).

7 Separating IFPC+WSC from IFPC+WSC+I

We define a class of *asymmetric* structures $\mathcal{K}$, i.e., structures without non-trivial automorphisms, for which isomorphism can be reduced to isomorphism of CFI graphs via an interpretation. To do so, we combine CFI graphs and the so-called multipedes.

7.1 Multipedes

We review the multipedes construction [24]. Let $G = (V, W, E, \leq)$ be an ordered bipartite graph, where every vertex in V has degree 3. We obtain the *multipede* $\mathsf{MP}(G)$ as follows. For every vertex $\mathfrak{u} \in W$, there is a vertex pair $F(\mathfrak{u}) = \{u_0, u_1\}$ called a *segment*. We also call $\mathfrak{u} \in W$ a segment. A single vertex u_i is a *foot*. Vertices $\mathfrak{v} \in V$ are *constraint vertices*. For every constraint vertex $\mathfrak{v} \in V$, a degree-3 CFI gadget with three edge-vertex-pairs $\{a^j_0, a^j_1\}$ ($j \in [3]$) is added. Let $N_G(\mathfrak{v}) = \{\mathfrak{u}^1, \mathfrak{u}^2, \mathfrak{u}^3\}$. Then a^j_i is identified with the foot u^j_i for all $j \in [3]$ and $i \in \mathbb{F}_2$. We use the relation-based CFI gadgets, i.e., we do not add further vertices. All base constraint vertices have degree 3 and we obtain a ternary $\{R, \preceq\}$-structure. The coloring $\preceq$ is obtained from $\leq$ such that feet in the same segment have the same color.

The *feet-induced* subgraph by $X \subseteq W$ is $G[[X]] := G[X \cup \{\mathfrak{v} \in V \mid N_G(\mathfrak{v}) \subseteq X\}]$. We extend the notation to the multipede: $\mathsf{MP}(G)[[X]]$ is the induced substructure of all feet whose segment is contained in X. For a tuple $\bar{u}$ of feet of $\mathsf{MP}(G)$, we define $S(\bar{u}) := \{\mathfrak{u} \in W \mid u_i \in F(\mathfrak{u}) \text{ for some } i \leq |\bar{u}|\}$ to be the set of the segments of the u_i.

A bipartite graph $G = (V, W, E, \leq)$ is *odd* if for every $\emptyset \neq X \subseteq W$, there exists a $\mathfrak{v} \in V$ such that $|X \cap N_G(\mathfrak{v})|$ is odd. The graph G is *k-meager*, if for every set $X \subseteq W$ of size $|X| \leq 2k$, it holds that $|\{\mathfrak{v} \in V \mid N_G(\mathfrak{v}) \subseteq X\}| \leq 2|X|$.

▶ **Lemma 22** ([24]). *If G is an odd and ordered bipartite graph, then $\mathsf{MP}(G)$ is asymmetric.*

▶ **Lemma 23** ([24]). *Let G be a k-meager bipartite graph, $\mathfrak{A} = \mathsf{MP}(G)$, and $\bar{u}, \bar{v} \in A^k$. If there is a local isomorphism $\varphi \in \mathsf{Aut}(\mathfrak{A}[[S(\bar{u}\bar{v})]])$ with $\varphi(\bar{u}) = \bar{v}$, then $(\mathfrak{A}, \bar{u}) \simeq^k_{\mathcal{C}} (\mathfrak{A}, \bar{v})$.*

Odd and k-meager graphs exist [24]. A closer inspection shows that for these graphs there are sets of vertices of pairwise large distance. For a bipartite graph $G = (V, W, E)$, a set $X \subseteq W$ is *k-scattered* if all distinct $\mathfrak{u}, \mathfrak{v} \in X$ have distance at least $2k$ in G.

▶ **Lemma 24.** *For every k, there is an odd and k-meager bipartite graph $G = (V, W, E)$ and a k-scattered set $X \subseteq W$ of size $|X| \geq k^2$.*

We will use a k-scattered set X to ensure that in the bijective k-pebble game placing a pebble on one foot of a segment in X creates no restrictions on the other segments in X. For now, fix a bipartite graph $G = (V, W, E, \leq)$. The *attractor* of a set $X \subseteq W$ is

$$\operatorname{attr}(X) := X \cup \bigcup_{u \in V \colon |N_G(u) \setminus X| \leq 1} N_G(u).$$

The set X is *closed* if $X = \operatorname{attr}(X)$. The *closure* $\operatorname{cl}(X)$ of X is the inclusion-wise minimal closed superset of X.

▶ **Lemma 25** ([24])**.** *Assume that $X \subseteq W$, $|X| \leq k$, G is k-meager, $\mathfrak{A} = \mathsf{MP}(G)$, and $\varphi \in \mathsf{Aut}(\mathfrak{A}[[X]])$. Then there is an extension of φ that is an automorphism of $\mathfrak{A}[[\operatorname{cl}(X)]]$.*

▶ **Lemma 26.** *Let G be $2k$-meager, $X = \{\mathfrak{u}_1, \dots, \mathfrak{u}_\ell\} \subseteq W$ be $6k$-scattered, $Y \subseteq W$ such that $X \cap \operatorname{cl}(Y) = \emptyset$ and $|X| + |Y| < k$, $\mathfrak{A} = \mathsf{MP}(G)$, and $\varphi \in \mathsf{Aut}(\mathfrak{A}[[Y]])$. Then for all $\bar{u}, \bar{u}' \in F(\mathfrak{u}_1) \times \cdots \times F(\mathfrak{u}_\ell)$, there is an extension ψ of φ to $\mathfrak{A}[[X \cup Y]]$ satisfying $\psi(\bar{u}) = \bar{u}'$.*

The previous lemma turns out to be useful in the bijective k-pebble game: If the pebbles are placed on the feet in Y, we can simultaneously for all feet in X place arbitrary pebbles and still maintain a local automorphism. Such sets X will allow us to glue another graph to the multipede at the feet in X: Whatever restrictions on placing pebbles are imposed by the other graph, we still can maintain partial automorphisms in the multipede.

7.2 Gluing Multipedes to CFI Graphs

We now use multipedes to make CFI graphs asymmetric. We alter the CFI graphs in this section. Instead of two edge-vertex-pairs for the same base edge $\{\mathfrak{u}, \mathfrak{v}\}$, we contract the edges between the two vertex pairs and obtain a single edge-vertex-pair with origin $\{\mathfrak{u}, \mathfrak{v}\}$. This preserves all relevant properties of CFI graphs. In this section we write $\mathsf{CFI}(H, f)$ for CFI graphs of this modified construction. A single edge-vertex-pair per base edge removes technical details from the following.

Let $G = (V^G, W^G, E^G, \leq^G)$ be an ordered bipartite graph, $H = (V^H, E^H, \leq^H)$ be an ordered base graph, $f \colon E^H \to \mathbb{F}_2$, and $X \subseteq W^G$ have size $|X| = |E^H|$. We define the *gluing* $\mathsf{MP}(G) \cup_X \mathsf{CFI}(H, f)$ of the multipede $\mathsf{MP}(G) = (A, R^{\mathsf{MP}(G)}, \preceq^{\mathsf{MP}(G)})$ and the CFI graph $\mathsf{CFI}(H, f) = (B, E^{\mathsf{CFI}(H,f)}, \preceq^{\mathsf{CFI}(H,f)})$ at X as follows: We start with the disjoint union of $\mathsf{MP}(G)$ and $\mathsf{CFI}(H, f)$ and identify the i-th edge-vertex-pair of $\mathsf{CFI}(H, f)$ (according to $\leq^H$) with the i-th segment in X (according to $\leq^G$). We turn the edges $E^{\mathsf{CFI}(H,f)}$ into a ternary relation by extending every edge (u, v) to (u, v, v). In that way, we obtain a $\{R, \preceq\}$-structure, where R is the union of $R^{\mathsf{MP}(G)}$ and the triples (u, v, v) defined before and $\preceq$ is the total preorder obtained from combining $\preceq^{\mathsf{MP}(G)}$ and $\preceq^{\mathsf{CFI}(H,f)}$.

▶ **Lemma 27.** *If $\mathsf{MP}(G)$ is asymmetric, then $\mathsf{MP}(G) \cup_X \mathsf{CFI}(H, f)$ is asymmetric.*

Let $\bar{u}$ be a tuple of at most k vertices of $\mathsf{MP}(G) \cup_X \mathsf{CFI}(H, f)$, i.e., $\bar{u}$ contains either gadget vertices of $\mathsf{CFI}(H, f)$ or feet of $\mathsf{MP}(G)$. We call the set of segments $S(\bar{u})$ of all feet in $\bar{u}$ *directly-fixed by* $\bar{u}$ and the segments $\operatorname{cl}(S(\bar{u})) \setminus S(\bar{u})$ *closure-fixed by* $\bar{u}$. A segment $\mathfrak{u} \in X$ is *gadget-fixed by* $\bar{u}$ if the feet of $\mathfrak{u}$ are identified with an edge-vertex-pair with origin $\{\mathfrak{v}, \mathfrak{w}\}$ in $\mathsf{CFI}(H, f)$ such that there is a gadget vertex with origin $\mathfrak{v}$ or $\mathfrak{w}$ in $\bar{u}$. A segment is *fixed by* $\bar{u}$ if it is directly fixed, closure-fixed, or gadget-fixed.

▶ **Lemma 28.** *Let $r \geq k \geq 2$. If H is r-regular, G is $2k$-meager, and X is $6k$-scattered, then at most $r \cdot |\bar{u}|$ segments are fixed. If $\bar{u}$ contains i gadget vertices and ℓ segments in X are directly-fixed, then at most $|\bar{u}| - i - \ell$ segments in X are closure-fixed.*

We now combine winning strategies of Duplicator on multipedes and CFI graphs:

▶ **Lemma 29.** *Let G be $2rk$-meager, H be r-regular and at least $(k+2)$-connected, and X be $6rk$-scattered. Then $\mathsf{MP}(G) \cup_X \mathsf{CFI}(H,0) \simeq^k_{\mathcal{C}} \mathsf{MP}(G) \cup_X \mathsf{CFI}(H,1)$.*

Proof Sketch. Assume $\mathfrak{A} = \mathsf{MP}(G)$, $\mathfrak{B} = \mathsf{CFI}(H,0)$, and $\mathfrak{B}' = \mathsf{CFI}(H,1)$. We show that Duplicator has a winning strategy in the bijective k-pebble game on $\mathfrak{A} \cup_X \mathfrak{B}$ and $\mathfrak{A} \cup_X \mathfrak{B}'$. For a set of segments Y and a tuple $\bar{u}$, we denote by $\bar{u}_Y$ the restriction of $\bar{u}$ to all feet whose segment is contained in Y, by $\bar{u}_{\mathrm{G}}$ the restriction to all gadget vertices, and by $\bar{u}_{\mathrm{F}}$ to all feet. Duplicator maintains the following invariant. At every position $(\mathfrak{A} \cup_X \mathfrak{B}, \bar{u}; \mathfrak{A} \cup_X \mathfrak{B}', \bar{u}')$ in the game, there exist tuples of feet $\bar{v}_{\mathrm{gf}}, \bar{v}_{\mathrm{cf}}$ of $\mathfrak{A} \cup_X \mathfrak{B}$ and $\bar{v}'_{\mathrm{gf}}, \bar{v}'_{\mathrm{cf}}$ of $\mathfrak{A} \cup_X \mathfrak{B}'$ satisfying the following:

1. $\bar{v}_{\mathrm{gf}}$ (respectively $\bar{v}'_{\mathrm{gf}}$) contains for every segment gadget-fixed by $\bar{u}$ exactly one foot and no others.
2. $\bar{v}_{\mathrm{cf}}$ (respectively $\bar{v}'_{\mathrm{cf}}$) contains for every segment in X closure-fixed by $\bar{u}$ exactly one foot and no others.
3. There is a local isomorphism $\varphi \in \mathsf{Aut}(\mathfrak{A}[[S(\bar{u}_{\mathrm{F}}\bar{v}_{\mathrm{gf}}\bar{v}_{\mathrm{cf}})]])$ satisfying $\varphi(\bar{u}_{\mathrm{F}}\bar{v}_{\mathrm{gf}}\bar{v}_{\mathrm{cf}}) = \bar{u}'_{\mathrm{F}}\bar{v}'_{\mathrm{gf}}\bar{v}'_{\mathrm{cf}}$.
4. $(\mathfrak{B}, \bar{u}_X\bar{u}_{\mathrm{G}}\bar{v}_{\mathrm{cf}}) \simeq^k_{\mathcal{C}} (\mathfrak{B}', \bar{u}'_X\bar{u}'_{\mathrm{G}}\bar{v}'_{\mathrm{cf}})$.
5. For every base vertex $\mathfrak{u}$, it holds that $(\mathfrak{B}', \bar{u}_{\mathrm{G}}\bar{v}_{\mathrm{gf}})[V_{\mathfrak{u}}] \cong (\mathfrak{B}, \bar{u}'_{\mathrm{G}}\bar{v}'_{\mathrm{gf}})[V_{\mathfrak{u}}]$, where $V_{\mathfrak{u}}$ is the set of all gadget vertices with origin $\mathfrak{u}$ and all edge vertices with origin $\{\mathfrak{u}, \mathfrak{v}\}$ for some $\mathfrak{v}$.

For Property 3, note that $S(\bar{u}_{\mathrm{F}}\bar{v}_{\mathrm{gf}}\bar{v}_{\mathrm{cf}}) = S(\bar{u}'_{\mathrm{F}}\bar{v}'_{\mathrm{gf}}\bar{v}'_{\mathrm{cf}})$ and $|\bar{u}_{\mathrm{F}}\bar{v}_{\mathrm{gf}}\bar{v}_{\mathrm{cf}}| = |\bar{u}'_{\mathrm{F}}\bar{v}'_{\mathrm{gf}}\bar{v}'_{\mathrm{cf}}| \leq rk$ by Lemma 28 because G is $2rk$-meager. For Property 4, note that $|\bar{u}_X\bar{u}_{\mathrm{G}}\bar{v}_{\mathrm{cf}}| = |\bar{u}'_X\bar{u}'_{\mathrm{G}}\bar{v}'_{\mathrm{cf}}| \leq k$: By Lemma 28, the number of closure-fixed segments in X is at most $|\bar{v}_{\mathrm{cf}}| \leq k - |\bar{u}_{\mathrm{G}}| - |\bar{u}_X|$. Property 5 guarantees that the vertices $\bar{v}_{\mathrm{gf}}$ and $\bar{v}'_{\mathrm{gf}}$ are picked consistently. This is needed because $|\bar{v}_{\mathrm{gf}}|$ exceeds k and thus cannot be included in Property 4.

We play two games. Game I is played with rk pebbles on $(\mathfrak{A}, \bar{u}_{\mathrm{F}}\bar{v}_{\mathrm{gf}}\bar{v}_{\mathrm{cf}}; \mathfrak{A}, \bar{u}'_{\mathrm{F}}\bar{v}'_{\mathrm{gf}}\bar{v}'_{\mathrm{cf}})$. Game II is played with k pebbles on $(\mathfrak{B}, \bar{u}_X\bar{u}_{\mathrm{G}}\bar{v}_{\mathrm{cf}}; \mathfrak{B}', \bar{u}'_X\bar{u}'_{\mathrm{G}}\bar{v}'_{\mathrm{cf}})$. From the winning strategies of Duplicator in both games (Lemmas 4 and 23) we construct a winning strategy on $(\mathfrak{A} \cup_X \mathfrak{B}, \bar{u}; \mathfrak{A} \cup_X \mathfrak{B}', \bar{u}')$. We can do so because in Game I we fixed all gadget-fixed segments and in Game II we fixed all closure-fixed segments in X. When placing a pebble on a gadget vertex, we extend the tuples $\bar{v}_{\mathrm{gf}}$ and $\bar{v}'_{\mathrm{gf}}$ using Lemma 26. When a pebble is placed on a segment not in X, at most one segment in X gets closure fixed and the edge vertices are in the same orbit of the CFI graphs (Lemma 5). ◀

▶ **Theorem 30.** *There is an* FO*-interpretation Θ and, for every $k \in \mathbb{N}$, a pair of ternary $\{R, \preceq\}$-structures $(\mathfrak{A}_k, \mathfrak{B}_k)$ such that $\preceq$ is a total preorder, $\mathfrak{A}_k$ and $\mathfrak{B}_k$ are asymmetric, $\mathfrak{A}_k \simeq^k_{\mathcal{C}} \mathfrak{B}_k$, $\mathfrak{A}_k \ncong \mathfrak{B}_k$, and $\Theta(\mathfrak{A}_k) \ncong \Theta(\mathfrak{B}_k)$ are CFI graphs of the same ordered base graph.*

Proof Sketch. We use the gluings constructed before for suitable base graphs and multipedes (Lemma 24). By Lemma 29, the odd and even gluing are $\mathcal{C}_k$-equivalent (but surely not isomorphic) and asymmetric by Lemmas 22 and 27. There is an FO-interpretation Θ removing the multipede: Shorten R-triples (u, v, v) back to edges (u, v) and remove the others. ◀

Proof Sketch of Theorem 1. Consider the $\{R, \preceq\}$-structures $\mathcal{K}$ from Theorem 30. To ensure that the reduct semantics does not add automorphisms, $\preceq$ is encoded into R by attaching paths of different lengths to the vertices. This preserves asymmetry and non-isomorphism. The paths are removed by an FO-interpretation $\Theta_{\mathcal{K}}$. All structures are asymmetric and have a single relation, so IFPC = IFPC+WSC and IFPC does not define isomorphism.

Let Φ_{CFI} be a WSCI(IFPC) = WSC(IFPC)-formula defining the CFI query for ordered base graphs (Corollary 13) and let Θ_{CFI} be the FO-interpretation extracting the CFI graphs from $\mathcal{K}$-structures given by Theorem 30. Then the I(WSC(IFPC))-formula $\mathsf{I}(\Theta_{\text{CFI}} \circ \Theta_{\mathcal{K}}; \Phi_{\text{CFI}})$ defines the isomorphism problem of $\mathcal{K}$-structures. ◀

▶ **Corollary 31.** IFPC+WSC $<$ *Ptime.*

▶ **Corollary 32.** WSC(IFPC) $<$ I(WSC(IFPC)).

Note that the prior corollary refines Corollary 21. We actually expect that

$$\text{WSC(IFPC)} < \text{I(WSC(IFPC))} < \text{WSC(I(WSC(IFPC)))}$$

because it seems unlikely that I(WSC(IFPC)) defines the CFI query of the base graphs of Theorem 3.

▶ **Corollary 33.** IFPC+WSC *is not closed under* IFPC*-interpretations and not even under* 1*-dimensional equivalence-free* FO*-interpretations.*

Using the same structures, we can answer an open question of Dawar and Richerby in [9]:

▶ **Corollary 34.** IFP+SC *is not closed under* 1*-dimensional equivalence-free* FO*-interpretations.*

8 Discussion

We defined the logics IFPC+WSC and IFPC+WSC+I to study the combination of witnessed symmetric choice and interpretations beyond simulating counting. Instead, we provided graph constructions to prove lower bounds. IFPC+WSC+I canonizes CFI graphs if it canonizes the base graphs, but operators have to be nested. We proved that this increase in nesting depth is unavoidable using double CFI graphs obtained by essentially applying the CFI construction twice. Does iterating our construction further show an operator nesting hierarchy in IFPC+WSC+I? We have seen that also in the presence of counting the interpretation operator strictly increases the expressiveness. So indeed both, witnessed symmetric choice and interpretations are needed to possibly capture Ptime. This answers the question to the relation between witnessed symmetric choice and interpretations for IFPC. But it remains open whether IFPC+WSC+I captures Ptime. Here, iterating our CFI construction is of interest again: If one shows an operator nesting hierarchy using this construction, then one in particular will separate IFPC+WSC+I from Ptime because our construction does not change the signature of the structures. Studying this remains for future work.

On the Complexity of Diameter and Related Problems in Permutation Groups

Markus Lohrey
Universität Siegen, Germany

Andreas Rosowski
Universität Siegen, Germany

Abstract

We prove that it is Π_2^{P}-complete to verify whether the diameter of a given permutation group $G = \langle A \rangle$ is bounded by a unary encoded number k. This solves an open problem from a paper of Even and Goldreich, where the problem was shown to be NP-hard. Verifying whether the diameter is exactly k is complete for the class consisting of all intersections of a Π_2^{P}-language and a Σ_2^{P}-language. A similar result is shown for the length of a given permutation π, which is the minimal k such that π can be written as a product of at most k generators from A. Even and Goldreich proved that it is NP-complete to verify, whether the length of a given π is at most k (with k given in unary encoding). We show that it is DP-complete to verify whether the length is exactly k. Finally, we deduce from our result on the diameter that it is Π_2^{P}-complete to check whether a given finite automaton with transitions labelled by permutations from S_n produces all permutations from S_n.

2012 ACM Subject Classification Theory of computation → Problems, reductions and completeness

1 Introduction

Algorithmic problems for finite groups, in particular permutation groups, are an active research at the borderline between mathematics and theoretical computer science. Among the many applications of permutation group algorithms in computer science, let us just mention the work on the graph isomorphism problem that culminated with Babai's quasi-polynomial time algorithm [2]. For a comprehensive introduction into the area permutation group algorithms, see Serres' textbook [23]. In this paper we are concerned with algorithmic problems related to the diameter of finite permutation groups. We start with a few basic definitions.

Let G be a finite group. For a subset $A \subseteq G$ we denote with $\langle A \rangle$ the subgroup of G generated by the elements from A (i.e., the closure of A under the group multiplication). If $\langle A \rangle = G$ then A is called a generating set of G. For $k \geq 0$ we write $A^{\leq k}$ for the set of all products $a_1 a_2 \cdots a_l \in G$ with $l \leq k$ and $a_1, \ldots, a_l \in A$. For an element $g \in \langle A \rangle$ we denote with $|g|_A$ (the A-length of g) the smallest integer k such that $g \in A^{\leq k}$. The diameter $d(G, A)$ of G with respect to the generating A is the smallest number d such that $\langle A \rangle = A^{\leq d}$. Note that such a d exists since G is finite. There is a quite extensive literature on upper and lower bounds on the diameter in various finite groups; see e.g. [3, 4, 5, 6, 7, 8, 9, 13, 17, 19]. Let us mention in this context a famous (and still open) conjecture of Babai and Seress [8] stating that for every finite non-abelian simple group G and every generating set A, $d(G, A)$

is bounded by $\mathcal{O}((\log |G|)^c)$ for some universal constant c. This would imply in particular that the diameters of A_n and S_n (with respect to any generating sets) are bounded by a polynomial in n. The currently best known upper bound is $\exp(\mathcal{O}(\log^4 n \log\log n))$ [13].

Many problems about mechanical puzzles reduce to questions about the diameter of finite groups. As an example let us mention Rubik's cube. For a long time it was open how many moves in Rubik's cube are needed to transform an arbitrary initial configuration into the target configuration. This number is simply the diameter of the so-called Rubik's cube group. The precise value of this diameter was open for a long time. In 2013 Rokicki et al. proved that is 20 [22].

1.1 Computing diameter and length

In the first part of the paper (Sections 3 and 4) we investigate the complexity of certain decision variants of the following computational problems:

(i) computing the length of a given element from a permutation group and

(ii) computing the diameter of a permutation group.

Let us define the problems that we will investigate more precisely. With S_n we denote the group of all permutations on $[1, n] = \{1, \ldots, n\}$. In the following problems, a permutation $\pi \in S_n$ is given by the list $\pi(1), \pi(2), \ldots, \pi(n)$. The size n of the domain (also called the degree of the permutations) is part of the input. For $A \subseteq S_n$ we write $d(A)$ for $d(\langle A \rangle, A)$. We then define the following computational problems:

▶ **Problem** (UNARY LENGTH).
Input: a set of permutations $A \subseteq S_n$, an element $\pi \in \langle A \rangle$, and a unary encoded number k.[1]
Question: Is $|\pi|_A \leq k$?

▶ **Problem** (UNARY DIAMETER).
Input: a set of permutations $A \subseteq S_n$ and a unary encoded number k.
Question: Is $d(A) \leq k$?

The problems BINARY LENGTH and BINARY DIAMETER are defined in the same way, except that the input number k is given in binary encoding.

Goldreich and Even [11] were the first who obtained results on the complexity of these problems. They proved that UNARY LENGTH is NP-complete and UNARY DIAMETER is NP-hard[2] but the exact complexity of UNARY DIAMETER remained open. A parameterized variant of UNARY LENGTH (with k as the parameter) is studied under the name PERMUTATION GROUP FACTORIZATION in [10] and shown to be W[1]-hard and in W[P]. The binary setting was first studied by Jerrum [15]. He proved that BINARY LENGTH is PSPACE-complete.

We also study exact versions of the above problems:

▶ **Problem** (UNARY EXACT LENGTH).
Input: a set of permutations $A \subseteq S_n$, a permutation $\pi \in \langle A \rangle$, and a unary encoded number k.
Question: Is $|\pi|_A = k$?

[1] It is well-known that there is a polynomial time algorithm that checks whether $\pi \in \langle A \rangle$ holds [12].

[2] The problem UNARY LENGTH is called MGS for "minimum generator sequence" in [11], whereas UNARY DIAMETER is called MBGS for "minimum upper bound on generator sequences". We believe that UNARY LENGTH and UNARY DIAMETER are more suggestive. Another point is that Even and Goldreich do not specify the encoding of integers in their paper, but from the NP-completeness result for UNARY LENGTH, it can deduced that they have the unary encoding of integers in mind.

▶ **Problem** (UNARY EXACT DIAMETER).
Input: a set of permutations $A \subseteq S_n$ and a unary encoded number k.
Question: Is $d(A) = k$?

Again, there are corresponding problems BINARY EXACT LENGTH and BINARY EXACT DIAMETER, where the input number k is given in binary notation.

The first main result of this paper solves the open problem left in [11]: UNARY DIAMETER is Π_2^{P}-complete, where Π_2^{P} is the second universal level of the polynomial time hierarchy. This result also holds for the restriction, where all permutations in the set $A \subseteq S_n$ pairwise commute and have order two (and hence $\langle A \rangle$ is an abelian group of exponent two). Moreover, we also show that BINARY DIAMETER with a set A of pairwise commuting permutations is Π_2^{P}-complete.

The complexity of BINARY DIAMETER for general permutation groups remains open. The problem is easily seen to be in PSPACE. The above mentioned result of Jerrum (PSPACE-completeness of BINARY LENGTH for a binary encoded number k) seems to have no implications for the complexity of BINARY DIAMETER. Nevertheless, we conjecture that BINARY DIAMETER is PSPACE-complete.

We then proceed to show that UNARY EXACT DIAMETER is complete for the complexity class DP_2, which is the class of all intersections of a Π_2^{P}-language and a Σ_2^{P}-language. Hardness for DP_2 already holds for the restriction of UNARY EXACT DIAMETER to abelian permutation groups of exponent two. To get DP_2-hardness, we use the fact that our Π_2^{P}-hardness proof of UNARY DIAMETER already holds for inputs $A \subseteq S_n$ and $k \in \mathbb{N}$ with the promise that the diameter of $\langle A \rangle$ is either k or $k+1$. Using similar techniques we can also show that UNARY EXACT LENGTH is DP-complete, where DP is the class of all intersections of an NP-language and a coNP-language.

1.2 Equality and universality for finite automata over permutation groups

In the second part of the paper (Section 5), we consider problems related to finite automata over permutation groups. The setting is as follows: Consider a nondeterministic finite automaton (NFA) $\mathcal{A}$ over a finite alphabet Σ of input letters and a mapping $h : \Sigma \to S_n$ to a symmetric group. The mapping h extends to a morphism $h : \Sigma^* \to S_n$ from the free monoid Σ^* to the group S_n (we use the same letter h for this extension). We may then ask whether a given permutation π belongs to $h(L(\mathcal{A}))$. This is the *rational subset membership problem for permutation groups*, where the input consists of the NFA $\mathcal{A}$, the mapping $h : \Sigma \to S_n$ (n is also part of the input) and the permutation π. It is shown in [16, 18] that the rational subset membership problem for permutation groups is NP-complete.[3]

To simplify notation, we omit the mapping $h : \Sigma^* \to S_n$ in the following, and replace in the NFA $\mathcal{A}$ every transition label $a \in \Sigma$ by the corresponding permutation $h(a) \in S_n$. Thus, we consider NFAs, where the transitions are labelled with elements of a symmetric group S_n. The set $L(\mathcal{A})$ accepted by $\mathcal{A}$ is then directly interpreted as a subset of S_n. Clearly, every subset of S_n is of the form $L(\mathcal{A})$ for an NFA $\mathcal{A}$ over S_n, but in general the number of

[3] In [18] stronger results are shown: (i) NP-hardness already holds for membership in sets $\pi^*\sigma^*\tau^*$, where π, σ, τ are input permutations, and (ii) membership in NP holds for black-box groups and a restricted class of context-free languages (where terminal symbols are again replaced by permutations). The general membership problem for context-free sets of permutations is PSPACE-complete [18].

transitions of $\mathcal{A}$ must be exponential in n (this follows from a simple counting argument). Note that for a finite set $A \subseteq S_n$ it is straightforward to come up with an automaton $\mathcal{A}$ over S_n with a single state and $|A|$ many transitions such that $L(\mathcal{A}) = \langle A \rangle$.

In Section 5, we consider the *rational equality problem for permutation groups*, RATIONAL EQUALITY for short:

▶ **Problem** (RATIONAL EQUALITY).
Input: two NFAs $\mathcal{A}$ and $\mathcal{B}$ over S_n (n is as usual part of the input).
Question: Does $L(\mathcal{A}) = L(\mathcal{B})$ hold?

As before, we also consider the abelian variant of this problem, where all permutations labelling the transitions of $\mathcal{A}$ and $\mathcal{B}$ pairwise commute. Moreover, we consider the following restriction of RATIONAL EQUALITY.

▶ **Problem** (RATIONAL UNIVERSALITY).
Input: an NFA $\mathcal{A}$ over S_n.
Question: Does $L(\mathcal{A}) = S_n$ hold?

Note that for RATIONAL UNIVERSALITY, the restriction where the permutations appearing in $\mathcal{A}$ pairwise commute is not interesting, since S_n is not abelian for $n \geq 3$.

We show that RATIONAL EQUALITY and RATIONAL UNIVERSALITY are both Π_2^{P}-complete and that Π_2^{P}-hardness for RATIONAL EQUALITY already holds for the abelian case. For the lower bounds we use reductions from UNARY DIAMETER.

Let us finally remark that our upper bound proofs do not use any specific properties of permutation groups. In particular, all upper bounds shown in this paper also hold for the black-box-group setting, where elements of a black-box group G are encoded by bit strings and there are oracles for (i) multiplying two elements of G, (ii) inverting an element of G, and (iii) checking whether two bit strings represent the same element of G (see [23] for more details on black-box groups).

2 Preliminaries

2.1 Background from complexity theory

We assume that the reader has some basic background from complexity theory, see e.g. [1] for more information. The levels Σ_k^{P} and Π_k^{P} of the *polynomial time hierarchy* [24] are defined as follows:

- $\Sigma_0^{\mathsf{P}} = \Pi_0^{\mathsf{P}} = \mathsf{P}$
- $\Sigma_{k+1}^{\mathsf{P}}$ is the set of all languages L such that there exists a language $K \in \Pi_k^{\mathsf{P}}$ and a polynomial p with $L = \{x \mid \exists y \in \{0,1\}^{p(|x|)} : x\#y \in K\}$ (here $\#$ is a separator symbol).
- Π_{k+1}^{P} is the set of all languages L such that there exists a language $K \in \Sigma_k^{\mathsf{P}}$ and a polynomial p with $L = \{x \mid \forall y \in \{0,1\}^{p(|x|)} : x\#y \in K\}$.

In particular, we have $\Sigma_1^{\mathsf{P}} = \mathsf{NP}$ and $\Pi_1^{\mathsf{P}} = \mathsf{coNP}$. We will make use of the computational problem $\forall\exists$SAT, where the input is a $\forall\exists$-formula

$$\Psi = \forall x_1 \cdots \forall x_n \exists y_1 \cdots \exists y_m F(x_1, \ldots, x_n, y_1, \ldots, y_m), \tag{1}$$

where F is a boolean formula in conjunctive normal form built from the boolean variables $x_1, \ldots, x_n, y_1, \ldots, y_m$. The question is whether Ψ holds. This problem is Π_2^{P}-complete [24].

The complexity class DP_k is defined as

$$\mathsf{DP}_k = \{L_1 \cap L_2 \mid L_1 \in \Sigma_k^{\mathsf{P}} \text{ and } L_2 \in \Pi_k^{\mathsf{P}}\}.$$

The class $\mathsf{DP}_1 = \{L_1 \cap L_2 \mid L_1 \in \mathsf{NP} \text{ and } L_2 \in \mathsf{coNP}\}$ is usually denoted by DP. It was defined in [21]. The only mentioning of the classes DP_k for $k \geq 2$ we are aware of is the stack exchange post [20].

2.2 Some notations for permutation groups

Recall that a permutation group is a subgroup of the *symmetric group* S_n for some n, where S_n is the group of all permutations on $[1, n] = \{1, \ldots, n\}$. We will use standard notations for permutation groups; see e.g., [23]. Permutations will be often written by their decomposition into disjoint cycles, called the *disjoint cycle decomposition*. A cycle of length two is a *transposition*. A product of permutations will be evaluated from left to right. For $a \in [1, n]$ and $\pi \in S_n$ we will also write a^π for $\pi(a)$. This fits nicely to the left-to-right evaluation order: $a^{\pi\tau} = (a^\pi)^\tau$. For a permutation π we denote by $\mathrm{ord}(\pi)$ the order of π, i.e., the smallest $k \geq 1$ such that π^k is the identity permutation.

Most of the hardness results in Sections 3 and 4 will be shown for the group $\mathbb{Z}_2^n$ (the n-fold direct product of the group $\mathbb{Z}_2$) for an $n \geq 0$. Clearly, this is an abelian group of exponent two (i.e., every element has order two). The group $\mathbb{Z}_2^n$ is isomorphic to the subgroup of S_{2n} generated by all transpositions $(2i-1, 2i)$ for $i \in [1, n]$. For a finite set V of size n, we will identify $\mathbb{Z}_2^n$ with the group $\mathbb{Z}_2^V$ of all mappings $f : V \to \mathbb{Z}_2$ with the group operation to be pointwise addition modulo 2. We write this abelian group additively. For a function $f : V \to \mathbb{Z}_2 = \{0, 1\}$ we define its support as $\mathrm{supp}(f) = \{v \in V \mid f(v) = 1\}$. For a subset $U \subseteq V$ we denote by $[U] \in \mathbb{Z}_2^V$ the unique group element with $\mathrm{supp}([U]) = U$.

3 Complexity of diameter for permutation groups

We come to the first main result of the paper: UNARY DIAMETER is Π_2^{P}-hard. In the following theorem, the additional statement that the diameter $d(A)$ is either k or $k+1$ will be needed later when we consider UNARY EXACT DIAMETER.

▶ **Theorem 3.1.** *There is a logspace reduction ϕ from $\forall\exists$SAT to* UNARY DIAMETER *such that for every $\forall\exists$-formula Ψ with $\phi(\Psi) = (A, k)$ we have: $A \subseteq \mathbb{Z}_2^n$ for some n, $\langle A \rangle = \mathbb{Z}_2^n$ and $d(A) \in \{k, k+1\}$.*

Proof. Let us fix a $\forall\exists$-formula Ψ as in (1). We can write F as $F = \bigwedge_{c \in C} c$, where C is a set of clauses (disjunctions of variables and negated variables). We start with several transformations that ensure some additional properties for Ψ.

Step 1. In order to bound the diameter of the group from above by $k+1$ we replace Ψ by the formula

$$\forall x_1 \cdots \forall x_n \exists y_1 \cdots \exists y_m \exists y^* \, G(x_1, \ldots, x_n, y_1, \ldots, y_m, y^*),$$

where y^* is a new variable and

$$G = \neg y^* \wedge \bigwedge_{c \in C} (y^* \vee c).$$

By this it is ensured that for every truth assignment of the universally quantified variables $x_1, \ldots, x_n$, there is a truth assignment of the existentially quantified variables $y_1, \ldots, y_m, y^*$ such that exactly one clause in G is unsatisfied (simply set y^* to the true value 1).

Step 2. Next, it is necessary to ensure that every variable appears in at most d clauses for a fixed constant d. This can be ensured similarly to [25] for 3SAT: for every variable $z \in \{x_1, \ldots, x_n, y_1, \ldots, y_m, y^*\}$ that appears in $l \geq 4$ clauses in G we introduce new variables $z_1, \ldots, z_l$ and replace the i-th occurrence of z by z_i. Then we add the clauses

$$(\neg z_1 \vee z_2), (\neg z_2 \vee z_3), \ldots, (\neg z_{l-1} \vee z_l), (\neg z_l \vee z_1) \tag{2}$$

which enforce that $z_1, \ldots, z_l$ must get the same truth value. If $z \in \{x_1, \ldots, x_n\}$ then we universally quantify z_1 and existentially quantify $z_2, \ldots, z_l$. If $z \in \{y_1, \ldots, y_m, y^*\}$ then all new variables z_i get existentially quantified. In the resulting formula, every variable occurs in at most 3 clauses.

Step 3. Finally, for our later arguments, it is necessary to add for every universally quantified variable x the trivial clause

$$c_x = (x \vee \neg x).$$

Of course, this trivial clause does not change the truth value of the formula. Now every variable occurs in at most 4 clauses. We still have the property that every truth assignment for the universally quantified variables can be extended by a truth assignment for the existentially quantified variables such that exactly one clause becomes unsatisfied. To see this, consider an arbitrary truth assignment for the universally quantified variables. The clauses c_x that we added in Step 3 are always satisfied. We now assign the truth value 1 to all variables y_i^* that replaced in Step 2 the variable y^* from Step 1. This ensures that all clauses that were derived from clauses $y^* \vee c$ with $c \in C$ in Step 2 are satisfied. All remaining clauses of the form (2) (with $z \neq y^*$) can be easily satisfied. If z_1 is universally quantified (so its truth value is already fixed) then all $z_2, \ldots, z_l$ are existentially quantified and we assign to these variables the truth value of z_1. Otherwise $z_1, \ldots, z_l$ are all existentially quantified and we can assign the truth value 1 to all of them (the truth value 0 would also work). At this point, only the single clause derived from $\neg y^*$ in Step 2 is not satisfied. Finally, note that each of the three steps preserves the truth value of the $\forall\exists$-formula.

This concludes the preprocessing of the $\forall\exists$-formula Ψ. To simplify notation, we denote the resulting formula again with

$$\Psi = \forall x_1 \cdots \forall x_n \exists y_1 \cdots \exists y_m F(x_1, \ldots, x_n, y_1, \ldots, y_m). \tag{3}$$

Let $X = \{x_1, \ldots, x_n\}$ and $Y = \{y_1, \ldots, y_m\}$. For a variable $z \in X \cup Y$ we denote with $\tilde{z}$ one of the literals z or $\neg z$. Moreover we denote by C the set of clauses of F. A clause is viewed as a set of literals. For a literal $\tilde{z}$ let $C(\tilde{z})$ be the set of all clauses containing $\tilde{z}$. Note that every set $C(\tilde{z})$ has size at most 4. Let

$$V = X \cup Y \cup C$$

(we assume that X, Y, C are pairwise disjoint). We will work in the group $\mathbb{Z}_2^V$ introduced in Section 2.2 and use the notation introduced there.

The logspace reduction ϕ from $\forall\exists$SAT to UNARY DIAMETER is defined by $\phi(\Psi) = (A, k)$ with $k = n + m$ and

$$A = \bigcup_{x \in X} A_x \cup \bigcup_{y \in Y} A_y,$$

where for all universally quantified variables $x \in X$,

$$A_x = \{[\{x\} \cup U] \mid U \subseteq C(x)\} \cup \{[U] \mid U \subseteq C(\neg x), U \neq \emptyset\}$$

and for all existentially quantified variables $y \in Y$,

$$A_y = \{[U] \mid U \subseteq \{y\} \cup C(y), U \neq \emptyset\} \cup \{[U] \mid U \subseteq \{y\} \cup C(\neg y), U \neq \emptyset\}.$$

Since every set $C(\tilde{z})$ has size at most 4, we can construct the instance (A, k) in logspace.

▷ Claim 3.2. $\langle A \rangle = \mathbb{Z}_2^V$.

Proof of Claim 3.2. It suffices to show that every $[\{v\}]$ for $v \in V$ belongs to $\langle A \rangle$. From the definition of A we immediately get $[\{x\}] \in A_x$ for all $x \in X$ and $[\{y\}] \in A_y$ for all $y \in Y$. Consider now a clause $c \in C$ and fix a literal $\tilde{z} \in c$. We have $c \in C(\tilde{z})$. If $z \in Y$ then $[\{c\}] \in A_z$. If $z \in X$ and $\tilde{z} = \neg z$, then again $[\{c\}] \in A_z$. Finally, if $z \in X$ and $\tilde{z} = z$ then $[\{z\}], [\{z, c\}] \in A_z$. Hence, $[\{c\}] = [\{z\}] + [\{z, c\}] \in \langle A \rangle$. ◁

▷ Claim 3.3. Let $f_X : X \to \{0, 1\}$ and $f : V \to \{0, 1\}$ be elements of $\mathbb{Z}_2^V$ with

$$f(x) = f_X(x)$$

for all $x \in X$ and

$$f(v) = 1$$

for all $v \in Y \cup C$. If $f \in A^{\leq n+m}$, then there is a function $f_Y : Y \to \{0, 1\}$ such that $f_X + f_Y$ is a satisfying truth assignment for F.

Proof of Claim 3.3. Suppose that $f \in A^{\leq n+m}$ and hence

$$f = f_1 + \cdots + f_s \tag{4}$$

for an $s \leq n + m$ with $f_i \in A$. Then the right-hand side of (4) must contain for every $x \in X$ a generator from A_x since $f(c_x) = 1$ (recall that we added the clause $c_x = \{x, \neg x\}$ since x is universally quantified) and only generators from A_x set the c_x-value to 1. Moreover, the right-hand side of (4) must contain for every $y \in Y$ a generator from A_y since $f(y) = 1$. Thus, the right-hand side of (4) must contain at least $|X| + |Y| = n + m$ generators. We get $s = n + m$ and obtain

$$f = \sum_{x \in X} g_x + \sum_{y \in Y} g_y \tag{5}$$

with $g_x \in A_x$ and $g_y \in A_y$. For $z \in X \cup Y$ let $C_z = \mathrm{supp}(g_z) \cap C$ be the set of clauses that appear in g_z in the sum (5). For all $y \in Y$ we must have $g_y = [\{y\} \cup C_y]$ since $f(y) = 1$.

We define the function $f_Y : Y \to \{0, 1\}$ by

$$f_Y(y) = \begin{cases} 1 & \text{if } C_y \subseteq C(y), \\ 0 & \text{otherwise.} \end{cases}$$

Note that if $f_Y(y) = 0$ then we must have $C_y \subseteq C(\neg y)$.

We claim that $f_X + f_Y$ satisfies F. Consider a clause $c \in C$. Since $f(c) = 1$ there must exist $z \in X \cup Y$ such that $c \in C_z$. If $z = y \in Y$, then one of the following two cases holds:

- $f_Y(y) = 1$, $g_y = [\{y\} \cup C_y]$, and $c \in C_y \subseteq C(y)$, i.e., $y \in c$,
- $f_Y(y) = 0$, $g_y = [\{y\} \cup C_y]$, and $c \in C_y \subseteq C(\neg y)$, i.e., $\neg y \in c$.

In both cases f_Y set a literal from c (either y or $\neg y$) to 1. Now, assume that $z = x \in X$. Then one of the following two cases holds:

- $f(x) = f_X(x) = 1$, $g_x = [\{x\} \cup C_x]$ and $c \in C_x \subseteq C(x)$, i.e., $x \in c$,
- $f(x) = f_X(x) = 0$, $g_x = [C_x]$ and $c \in C_x \subseteq C(\neg x)$, i.e., $\neg x \in c$.

Again, in both cases f_X sets a literal from c (either x or $\neg x$) to 1. ◁

Our proof of Claim 3.3 also shows that $d(A) \leq k$ implies $d(A) = k$: if $d(A) \leq k$ then for any of the functions f from Claim 3.3 we have $|f|_A = k$.

From Claims 3.2 and 3.3 it follows that if $\langle A \rangle = A^{\leq n+m}$ then for every $f_X : X \to \{0,1\}$ there must exist $f_Y : Y \to \{0,1\}$ such that $f_X + f_Y$ satisfies F. Hence, the formula Ψ from (3) holds.

Now suppose that Ψ holds. Let $f \in \mathbb{Z}_2^V$. We want to show $f \in A^{\leq n+m}$. First observe that there are unique functions $f_X : X \to \{0,1\}$ and $g : Y \cup C \to \{0,1\}$ such that $f = f_X + g$. Since Ψ holds, there is a partial truth assignment $f_Y : Y \to \{0,1\}$ such that $f_X + f_Y$ satisfies F. We define for every variable $z \in X \cup Y$ the set $U(z) \subseteq V$ as follows:

- if $z = x \in X$ and $f_X(x) = 1$ then $U(x) = \{x\} \cup C(x)$,
- if $z = x \in X$ and $f_X(x) = 0$ then $U(x) = C(\neg x)$,
- if $z = y \in Y$ and $f_Y(y) = 1$ then $U(y) = \{y\} \cup C(y)$,
- if $z = y \in Y$ and $f_Y(y) = 0$ then $U(y) = \{y\} \cup C(\neg y)$.

Note that $[U(z)] \in A_z$ for every variable $z \in X \cup Y$, except for the case that $z = x \in X$, $f_X(x) = 0$ and $C(\neg x) = \emptyset$ (then, $U(z) = \emptyset$). Define

$$U = \bigcup_{z \in X \cup Y} U(z).$$

Since all clauses evaluate to 1 under $f_X + f_Y$, we have $C \cup Y \subseteq U$. Moreover, $x \in U$ if and only if $x \in \mathrm{supp}(f)$ for all $x \in X$. We therefore have

$$\mathrm{supp}(f) \subseteq U.$$

We can choose pairwise disjoint (possibly empty) subsets $U'(z) \subseteq U(z)$ such that

$$U = \bigcup_{z \in X \cup Y} U'(z)$$

is a partition of U. It follows that

$$\mathrm{supp}(f) = \bigcup_{z \in X \cup Y} (U'(z) \cap \mathrm{supp}(f))$$

is a partition of $\mathrm{supp}(f)$. Let $Z \subseteq X \cup Y$ be the set of all $z \in X \cup Y$ such that $U'(z) \cap \mathrm{supp}(f) \neq \emptyset$. Then we have

$$f = \sum_{z \in Z} [U'(z) \cap \mathrm{supp}(f)]$$

and $|Z| \leq n + m$. It remains to show that $[U'(z) \cap \mathrm{supp}(f)]$ is a generator from A_z. This is clear if $z = y \in Y$ or ($z = x \in X$ and $U(x) = C(\neg x)$). In those case, for every non-empty subset $U' \subseteq U(z)$, $[U']$ belongs to A_z. Finally, if $z = x \in X$ and $U(x) = \{x\} \cup C(x)$ then also $x \in U'(x)$ must hold because $x \in U(x) \subseteq U = \bigcup_{z \in X \cup Y} U'(z)$ and $x \notin U'(z)$ for $z \neq x$. Moreover, $U(x) = \{x\} \cup C(x)$ implies $f(x) = f_X(x) = 1$, i.e., $x \in \mathrm{supp}(f)$. Therefore, $[U'(x) \cap \mathrm{supp}(f)]$ is of the form $[\{x\} \cup C']$ for some $C' \subseteq C(x)$, which belongs to A_x. We obtain $f \in A^{\leq n+m}$, which shows that ϕ is indeed a logspace reduction from $\forall\exists$SAT to UNARY DIAMETER.

▷ Claim 3.4. $d(A) \leq k+1$.

Proof of Claim 3.4. Our preprocessing ensured that every partial truth assignment of the universally quantified variables can be extended by a truth assignment for the existentially quantified variables such that exactly one clause $c \in C$ is unsatisfied. Let $f \in \mathbb{Z}_2^Y$. Then there are functions $f_X : X \to \{0,1\}$ and $g : Y \cup C \to \{0,1\}$ such that $f = f_X + g$. Moreover, there is a partial truth assignment $f_Y : Y \to \{0,1\}$ such that $f_X + f_Y$ satisfies all clauses from $C \setminus \{c\}$. As above we define for every variable $z \in X \cup Y$ the set $U(z) \subseteq V$ as follows:

- if $z = x \in X$ and $f_X(x) = 1$ then $U(x) = \{x\} \cup C(x)$,
- if $z = x \in X$ and $f_X(x) = 0$ then $U(x) = C(\neg x)$,
- if $z = y \in Y$ and $f_Y(y) = 1$ then $U(y) = \{y\} \cup C(y)$,
- if $z = y \in Y$ and $f_Y(y) = 0$ then $U(y) = \{y\} \cup C(\neg y)$.

Note that $c = \{\neg y\}$ for an existentially quantified variable $y \in Y$ (see Step 1 in our preprocessing). Hence, we have $c \in C(\neg y)$ and $[\{c\}] \in A_y$ is a generator. We define $U(c) = \{c\}$ and

$$U = \bigcup_{z \in X \cup Y \cup \{c\}} U(z).$$

The rest of the argument is the same as above: Since all clauses except for c evaluate to 1 under $f = f_X + f_Y$, we have $C \cup Y \subseteq U$. Moreover, $x \in U$ if and only if $x \in \mathrm{supp}(f)$ for all $x \in X$. We therefore have

$$\mathrm{supp}(f) \subseteq U.$$

Then there are pairwise disjoint subsets $U'(z) \subseteq U(z)$ such that

$$U = \bigcup_{z \in X \cup Y \cup \{c\}} U'(z) \quad \text{and} \quad \mathrm{supp}(f) = \bigcup_{z \in X \cup Y \cup \{c\}} (U'(z) \cap \mathrm{supp}(f))$$

are partitions of U and $\mathrm{supp}(f)$, respectively. Let $Z \subseteq X \cup Y \cup \{c\}$ be the set of all $z \in X \cup Y \cup \{c\}$ such that $U'(z) \cap \mathrm{supp}(f) \neq \emptyset$. Then we have

$$f = \sum_{z \in Z} [U'(z) \cap \mathrm{supp}(f)]$$

and $|Z| \leq n + m + 1$. As above it can easily be shown that $[U'(z) \cap \mathrm{supp}(f)]$ is a generator. Hence $f \in A^{\leq n+m+1}$. ◁

It now follows that $d(A)$ is either k or $k+1$: if $d(A) \leq k$ then $d(A) = k$ (see the remark after the proof of Claim 3.3), and if $d(A) > k$ then $d(A) = k+1$ by Claim 3.4. ◀

▶ **Corollary 3.5.** *The following problems are all Π_2^{P}-complete:*

(i) *UNARY DIAMETER (without a restriction on the permutation group $\langle A \rangle$),*

(ii) *UNARY DIAMETER restricted to abelian permutation groups $\langle A \rangle$ of exponent two,*

(iii) *BINARY DIAMETER restricted to abelian permutation groups $\langle A \rangle$.*

Proof. In all cases the lower bound follows from Theorem 3.1. It remains to show the upper bound in cases (i) and (iii). For (i), this is straightforward: Let $G = \langle A \rangle$ where $A \subseteq S_n$ is a set of permutations and take a unary encoded $k > 0$. First of all we universally guess an element $\pi \in G$. More precisely, we guess an arbitrary permutation $\pi \in S_n$ and then check in polynomial time (using [12]) whether $\pi \in \langle A \rangle$. If this does not hold, we immediately accept, otherwise we proceed with existentially guessing a sequence $a_1 a_2 \cdots a_l$ with $a_i \in A$ and $l \leq k$. We accept if and only if $a_1 a_2 \cdots a_l = \pi$.

The upper bound in case (iii) can be shown in a similar way. We follow the procedure for UNARY DIAMETER up to the point where we guess a sequence $a_1 a_2 \cdots a_l$ with $a_i \in A$ and $l \leq k$. Since k is given in binary encoding this is not feasible. Instead, we guess for each $a \in A$ a binary encoded number $k_a \geq 0$ whose bit length is bounded by the bit length of k. We accept if and only if the following two conditions hold:

- $\sum_{a \in A} k_a \leq k$,
- $\prod_{a \in A} a^{k_a} = \pi$.

Both conditions can be checked in polynomial time. For the second point note that a^{k_a} can be computed in time $\mathcal{O}(n \log k_a)$ by iterated squaring. ◀

▶ **Theorem 3.6.** *UNARY EXACT DIAMETER is DP_2-complete for general permutation groups as well as abelian permutation groups of exponent two.*

Proof. Let $A \subseteq S_n$ be a set of permutations and let k be a unary encoded number. Then we have $d(A) = k$ if and only if $d(A) \leq k$ and $d(A) > k - 1$. This is the intersection of a Π_2^{P}-property and a Σ_2^{P}-property. Hence, UNARY EXACT DIAMETER belongs to DP_2.

Now let $L = L_1 \cap L_2$ be a language from DP_2 with $L_1 \in \Sigma_2^{\mathsf{P}}$ and $L_2 \in \Pi_2^{\mathsf{P}}$. By Theorem 3.1 we can compute from x two pairs (A_1, k_1) and (A_2, k_2) (with $A_i \subseteq S_{n_i}$ and k_i a unary encoded natural number) such that

- $x \in L_1$ if and only if $d(A_1) = k_1 + 1$ if and only if $d(A_1) \neq k_1$, and
- $x \in L_2$ if and only if $d(A_2) = k_2$ if and only if $d(A_2) \neq k_2 + 1$.

Hence, $x \in L$ if and only if $d(A_1) = k_1 + 1$ and $d(A_2) = k_2$.

Consider the subgroup of $S_{n_2} \times S_{n_2} \leq S_{2n_2}$ generated by

$$B := (A_2 \times \{1\}) \cup (\{1\} \times A_2).$$

Here, 1 denotes the identity permutation. Since we have either $d(A_2) = k_2$ or $d(A_2) = k_2 + 1$ we obtain either $d(B) = 2k_2$ or $d(B) = 2k_2 + 2$.

Finally, consider the subgroup of $S_{n_1} \times S_{n_2} \times S_{n_2} \leq S_{n_1 + 2n_2}$ generated by

$$A := (A_1 \times \{(1,1)\}) \cup (\{1\} \times B).$$

There are four cases for the diameter of the group generated by A:

$$d(A) = \begin{cases} k_1 + 2k_2 & \text{if } d(A_1) = k_1 \text{ and } d(A_2) = k_2 \\ k_1 + 2k_2 + 1 & \text{if } d(A_1) = k_1 + 1 \text{ and } d(A_2) = k_2 \\ k_1 + 2k_2 + 2 & \text{if } d(A_1) = k_1 \text{ and } d(A_2) = k_2 + 1 \\ k_1 + 2k_2 + 3 & \text{if } d(A_1) = k_1 + 1 \text{ and } d(A_2) = k_2 + 1. \end{cases}$$

Thus, we have $x \in L$ if and only if $d(A) = k_1 + 2k_2 + 1$, which shows the DP_2-hardness of UNARY EXACT DIAMETER. ◀

4 Complexity of computing the length in permutation groups

Recall that Even and Goldreich [11] proved that UNARY LENGTH is NP-complete. We present below an alternative proof for the NP-hardness, where the reduction has additional properties (similar to Theorem 3.1) that will be needed in order to settle the complexity of UNARY EXACT LENGTH. Our techniques are similar to those from Section 3.

▶ **Theorem 4.1.** *There is a logspace reduction ϕ from SAT to UNARY LENGTH such that for every CNF formula F with $\phi(\Psi) = (A, \pi, k)$ we have: $A \subseteq \mathbb{Z}_2^n$ for some n, $\pi \in \langle A \rangle = \mathbb{Z}_2^n$ and $|\pi|_A \in \{k, k+1\}$.*

Proof. Let $F = \bigwedge_{c \in C} c$ be a conjunction of clauses $c \in C$ with boolean variables from the set X. We preprocess F as in the proof of Theorem 3.1. First, we replace F by $F' = \neg y^* \wedge \bigwedge_{c \in C}(y^* \vee c)$, where $y^* \notin X$ is a new variable ensuring that there is a truth assignment such that exactly one clause in F' is unsatisfied. Moreover, F is satisfiable if and only if F' is satisfiable.

Then we apply the construction of [25] that we also used in the proof of Theorem 3.1 in order to ensure that every variable occurs in at most three clauses. We replace the occurrences of every variable $z \in X \cup \{y^*\}$ that occurs in $l \geq 4$ clauses (negated or unnegated) by new variables $z_1, \ldots, z_l$ and add the clauses $z_l \vee \neg z_1$ and $z_i \vee \neg z_{i+1}$ for $i \in [1, l-1]$. Let F'' be the resulting CNF formula. It still has the property that there is a truth assignment such that exactly one clause in F'' is unsatisfied. One can take the truth assignment that sets all variables of F'' to 1. Moreover, F is satisfiable if and only if F'' is satisfiable.

From this consideration, it follows that we can assume that our input CNF formula F has the following two properties:

- Every variable occurs in at most three clauses.
- There is a truth assignment for F such that exactly one clause of F is not satisfied.

Let X be the variables that occur in F and let C be the set of clauses in F. Moreover, let $V = X \cup C$. With $L = X \cup \{\neg x \mid x \in X\}$ we denote the set of all literals.

We reuse several notations that we have introduced in the proof of Theorem 3.1. For a literal $\tilde{x} \in L$ we denote with $C(\tilde{x}) \subseteq C$ the set of all clauses containing $\tilde{x}$. Note that we have $|C(x)| + |C(\neg x)| \leq 3$. For the reduction we work with the group $\mathbb{Z}_2^V$ and use the notations from Section 2.2. Now we define the set A of generators by

$$A = \bigcup_{c \in C} A_c \cup \bigcup_{\tilde{x} \in L} A_{\tilde{x}},$$

where for $x \in X$ and $c \in C$ we take

$$\begin{aligned} A_x &= \{[\{x\} \cup U] \mid U \subseteq C(x)\}, \\ A_{\neg x} &= \{[\{x\} \cup U] \mid U \subseteq C(\neg x)\}, \\ A_c &= \{[\{c\}]\}. \end{aligned}$$

Note that $\langle A \rangle = \mathbb{Z}_2^V$.

We define $\pi = [V]$ and $k = |X|$. This defines our logspace reduction $\phi : F \mapsto (A, \pi, k)$. To compute ϕ in logspace, it is important that all sets $C(\tilde{x})$ have constant size.

Now we show that $|\pi|_A \leq k$ if and only if F is satisfiable. Suppose $|\pi|_A \leq k$. Since $X \subseteq \mathrm{supp}(\pi)$, we need a generator from every $A_x \cup A_{\neg x}$ ($x \in X$) to produce π. This implies $|\pi|_A = k$ and we can write

$$\pi = \sum_{x \in X} \pi_x$$

with $\pi_x \in A_x \cup A_{\neg x}$. Let $\pi_x = [\{x\} \cup U_x]$ with $U_x \subseteq C$. We define a truth assignment by

$$\sigma(x) = \begin{cases} 1 & \text{if } \pi_x \in A_x, \\ 0 & \text{if } \pi_x \in A_{\neg x} \setminus A_x. \end{cases}$$

for all $x \in X$. From $C \subseteq \mathrm{supp}(\pi)$ it follows that for every clause $c \in C$ there must exist a variable $x \in X$ such that $c \in U_x$. If $\pi_x \in A_x$ (i.e., $\sigma(x) = 1$) then $c \in U_x \subseteq C(x)$, i.e., x appears in the clause c. Hence, π satisfies c. Similarly, if $\pi_x \in A_{\neg x}$ (i.e., $\sigma(x) = 0$) then $\neg x$ appears in the clause c. Therefore, σ satisfies F.

Now suppose that F is satisfiable and let σ be a satisfying truth assignment. Hence, every clause is satisfied. Let $X_0 = \{x \in X \mid \sigma(x) = 0\}$ and $X_1 = \{x \in X \mid \sigma(x) = 1\}$. Then we have

$$\operatorname{supp}(\pi) = V = X \cup C = \bigcup_{x \in X_0} \{x\} \cup C(\neg x) \cup \bigcup_{x \in X_1} \{x\} \cup C(x).$$

Then we can choose for every $x \in X_0$ a subset $U_x \subseteq C(\neg x)$ and for every $x \in X_1$ a subset $U_x \subseteq C(x)$ such that

$$\operatorname{supp}(\pi) = \bigcup_{x \in X} \{x\} \cup U_x$$

is a partition of $\operatorname{supp}(\pi)$. Hence, we have

$$\pi = \sum_{x \in X} [\{x\} \cup U_x].$$

Since $[\{x\} \cup U_x] \in A_x \cup A_{\neg x}$, we finally obtain $|\pi|_A = k$. This show that ϕ is indeed a logspace reduction from SAT to UNARY LENGTH.

We have already noted that $|\pi|_A \leq k$ implies $|\pi|_A = k$. The converse implication is trivially true. Therefore, we have $|\pi|_A \leq k$ if and only if $|\pi|_A = k$. It remains to show that $|\pi|_A \in \{k, k+1\}$. For this it suffices to show $|\pi|_A \leq k+1$.

We know that there is a truth assignment σ such that exactly one clause $c \in C$ is unsatisfied. As above we can choose generators $\pi_x \in A_x \cup A_{\neg x}$ for all $x \in X$ such that

$$\operatorname{supp}(\pi) \setminus \{c\} = \bigcup_{x \in X} \operatorname{supp}(\pi_x)$$

is a partition of $\operatorname{supp}(\pi) \setminus \{x\}$. From this we obtain

$$\pi = [\{c\}] + \sum_{x \in X} \pi_x$$

and hence $|\pi|_A \leq k+1$, which concludes the proof. ◀

▶ **Theorem 4.2.** *UNARY EXACT LENGTH is* DP*-complete for general permutation groups as well as abelian permutation groups of exponent two.*

Proof. Let A be a set of generators of a permutation group, k a unary encoded integer, and $\pi \in \langle A \rangle$ a permutation. Then we have $|\pi|_A = k$ if and only if $|\pi|_A \leq k$ and $|\pi|_A > k-1$. This is the conjunction of an NP-property and a coNP-property. Thus UNARY EXACT LENGTH is the intersection of a language in NP with a language in coNP and therefore belongs to DP.

We show DP-hardness of UNARY EXACT LENGTH by a reduction from SAT-UNSAT. The input for the latter problem is a pair (F, G) of two CNF formulas and the question is whether F is satisfiable and G is unsatisfiable. This problem is known to DP-complete, see [21].

Let (F, G) be an input for SAT-UNSAT. By Theorem 4.1 we can compute from (F, G) in logspace two triples (A_1, π_1, k_1) and (A_2, π_2, k_2) (with $A_i \subseteq S_{n_i}$, $\pi_i \in \langle A_i \rangle$ and k_i a unary encoded natural number) such that

- F is satisfiable if and only if $|\pi_1|_{A_1} = k_1$ if and only if $|\pi_1|_{A_1} \neq k_1 + 1$ and
- G is unsatisfiable if and only if $|\pi_2|_{A_2} \neq k_2$ if and only if $|\pi_2|_{A_2} = k_2 + 1$.

Hence, (F, G) is a positive instance of SAT-UNSAT if and only if $|\pi_1|_{A_1} = k_1$ and $|\pi_2|_{A_2} = k_2 + 1$.

Consider the subgroup of $S_{n_2} \times S_{n_2} \leq S_{2n_2}$ with the generating set

$$B := (A_2 \times \{1\}) \cup (\{1\} \times A_2).$$

Since we have $|\pi_2|_{A_2} \in \{k_2, k_2+1\}$ we obtain $|(\pi_2, \pi_2)|_B \in \{2k_2, 2k_2+2\}$.

Finally, consider the group $\langle A_1 \rangle \times \langle A_2 \rangle \times \langle A_2 \rangle \leq S_{n_1+2n_2}$ with the generating set

$$A := (A_1 \times \{(1,1)\}) \cup (\{1\} \times B).$$

For the length $|(\pi_1, \pi_2, \pi_2)|_A$ we obtain

$$|(\pi_1, \pi_2, \pi_2)|_A = \begin{cases} k_1 + 2k_2 & \text{if } |\pi_1|_{A_1} = k_1 \text{ and } |\pi_2|_{A_2} = k_2 \\ k_1 + 2k_2 + 1 & \text{if } |\pi_1|_{A_1} = k_1 + 1 \text{ and } |\pi_2|_{A_2} = k_2 \\ k_1 + 2k_2 + 2 & \text{if } |\pi_1|_{A_1} = k_1 \text{ and } |\pi_2|_{A_2} = k_2 + 1 \\ k_1 + 2k_2 + 3 & \text{if } |\pi_1|_{A_1} = k_1 + 1 \text{ and } |\pi_2|_{A_2} = k_2 + 1. \end{cases}$$

Hence, (F, G) is a positive instance of SAT-UNSAT if and only if $|(\pi_1, \pi_2, \pi_2)|_A = k_1 + 2k_2 + 2$, which concludes the proof. ◀

Since BINARY LENGTH is PSPACE-complete [15], one might expect that also BINARY EXACT LENGTH is PSPACE-complete. The following result confirms this.

▶ **Theorem 4.3.** *BINARY EXACT LENGTH is* PSPACE*-complete.*

Proof of Theorem 4.3. Since PSPACE is closed under complement, and $|\pi|_A = k$ if and only if $\pi \in A^{\leq k}$ and $\pi \notin A^{\leq k-1}$, it follows that also BINARY EXACT LENGTH belongs to PSPACE.

For the lower bound let $A \subseteq S_n$ be a set of permutations on $[1, n]$, $\pi \in \langle A \rangle$ and k be a binary encoded number. We construct from A, π, k in logspace a new instance B, τ, k such that $\pi \in A^{\leq k}$ if and only if $|\tau|_B = k$ holds. This proves that BINARY EXACT LENGTH is PSPACE-complete.

Clearly, $S_n \leq S_m$ for $n \leq m$. In the following, we will identify a permutation $\pi \in S_n$ with a permutation from S_m by defining $a^\pi = a$ for $a \in [n+1, m]$.

Let d be the number of bits of k. Then $\log_2(k) < d \leq \log_2(k)+1$. Let $p_1 = 2, p_2 = 3, \ldots, p_d$ be the first d primes. Note that since d is polynomially bounded in the input length, the primes p_i are so too and therefore can be stored in logarithmic space. Let $m = \sum_{i=1}^{d} p_i$ and let $\alpha_1, \ldots, \alpha_d$ be permutations with pairwise disjoint support on $[n+1, n+m]$ such that α_i is a cycle of length p_i. Moreover let $r_1, \ldots, r_d \in [0, p_i - 1]$ such that

$$k \equiv r_i \bmod p_i.$$

These numbers can be computed in logspace; see e.g. [14]. Moreover let $\alpha = \alpha_1 \cdots \alpha_d$, $\beta = \alpha_1^{r_1} \cdots \alpha_d^{r_d}$ and $\tau = \pi\beta$. We have

$$\mathrm{ord}(\alpha) = \prod_{i=1}^{d} p_i \geq 2^d > 2^{\log_2(k)} = k.$$

Finally, we define the set of permutations

$$B = \{\gamma\alpha \mid \gamma \in A\} \cup \{\alpha\} \subseteq S_{n+m}.$$

Since $\beta = \alpha^k$, i.e., $\tau = \pi\alpha^k$ and $\mathrm{ord}(\alpha) > k$, we obtain $\pi \in A^{\leq k}$ if and only if $|\tau|_B = k$, which concludes the reduction. ◀

5 Complexity of equality and universality for NFAs over permutation groups

In this section we determine the complexity of RATIONAL EQUALITY and RATIONAL UNIVERSALITY (defined in Section 1.2).

▶ **Theorem 5.1.** *The following problems are Π_2^{P}-complete for permutation groups:*

(i) *RATIONAL EQUALITY*

(ii) *RATIONAL EQUALITY restricted to the case where all permutations in the two input NFAs $\mathcal{A}$ and $\mathcal{B}$ pairwise commute and have order two.*

(iii) *RATIONAL UNIVERSALITY*

Proof. For the upper bounds, we only have to consider RATIONAL EQUALITY. Membership of RATIONAL EQUALITY in Π_2^{P} follows from the fact that the rational subset membership problem for permutation groups (see Section 1.2) is in NP. More precisely, the following formula expresses the equality $L(\mathcal{A}_0) = L(\mathcal{A}_1)$ for two NFAs $\mathcal{A}_0$ and $\mathcal{A}_1$ over S_n:

$$\forall i \in \{0,1\} \forall \pi \in S_n : \pi \notin L(\mathcal{A}_i) \vee \pi \in L(\mathcal{A}_{1-i}).$$

Since the rational subset membership problem for permutation groups is in NP, the above formula is equivalent to a statement of the form

$$\forall i \in \{0,1\} \forall \pi \in S_n \forall u \exists v : u \text{ is not a witness for } \pi \in L(\mathcal{A}_i) \vee v \text{ is a witness for } \pi \in L(\mathcal{A}_{1-i}).$$

Here u and v are bit strings of size polynomial in the input length.

The lower bound in (ii) is a direct consequence of Corollary 3.5, since for a finite set $A \subseteq S_n$ and a unary encoded number k both $\langle A \rangle$ and $A^{\leq k}$ can be defined by logspace computable NFAs.

It remains to show Π_2^{P}-hardness of RATIONAL UNIVERSALITY. For this we give a reduction from UNARY DIAMETER to RATIONAL UNIVERSALITY. Before we come to the actual reduction, let us explain an auxiliary construction. Fix an $n \geq 1$ and consider the symmetric group S_{2n} on the domain $\Omega = [1, 2n]$. We define the following sets of transpositions:

$$T_i = \{(a,b) \mid a,b \in \Omega \setminus \{i\}, a \neq b\} \subseteq S_{2n} \text{ for all } i \in \Omega, \tag{6}$$

$$Z = \{(2i-1, 2i) \mid 1 \leq i \leq n\} \subseteq S_{2n}. \tag{7}$$

Note that $\langle Z \rangle \cong \mathbb{Z}_2^n$ and $\langle T_i \rangle$ is the set of permutations that fix i.

For every $1 \leq i < j \leq 2n$ with $(i,j) \notin Z$ we can construct in space $\mathcal{O}(\log n)$ three automata $\mathcal{A}_{i,j}, \mathcal{B}_{i,j}, \mathcal{C}_{i,j}$ over S_{2n} such that the following hold:

$$L(\mathcal{A}_{i,j}) = \bigcup_{\ell \in \Omega \setminus \{i,j\}} (i,j)(j,\ell)\langle T_i \cap T_j \rangle \tag{8}$$

$$L(\mathcal{B}_{i,j}) = \bigcup_{\ell \in \Omega \setminus \{i,j\}} (j,i)(i,\ell)\langle T_i \cap T_j \rangle \tag{9}$$

$$L(\mathcal{C}_{i,j}) = (i,j)\langle T_i \cap T_j \rangle \tag{10}$$

▷ Claim 5.2. We have

$$\langle Z \rangle \cap \bigcup_{\substack{1 \leq i < j \leq 2n \\ (i,j) \notin Z}} (L(\mathcal{A}_{i,j}) \cup L(\mathcal{B}_{i,j}) \cup L(\mathcal{C}_{i,j})) = \emptyset.$$

Proof of Claim 5.2. Suppose there is a $\tau \in \langle Z \rangle$ such that $\tau \in L(\mathcal{A}_{i,j}) \cup L(\mathcal{B}_{i,j}) \cup L(\mathcal{C}_{i,j})$ for some $1 \leq i < j \leq 2n$ with $(i,j) \notin Z$. For every $a \in [1,n]$ we have either $(2a-1)^\tau = 2a-1$ and $(2a)^\tau = 2a$ or $(2a-1)^\tau = 2a$ and $(2a)^\tau = 2a-1$.

Case 1. $\tau \in L(\mathcal{A}_{i,j})$. Then we can write $\tau = (i,j)(j,\ell)\pi$ with $\ell \in \Omega \setminus \{i,j\}$ and $\pi \in \langle T_i \cap T_j \rangle$. Then we obtain

$$j^\tau = j^{(i,j)(j,\ell)\pi} = i^{(j,\ell)\pi} = i^\pi = i.$$

We can exclude the case $j = j^\tau = i$, since $i < j$. Hence, we have $j^\tau \in \{j+1, j-1\}$. If j is odd we obtain $j+1 = j^\tau = i$, which is a contradiction since $i < j$. If j is even we obtain $j-1 = j^\tau = i$, and hence $(i,j) \in Z$, which is also a contradiction.

Case 2. $\tau \in L(\mathcal{B}_{i,j})$. Then we can write $\tau = (j,i)(i,\ell)\pi$ with $\ell \in \Omega \setminus \{i,j\}$ and $\pi \in \langle T_i \cap T_j \rangle$. In this case we obtain

$$i^\tau = i^{(j,i)(i,\ell)\pi} = j^{(i,\ell)\pi} = j^\pi = j.$$

We can exclude the case $i = i^\tau = j$, since $i < j$. Hence, we have $i^\tau \in \{i+1, i-1\}$. If i is odd we obtain $i+1 = i^\tau = j$ and hence $(i,j) \in Z$, which is a contradiction. If i is even we obtain $i-1 = i^\tau = j$, which contradicts $i < j$.

Case 3. $\tau \in L(\mathcal{C}_{i,j})$. Then we can write $\tau = (i,j)\pi$ with $\pi \in \langle T_i \cap T_j \rangle$ and get

$$i^\tau = i^{(i,j)\pi} = j^\pi = j.$$

We obtain a contradiction in the same way as in Case 2. ◁

▷ Claim 5.3. We have

$$\bigcup_{\substack{1 \le i < j \le 2n \\ (i,j) \notin Z}} (L(\mathcal{A}_{i,j}) \cup L(\mathcal{B}_{i,j}) \cup L(\mathcal{C}_{i,j})) = S_{2n} \setminus \langle Z \rangle. \tag{11}$$

Proof of Claim 5.3. By Claim 5.2 it suffices to show

$$S_{2n} \setminus \langle Z \rangle \subseteq \bigcup_{\substack{1 \le i < j \le 2n \\ (i,j) \notin Z}} (L(\mathcal{A}_{i,j}) \cup L(\mathcal{B}_{i,j}) \cup L(\mathcal{C}_{i,j})). \tag{12}$$

Let $\tau \in S_{2n} \setminus \langle Z \rangle$. We have to show that τ belongs to the union on the right-hand side of (12). Let $\tau = \gamma_1 \cdots \gamma_m$ be the disjoint cycle decomposition of τ. Since $\tau \notin \langle Z \rangle$ we can assume that w.l.o.g. $\gamma_1 \notin \langle Z \rangle$. Let $\alpha = \gamma_1$ and let $\beta = \gamma_2 \cdots \gamma_m$. Then we can write $\tau = \alpha\beta = \beta\alpha$ in which $\alpha = (i_d, \ldots, i_2, i_1)$ is a cycle of length $d \ge 2$. Note that $i_q \ne i_p$ for all $q \ne p$.

Case 1. $d = 2$. W.l.o.g. we can assume $i_1 < i_2$. Then $(i_1, i_2) \notin Z$ and by this the NFA $\mathcal{C}_{i_1,i_2}$ is defined. We have $(i_1,i_2)\pi \in L(\mathcal{C}_{i_1,i_2})$ for all $\pi \in \langle T_{i_1} \cap T_{i_2} \rangle$. Since β fixes i_1 and i_2, we have $\beta \in \langle T_{i_1} \cap T_{i_2} \rangle$ and hence $\tau = (i_1,i_2)\beta \in L(\mathcal{C}_{i_1,i_2})$.

Case 2. $d \ge 3$ and $(i_1,i_2) \notin Z$. Then, $\mathcal{A}_{i_1,i_2}$ is defined if $i_1 < i_2$ and $\mathcal{B}_{i_2,i_1}$ is defined if $i_2 < i_1$. We have

$$\alpha = (i_d, \ldots, i_1) = (i_1,i_2)(i_2,i_3)(i_3,i_4)\cdots(i_{d-1},i_d).$$

Let $\gamma = (i_3,i_4)\cdots(i_{d-1},i_d)\beta$. We get $\tau = \alpha\beta = (i_1,i_2)(i_2,i_3)\gamma$. Moreover, $\gamma \in \langle T_{i_1} \cap T_{i_2} \rangle$, since β fixes i_1 and i_2 and $i_q \ne i_p$ for $q \ne p$. If $i_1 < i_2$ we have $(i_1,i_2)(i_2,\ell)\pi \in L(\mathcal{A}_{i_1,i_2})$ for all $\ell \in \Omega \setminus \{i_1,i_2\}$ and $\pi \in \langle T_{i_1} \cap T_{i_2} \rangle$. Hence we obtain $\tau = (i_1,i_2)(i_2,i_3)\gamma \in L(\mathcal{A}_{i_1,i_2})$. If $i_2 < i_1$ we have $(i_1,i_2)(i_2,\ell)\pi \in L(\mathcal{B}_{i_2,i_1})$ for all $\ell \in \Omega \setminus \{i_1,i_2\}$ and $\pi \in \langle T_{i_1} \cap T_{i_2} \rangle$. Thus we analogously obtain $\tau = (i_1,i_2)(i_2,i_3)\gamma \in L(\mathcal{B}_{i_2,i_1})$.

Case 3. $d \geq 3$ and $(i_1, i_2) \in Z$. We then have $(i_2, i_3) \notin Z$ (otherwise, we would get $i_3 = i_1$) and $\mathcal{A}_{i_2,i_3}$ is defined if $i_2 < i_3$ and $\mathcal{B}_{i_3,i_2}$ is defined if $i_3 < i_2$. We have

$$\alpha = (i_d, \ldots, i_1) = (i_1, i_d, i_{d-1} \ldots, i_2) = (i_2, i_3)(i_3, i_4)(i_4, i_5) \cdots (i_{d-1}, i_d)(i_d, i_1).$$

Let $\gamma = (i_4, i_5) \cdots (i_{d-1}, i_d)(i_d, i_1)\beta$. Then we obtain $\tau = \alpha\beta = (i_2, i_3)(i_3, i_4)\gamma$ (if $d = 3$ we have $\gamma = \beta$ and $i_4 = i_1$). Analogously to Case 2, we obtain $(i_2, i_3)(i_3, i_4)\gamma \in L(\mathcal{A}_{i_2,i_3})$ if $i_2 < i_3$ and $(i_2, i_3)(i_3, i_4)\gamma \in L(\mathcal{B}_{i_3,i_2})$ if $i_3 < i_2$. ◁

Now we come to the reduction from UNARY DIAMETER to RATIONAL UNIVERSALITY. The proof of Theorem 3.1 shows that we can start with an input instance (A, k) of UNARY DIAMETER, where $A \subseteq \mathbb{Z}_2^n$ for some $n \in \mathbb{N}$ and $k \in \mathbb{N}$ is given in unary encoding. We can therefore assume that $\langle A \rangle = \langle Z \rangle$ for the above Z from (7). From A and k we can easily construct in logspace an NFA $\mathcal{A}$ such that

$$L(\mathcal{A}) = A^{\leq k} \cup \bigcup_{\substack{1 \leq i < j \leq 2n \\ (i,j) \notin Z}} (L(\mathcal{A}_{i,j}) \cup L(\mathcal{B}_{i,j}) \cup L(\mathcal{C}_{i,j})) = A^{\leq k} \cup (S_{2n} \setminus \langle A \rangle),$$

where the second equality follows from Claim 5.3. It is also important that k is given in unary encoding, which allows to construct in logspace an NFA for $A^{\leq k}$. We have $L(\mathcal{A}) = S_{2n}$ if and only if $d(A) \leq k$ which concludes the reduction. ◀

Note that in the above proof we write the complement $S_{2n} \setminus \langle A \rangle = S_{2n} \setminus \langle Z \rangle$ as a union of a polynomial number of cosets (see (8)–(10) and (11)). One might ask why we do not write $S_{2n} \setminus \langle A \rangle$ simply as union of cosets of $\langle A \rangle$. The problem is that the latter would require $|S_{2n}|/|\langle A \rangle| = (2n!)/2^n - 1$ cosets, which is not polynomial in n.

6 Open problems

The main open problem that remains is the complexity of BINARY DIAMETER. We conjecture that this problem is PSPACE-complete. Recall that we proved BINARY DIAMETER to be Π_2^{P}-complete for abelian permutation groups. We conjecture that this result can be extended to nilpotent permutation groups (and maybe even solvable permutation groups).

We conjecture that UNARY DIAMETER is Π_2^{P}-complete for input instances (A, k), where A generates the full symmetric group S_n. The Π_2^{P}-completeness of RATIONAL UNIVERSALITY would directly follow from this. Moreover, we mentioned in the introduction the conjecture according to which the diameter of S_n (with respect to any generating set) is bounded by a polynomial in n. This conjecture would imply that BINARY DIAMETER belongs to Π_2^{P} for input instances (A, k), where A generates the full symmetric group S_n.

Abstract

We use model-theoretic tools originating from stability theory to derive a result we call the Finitary Substitute Lemma, which intuitively says the following. Suppose we work in a stable graph class $\mathscr{C}$, and using a first-order formula φ with parameters we are able to define, in every graph $G \in \mathscr{C}$, a relation R that satisfies some hereditary first-order assertion ψ. Then we are able to find a first-order formula φ' that has the same property, but additionally is *finitary*: there is finite bound $k \in \mathbb{N}$ such that in every graph $G \in \mathscr{C}$, different choices of parameters give only at most k different relations R that can be defined using φ'.

We use the Finitary Substitute Lemma to derive two corollaries about the existence of certain canonical decompositions in classes of well-structured graphs.

- We prove that in the Splitter game, which characterizes nowhere dense graph classes, and in the Flipper game, which characterizes monadically stable graph classes, there is a winning strategy for Splitter, respectively Flipper, that can be defined in first-order logic from the game history. Thus, the strategy is canonical.
- We show that for any fixed graph class $\mathscr{C}$ of bounded shrubdepth, there is an $\mathcal{O}(n^2)$-time algorithm that given an n-vertex graph $G \in \mathscr{C}$, computes in an isomorphism-invariant way a structure H of bounded treedepth in which G can be interpreted. A corollary of this result is an $\mathcal{O}(n^2)$-time isomorphism test and canonization algorithm for any fixed class of bounded shrubdepth.

Acknowledgements We are indebted to Pierre Simon for enlightening discussions about classic results in stability theory that greatly helped in deriving the results presented in this work. We also thank Jakub Gajarský, Rose McCarty, and Marek Sokołowski for their contribution in discussions around the topic of this work.

1 Introduction

Stability theory is a well-established branch of model theory devoted to the study of stable theories, or equivalently classes of structures that are models of such theories. Here, we say that a formula[1] $\varphi(\bar{x};\bar{y})$ is *stable* on a class of relational structures $\mathscr{C}$ if there is an integer $k \in \mathbb{N}$ such that for every $\mathbf{M} \in \mathscr{C}$, one cannot find tuples $\bar{u}_1, \ldots, \bar{u}_k \in \mathbf{M}^{\bar{x}}$ and $\bar{v}_1, \ldots, \bar{v}_k \in \mathbf{M}^{\bar{y}}$ such that for all $i, j \in \{1, \ldots, k\}$,

$$\mathbf{M} \models \varphi(\bar{u}_i, \bar{v}_j) \qquad \text{if and only if} \qquad i < j.$$

Then $\mathscr{C}$ is stable if every formula is stable on $\mathscr{C}$. Intuitively, this means that using a fixed formula, one cannot interpret arbitrarily long total orders in structures from $\mathscr{C}$. We refer to the textbooks of Pillay [24] or of Tent and Ziegler [27] for an introduction to stability.

The goal of this paper is to use certain classic results of stability theory, particularly the understanding of *forking* in stable theories, to derive statements about the existence of canonical decompositions in certain classes of well-structured graphs. Here, we model graphs as relational structures with one binary adjacency relation that is symmetric.

Finitary Substitute Lemma. Our main model-theoretic tool is the Finitary Substitute Lemma, which we state below in a simplified form; see Lemma 10 for a full statement.

To state the lemma, we need some definitions. A formula $\varphi(\bar{x};\bar{y})$ is *finitary* on a class of structures $\mathscr{C}$ if there exists $k \in \mathbb{N}$ such that for every $\mathbf{M} \in \mathscr{C}$, we have

$$\left|\left\{\varphi(\mathbf{M}^{\bar{x}}, \bar{v}) \colon \bar{v} \in \mathbf{M}^{\bar{y}}\right\}\right| \leqslant k,$$

where $\varphi(\mathbf{M}^{\bar{x}}, \bar{v}) = \{\bar{u} \in \mathbf{M}^{\bar{x}} \mid \mathbf{M} \models \varphi(\bar{u}, \bar{v})\}$. In other words, $\varphi(\bar{x};\bar{y})$ is finitary on $\mathscr{C}$ if by substituting different parameters for $\bar{y}$ in any model $\mathbf{M} \in \mathscr{C}$, one can define only at most k different relations on $\bar{x}$-tuples. Next, a sentence ψ is *hereditary* if for every model $\mathbf{M}$ and its induced substructure $\mathbf{M}'$, $\mathbf{M} \models \psi$ implies $\mathbf{M}' \models \psi$. Finally, for a relation $R(\bar{x})$ present in the signature, formula $\varphi(\bar{x})$ (possibly with parameters), and sentence ψ, by $\psi[R(\bar{x})/\varphi(\bar{x})]$ we mean the sentence derived from ψ by substituting every occurrence of R with formula φ.

▶ **Lemma 1** (Finitary Substitute Lemma, simplified version)**.** *Let $\mathscr{C}$ be a stable class of structures. Suppose $\varphi(\bar{x};\bar{y})$ is a formula and ψ a hereditary sentence such that for every $G \in \mathscr{C}$,*

$$\text{there exists } \bar{s} \in G^{\bar{y}} \text{ such that } G \models \psi[R(\bar{x})/\varphi(\bar{x};\bar{s})]. \tag{1}$$

Then there exists a formula $\varphi'(\bar{x},\bar{z})$ that also satisfies (1)*, but is additionally finitary on $\mathscr{C}$.*

Thus, intuitively, the Finitary Substitute Lemma says that in stable classes, every relation that is definable with parameters can be replaced by a finitary one, as long as we care that the relation satisfies some hereditary first-order assertion. The main observation of this paper is that this can be used in the context of various graph decompositions. Intuitively, if every step in decomposing the graph can be defined by a first-order formula with parameters, and the validity of the step can be verified using a hereditary first-order sentence, then we can use the Finitary Substitute Lemma to derive an equivalent definition of a step that is finitary. This yields only a bounded number of different steps that can be taken, making it possible to construct a decomposition that, in a certain sense, is canonical.

[1] All formulas considered in this paper are first-order, unless explicitly stated.

Classes of bounded shrubdepth. Our first application concerns classes of *bounded shrubdepth*. The concept of shrubdepth was introduced by Ganian et al. [17] to capture dense graphs that are well-structured in a shallow way. On one hand, classes of bounded shrubdepth are exactly those that can be interpreted, using first-order formulas with two free variables, in classes of forests of bounded depth. On the other hand, graphs from any fixed class of bounded shrubdepth admit certain decompositions, called *connection models*, which are essentially clique expressions of bounded depth. (See Section 5.1 for a definition of a connection model.) Thus, in particular every graph class of bounded shrubdepth has bounded cliquewidth, but classes of bounded shrubdepth are in addition stable [17].

Shrubdepth is a dense counterpart of *treedepth*, defined as follows: the treedepth of a graph G is the smallest integer d such that G is a subgraph of the ancestor/descendant closure of a rooted forest of depth at most d. In particular, every class of graphs of bounded treedepth has bounded shrubdepth; boundedness of treedepth and of shrubdepth is in fact equivalent assuming that the class excludes some biclique $K_{t,t}$ as a subgraph [17]. In essence, treedepth is a bounded-depth counterpart of treewidth in the same way as shrubdepth is a bounded-depth counterpart of cliquewidth.

In spite of the above, the combinatorial properties of shrubdepth are still much less understood than those of treedepth. For instance, a good understanding of subgraph obstacles allows one to construct suitable canonical decompositions for graphs of bounded treedepth. This allowed Bouland et al. [4] to design a graph isomorphism test that works in fixed-parameter time parameterized by the treedepth, or more precisely, in time $f(d) \cdot n^3 \log n$, where f is a computable function. While it is known that every class of bounded shrubdepth can be characterized by a finite number of forbidden induced subgraphs [17], it is unclear how to use just this result to design any kind of canonical decompositions for classes of bounded shrubdepth. Consequently, so far it was unknown whether the graph isomorphism problem can be solved in fixed-parameter time on classes of bounded shrubdepth[2]. The most efficient isomorphism test in this context is the one designed by Grohe and Schweitzer [20] for the cliquewidth parameterization: it works in XP time, that is, in time $n^{f(k)}$ where k is the cliquewidth and f is a computable function. See also the later work of Grohe and Neuen [19], which improves the XP running time and applies to the more general canonization problem.

We show that the Finitary Substitute Lemma can be used to bridge this gap by proving the following result.

▶ **Theorem 2.** *Let $\mathscr{C}$ be a class of graphs of bounded shrubdepth. Then there is a class $\mathscr{D}$ of binary structures of bounded treedepth and a mapping $\mathcal{A}\colon \mathscr{C} \to \mathscr{D}$ such that:*

- *For each $G \in \mathscr{C}$, the vertex set of G is contained in the domain of $\mathcal{A}(G)$ and the mapping $G \mapsto \mathcal{A}(G)$ is isomorphism-invariant.*
- *Given an n-vertex graph $G \in \mathscr{C}$, the structure $\mathcal{A}(G)$ has $\mathcal{O}(n)$ elements and can be computed in time $\mathcal{O}(n^2)$.*
- *There is a simple first-order interpretation I such that $G = \mathsf{I}(\mathcal{A}(G))$, for every $G \in \mathscr{C}$.*

Here, by isomorphism-invariance we mean that every isomorphism between $G, G' \in \mathscr{C}$ extends to an isomorphism between $\mathcal{A}(G)$ and $\mathcal{A}(G')$. Further, by a *simple* interpretation we mean a first-order interpretation that is 1-dimensional: vertices of G are interpreted in

[2] This statement is somewhat imprecise, as shrubdepth is defined as a parameter of a graph class, rather than of a single graph. By this we mean that there is a universal constant c such that for every graph class $\mathscr{C}$ of bounded shrubdepth, the isomorphism of graphs from $\mathscr{C}$ can be tested in $\mathcal{O}(n^c)$ time, with the constant hidden in the $\mathcal{O}(\cdot)$ notation possibly depending on $\mathscr{C}$.

single elements of $\mathcal{A}(G)$ (actually, every vertex is interpreted in itself). Thus, $\mathcal{A}(G)$ can be regarded as a canonical – obtained in an isomorphism-invariant way – sparse decomposition of G that encodes G faithfully and takes the form of a structure of bounded treedepth. We remark that certain logic-based sparsification procedures for classes of bounded shrubdepth were proposed in [8, 14], but these are insufficient for our applications, which we explain next.

The third point above together with the fact that $\mathcal{A}$ is isomorphism-invariant imply the following: for all $G, G' \in \mathscr{C}$, G and G' are isomorphic if and only if $\mathcal{A}(G)$ and $\mathcal{A}(G')$ are. We can now combine Theorem 2 with the approach of Bouland et al. [4] to give a fixed-parameter isomorphism test on classes of bounded shrubdepth.

▶ **Theorem 3.** *For every graph class $\mathscr{C}$ of bounded shrubdepth there is an $\mathcal{O}(n^2)$-time algorithm that given n-vertex graphs $G, G' \in \mathscr{C}$, decides whether G and G' are isomorphic.*

In fact, our algorithm solves also the general canonization problem, see Section 5.4.

We remark that the algorithm of Theorem 3 is non-uniform, in the sense that we obtain a different algorithm for every class $\mathscr{C}$. Despite the existence of parameters such as rankdepth [22] or SC-depth [17] that are suited for the treatment of single graphs and are equivalent in terms of boundedness on classes to shrubdepth, we do not know how to make our algorithm uniform even for the rankdepth or SC-depth parameterizations.

Finally, we believe that the construction behind our proof of Theorem 2 can be used to obtain an alternative proof of a result of Hliněný and Gajarský [13], later reproved by Chen and Flum [8]: the expressive power of first-order and monadic second-order logic coincide on classes of bounded shrubdepth. This direction will be explored in future research.

Nowhere dense and monadically stable classes. Second, we use the Finitary Substitute Lemma to provide canonical strategies in game characterizations of two important concepts in structural graph theory: nowhere dense classes and monadically stable classes. In both cases, a strategy in the game can be regarded as decompositions of the graph in question.

We start with some definitions. A *unary lift* of a class of graphs $\mathscr{C}$ is any class of structures $\mathscr{C}^+$ such that every member of $\mathscr{C}^+$ is obtained from a graph belonging to $\mathscr{C}$ by adding any number of unary predicates on vertices. A class of graphs $\mathscr{C}$ is *monadically stable* if every unary lift of $\mathscr{C}$ is stable. On the other hand, a class of graphs $\mathscr{C}$ is *nowhere dense* if for every $d \in \mathbb{N}$ there exists t such that no graph in $\mathscr{C}$ contains the d-subdivision of K_t as a subgraph.

Nowhere denseness is the most fundamental concept of uniform sparsity in graphs considered in the theory of Sparsity; see the monograph of Nešetřil and Ossona de Mendez [23] for an introduction to this area. A pinnacle result of this theory was derived by Grohe et al. [18]: the model-checking problem for first-order logic is fixed-parameter tractable on any nowhere dense graph class. As observed by Adler and Adler [2] using earlier results of Podewski and Ziegler [25], monadically stable classes are dense counterparts of nowhere dense classes in the following sense: every nowhere dense class is monadically stable, and nowhere denseness and monadic stability coincide when we assume the class to be sparse, for instance to exclude some biclique $K_{t,t}$ as a subgraph. This motivated the following conjecture [1], which is an object of intensive studies for the last few years: The model-checking problem for first-order logic is fixed-parameter tractable on every monadically stable class of graphs $\mathscr{C}$.

To approach this conjecture, it is imperative to obtain a better structural understanding of graphs from monadically stable classes. This is the topic of several very recent works [5, 6, 7, 11, 15]. In this work we are particularly interested in the results of Gajarský et al. [15], who characterized monadically stable classes of graphs through a game model called the *Flipper game*, which reflects the characterization of nowhere dense classes through the *Splitter game*, due to Grohe et al. [18].

The radius-r Splitter game is played on a graph G between two players: *Splitter* and *Connector*. In every round, Connector first chooses any vertex u and the current *arena* – graph on which the game is played – gets restricted to a ball of radius r around u. Then Splitter removes any vertex of the graph. The game finishes, with Splitter's win, when the arena becomes empty. Splitter's goal is to win the game as quickly as possible, while Connector's goal is to avoid losing for as long as possible. The *Flipper game* is defined similarly, except that the moves of *Flipper* – who replaces Splitter – are as follows. Instead of removing a vertex, Flipper selects any subset of vertices F and performs a *flip*: replaces all edges with both endpoints in F with non-edges, and vice versa. Also, the game finishes when the arena consists of one vertex.

Grohe et al. [18] proved that a class of graphs $\mathscr{C}$ is nowhere dense if and only if for every radius $r \in \mathbb{N}$ there exists $\ell \in \mathbb{N}$ such that on every graph from $\mathscr{C}$, Splitter can win the radius-r Splitter game within at most ℓ rounds. This characterization is the backbone of their model-checking result for nowhere dense classes, as a strategy in the Splitter game provides a shallow decomposition of the graph in question, useful for understanding its first-order properties. Very recently, Gajarský et al. [15] proved an analogous characterization of monadically stable classes in terms of the Flipper game, and subsequently Dreier et al. [10] used this characterization to prove fixed-parameter tractability of the model-checking first order logic on monadically stable classes of graphs which possess so-called sparse neighborhood covers. Given this state-of-the-art, it is clear that a better understanding of strategies for Splitter and Flipper in the respective games may lead to a deeper insight into decompositional properties of nowhere dense and monadically stable graph classes.

In the Splitter game, we prove using just basic compactness, that in any arena there is only a bounded number of possible Splitter's moves that are *progressing*: lead to an arena where the Splitter can win in one less round. (See Theorem 6 for a formal statement.) So this gives a transparent canonical strategy for Splitter: just play all progressive moves one by one, in any order. Obtaining a similar canonicity result for strategies in the Flipper game requires the full power of our Finitary Substitute Lemma, discussed above.

In the interest of space, we have omitted from this version our results about canonical strategies in the Flipper game, as well as most proofs. For a complete exposition, we refer to the full version of the paper.

2 Preliminaries

Models. We work with first-order logic over a fixed signature Σ that consists of (possibly infinitely many) constant symbols and relation symbols. A *model* is a Σ-structure, and is typically denoted $\mathbf{M}, \mathbf{N}$, etc. We usually do not distinguish between a model and its domain, when writing, for instance, $m \in \mathbf{M}$ or $X \subseteq \mathbf{M}$. A graph G is viewed as a model over the signature consisting of one binary relation denoted E, indicating adjacency between vertices.

If $\bar{x}$ is a finite set of variables, then we write $\varphi(\bar{x})$ to denote a first-order formula φ with free variables contained in $\bar{x}$. We may also write $\varphi(\bar{x}_1, \ldots, \bar{x}_k)$ to denote a formula whose free variables are contained in $\bar{x}_1 \cup \ldots \cup \bar{x}_k$. We will write x instead of $\{x\}$ in case of a singleton set of variables, e.g. $\varphi(x, y)$ will always refer to a formula with two free variables x and y. We sometimes write $\varphi(\bar{x}; \bar{y})$ to distinguish a partition of the set of free variables of φ into two parts, $\bar{x}$ and $\bar{y}$; this partition plays an implicit role in some definitions. A Σ-formula $\varphi(\bar{x})$ *with parameters* from a set $A \subseteq \mathbf{M}$ is a formula $\varphi(\bar{x})$ over the signature $\Sigma \uplus A$, where the elements of A are treated as constant symbols (which are interpreted by themselves).

If U is a set and $\bar{x}$ is a set of variables, then $U^{\bar{x}}$ denotes the set of all *$\bar{x}$-tuples* $\bar{a}\colon \bar{x} \to U$ of $\bar{x}$ in U. For a formula $\varphi(\bar{x})$ (with or without parameters) and an $\bar{x}$-tuple $\bar{m} \in \mathbf{M}^{\bar{x}}$, we write $\mathbf{M} \models \varphi(\bar{m})$ if the valuation $\bar{m}$ satisfies the formula $\varphi(\bar{x})$ in $\mathbf{M}$. For a formula $\varphi(\bar{x};\bar{y})$ and a tuple $\bar{b} \in \mathbf{M}^{\bar{y}}$ we denote by $\varphi(\mathbf{M}^{\bar{x}};\bar{b})$ the set of all $\bar{a} \in \mathbf{M}^{\bar{x}}$ such that $\mathbf{M} \models \varphi(\bar{a};\bar{b})$.

Theories and compactness. A *theory* T (over Σ) is a set of Σ-sentences. The theory of a class of structures $\mathscr{C}$ is the set of sentences that hold in every structure $\mathbf{M} \in \mathscr{C}$. For instance, the theory of a class of graphs $\mathscr{C}$ contains sentences expressing that the relation E is symmetric and irreflexive. A model of a theory T is a structure $\mathbf{M}$ such that $\mathbf{M} \models \varphi$ for all $\varphi \in T$. When a theory has a model, it is said to be *consistent*.

▶ **Theorem 4** (Compactness). *A theory T is consistent if and only if every finite subset of T is consistent.*

Elementary extensions. Let $\mathbf{M}$ and $\mathbf{N}$ be two structures with $\mathbf{M} \subseteq \mathbf{N}$, that is, the domain of $\mathbf{M}$ is contained in the domain of $\mathbf{N}$. Then $\mathbf{N}$ is an *elementary extension* of $\mathbf{M}$, written $\mathbf{M} \prec \mathbf{N}$, if for every formula $\varphi(\bar{x})$ (without parameters) and tuple $\bar{m} \in \mathbf{M}^{\bar{x}}$, the following equivalence holds:

$$\mathbf{M} \models \varphi(\bar{m}) \qquad \text{if and only if} \qquad \mathbf{N} \models \varphi(\bar{m}).$$

We also say that $\mathbf{M}$ is an *elementary substructure* of $\mathbf{N}$. In other words, $\mathbf{M}$ is an elementary substructure of $\mathbf{N}$ if $\mathbf{M}$ is an induced substructure of $\mathbf{N}$, where we imagine that $\mathbf{M}$ and $\mathbf{N}$ are each equipped with every relation R_φ of arity k (for $k \in \mathbb{N}$) that is defined by any fixed first-order formula $\varphi(x_1, \ldots, x_k)$. In this intuition, formulas of arity 0 correspond to Boolean flags, with the same valuation for both $\mathbf{M}$ and $\mathbf{N}$.

Interpretations and transductions. A *simple interpretation* I between signatures Σ and Γ is specified by a domain formula $\delta(x)$ and a formula $\alpha_R(x_1, \ldots, x_k)$ for each relation symbol $R \in \Gamma$ of arity k, with δ and the α_R's being in the signature Σ. For a given Σ-structure $\mathbf{M}$, the interpretation outputs the Γ-structure $\mathsf{I}(\mathbf{M})$ whose domain is $\delta(\mathbf{M})$ and in which the interpretation of each relation R of arity k consists of the tuples $\bar{m}$ such that $\mathbf{M} \models \alpha_R(\bar{m})$. In this paper, we only consider simple interpretations, and therefore we will call them interpretations for conciseness.

For an integer $k \in \mathbb{N}$ and a structure $\mathbf{M}$, we define $k \times \mathbf{M}$ to be the structure consisting of k disjoint copies of $\mathbf{M}$, together with a new symmetric binary relation S containing all pairs (m, m') such that m and m' originate from the same element of $\mathbf{M}$. A *transduction* from Σ to Γ consists of an integer k, unary symbols $U_1, \ldots, U_\ell$ and an interpretation I from $\Sigma \cup \{S, U_1, \ldots, U_\ell\}$ to Γ.

For a transduction T and an input Σ-structure $\mathbf{M}$, the output $\mathsf{T}(\mathbf{M})$ consists of all Γ-structures $\mathbf{N}$ such that there exists a coloring $\widehat{\mathbf{M}}$ of $k \times \mathbf{M}$ with fresh unary predicates $U_1, \ldots, U_\ell$ such that $\mathbf{B} = \mathsf{I}(\widehat{\mathbf{M}})$. We say that a class of Σ-structures $\mathscr{C}$ *transduces* a class of Γ-structure $\mathcal{D}$ if there exists a transduction T such that for every structure $\mathbf{N} \in \mathscr{D}$ there is $\mathbf{M} \in \mathscr{C}$ satisfying $\mathbf{N} \in \mathsf{T}(\mathbf{M})$.

Graphs. We use standard graph theory notation. For a graph parameter π, we say that a graph class $\mathscr{C}$ has *bounded* π if there exists $k \in \mathbb{N}$ such that $\pi(G) \leqslant k$ for all $G \in \mathscr{C}$. Similarly, a class of structures $\mathscr{C}$ has bounded π if the class of Gaifman graphs of structures in $\mathscr{C}$ has bounded π.

3 Canonical Splitter-strategies in nowhere dense graphs

In this section, we show how compactness can be used to derive canonical decompositions for nowhere dense classes. More precisely, we will show that in the Splitter game, which characterizes nowhere dense classes [18], there is a constant k (depending only on the graph class $\mathscr{C}$) such that for any graph in $\mathscr{C}$ there are at most k optimal Splitter moves. This will allow us to illustrate the general methodology used in the paper.

Splitter game. First, we recall the rules of the Splitter game. The radius-r Splitter game is played on a graph G by two players, Splitter and Connector, in rounds $i = 1, 2, \dots$ as follows. Initially the arena G_1 is the whole graph G. In the i-th round,

- Connector chooses a vertex $c_i \in G_i$;
- Splitter chooses a vertex $s_i \in G_i$ and we let $G_{i+1} = G_i[B^r_{G_i}(c_i)] - s_i$;
- Splitter wins if G_{i+1} is the empty graph, otherwise the game continues.

Here, $B^r_H(u) = \{v \in V(H) \mid \operatorname{dist}_H(u, v) \leqslant r\}$ denotes the ball of radius r around u in H.

The following result is instrumental in the celebrated proof of model-checking on nowhere dense classes [18].

▶ **Theorem 5** (Theorems 4.2 and 4.5 in [18]). *A class of graphs $\mathscr{C}$ is nowhere dense if and only if for every r, there exists ℓ such that on every graph $G \in \mathscr{C}$, Splitter can win the radius-r game in at most ℓ rounds.*

The *r-Splitter number* of a graph G is the minimal ℓ such that Splitter wins the radius-r game in ℓ rounds. Fix a nowhere dense class $\mathscr{C}$ and a radius r, and let ℓ be as in the theorem (hence ℓ is an upper bound to all r-Splitter numbers of graphs in $\mathscr{C}$). Observe that for a given $\ell' \leqslant \ell$ there is a first-order sentence expressing that Splitter wins the radius-r game in $\leqslant \ell'$ rounds, and therefore, there is a first-order sentence expressing that G has Splitter number ℓ'. Given a Connector move $c \in V(G)$, we say that a Splitter move $s \in V(G)$ is *r-progressing against c* if the r-Splitter number of $G[B_r(c)] - s$ is strictly smaller than the r-Splitter number of $G[B_r(c)]$. In other words, playing s is strictly better for Splitter than not playing any vertex. Again, since an upper bound to Splitter numbers depends only on $\mathscr{C}$, this can be expressed by a formula $\varphi_r(s; c)$. This leads to the following result.

▶ **Theorem 6.** *Let $\mathscr{C}$ be a nowhere dense class of graphs, and $r \in \mathbb{N}$. There is a constant k such that for every graph $G \in \mathscr{C}$, and every Connector move c, there are at most k progressing moves against c in G.*

In particular, this gives an isomorphism-invariant strategy for Splitter: simply play all progressing moves (either one by one, in any order, or all at once in an extended variant of the game considered in [18], where Splitter can remove a bounded number of vertices in each turn, instead of just one.) The idea of the proof is to extend, by compactness, progressive moves towards outside the model (in an elementary extension), and conclude by observing that "being a progressive move" is a definable and hereditary property.

Proof. Let T be the theory of $\mathscr{C}$. Note that T contains the sentence "Splitter wins the radius-r game in $\leqslant \ell$ rounds". Our aim is to prove that for some k, it contains the sentence "for all connector moves c, there are at most k progressing Splitter moves against c". We show that for any model of T and any connector move c, there are finitely many progressing Splitter moves against c; the result then follows from an easy application of compactness.

Assume for contradiction that there is a model $\mathbf{M}$ of T and a connector move $c \in \mathbf{M}$ such that Splitter has infinitely many progressing moves against c. We now let T' be the theory over the signature extended by a constant corresponding to each element $m \in \mathbf{M}$ and an additional constant s, such that T' consists of:

- all sentences in T,
- all sentences (with parameters in $\mathbf{M}$) which hold in $\mathbf{M}$,
- a sentence expressing that s is a progressing move against c, and
- for each $m \in \mathbf{M}$, the sentence $s \neq m$.

Since every finite subset T'' of T' mentions finitely many $m \in \mathbf{M}$, one can construct a model of T'' by starting from $\mathbf{M}$ and setting s to be one of those progressing moves that are not mentioned. We conclude from compactness (Theorem 4) that T' is consistent.

Let $\mathbf{N}$ be a model of T'. By construction $\mathbf{N}$ is an elementary extension of $\mathbf{M}$ – in particular, $\mathbf{N}[B_r(c)]$ has the same Splitter number ℓ' as $\mathbf{M}[B_r(c)]$ – and contains a progressing move $s \in \mathbf{N} - \mathbf{M}$ against c. This means that $\mathbf{N}[B_r(c)] - s$ has Splitter number $< \ell'$. But $\mathbf{M}[B_r(c)]$ is a subgraph of $\mathbf{N}[B_r(c)] - s$ with Splitter number ℓ': this is absurd. ◀

The next section presents more elaborate tools from stability theory that will allow us to extend the above idea to different settings.

4 Stability, forking, and Finitary Substitution

This section collects notions and a few basic results from stability theory. The purpose is to give a self-contained exposition culminating in our Finitary Substitution Lemma; for more context and explanations we refer to [27].

4.1 Stability and definability of types

We say that a formula $\varphi(\bar{x}; \bar{y})$ defines a *ladder* of order k in a model $\mathbf{M}$ if there are sequences $\bar{a}_1, \dots \bar{a}_k \in \mathbf{M}^{\bar{x}}$ and $\bar{b}_1, \dots, \bar{b}_k \in \mathbf{M}^{\bar{y}}$ satisfying

$$\mathbf{M} \models \varphi(\bar{a}_i; \bar{b}_j) \qquad \text{if and only if} \qquad i < j, \qquad \text{for } 1 \leqslant i, j \leqslant k.$$

For a formula $\varphi(\bar{x}; \bar{y})$ we call the largest k such that φ defines a ladder of order k the *ladder index* of φ in $\mathbf{M}$. If no such k exists, we say that the ladder index of φ is ∞.

We say that φ is *stable* in $\mathbf{M}$ if its ladder index is finite. We say that φ is stable in a theory T if it is stable in all models of T. Moreover, we say that a model (or a theory) is stable if every formula is stable.

We now state a fundamental result about stable formulas; it states that sets definable by stable formulas with parameters in some elementary extension can actually be defined from the model itself.

▶ **Theorem 7** (Definability of types). *Let $\mathbf{M} \prec \mathbf{N}$ be two models and $\varphi(\bar{x}; \bar{y})$ be a stable formula of ladder index d in $\mathbf{M}$. For every $\bar{n} \in \mathbf{N}^{\bar{y}}$ there is a formula $\psi(\bar{x})$, which is a positive boolean combination of formulas of the form $\psi(\bar{x}; \bar{m})$ using a tuple $\bar{m}$ of $2d + 1$ parameters from $\mathbf{M}$, such that for every $\bar{a} \in \mathbf{M}^{\bar{x}}$,*

$$\mathbf{N} \models \varphi(\bar{a}; \bar{n}) \qquad \textit{if and only if} \qquad \mathbf{M} \models \psi(\bar{a}).$$

4.2 Forking in stable theories

We move on to the definition of forking, which was first defined by Shelah in order to study stable theories [26], and later grew to become the central notion of stability theory. In stable theories, forking coincides with the simpler notion of dividing, so by a slight abuse we will only work with dividing (and call it forking). We first need to formally introduce types, then we give a definition of forking in stable theories and a few useful properties.

Types. Fix a model $\mathbf{M}$ over a signature Σ. A set π of formulas in variables $\bar{x}$ with parameters from $A \subseteq \mathbf{M}$ is called a *partial type over* A if it is *consistent*: for every finite subset $\pi' \subseteq \pi$ there is $\bar{m} \in \mathbf{M}^{\bar{x}}$ which satisfies all the formulas from π' (i.e. for every formula $\varphi(\bar{x}) \in \pi'$ we have $\mathbf{M} \models \varphi(\bar{m})$). We sometimes write $\pi(\bar{x})$ to explicitly mention free variables. Partial types p which are maximal are called *types*; this amounts to stating that for every formula $\varphi(\bar{x})$ with parameters from A, either $\varphi(\bar{x}) \in p$ or $\neg\varphi(\bar{x}) \in p$. Observe that for sets $A \subseteq B \subseteq \mathbf{M}$ every type p over A can be seen as a partial type over B. We denote the set of types over A in variables $\bar{x}$ by $S_{\bar{x}}(A)$.

For a tuple $\bar{a} \in \mathbf{M}^{\bar{x}}$ and a set $A \subseteq \mathbf{M}$ of parameters, the type of $\bar{a}$ over A, denoted $\mathrm{tp}(\bar{a}/A) \in S_{\bar{x}}(A)$, is the set of all formulas $\varphi(\bar{x})$ with parameters from A such that $\mathbf{M} \models \varphi(\bar{a})$. It follows from compactness that for every $p \in S_{\bar{x}}(\mathbf{M})$ there is some $\mathbf{N} \succ \mathbf{M}$ and an $\bar{x}$-tuple $\bar{n} \in \mathbf{N}^{\bar{x}}$ such that $\mathrm{tp}(\bar{n}/\mathbf{M}) = p$.

Forking. Fix a stable model $\mathbf{M}$ over a signature Σ and a set $A \subseteq \mathbf{M}$. Let $\varphi(\bar{x};\bar{y})$ be a formula without parameters and let $\bar{b} \in \mathbf{M}^{\bar{y}}$. We say that $\varphi(\bar{x};\bar{b})$ *forks over* A if there is an elementary extension $\mathbf{N} \succ \mathbf{M}$, a sequence $\bar{b}_1, \bar{b}_2, \ldots \in \mathbf{N}^{\bar{y}}$ satisfying $\mathrm{tp}(\bar{b}_i/A) = \mathrm{tp}(\bar{b}/A)$ for every i and an integer k such that $S = \{\varphi(\bar{x};\bar{b}_i) : i \in \mathbb{N}\}$ is k-inconsistent: no k-element subset of S is consistent. For a type $p \in S_{\bar{x}}(B)$ over a set $B \subseteq \mathbf{M}$, we say that p forks over A if there is a formula $\varphi(\bar{x};\bar{b}) \in p$ which forks over A.

We will make use of the following important property of forking which is often called *(full) existence*.

▶ **Theorem 8** (See [27, Corollary 7.2.7]). *Let $\mathbf{M}$ be a stable model and let $A \subseteq B \subseteq \mathbf{M}$. For every $p \in S_{\bar{x}}(A)$ there is some $q \in S_{\bar{x}}(B)$ such that $p \subseteq q$ and q does not fork over A.*

Finitary formulas. We say that a formula $\varphi(\bar{x};\bar{y})$ is *finitary* in a theory T if for every model $\mathbf{M}$ of T, the set $\{\varphi(\mathbf{M}^{\bar{x}};\bar{m}) : m \in \mathbf{M}^{\bar{y}}\}$ is finite. By compactness, this is equivalent to the following assertion: there exists $k \in \mathbb{N}$ such that $|\{\varphi(\mathbf{M}^{\bar{x}};\bar{m}) : m \in \mathbf{M}^{\bar{y}}\}| \leqslant k$ for every model $\mathbf{M}$ of T. We now relate forking and finitary formulas.

▶ **Theorem 9** (Special case of [27, Theorem 8.5.1][3]). *Let $\mathbf{M}$ be a stable model, $\mathbf{N}$ an elementary extension of $\mathbf{M}$, $\varphi(\bar{x};\bar{y})$ a formula, $\bar{n} \in \mathbf{N}^{\bar{y}}$, and $A \subseteq \mathbf{M}$. If $\mathrm{tp}(\bar{n}/\mathbf{M})$ does not fork over A, then there is a finitary formula $\varphi'(\bar{x};\bar{z})$ and a tuple $\bar{r} \in \mathbf{M}^{\bar{z}}$ such that $\varphi(\mathbf{N}^{\bar{x}};\bar{n}) \cap \mathbf{M}^{\bar{x}} = \varphi'(\mathbf{M}^{\bar{x}};\bar{r})$.*

Combining Theorems 8 and 9 yields the following statement.

▶ **Lemma 10.** *Let $\mathbf{M}$ be a stable model over the signature Σ, $\varphi(\bar{x};\bar{y})$ a Σ-formula, and ψ a sentence over signature $\Sigma \cup \{R\}$, where $R \notin \Sigma$ has arity $|\bar{x}|$. Let $\bar{s} \in \mathbf{M}^{\bar{y}}$ be such that $\mathbf{M} \models \psi[R(\bar{x})/\varphi(\bar{x};\bar{s})]$. Then there is an elementary extension $\mathbf{N}$ of $\mathbf{M}$, a tuple $\bar{s}' \in \mathbf{N}^{\bar{y}}$, a finitary formula $\varphi'(\bar{x};\bar{z})$ and a tuple $\bar{r} \in \mathbf{M}^{\bar{z}}$, such that $\mathbf{N} \models \psi[R(\bar{x})/\varphi(\bar{x};\bar{s}')]$ and $\varphi(\mathbf{N}^{\bar{x}};\bar{s}') \cap \mathbf{M}^{\bar{x}} = \varphi'(\mathbf{M}^{\bar{x}};\bar{r})$.*

Proof. Consider $p = \mathrm{tp}(\bar{s}/\emptyset)$. By Theorem 8, p extends to a type $q \in S_{\bar{y}}(\mathbf{M})$ which does not fork over $\emptyset$. By compactness there is an elementary extension $\mathbf{N} \succ \mathbf{M}$ and a tuple $\bar{s}' \in \mathbf{N}^{\bar{y}}$ such that $\mathrm{tp}(\bar{s}'/\mathbf{M}) = q$. In particular $\mathrm{tp}(\bar{s}'/\emptyset) = p = \mathrm{tp}(\bar{s}/\emptyset)$, and therefore $\mathbf{N} \models \psi[R(\bar{x})/\varphi(\bar{x};\bar{s}')]$ as required. Applying Theorem 9 we get a finitary formula $\varphi'(\bar{x};\bar{z})$ and a tuple $\bar{r} \in \mathbf{M}^{\bar{z}}$ with the wanted properties. ◀

[3] Formally, [27, Theorem 8.5.1] speaks about definability with *imaginaries*, which is known to be equivalent to the existence of finitary formulas (see for instance [9, Lemma 1.3.2 (5), Lemma 1.3.7]).

4.3 Finitary Substitute Lemma

Recall from Section 3 that applying our method requires a mechanism for moving the wanted property ψ back towards the structure $\mathbf{M}$ we started from. This is formalized by the following definition. In a theory T, and given two sentences ψ and ψ' over the signature $\Sigma \cup \{R\}$, we say that a sentence ψ *induces* ψ' *on semi-elementary substructures* if for every model $\mathbf{M}$ of T, for every elementary extension $\mathbf{N}$ and for every $\mathcal{R} \subseteq \mathbf{N}^k$, where k is the arity of R,

$$\mathbf{N}[R/\mathcal{R}] \models \psi \qquad \text{implies} \qquad \mathbf{M}[R/\mathcal{R}|_{\mathbf{M}}] \models \psi'.$$

As an important special case, if ψ is hereditary then ψ induces ψ on semi-elementary substructures. We are now ready to state our main model-theoretic tool.

▶ **Lemma 11** (Finitary Substitute Lemma). *Let T be a theory with signature Σ, $\varphi(\bar{x};\bar{y})$ a stable formula, and ψ, ψ' be sentences over the signature $\Sigma \cup \{R\}$, where $R \notin \Sigma$ has arity $|\bar{x}|$, such that ψ induces ψ' on semi-elementary substructures. Assume that $T \models \exists \bar{s}.\psi[R(\bar{x})/\varphi(\bar{x};\bar{s})]$. Then there is a finitary formula $\varphi'(\bar{x};\bar{z})$ such that $T \models \exists \bar{s}.\psi'[R(\bar{x})/\varphi'(\bar{x};\bar{s})]$.*

The proof follows from Lemma 10 by applying compactness; we refer to the full version for details.

5 Canonization of graphs of bounded shrubdepth

In this section, we prove Theorems 2 and 3 which we now recall for convenience.

▶ **Theorem 2.** *Let $\mathscr{C}$ be a class of graphs of bounded shrubdepth. Then there is a class $\mathscr{D}$ of binary structures of bounded treedepth and a mapping $\mathcal{A}\colon \mathscr{C} \to \mathscr{D}$ such that:*

- *For each $G \in \mathscr{C}$, the vertex set of G is contained in the domain of $\mathcal{A}(G)$ and the mapping $G \mapsto \mathcal{A}(G)$ is isomorphism-invariant.*
- *Given an n-vertex graph $G \in \mathscr{C}$, the structure $\mathcal{A}(G)$ has $\mathcal{O}(n)$ elements and can be computed in time $\mathcal{O}(n^2)$.*
- *There is a simple first-order interpretation I such that $G = \mathsf{I}(\mathcal{A}(G))$, for every $G \in \mathscr{C}$.*

▶ **Theorem 3.** *For every graph class $\mathscr{C}$ of bounded shrubdepth there is an $\mathcal{O}(n^2)$-time algorithm that given n-vertex graphs $G, G' \in \mathscr{C}$, decides whether G and G' are isomorphic.*

The proof is broken into three parts.

- The first part combines insights about classes of bounded shrubdepth with our Finitary Substitute Lemma developed in the previous section, to conclude that the first level in a shrubdepth decomposition (which we will call a dicing, defined below) can be defined using finitary formulas. This result is stated as Theorem 12 below.
- The second part builds on Theorem 12 to propose a canonical transformation from classes of bounded shrubdepth to classes of bounded treedepth. This proves Theorem 2.
- In the third part, we show how Theorem 3 is derived from Theorem 2, and also establish a stronger result about the canonization problem.

We start by recalling a few preliminaries about shrubdepth in Section 5.1, and proceed with the three parts outlined above in Sections 5.2, 5.3 and 5.4.

5.1 Preliminaries on shrubdepth

Shrubdepth. The decomposition notion underlying shrubdepth is that of *connection models*, defined as follows. Let G be a graph. A *connection model* for G consists of:

- a finite set of labels Labels;
- a labelling $\mathsf{label}\colon V(G) \to \mathsf{Labels}$;
- a rooted tree T whose leaf set coincides with the vertex set of G; and
- for every non-leaf node x of T, a symmetric relation $\mathsf{Adj}(x) \subseteq \mathsf{Labels} \times \mathsf{Labels}$, called the *adjacency table* at x.

The rule is as follows: for every distinct vertices u, v of G, u and v are adjacent in G if and only if $(\mathsf{label}(u), \mathsf{label}(v)) \in \mathsf{Adj}(x)$, where x is the lowest common ancestor of u and v in T.

The *depth* of a connection model is the depth of T. The *shrubdepth* of a graph class $\mathscr{C}$ is the least integer d with the following property: there exists a finite set of labels Labels such that every graph $G \in \mathscr{C}$ has a connection model of depth at most d that uses label set Labels.

Dicings. Our inductive proof requires manipulating the first level (just below the root) of a connection model; we will call this a dicing. Formally, for a graph G, a pair $(\mathcal{P}, \mathcal{L})$ of partitions of the vertex set of G is called a *dicing* of G if for every pair of vertices u, v belonging to different parts of $\mathcal{P}$, whether u and v are adjacent in G depends only on the pair of parts of $\mathcal{L}$ that u and v belong to. In other words, there is a symmetric relation $Z \subseteq \mathcal{L} \times \mathcal{L}$ such that for all u, v belonging to different parts of $\mathcal{P}$,

$$u \text{ and } v \text{ are adjacent in } G \qquad \text{if and only if} \qquad (\mathcal{L}(u), \mathcal{L}(v)) \in Z,$$

where $\mathcal{L}(w)$ denotes the part of $\mathcal{L}$ to which w belongs. In the context of a dicing $(\mathcal{P}, \mathcal{L})$, partition $\mathcal{P}$ will be called the *component partition*, and partition $\mathcal{L}$ will be called the *label partition*. The *order* of a dicing $(\mathcal{P}, \mathcal{L})$ is $|\mathcal{L}|$, the number of parts in the label partition.

Dicings appear naturally in connection models for shrubdepth: given a connection model for a graph G, using "having a common ancestor below the root" as component partition $\mathcal{P}$ and label-classes as label partition $\mathcal{L}$ defines a dicing of G.

5.2 Definability of canonical dicings

We say that a formula $\varphi(\bar{x}; \bar{y})$ with $|\bar{x}| = 2$ *defines a partition* if for every graph G and $\bar{b} \in G^{\bar{y}}$, $\varphi(G^{\bar{x}}; \bar{b})$ is an equivalence relation on the vertex set of G. (Note that for different choices of $\bar{b}$, φ can yield different equivalence relations.) Abusing the notation, by $\varphi(G^{\bar{x}}; \bar{b})$ we will also denote the partition of the vertex set into the equivalence classes of $\varphi(G^{\bar{x}}; \bar{b})$. Recall that a formula $\varphi(\bar{x}; \bar{y})$ is said to be finitary in (the theory of) a graph class $\mathscr{C}$ if there exists k such that for all graph $G \in \mathscr{C}$,

$$|\{\varphi(G^{\bar{x}}; \bar{b}) : \bar{b} \in G^{\bar{y}}\}| \leqslant k.$$

This section is focused on establishing the following result.

▶ **Theorem 12.** *Let $\mathscr{C}$ be a class of shrubdepth at most d, where $d > 1$. Then there exists a hereditary class $\mathscr{C}'$ of shrubdepth at most $d - 1$, finitary first-order formulas $\varphi(\bar{x}; \bar{y})$ and $\lambda(\bar{x}; \bar{y})$, each defining a partition, and $\ell \in \mathbb{N}$, such that the following holds: for every graph $G \in \mathscr{C}$ there exists $\bar{s} \in G^{\bar{y}}$ such that*

- *$(\varphi(G^{\bar{x}}; \bar{s}), \lambda(G^{\bar{x}}; \bar{s}))$ is a dicing of G of order at most ℓ; and*
- *for every part A of $\varphi(G^{\bar{x}}; \bar{s})$, we have $G[A] \in \mathscr{C}'$.*

On a high level, this proves that connection models can be defined using first-order formulas $\varphi(\bar{x};\bar{y}), \lambda(\bar{x};\bar{y})$ and parameters $\bar{s} \in G^{\bar{y}}$. While a good start towards sparsification, this alone would be insufficient for our needs, as different choices of $\bar{s}$ may lead to many different connection models, and choosing an arbitrary $\bar{s}$ would not give an isomorphism-invariant construction. This difficulty is overcome by the finitariness of φ and λ: our construction will take into account all of the (boundedly many) possible dicings (see Section 5.3).

The proof of Theorem 12 is broken into three parts as follows.

- The first part consists of proving that the label partition $\mathcal{L}$ can be chosen to be definable as a partition $\lambda(G^{\bar{x}};\bar{s})$ into $\bar{s}$-types. This is achieved thanks to a more general result of Bonnet et al. [3] pertaining to classes of bounded VC-dimension.
- We then show that the component partition $\mathcal{P}$ can be chosen to be definable by a formula $\varphi(G^{\bar{x}};\bar{s})$ using the same parameters $\bar{s}$. This relies on known properties of classes of bounded shrubdepth [16].
- We then apply our Finitary Substitute Lemma (Lemma 11) and prove that φ and λ can be taken to be finitary.

Definability of the label partition. For a subset of vertices S of a graph G we let $\mathcal{L}_S$ denote the partition of the vertex set of G into neighborhood classes with respect to S: u and v belong to the same part of $\mathcal{L}_S$ if and only if

$$\{w \in S \mid u \text{ and } w \text{ are adjacent}\} = \{w \in S \mid v \text{ and } w \text{ are adjacent}\}.$$

Note that we have $|\mathcal{L}_S| \leqslant 2^{|S|}$. It turns out that label partitions can be taken of this form.

▶ **Lemma 13** (follows from Theorem 3.5 of [3]). *Let $\mathscr{C}$ be graph class of bounded shrubdepth. Then for every graph $G \in \mathscr{C}$ and dicing $(\mathcal{P},\mathcal{L})$ of G of order at most t, there exists $S \subseteq V(G)$ with $|S| \leqslant \mathcal{O}(t^2)$ such that $(\mathcal{P},\mathcal{L}_S)$ is also a dicing of G.*

Definability of the component partition. We now show that the component partition $\mathcal{P}$ can also be defined using a first-order formula.

▶ **Lemma 14.** *Let $\mathscr{C}$ be a graph class of bounded shrubdepth and $t \in \mathbb{N}$ be an integer. There exist formulas $\varphi(\bar{x};\bar{y})$ and $\lambda(\bar{x};\bar{y})$, both defining a partition, such that the following holds: for every graph $G \in \mathscr{C}$ and dicing $(\mathcal{P},\mathcal{L})$ of G of order at most t, there exists $\bar{s} \in G^{\bar{y}}$ such that*

$$(\mathcal{P}',\mathcal{L}') = \big(\varphi(G^{\bar{x}};\bar{s}), \lambda(G^{\bar{x}};\bar{s})\big)$$

is a dicing of G of order at most $2^{\mathcal{O}(t^2)}$. Further, every part of $\mathcal{P}'$ is entirely contained in some part of $\mathcal{P}$.

Proof sketch. By Lemma 13, there exists a vertex subset S with $|S| \leqslant \mathcal{O}(t^2)$ such that $(\mathcal{P},\mathcal{L}_S)$ is also a dicing of G, with relation $Z \subseteq \mathcal{L}_S \times \mathcal{L}_S$. We let H denote the graph obtained by "flipping according to the dicing $(\mathcal{P},\mathcal{L}_S)$", meaning that we exchange edges and non-edges between pairs of parts in $\mathcal{L}_S$ that belong to Z. Since $(\mathcal{P},\mathcal{L}_S)$ is a dicing, connected components of H are contained in single parts of $\mathcal{P}$; let $\mathcal{P}'$ denote the partition of $V(G) = V(H)$ into connected components in H. Since H can be transduced from G, it has bounded shrubdepth, and thus we get that each part of $\mathcal{P}'$ have diameter bounded by a constant; this is because every class of bounded shrubdepth does not admit arbitrarily long induced paths [16]. We deduce that there is a formula expressing that two vertices belong to the same $\mathcal{P}'$-component, and the result follows. ◀

Finitariness of the definition. We are now ready to derive the theorem.

Proof sketch for Theorem 12. Let Labels be a large enough set of labels so that graphs in $\mathscr{C}$ admit connection models with labels in Labels, and let $\mathscr{C}'$ be the class of all graphs that admit a connection model of depth at most $d-1$ using the label set Labels. By Lemma 14, there exist formulas $\varphi(\bar{x};\bar{y})$ and $\lambda(\bar{x};\bar{y})$, depending only on $\mathscr{C}$, such that there is $\bar{s} \in G^{\bar{y}}$ for which $(\varphi(G^{\bar{x}};\bar{s}), \lambda(G^{\bar{x}};\bar{s}))$ is a dicing of G of order at most ℓ, where $\ell \in 2^{\mathcal{O}(|\mathsf{Labels}|^2)}$ is a constant depending only on $\mathscr{C}$. Moreover, every part of $\varphi(G^{\bar{x}};\bar{s})$ is entirely contained in a single part of $\mathcal{P}$, which implies that for every part A' of $\varphi(G^{\bar{x}},\bar{s})$ we have $G[A'] \in \mathscr{C}'$. It remains to transform φ and λ into finitary formulas. Let T be the theory of $\mathscr{C}$.

Let R be a relation symbol of arity 4 and consider the following assertion:

> "R is the product of two partitions $\mathcal{P}$ and $\mathcal{L}$ such that $(\mathcal{P},\mathcal{L})$ is a dicing of G of order at most ℓ. Moreover, for every part A of $\mathcal{P}$ it holds that $G[A] \in \mathscr{C}'$".

It follows from [16, Corollary 3.9] that the assertion above can be expressed by a first order sentence ψ over the signature $\{E, R\}$. Moreover, ψ is hereditary, so we may apply the Finitary Substitute Lemma to the formula $\eta(\bar{x}_1,\bar{x}_2;\bar{y}) = \varphi(\bar{x}_1;\bar{y}) \wedge \lambda(\bar{x}_2,\bar{y})$; we get a finitary $\eta'(\bar{x}_1,\bar{x}_2;\bar{y})$ such that

$$T \quad \text{implies} \quad \exists \bar{s}.\psi[R(\bar{x}_1,\bar{x}_2)/\eta'(\bar{x}_1,\bar{x}_2;\bar{s})].$$

Then the formulas

$$\varphi'(\bar{x};\bar{y}) = \exists z.\eta'(\bar{x},z,z;\bar{y}) \quad \text{and} \quad \lambda'(\bar{x};\bar{y}) = \exists z.\eta'(z,z,\bar{x};\bar{y})$$

yield the wanted result. ◀

5.3 Canonical reduction to bounded treedepth

With Theorem 12 in hand, we proceed to the proof of Theorem 2. Fix a class $\mathscr{C}$ of shrubdepth at most d.

Properties of the construction. We describe a construction that, given a graph $G \in \mathscr{C}$, constructs a structure $\mathcal{A}(G)$ of the following shape.

- $\mathcal{A}(G)$ is a structure over a signature consisting of several unary relations and one binary relation. Thus, we see $\mathcal{A}(G)$ as a vertex-colored directed graph, and we will apply the usual directed graphs terminology to $\mathcal{A}(G)$.
- The vertex set of G is contained in the vertex set of $\mathcal{A}(G)$. The elements of $V(G)$ will be called *leaves* of $\mathcal{A}(G)$. In $\mathcal{A}(G)$ there is a unary predicate marking all the leaves.
- In $\mathcal{A}(G)$ there is a specified vertex, called the *root*, such that for every vertex u of $\mathcal{A}(G)$ there is an arc from u to the root. The root is identified using a unary predicate.

The construction will satisfy the following properties.

- The mapping $G \mapsto \mathcal{A}(G)$ is isomorphism-invariant within the class $\mathscr{C}$.
- For every vertex u of $\mathcal{A}(G)$, there are at most c arcs with tail at u, for some constant c depending only on $\mathscr{C}$.
- There is a transduction T depending on $\mathscr{C}$ such that $\mathcal{A}(G) \in \mathsf{T}(G)$.
- The class $\{\mathcal{A}(G) \mid G \in \mathscr{C}\}$ has bounded treedepth.
- There is an interpretation I depending on $\mathscr{C}$ such that $G = \mathsf{I}(\mathcal{A}(G))$.
- Given G, $\mathcal{A}(G)$ can be computed in time $\mathcal{O}(n^2)$, where n is the vertex count of G.

We proceed by induction on d, the shrubdepth of $\mathscr{C}$; the base case $d = 1$ is obvious.

Preparation for the inductive construction. Suppose $d > 1$. Let $\varphi(\bar{x};\bar{y})$, $\lambda(\bar{x};\bar{y})$, $\ell \in \mathbb{N}$, and $\mathscr{C}'$ be the finitary formulas, the bound, and the class provided by Theorem 12. Since the shrubdepth of $\mathscr{C}'$ is at most $d-1$, by induction assumption we get a suitable mapping $\mathcal{A}'(\cdot)$, constant c', transduction T', and interpretation I' that satisfy the properties stated above for $\mathscr{C}'$.

Call a tuple $\bar{s} \in G^{\bar{y}}$ *good* if $(\varphi(G^{\bar{x}};\bar{s}), \lambda(G^{\bar{x}};\bar{s}))$ is a dicing of G of order at most ℓ satisfying that for every part A of $\varphi(G^{\bar{x}},\bar{s})$ it holds that $G[A] \in \mathscr{C}'$. Define

$$\mathcal{F} = \{\, (\varphi(G^{\bar{x}};\bar{s}), \lambda(G^{\bar{x}};\bar{s})) \;:\; \bar{s} \in G^{\bar{y}} \text{ is a good tuple} \,\}.$$

By Theorem 12, we have

$$1 \leqslant |\mathcal{F}| \leqslant k$$

for some constant $k \in \mathbb{N}$ depending only on $\mathscr{C}$.

Let $\widehat{\mathcal{L}}$ be the coarsest partition that refines all label partitions of the dicings belonging to $\mathcal{F}$; that is, u, v are in the same part of $\widehat{\mathcal{L}}$ if and only if u, v are in the same part of $\mathcal{L}$ for each $(\mathcal{P},\mathcal{L}) \in \mathcal{F}$. Similarly, let $\widehat{\mathcal{P}}$ be the coarsest partition that refines all component partitions of the dicings belonging to $\mathcal{F}$. Since $|\mathcal{F}| \leqslant k$ and $|\mathcal{L}| \leqslant \ell$ for each label partition featured in $\mathcal{F}$, we have

$$|\widehat{\mathcal{L}}| \leqslant \ell^k.$$

Moreover, every part of $\widehat{\mathcal{P}}$ is contained in a single part of any component partition featured in $\mathcal{F}$, hence $G[B] \in \mathscr{C}'$ for every part B of $\widehat{\mathcal{P}}$.

Let $\widehat{\mathcal{F}} = \{(\mathcal{P},\widehat{\mathcal{L}}) \colon (\mathcal{P},\mathcal{L}) \in \mathcal{F}\}$. Since $\widehat{\mathcal{L}}$ refines each label partition featured in $\mathcal{F}$, it follows that every element of $\widehat{\mathcal{F}}$ is a dicing of G. Then, for a component partition $\mathcal{P}$ featured in $\mathcal{F}$, let $Z_{\mathcal{P}} \subseteq \widehat{\mathcal{L}} \times \widehat{\mathcal{L}}$ be the symmetric relation witnessing that $(\mathcal{P},\widehat{\mathcal{L}})$ is a dicing.

Definition of the construction. We now describe the structure $\mathcal{A}(G)$; see Figure 1. Construct:

- a root vertex r;
- for every part $L \in \widehat{\mathcal{L}}$, a vertex x_L;
- for every component partition $\mathcal{P}$ featured in $\mathcal{F}$, a vertex $y_{\mathcal{P}}$;
- for every component partition $\mathcal{P}$ featured in $\mathcal{F}$, and every part $A \in \mathcal{P}$, a vertex $z_{\mathcal{P},A}$; and
- for every component partition $\mathcal{P}$ featured in $\mathcal{F}$, and every (unordered) pair $LL' \in Z_{\mathcal{P}}$, a vertex $q_{\mathcal{P},LL'}$. (Note here that $Z_{\mathcal{P}}$ is symmetric, so we may treat its elements as unordered pairs of elements of $\widehat{\mathcal{L}}$.)

Further, for every part B of $\widehat{\mathcal{P}}$ we have $G[B] \in \mathscr{C}'$, hence we may apply the construction $\mathcal{A}'$ to $G[B]$, yielding a structure $H_B = \mathcal{A}'(G[B])$. Let r_B be the root of H_B. We add all structures H_B obtained in this way to $\mathcal{A}(G)$. We then connect these with the following arcs:

1. for every vertex u of $\mathcal{A}(G)$ there is an arc (u,r);
2. for every vertex of the form $z_{\mathcal{P},A}$ there is an arc $(z_{\mathcal{P},A}, y_{\mathcal{P}})$;
3. for every vertex of the form $q_{\mathcal{P},LL'}$, there are arcs $(q_{\mathcal{P},LL'}, x_L)$, $(q_{\mathcal{P},LL'}, x_{L'})$, and $(q_{\mathcal{P},LL'}, y_{\mathcal{P}})$;
4. for every part B of $\widehat{\mathcal{P}}$ and every component partition $\mathcal{P}$ featured in $\mathcal{F}$, there is an arc $(r_B, z_{\mathcal{P},A})$, where A is the unique part of $\mathcal{P}$ that contains B;
5. for every vertex u of G there is an arc (u, x_L), where L is the unique part of $\widehat{\mathcal{L}}$ that contains u. (Recall that the vertex set of G is the union of the leaf sets of H_B for $B \in \widehat{\mathcal{P}}$.)

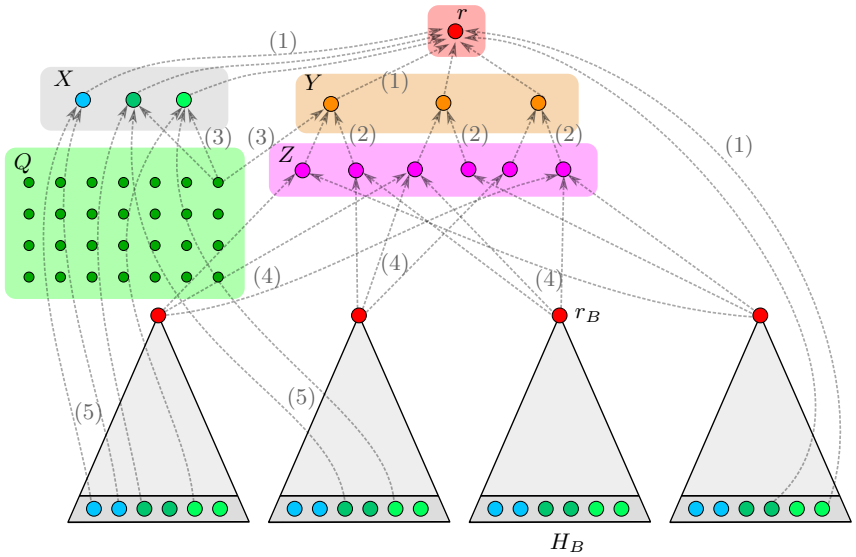

Figure 1 Inductive construction of $\mathcal{A}(G)$. Vertices of the form r, $y_{\mathcal{P}}$, $z_{\mathcal{P},A}$, $q_{\mathcal{P},LL'}$ are depicted in red, orange, violet, and green, respectively. Vertices of the form x_L are depicted in the top-left corner of the figure in different soft colors (which do not correspond to unary predicates), matching the colors of vertices of G that point to them; thus the soft color partition is $\widehat{\mathcal{L}}$. We depict a few representatives for each type of arcs.

Finally, we add five fresh unary predicates, called R, X, Y, Z, Q, respectively selecting the root r, the vertices of the form x_L, the vertices of the form $y_{\mathcal{P}}$, the vertices of the form $z_{\mathcal{P},A}$, and the vertices of the form $q_{\mathcal{P},LL'}$. Note here that H contains more unary predicates: those that come with structures H_B constructed by induction. These include a unary relation selecting the leaves.

This concludes the construction of $\mathcal{A}(G)$. We do not include detailed proofs of the properties listed above, and refer instead to the full version. That the transformation is isomorphism-invariant and that every element is the tail of a bounded number of arcs follows directly from the construction. Also, it is quite straightforward to transduce $\mathcal{A}(G)$ from G, by guessing good tuples $\bar{s}_1, \ldots, \bar{s}_{k'}$; then it follows from the results of Ganian et al. [16] that the class of $\mathscr{D} = \{\mathcal{A}(G) \colon G \in \mathscr{C}\}$ has bounded shrubdepth. This, together with the sparsity of $\mathcal{A}(G)$ following from the bound on outdegrees, implies that $\mathscr{D}$ in fact has bounded treedepth. Further, there is no difficulty in interpreting G in $\mathcal{A}(G)$. To compute $\mathcal{A}(G)$ in quadratic time, we rely on algorithmic meta-theorems over graphs of bounded cliquewidth obtained from combining [12, 21]. Theorem 2 follows.

5.4 Canonization and isomorphism test

We now use Theorem 2 to prove Theorem 3, that is, give a quadratic-time isomorphism test for any class of graphs of bounded shrubdepth. As mentioned in the introduction, in fact we solve the more general canonization problem, defined as follows.

For a class of structures $\mathscr{C}$, a *canonization map* for $\mathscr{C}$ is a mapping $\mathfrak{c}$ with the following property: for every $\mathbf{M} \in \mathscr{C}$, $\mathfrak{c}(\mathbf{M})$ is a total order on elements of $\mathbf{M}$ so that if $\mathbf{M}, \mathbf{M}' \in \mathscr{C}$ are isomorphic, then associating elements with same index in $\mathfrak{c}(\mathbf{M})$ and in $\mathfrak{c}(\mathbf{M}')$ yields an isomorphism between $\mathbf{M}$ and $\mathbf{M}'$. Note that if there is a canonization map $\mathfrak{c}$ for $\mathscr{C}$ that is efficiently computable, then this immediately gives an isomorphism test within the same time complexity.

For classes of bounded treedepth, Bouland et al. [4] gave a relatively easy fixed-parameter isomorphism test. Their techniques can be easily extended to the canonization problem for binary structures of bounded treedepth.

▶ **Theorem 15** (Adapted from [4]). *Let $\mathcal{D}$ be a class of binary structures of bounded treedepth. There exists a canonization map $\mathfrak{c}$ on $\mathcal{D}$ that is computable in time $\mathcal{O}(n \log^2 n)$, where n is the size of the universe of the input structure.*

We can now prove the main result of this section.

▶ **Theorem 16.** *Let $\mathscr{C}$ be a class of graphs of bounded shrubdepth. There exists a canonization map $\mathfrak{c}$ on $\mathscr{C}$ that is computable in time $\mathcal{O}(n^2)$, where n is the vertex count of the input graph.*

Proof. Let $\mathscr{D}$ be the class of bounded treedepth and $\mathcal{A}\colon \mathscr{C} \to \mathscr{D}$ be the mapping provided by Theorem 2 for the class $\mathscr{C}$. Then to get a suitable canonization map for $\mathscr{C}$, it suffices to compose $\mathcal{A}$ with the canonization map for $\mathscr{D}$, provided by Theorem 15, and restrict the output order to the vertex set of the original graph. ◀

As discussed, Theorem 3 follows immediately from Theorem 16.

Abstract

We introduce Probabilistic Guarded Kleene Algebra with Tests (ProbGKAT), an extension of GKAT that allows reasoning about uninterpreted imperative programs with probabilistic branching. We give its operational semantics in terms of special class of probabilistic automata. We give a sound and complete Salomaa-style axiomatisation of bisimilarity of ProbGKAT expressions. Finally, we show that bisimilarity of ProbGKAT expressions can be decided in $O(n^3 \log n)$ time via a generic partition refinement algorithm.

1 Introduction

Randomisation is an important feature in the design of efficient algorithms, cryptographic protocols, and stochastic simulation [9]. For a simple example of randomisation, imagine simulating a three-sided die [64]. There are at least two ways to do this:

- A reference implementation could use a fair coin and a biased coin with probability $\frac{1}{3}$ of landing on `heads`: Toss the biased coin first. If it lands on `heads`, return ⚀, and otherwise toss the fair coin and return ⚁ if it lands on `heads` or ⚂ otherwise.
- Another way to do this is with two consecutive tosses of a fair coin: if the outcome is `heads-heads`, then return ⚀; if it is `heads-tails`, return ⚁; if it is `tails-heads`, return ⚂; and if it is `tails-tails`, repeat the process [34].

These programs can be written using a function `flip`(p) that returns `true` (`heads`) with probability p, and `false` (`tails`) with probability $1-p$, see Figure 1. If we can prove that those programs are equivalent, then we can be certain they implement the same distribution.

```
while true do
    if flip(0.5) then
        if flip(0.5) then
            return ⚀
        else
            return ⚁
    else
        if flip(0.5) then
            return ⚂
        else
            skip
```

```
if flip(1/3) then
    return ⚀
else
    if flip(0.5) then
        return ⚁
    else
        return ⚂
```

Figure 1 On the left, the Knuth-Yao process to simulate a three-sided die with two throws of a fair coin. On the right, direct implementation of the three-sided die (note that the probability of the first else-branch is $\frac{2}{3}$, hence both ⚀ and ⚁ are returned with probability $\frac{1}{3}$).

In this paper, we introduce Probabilistic GKAT (ProbGKAT), a language based on Guarded Kleene Algebra with Tests (GKAT) [39, 58, 53] augmented with extra constructs for reasoning about such randomised programs. The laws of GKAT allow reasoning about the equivalence of uninterpreted programs with deterministic control flow in the form of Boolean branching (`if-then-else`) and looping (`while-do`) constructs. GKAT comes equipped with an automata-theoretic operational semantics, a *nearly linear* decision procedure, and complete axiomatic systems for reasoning about trace equivalence [58] and bisimilarity [53] of expressions, both inspired by Salomaa's axiomatisation of Kleene Algebra [52].

ProbGKAT extends GKAT with three new syntactic constructs: (1) a probabilistic choice operator, representing branching based on a (possibly biased) coin flip; (2) a probabilistic loop operator, representing a generalised Bernoulli process; and (3) return values, which allow a limited form of non-local control flow akin to `return` statements in imperative programming.

The main focus of this paper is the problem of axiomatising bisimilarity of ProbGKAT expressions. We build on an inference system for reasoning about bisimilarity of GKAT expressions [53], which includes a generalisation of Salomaa's axiomatisation of the Kleene star [52] called the Uniqueness of Solutions axiom (UA), also known in the process algebra community as Recursive Specification Principle (RSP) [10]. In the presence of both Boolean guarded and probabilistic branching, axiomatisation becomes significantly more involved. Besides adding intuitive rules governing the behaviour of probabilistic choice and loops, we add axioms capturing the interaction of both kinds of branching when combined with looping constructs. Moreover, in the case of ProbGKAT, showing the soundness of UA becomes highly nontrivial. We do so by exploiting the topological structure of the operational model, namely the *behavioural pseudometric* associated with bisimilarity. Despite the jump in difficulty, our completeness proof follows a similar strategy as the one for GKAT modulo bisimilarity [53].

Our main contributions are as follows.

- We provide an operational semantics of ProbGKAT programs, which relies on a type of automata that have both Boolean guarded and probabilistic transitions (Section 3).
- We concretely characterise bisimulations for our automata using an adaption of the flow network characterisation of bisimilarity of Markov chains [30, 8] (Section 4).
- We give a sound and complete Salomaa-style axiomatisation of bisimulation equivalence of ProbGKAT expressions (Sections 5 and 6).

\end{array}
$$

Figure 2 Syntax of ProbGKAT.

- We show that, when the number of tests is fixed, bisimilarity of ProbGKAT expressions can be efficiently decided in $\mathcal{O}(n^3 \log n)$ time, where n is the total size of programs under comparison, by using *coalgebraic partition refinement* [17, 67] (Section 7).

In Section 2 we define the syntax of ProbGKAT. We survey related work in Section 8; conclusions and further work appear in Section 9. Proofs appear in the full version [51].

2 Syntax

ProbGKAT has a two-sorted syntax consisting of a set of *expressions* $\mathtt{Exp}$ that contains a set $\mathtt{BExp}$ of *Boolean assertions* or *tests*. For a fixed finite set T of *primitive tests*, the syntax for tests is denoted $\mathtt{BExp}$ and generated by the grammar

$$\mathsf{b}, \mathsf{c} \in \mathtt{BExp} ::= 0 \mid 1 \mid t \in \mathsf{T} \mid \mathsf{b} + \mathsf{c} \mid \mathsf{bc} \mid \bar{\mathsf{b}}$$

Here, 0 and 1 respectively denote false and true, $\bar{\cdot}$ denotes negation, $+$ is disjunction, and juxtaposition is conjunction. Let $\equiv_{\mathsf{BA}}$ denote Boolean equivalence in $\mathtt{BExp}$. Entailment is a preorder on $\mathtt{BExp}$ given by $\mathsf{b} \leq_{\mathsf{BA}} \mathsf{c} \iff \mathsf{b}+\mathsf{c} \equiv_{\mathsf{BA}} \mathsf{c}$. The quotient of $\mathtt{BExp}$ by $\equiv_{\mathsf{BA}}$ is the free Boolean algebra on the set of generators T, in which entailment – $[\mathsf{b}]_{\equiv_{\mathsf{BA}}} \leq [\mathsf{c}]_{\equiv_{\mathsf{BA}}} \iff \mathsf{b} \leq_{\mathsf{BA}} \mathsf{c}$ – is a partial order, with bottom and top elements being the equivalence classes of 0 and 1 respectively. The minimal non-zero elements of that partial order are called *atoms*, and we will use At to denote the set of atoms. For fixed sets Act of *atomic actions* and Out of *return values*, the set $\mathtt{Exp}$ of ProbGKAT expressions is defined by the grammar in Figure 2.

The syntax of GKAT is captured by the first five cases in Figure 2, and so is a proper fragment of ProbGKAT. There are three new constructs: *return values*, *probabilistic choices*, and *probabilistic loops*. Return values behave like return statements in imperative programs, introducing a form of non-local control flow. The probabilistic choice $\mathsf{e} \oplus_r \mathsf{f}$ flips a biased coin with real bias $r \in [0, 1]$ and depending on the outcome runs e with probability r and f with probability $1 - r$. The probabilistic loop $\mathsf{e}^{[r]}$ also begins with a biased coin flip, and depending on the outcome it either executes e and starts again (probability r) or terminates (probability $1 - r$). A probabilistic loop can be regarded as a generalised Bernoulli processes.

▶ **Example 1.** Recall the two programs from the introduction (Figure 1): one directly implementing a 3-sided die and the other simulating a 3-sided die with a fair coin. We can express these programs using three output values, ⚀, ⚁, and ⚂, to model the possible outcomes of the three-sided die. The first program is the infinite while loop $\mathsf{f} = \mathsf{g}^{(1)}$, where

the loop body is given by $\mathsf{g} = (\boxdot \oplus_{\frac{1}{2}} \boxdot) \oplus_{\frac{1}{2}} (\boxdot \oplus_{\frac{1}{2}} 1)$. In f, $\boxdot$ represents `heads-heads`, $\boxdot$ is `heads-tails`, $\boxdot$ is `tails-heads`, and `tails-tails` prompts a rethrow. The second program encodes the ProbGKAT expression $\mathsf{e} = \boxdot \oplus_{\frac{1}{3}} (\boxdot \oplus_{\frac{1}{2}} \boxdot)$.

3 Operational semantics

In this section, we formally introduce ProbGKAT automata, the operational models of ProbGKAT expressions. We associate a ProbGKAT automaton with each expression via a small-step semantics inspired by Brzozowski derivatives [13]. As we will see, the biggest hurdle is the semantics of the probabilistic loop. Before we provide our small-step semantics, we introduce the notation and operations on probability distributions that we will need.

Preliminary definitions. A function $\nu : X \to [0, 1]$ is called a *(probability) distribution on* X if it satisfies $\sum_{x \in X} \nu(x) = 1$. In case $\sum_{x \in X} \nu(x) \leq 1$ we call ν a *subprobability distribution*, or *subdistribution*. Every (sub)distribution ν in this paper is *finitely supported*, which means that the set $\mathtt{supp}(\nu) = \{x \in X \mid \nu(x) > 0\}$ is finite. Given $A \subseteq X$, we define $\nu[A] = \sum_{x \in A} \nu(x)$. This sum is well-defined because only finitely many summands have non-zero probability.

We use $\mathcal{D}_\omega(X)$ to denote the set of finitely supported probability distributions on the set X. A function $f : X \to Y$ can be *lifted* to a map $\mathcal{D}_\omega(f) : \mathcal{D}_\omega(X) \to \mathcal{D}_\omega(Y)$ between distributions by setting $\mathcal{D}_\omega(f)(\nu) = \nu[f^{-1}(y)]$. Given $x \in X$, its *Dirac delta* is the distribution δ_x; here $\delta_x(y)$ is equal to 1 when $x = y$, and 0 otherwise. Given $f : X \to \mathcal{D}_\omega(Y)$, there is a unique map $\bar{f} \colon \mathcal{D}_\omega(X) \to \mathcal{D}_\omega(Y)$ such that $f = \bar{f} \circ \delta$, called the *convex extension of* f, and explicitly given by $\bar{f}(\nu)(y) = \sum_{x \in X} \nu(x) f(x)(y)$.

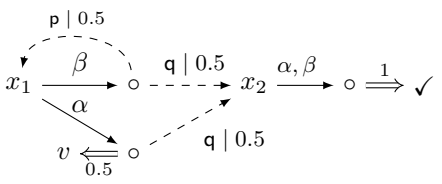
When $\nu, \mu : X \to [0, 1]$ are probability distributions and $r \in [0, 1]$, we write $r\nu + (1 - r)\mu$ for the *convex combination* of ν and μ, which is the probability distribution given by $(r\nu + (1 - r)\mu)(x) = r\nu(x) + (1 - r)\mu(x)$; this operation preserves finite support.

Operational model. Operationally, ProbGKAT expressions denote states in a transition system called a ProbGKAT *automaton*. Below, we write $2 = \{\text{✗}, \text{✓}\}$ for a two element set of symbols denoting rejection and acceptance respectively.

▶ **Definition 2.** *A* ProbGKAT automaton *is a pair* (X, β) *consisting of set of* states X *and a* transition function $\beta : X \times \mathsf{At} \to \mathcal{D}_\omega(2 + \mathsf{Out} + \mathsf{Act} \times X)$.

A state in a ProbGKAT automaton associates each Boolean atom $\alpha \in \mathsf{At}$ (capturing the global state of the Boolean variables) with a finitely supported probability distribution over several possible outcomes. One possible outcome is *termination*, which ends execution and either signals success (✓) or failure (✗), or returns an output value ($v \in \mathsf{Out}$). The other possible outcome is *progression*, performing an action ($\mathsf{p} \in \mathsf{Act}$) and transitioning to a state.

▶ **Example 3.** Let $X = \{x_1, x_2\}$, $\mathsf{At} = \{\alpha, \beta\}$, $\mathsf{Act} = \{\mathsf{p}, \mathsf{q}\}$ and $\mathsf{Out} = \{v\}$. On the right, there is a definition of a transition function $\tau : X \times \mathsf{At} \to \mathcal{D}_\omega(2 + \mathsf{Out} + \mathsf{Act} \times X)$, while on the left there is a visual representation of (X, τ). Given a state $x \in X$ and an atom $\alpha \in \mathsf{At}$, we write $\tau(x)_\alpha$ rather than $\tau(x)(\alpha)$.



$$\tau(x_1)_\alpha = \frac{1}{2}\delta_{(\mathsf{q},x_2)} + \frac{1}{2}\delta_v$$

$$\tau(x_1)_\beta = \frac{1}{2}\delta_{(\mathsf{p},x_1)} + \frac{1}{2}\delta_{(\mathsf{q},x_2)}$$

$$\tau(x_2)_\alpha = \tau(x_2)_\beta = \delta_\text{✓}$$

We use solid lines annotated with (sets of) atoms to denote Boolean guarded branching, dashed lines annotated with atomic actions and probabilities to denote probabilistic labelled transitions to a next state, and double bar arrows pointing at elements of $2 + \mathsf{Out}$ annotated with probabilities to denote probabilistic transitions that result in termination or output.

The following notions of homomorphism and bisimulation describe structure-preserving maps and relations between ProbGKAT automata.

▶ **Definition 4.** *A* homomorphism *between* ProbGKAT *automata* (X, β) *and* (Y, γ) *is a function* $f : X \to Y$ *satisfying for all* $x \in X$ *and* $\alpha \in \mathsf{At}$

1. *For any* $o \in 2 + \mathsf{Out}$, $\gamma(f(x))_\alpha(o) = \beta(x)_\alpha(o)$
2. *For any* $(\mathsf{p}, y) \in \mathsf{Act} \times Y$, $\gamma(f(x))_\alpha(\mathsf{p}, y) = \beta(x)_\alpha[\{\mathsf{p}\} \times f^{-1}(y)]$

▶ **Definition 5.** *Let* (X, β) *and* (Y, γ) *be* ProbGKAT *automata and let* $R \subseteq X \times Y$ *be a relation.* R *is a* bisimulation *if there exists a transition function* $\rho : R \times \mathsf{At} \to \mathcal{D}_\omega(2 + \mathsf{Out} + \mathsf{Act} \times R)$ *such that projection maps* $\pi_1 : R \to X$ *and* $\pi_2 : R \to Y$ *given by* $\pi_1(x, y) = x$ *and* $\pi_2(x, y) = y$ *are homomorphisms from* (R, ρ) *to* (X, β) *and* (Y, γ) *respectively.*

▶ Remark 6. Definitions 4 and 5 are direct translations from the coalgebraic theory of ProbGKAT automata [51, Appendix A]. Coalgebra plays a central role in our proofs, but for purposes of exposition it does not appear in the body of the present paper.

Brzozowski construction. ProbGKAT expressions can be endowed with an operational semantics in the form of a ProbGKAT automaton $\partial : \mathtt{Exp} \times \mathsf{At} \to \mathcal{D}_\omega(2 + \mathsf{Out} + \mathsf{Act} \times \mathtt{Exp})$, which we refer to as the *Brzozowski derivative*, as it is reminiscent of the analogous construction for regular expressions and deterministic finite automata due to Brzozowski [13].

Given $\alpha \in \mathsf{At}$, $\mathsf{e}, \mathsf{f} \in \mathtt{Exp}$, $\mathsf{b} \in \mathtt{BExp}$, $v \in \mathsf{Out}$, $r \in [0, 1]$, and $\mathsf{p} \in \mathsf{Act}$, we define

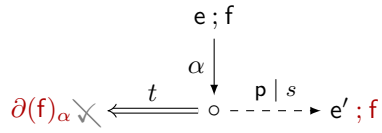
$$\partial(\mathsf{b})_\alpha = \begin{cases} \delta_\checkmark & \alpha \leq_{\mathsf{BA}} \mathsf{b} \\ \delta_\times & \alpha \leq_{\mathsf{BA}} \overline{\mathsf{b}} \end{cases} \qquad \partial(\mathsf{e} +_\mathsf{b} \mathsf{f})_\alpha = \begin{cases} \partial(\mathsf{e})_\alpha & \alpha \leq_{\mathsf{BA}} \mathsf{b} \\ \partial(\mathsf{f})_\alpha & \alpha \leq_{\mathsf{BA}} \overline{\mathsf{b}} \end{cases}$$

$$\partial(v)_\alpha = \delta_v \qquad \partial(\mathsf{p})_\alpha = \delta_{(\mathsf{p},1)} \qquad \partial(\mathsf{e} \oplus_r \mathsf{f})_\alpha = r\partial(\mathsf{e})_\alpha + (1 - r)\partial(\mathsf{f})_\alpha$$

The derivatives of sequential composition and loops are defined below. The outgoing transitions of $\mathsf{b} \in \mathtt{BExp}$ depend on whether or not the input atom $\alpha \in \mathsf{At}$ satisfies b, either outputting ✓ (success) or ✗ (abort) with probability 1. The outgoing transitions of a guarded choice $\mathsf{e} +_\mathsf{b} \mathsf{f}$ consist of the outgoing transitions of e labelled by atoms satisfying b and the outgoing transitions of f labelled by atoms satisfying $\overline{\mathsf{b}}$ (as in GKAT). The output value $v \in \mathsf{Out}$ returns the value v with probability 1 given any input atom. The atomic action $\mathsf{p} \in \mathsf{Act}$ emits p given any input atom and transitions to the expression 1. The outgoing transitions of the probabilistic choice $\mathsf{e} \oplus_r \mathsf{f}$ consist of the outgoing transitions of e with probabilities scaled by r and the outgoing transitions of f scaled by $1 - r$.

The behaviour of the sequential composition $\mathsf{e}\,;\mathsf{f}$ is more complicated. We need to factor in the possibility that e may accept with some probability t given an input atom α, in which case the α-labelled outgoing transitions of f contribute to the outgoing transitions of $\mathsf{e}\,;\mathsf{f}$. Formally, we write $\partial(\mathsf{e}\,;\mathsf{f})_\alpha = \partial(\mathsf{e})_\alpha \lhd_\alpha \mathsf{f}$, where given $\alpha \in \mathsf{At}$ and $\mathsf{f} \in \mathtt{Exp}$ we define $(- \lhd_\alpha \mathsf{f}) : \mathcal{D}_\omega(2 + \mathsf{Out} + \mathsf{Act} \times \mathtt{Exp}) \to \mathcal{D}_\omega(2 + \mathsf{Out} + \mathsf{Act} \times \mathtt{Exp})$ to be the convex extension of $c_{\alpha,\mathsf{f}} : 2 + \mathsf{Out} + \mathsf{Act} \times \mathtt{Exp} \to \mathcal{D}_\omega(2 + \mathsf{Out} + \mathsf{Act} \times \mathtt{Exp})$ given below on the left.

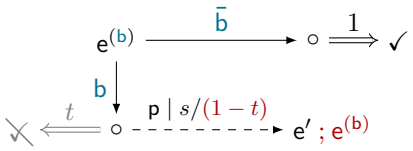
$$c_{\alpha,\mathsf{f}}(x) = \begin{cases} \delta_x & x \in \{\checkmark\} \cup \mathsf{Out} \\ \partial(\mathsf{f})_\alpha & x = \checkmark \\ \delta_{(\mathsf{p},\mathsf{e}';\mathsf{f})} & x = (\mathsf{p},\mathsf{e}') \end{cases}$$



Intuitively, $c_{\alpha,\mathsf{f}}$ reroutes the transitions coming out of e: acceptance (the second case) is replaced by the behaviour of f, and the probability mass of transitioning to e' (the third case) is reassigned to $\mathsf{e}\,;\mathsf{f}$. The branches that output the elements of $\{\checkmark\} + \mathsf{Out}$ are unchanged by this operation. A pictorial representation of the effect on the derivatives of $\mathsf{e}\,;\mathsf{f}$ is given above on the right. Here, we assume that $\partial(\mathsf{e})_\alpha$ can perform a p-transition to e' with probability s; we make the same assumption in the informal descriptions of derivatives for loops, below.

For guarded loops, we consider three cases when defining $\partial\left(\mathsf{e}^{(\mathsf{b})}\right)_\alpha$. If $\alpha \leq_{\mathsf{BA}} \bar{\mathsf{b}}$, then the current state does not satisfy the loop guard and can be skipped: $\partial\left(\mathsf{e}^{(\mathsf{b})}\right)_\alpha = \delta_\checkmark$. If $\alpha \leq_{\mathsf{BA}} \mathsf{b}$ and $\partial(\mathsf{e})_\alpha(\checkmark) = 1$, then the loop body is called, but the inner program e does not perform actions. We identify divergent loops with rejection and so in this case we set $\partial\left(\mathsf{e}^{(\mathsf{b})}\right)_\alpha = \delta_\checkmark$. If $\alpha \leq_{\mathsf{BA}} \mathsf{b}$ and $\partial(\mathsf{e})_\alpha(\checkmark) < 1$, the program executes the loop body and starts again, having to redistribute the probability mass of immediate acceptance $\partial(\mathsf{e})_\alpha(\checkmark)$ through each execution. So, for $\alpha \leq_{\mathsf{BA}} \mathsf{b}$ and $\partial(\mathsf{e})_\alpha(\checkmark) < 1$, the definition of $\partial(\mathsf{e}^{(\mathsf{b})})_\alpha$ is given below on the left: it rejects or returns when e does, and transitions to $\mathsf{e}'\,;\mathsf{e}^{(\mathsf{b})}$ when e transitions to e'.

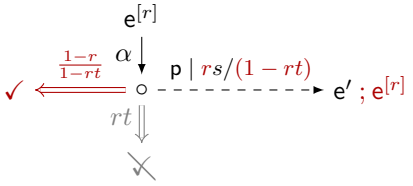
$$\partial(\mathsf{e}^{(\mathsf{b})})_\alpha(x) = \begin{cases} \frac{\partial(\mathsf{e})_\alpha(x)}{1-\partial(\mathsf{e})_\alpha(\checkmark)} & x \in \{\checkmark\} \cup \mathsf{Out} \\ \frac{\partial(\mathsf{e})_\alpha(\mathsf{p},\mathsf{e}')}{1-\partial(\mathsf{e})_\alpha(\checkmark)} & x = \left(\mathsf{p}, \left(\mathsf{e}'\,;\mathsf{e}^{(\mathsf{b})}\right)\right) \\ 0 & \text{otherwise} \end{cases}$$



The reweighing of probabilities used in the definition of the loops comes from defining loops as least fixpoints w.r.t. to an order on distributions, similarly to Stark and Smolka [62].

Finally, we specify the behaviour of the probabilistic loop. In the special case where $\partial(\mathsf{e})_\alpha(\checkmark) = 1$ and $r = 1$, the loop will not terminate; hence we set $\partial\left(\mathsf{e}^{[r]}\right)_\alpha = \delta_\checkmark$. In all other cases, we look at $\partial(\mathsf{e})_\alpha$ to build $\partial(\mathsf{e}^{[r]})_\alpha$ for each $\alpha \in \mathsf{At}$. First, we make sure that the loop may be skipped with probability $1 - r$. Next, we account for the possibility that e may reject or return a value, and we modify the productive branches by adding $\mathsf{e}^{[r]}$ to be executed next, as was done for the guarded loop. The remaining mass is $r\partial(e)_\alpha(\checkmark)$, the probability that we will enter the loop with an atom that can skip over the loop body. As was the case for the guarded loop, we discard this possibility and redistribute it among the remaining branches. The resulting definition of $\partial(\mathsf{e}^{[r]})_\alpha$ is given below on the left.

$$\partial\left(\mathsf{e}^{[r]}\right)_\alpha(x) = \begin{cases} \frac{1-r}{1-r\partial(\mathsf{e})_\alpha(\checkmark)} & x = \checkmark \\ \frac{r\partial(\mathsf{e})_\alpha(x)}{1-r\partial(\mathsf{e})_\alpha(\checkmark)} & x \in \{\checkmark\} \cup \mathsf{Out} \\ \frac{r\partial(\mathsf{e})_\alpha(\mathsf{p},\mathsf{e}')}{1-r\partial(\mathsf{e})_\alpha(\checkmark)} & x = \left(\mathsf{p}, \left(\mathsf{e}'\,;\mathsf{e}^{[r]}\right)\right) \\ 0 & \text{otherwise} \end{cases}$$



As before, we provide an informal visual depiction of the probabilistic loop semantics above on the right, using the same conventions.

Reachable states. For any ProbGKAT automaton (X, β) and any $x \in X$, we denote by $\langle x \rangle_\beta$ the set of states reachable from x via β. Clearly, $(\langle x \rangle_\beta, \beta)$ is a ProbGKAT automaton and is the smallest subautomaton of (X, β) containing x. The canonical inclusion map

$(\langle x\rangle_\beta, \beta) \to (X, \beta)$ is a ProbGKAT automaton homomorphism. In particular, $(\langle \mathsf{e}\rangle_\partial, \partial)$ is the smallest subautomaton of $(\mathtt{Exp}, \partial)$ containing e. We will refer to this subautomaton as the small-step semantics of e. We will often abuse notation and write $\langle \mathsf{e}\rangle_\partial$ for $(\langle \mathsf{e}\rangle_\partial, \partial)$.

The following lemma says that every ProbGKAT expression generates a finite automaton.

▶ **Lemma 7.** *For all* $\mathsf{e} \in \mathtt{Exp}$, $\langle \mathsf{e}\rangle_\partial$ *is finite. In fact, the number of states is bounded above by* $\#(\mathsf{e}) : \mathtt{Exp} \to \mathbb{N}$, *where* $\#(-)$ *is defined recursively by*

$$\#(\mathsf{b}) = 1 \quad \#(v) = 1 \quad \#(\mathsf{p}) = 2 \quad \#(\mathsf{e} +_\mathsf{b} \mathsf{f}) = \#(\mathsf{e}) + \#(\mathsf{f}) \quad \#(\mathsf{e} \oplus_r \mathsf{f}) = \#(\mathsf{e}) + \#(\mathsf{f})$$

$$\#(\mathsf{e}\,;\mathsf{f}) = \#(\mathsf{e}) + \#(\mathsf{f}) \quad \#\left(\mathsf{e}^{(\mathsf{b})}\right) = \#(\mathsf{e}) \quad \#\left(\mathsf{e}^{[r]}\right) = \#(\mathsf{e})$$

4 Bisimulations and their properties

Verifying that a given relation is a bisimulation (Definition 5) requires that we construct a suitable transition structure on the relation. In this section, we give necessary and sufficient conditions for the existence of such a transition structure. We also study properties of the bisimilarity relation $\sim$, the largest bisimulation [50].

Concrete characterisation of bisimulation equivalence. There is a beautiful characterisation of bisimulations between Markov chains in [30], whose proof makes use of the max-flow min-cut theorem. Adapting this work to ProbGKAT automata produces a useful characterisation of *bisimulation equivalences*, bisimulations that are also equivalence relations.

▶ **Lemma 8.** *Let* (X, β) *be a* ProbGKAT *automaton and let* $R \subseteq X \times X$ *be an equivalence relation.* R *is a bisimulation if and only if and only if for all* $(x, y) \in R$ *and* $\alpha \in \mathsf{At}$,

1. *for all* $o \in 2 + \mathsf{Out}$, $\beta(x)_\alpha(o) = \beta(y)_\alpha(o)$, *and*
2. *for all equivalence classes* $Q \in X/R$ *and all* $\mathsf{p} \in \mathsf{Act}$, $\beta(x)_\alpha[\{p\} \times Q] = \beta(y)_\alpha[\{p\} \times Q]$

This lemma can be seen as an extension of Larsen-Skou bisimilarity [40] to systems with outputs. Intuitively, R is a bisimulation equivalence if for any atom $\alpha \in \mathsf{At}$ and $(x, y) \in R$, the transitions assign the same probabilities to any output, and the probability of transitioning into any given equivalence class after emitting p is the same for both x and y.

Bisimilarity and its properties. Given a relation $R \subseteq X \times Y$, define $R^{-1} = \{(y, x) \mid x\ R\ y\}$, and given $A \subseteq X$, write $R(A) = \{y \in Y \mid x\ R\ y, x \in A\}$. The bisimilarity relation $\sim_{\beta,\gamma} \subseteq X \times Y$ between (X, β) and (Y, γ) is the *greatest fixpoint* of the following operator.

▶ **Definition 9.** *Let* (X, β) *and* (Y, γ) *be* ProbGKAT *automata and let* $R \subseteq X \times Y$. *We define the operator* $\Phi_{\beta,\gamma} : 2^{X\times Y} \to 2^{X\times Y}$ *so that* $(x, y) \in \Phi_{\beta,\gamma}(R)$ *if for any given* $\alpha \in \mathsf{At}$,

- *for all* $o \in 2 + \mathsf{Out}$, $\beta(x)_\alpha(o) = \gamma(y)_\alpha(o)$,
- *for all* $A \subseteq X$ *and all* $\mathsf{p} \in \mathsf{Act}$, $\beta(x)_\alpha[\{\mathsf{p}\} \times A] \leq \gamma(y)_\alpha[\{\mathsf{p}\} \times R(A)]$, *and*
- *for all* $B \subseteq Y$ *and* $\mathsf{p} \in \mathsf{Act}$, $\gamma(y)_\alpha[\{\mathsf{p}\} \times B] \leq \beta(x)_\alpha[\{\mathsf{p}\} \times R^{-1}(B)]$.

From now on, we will omit the subscripts from Φ *when the automata are clear from context.*

The operator $\Phi_{\beta,\gamma}$ can also be used to define a behavioural pseudometric. Let (X, β) be a ProbGKAT automaton. A *relation refinement chain* is an indexed family $\{\sim^{(i)}\}_{i\in\mathbb{N}}$ of relations on X defined as: $\sim^{(0)} = X \times X$, $\sim^{(i+1)} = \Phi(\sim^{(i)})$. We can intuitively think of successive elements of this chain as closer approximations of bisimilarity (see also [26]).

▶ **Theorem 10.** *Let* (X, β) *be a* ProbGKAT *automaton. For any* $x, y \in X$, $x \sim y$ *if and only if for all* $i \in \mathbb{N}$, *we have* $x \sim^{(i)} y$.

Table 1 Axiomatisation of ProbGKAT. In the figure $\mathsf{e}, \mathsf{f}, \mathsf{g} \in \mathtt{Exp}$, $\mathsf{b}, \mathsf{c} \in \mathtt{BExp}$, $v \in \mathsf{Out}$, $\mathsf{p} \in \mathsf{Act}$ and $r, s \in [0,1]$. Laws involving division of probabilities apply when the denominator is not zero. To simplify the notation, we write $\mathsf{E}(\mathsf{e}) = 0$ to denote that for all $\alpha \in \mathsf{At}$ it holds that $\mathsf{E}(\mathsf{e})_\alpha = 0$.

Guarded Choice Axioms

(G1) $\mathsf{e} +_\mathsf{b} \mathsf{e} \equiv \mathsf{e}$

(G2) $\mathsf{e} +_\mathsf{b} \mathsf{f} \equiv \mathsf{b} ; \mathsf{e} +_\mathsf{b} \mathsf{f}$

(G3) $\mathsf{e} +_\mathsf{b} \mathsf{f} \equiv \mathsf{f} +_{\bar{\mathsf{b}}} \mathsf{e}$

(G4) $(\mathsf{e} +_\mathsf{b} \mathsf{f}) +_\mathsf{c} \mathsf{g} \equiv \mathsf{e} +_{\mathsf{bc}} (\mathsf{f} +_\mathsf{c} \mathsf{g})$

Distributivity Axiom

(D) $\mathsf{e} \oplus_r (\mathsf{f} +_\mathsf{b} \mathsf{g}) \equiv (\mathsf{e} \oplus_r \mathsf{f}) +_\mathsf{b} (\mathsf{e} \oplus_r \mathsf{g})$

Sequencing Axioms

(S1) $1 ; \mathsf{e} \equiv \mathsf{e}$

(S2) $\mathsf{e} ; 1 \equiv \mathsf{e}$

(S3) $(\mathsf{e} ; \mathsf{f}) ; \mathsf{g} \equiv \mathsf{e} ; (\mathsf{f} ; \mathsf{g})$

(S4) $0 ; \mathsf{e} \equiv 0$

(S5) $(\mathsf{e} +_\mathsf{b} \mathsf{f}) ; \mathsf{g} \equiv \mathsf{e} ; \mathsf{g} +_\mathsf{b} \mathsf{f} ; \mathsf{g}$

(S6) $(\mathsf{e} \oplus_r \mathsf{f}) ; \mathsf{g} \equiv \mathsf{e} ; \mathsf{g} \oplus_r \mathsf{f} ; \mathsf{g}$

(S7) $v ; \mathsf{e} \equiv v$

(S8) $\mathsf{b} ; \mathsf{c} \equiv \mathsf{bc}$

Loop Axioms

(L1) $\mathsf{e}^{(\mathsf{b})} \equiv \mathsf{e} ; \mathsf{e}^{(\mathsf{b})} +_\mathsf{b} 1$

(L2) $\mathsf{e}^{[r]} \equiv \mathsf{e} ; \mathsf{e}^{[r]} \oplus_r 1$

(L3) $(\mathsf{e} +_\mathsf{c} 1)^{(\mathsf{b})} \equiv (\mathsf{c} ; \mathsf{e})^{(\mathsf{b})}$

(L4) $\mathsf{e}^{(1)} \equiv \mathsf{e}^{[1]}$

(L5) $$\frac{\mathsf{e} \equiv (\mathsf{f} \oplus_s 1) +_\mathsf{c} \mathsf{g} \qquad s > 0}{\mathsf{c} ; \mathsf{e}^{(\mathsf{b})} \equiv \mathsf{c} ; \left(\mathsf{f} ; \mathsf{e}^{(\mathsf{b})} +_\mathsf{b} 1\right)}$$

(L6) $$\frac{\mathsf{e} \equiv (\mathsf{f} \oplus_s 1) +_\mathsf{c} \mathsf{g}}{\mathsf{c} ; \mathsf{e}^{[r]} \equiv \mathsf{c} ; \left(\mathsf{f} ; \mathsf{e}^{[r]} \oplus_{\frac{rs}{1-r(1-s)}} 1\right)}$$

Probabilistic Choice Axioms

(P1) $\mathsf{e} \oplus_r \mathsf{e} \equiv \mathsf{e}$

(P2) $\mathsf{e} \oplus_1 \mathsf{f} \equiv \mathsf{e}$

(P3) $\mathsf{e} \oplus_r \mathsf{f} \equiv \mathsf{f} \oplus_{1-r} \mathsf{e}$

(P4) $(\mathsf{e} \oplus_r \mathsf{f}) \oplus_s \mathsf{g} \equiv \mathsf{e} \oplus_{rs} (\mathsf{f} \oplus_{\frac{(1-r)s}{1-rs}} \mathsf{g})$

Fixpoint Rules

(F1) $$\frac{\mathsf{g} \equiv \mathsf{e} ; \mathsf{g} +_\mathsf{b} \mathsf{f} \qquad \mathsf{E}(\mathsf{e}) = 0}{\mathsf{g} \equiv \mathsf{e}^{(\mathsf{b})} ; \mathsf{f}}$$

(F2) $$\frac{\mathsf{g} \equiv \mathsf{e} ; \mathsf{g} \oplus_r \mathsf{f} \qquad \mathsf{E}(\mathsf{e}) = 0}{\mathsf{g} \equiv \mathsf{e}^{[r]} ; \mathsf{f}}$$

Define $\mathsf{E} : \mathtt{Exp} \to \mathsf{At} \to [0,1]$ inductively by

$$\mathsf{E}(\mathsf{p})_\alpha = \mathsf{E}(v)_\alpha = 0$$

$$\mathsf{E}(\mathsf{b})_\alpha = \begin{cases} 1 & \alpha \leq_{\mathsf{BA}} \mathsf{b} \\ 0 & \alpha \leq_{\mathsf{BA}} \bar{\mathsf{b}} \end{cases}$$

$$\mathsf{E}(\mathsf{e} +_\mathsf{b} \mathsf{f})_\alpha = \begin{cases} \mathsf{E}(\mathsf{e})_\alpha & \alpha \leq_{\mathsf{BA}} \mathsf{b} \\ \mathsf{E}(\mathsf{f})_\alpha & \alpha \leq_{\mathsf{BA}} \bar{\mathsf{b}} \end{cases}$$

$$\mathsf{E}(\mathsf{e} \oplus_r \mathsf{f})_\alpha = r\mathsf{E}(\mathsf{e})_\alpha + (1-r)\mathsf{E}(\mathsf{f})_\alpha$$

$$\mathsf{E}(\mathsf{e} ; \mathsf{f})_\alpha = \mathsf{E}(\mathsf{e})_\alpha \, \mathsf{E}(\mathsf{f})_\alpha$$

$$\mathsf{E}\left(\mathsf{e}^{(\mathsf{b})}\right)_\alpha = \mathsf{E}\left(\bar{\mathsf{b}}\right)_\alpha$$

$$\mathsf{E}\left(\mathsf{e}^{[r]}\right)_\alpha = \begin{cases} 0 & r = 1 \text{ and } \mathsf{E}(\mathsf{e})_\alpha = 1 \\ \frac{1-r}{1-r\mathsf{E}(\mathsf{e})_\alpha} & \text{otherwise} \end{cases}$$

Thus, if $x, y \in X$ are not bisimilar, then there exists a maximal $i \in \mathbb{N}$ such that $x \sim^{(i)} y$. In Section 6, we use this to define a pseudometric on the states of any ProbGKAT automaton. Informally speaking, this allows us to quantify *how close* to being bisimilar two states are.

Our main goal is to axiomatise bisimilarity of ProbGKAT expressions with a set of equational laws and reason about equivalence using *equational logic*. For such an axiomatisation to exist, bisimilarity needs to be both an equivalence relation and a congruence with respect to the ProbGKAT operations. The greatest bisimulation on any ProbGKAT automaton is an equivalence [50], but being congruence requires an inductive argument.

▶ **Theorem 11.** *The greatest bisimulation on* $(\mathtt{Exp}, \partial)$ *is a congruence with respect to* ProbGKAT *operations.*

5 Axiomatisation

We turn our attention to *axiomatisation* of bisimilarity of ProbGKAT expressions, using an axiom system based on GKAT modulo bisimilarity [53]. First, we give an overview of the axioms, and establish their soundness. Finally, we show that our axioms are strong enough to decompose every expression into a certain syntactic normal form relating the expressions to their small-step semantics. Completeness is tackled in the next section.

Overview of the axioms. Table 1 contains the axioms, which are either *equational* (of the form $\mathsf{e} \equiv \mathsf{f}$), or *quasi-equational* (of the form $\mathsf{e}_1 \equiv \mathsf{f}_1, \dots \mathsf{e}_n \equiv \mathsf{f}_n \implies \mathsf{e} \equiv \mathsf{f}$). It also holds the definition of the function $\mathsf{E}(-)$, which is necessary to give a side condition to the fixpoint rules. We define $\equiv \subseteq \mathtt{Exp} \times \mathtt{Exp}$ as the smallest congruence relation satisfying the axioms.

Axioms G1–G4 are inherited from GKAT and govern the behaviour of Boolean guarded choice. P1–P4 can be thought of as their analogues, but for the probabilistic choice. The distributivity axiom D states that guarded choice distributes over a probabilistic choice, which reflects the way our operational model resolves both types of branching.

The sequencing axioms S1–S8 are mostly inherited from GKAT. The new axioms include S6 which talks about right distributivity of sequencing over probabilistic choice and S7 which captures the intuitive property that any code executed after a `return` statement is not executed. L1 and L3 come from GKAT, while L2 is a probabilistic loop analogue of L1, which captures the semantics of the probabilistic loop in terms of recursive unrolling. L4 equates the `while(true)` and `while(flip(1))` loops. F1 and F2 are inspired by Salomaa's axioms [52] and provide a partial converse to L1 and L2 respectively, given the loop body cannot immediately terminate. The property that a loop body has a zero probability of outputting ✓ is formally writen using the side condition $\mathsf{E}(\mathsf{e}) = 0$, which can be thought of as *empty word property* from Salomaa's axiomatisation [52].

This leaves us with L5 and L6, which describe the behaviour of guarded and probabilistic loops where parts of the loop body may be skipped. These are quasi-equational, but can be replaced by equivalent equations – see [51, Remark 49]. L5 concerns a loop on an expression e that has probability $1 - s$ of not performing any action, given that c holds. The rule says that, if we start the loop on e given that c holds, then either b holds and we execute f, or it does not, and the loop is skipped. The reason that we can disregard the 1 part of e is that if this branch is taken, then c still holds on the next iteration of the loop, and so the program will have to choose probabilistically between f and 1 once more. Since $s > 0$, it will eventually choose the probabilistic branch f with almost sure probability.

The second rule, L6, is the analogue of L5 for probabilistic choice. In this case, however, a choice for 1 also means another probabilistic experiment to determine whether the loop needs to be executed once more, with probability r. The consequence is that if the loop on e is started given that c holds, some more probability mass will shift towards skipping, as a result executing 1 some number of times before halting the loop.

Soundness with respect to bisimilarity. Using the characterisation from Section 4, we can show that $\equiv$ is a bisimulation equivalence on $(\mathtt{Exp}, \partial)$. The proof is available in the full version of the paper [51, Appendix D].

▶ **Lemma 12.** *$\equiv$ is a bisimulation equivalence on $(\mathtt{Exp}, \partial)$*

We immediately obtain that provable equivalence is contained in bisimilarity.

▶ **Theorem 13** (Soundness). *For all $\mathsf{e}, \mathsf{f} \in \mathtt{Exp}$, if $\mathsf{e} \equiv \mathsf{f}$ then $\mathsf{e} \sim \mathsf{f}$*

Example of equational reasoning. Since our axioms are sound, we can reason about ProbGKAT expressions equationally, without constructing bisimulations by hand. Once again, we revisit the algorithm from Figure 1. To show correctness, we need to prove the equivalence of expressions e and $\mathsf{g}^{(1)}$ from Example 1, as follows:

$$
\begin{aligned}
\mathsf{g}^{(1)} &\equiv \Big(\Big(\boxdot \oplus_{\frac{1}{2}} \boxdot\Big) \oplus_{\frac{1}{2}} \Big(\boxdot \oplus_{\frac{1}{2}} 1\Big)\Big)^{(1)} && \text{(Def. of g)}\\
&\equiv \Big(\Big(\Big(\boxdot \oplus_{\frac{1}{2}} \boxdot\Big) \oplus_{\frac{2}{3}} \boxdot\Big) \oplus_{\frac{1}{2}} 1\Big)^{(1)} && \text{(See below)}\\
&\equiv \Big(\Big(\Big(\Big(\boxdot \oplus_{\frac{1}{2}} \boxdot\Big) \oplus_{\frac{2}{3}} \boxdot\Big) \oplus_{\frac{1}{2}} 1\Big) +_1 0\Big)^{(1)} && \text{(See below)}\\
&\equiv \Big(\Big(\boxdot \oplus_{\frac{1}{2}} \boxdot\Big) \oplus_{\frac{2}{3}} \boxdot\Big)^{(1)} && \text{(Axioms L5 and S1)}\\
&\equiv \Big(\boxdot \oplus_{\frac{1}{3}} \Big(\boxdot \oplus_{\frac{1}{2}} \boxdot\Big)\Big)^{(1)} && \text{(Axiom P4)}\\
&\equiv \Big(\boxdot \oplus_{\frac{1}{3}} \Big(\boxdot \oplus_{\frac{1}{2}} \boxdot\Big)\Big) ; \Big(\boxdot \oplus_{\frac{1}{3}} \Big(\boxdot \oplus_{\frac{1}{2}} \boxdot\Big)\Big)^{(1)} +_1 1 && \text{(Axiom L1)}\\
&\equiv \Big(\boxdot \oplus_{\frac{1}{3}} \Big(\boxdot \oplus_{\frac{1}{2}} \boxdot\Big)\Big) ; \mathsf{e}^{(1)} +_1 1 && \text{(Def. e)}\\
&\equiv \Big(\boxdot \oplus_{\frac{1}{3}} \Big(\boxdot \oplus_{\frac{1}{2}} \boxdot\Big)\Big) ; \mathsf{e}^{(1)} && \text{(See below)}\\
&\equiv \Big(\boxdot ; e^{(1)} \oplus_{\frac{1}{3}} \Big(\boxdot ; e^{(1)} \oplus_{\frac{1}{2}} \boxdot ; e^{(1)}\Big)\Big) && \text{(Axiom S6)}\\
&\equiv \Big(\boxdot \oplus_{\frac{1}{3}} \Big(\boxdot \oplus_{\frac{1}{2}} \boxdot\Big)\Big) && \text{(Axiom S7)}\\
&\equiv \mathsf{e} && \text{(Def. e)}
\end{aligned}
$$

In the second step, we used that for all $\mathsf{e}_1, \mathsf{e}_2, \mathsf{e}_3 \in \mathtt{Exp}$ and $r, s \in [0,1]$ with $(1-r)(1-s) > 0$, we have $\mathsf{e}_1 \oplus_r (\mathsf{e}_2 \oplus_s \mathsf{e}_3) \equiv (\mathsf{e}_1 \oplus_k \mathsf{e}_2) \oplus_l \mathsf{e}_3$, where $k = \frac{r}{1-(1-r)(1-s)}$ and $l = 1-(1-r)(1-s)$. In the third and eighth steps, we used that for all $\mathsf{e}, \mathsf{f} \in \mathtt{Exp}$, we have that $\mathsf{e} +_1 \mathsf{f} \equiv \mathsf{e}$. Both those equivalences follow from the other axioms; see [51, Lemma 50] in the full version of the paper for details.

Fundamental theorem. Every expression in the language of KA (resp. KAT, GKAT) can be reconstructed from its small-step semantics, up to $\equiv$. This property, often referred to as the *fundamental theorem* of (in analogy with the fundamental theorem of calculus and following the terminology of Rutten [50]) is useful in many contexts, and we will need it later on.

▶ **Theorem 14** (Fundamental Theorem). *For every* $\mathsf{e} \in \mathtt{Exp}$ *it holds that*

$$\mathsf{e} \equiv \bigdotplus_{\alpha \in \mathsf{At}} \left(\bigoplus_{d \in \mathtt{supp}(\partial(\mathsf{e})_\alpha)} \partial(\mathsf{e})_\alpha(d) \cdot \mathtt{exp}(d) \right)$$

where $\mathtt{exp}$ *defines a function* $2 + \mathsf{Out} + \mathsf{Act} \times \mathtt{Exp} \to \mathtt{Exp}$ *given by*

$$\mathtt{exp}(\times) = 0 \quad \mathtt{exp}(\checkmark) = 1 \quad \mathtt{exp}(v) = v \quad \mathtt{exp}(\mathsf{a}, \mathsf{f}) = \mathsf{a};\mathsf{f} \qquad (v \in \mathsf{Out}, \mathsf{a} \in \mathsf{Act} \text{ and } \mathsf{f} \in \mathtt{Exp})$$

The proof is given in the appendix. We use a generalised type of guarded and probabilistic choice ranging over indexed collections of expressions, which is defined in [51, Appendix D.2].

6 Completeness

Given the axioms presented in the previous section, a natural question is to ask whether they are *complete* w.r.t. bisimilarity – i.e., whether any bisimilar pair can be proved equivalent using the axioms that make up $\equiv$. The traditional strategy is to develop the idea of *systems of equations* within the calculus, and show that these systems have unique (least) solutions up to provable equivalence. If we can characterise the expressions of interest as solutions to a common system of equations (typically derived from the bisimulation that relates them), then uniqueness of solutions guarantees their equivalence. Unfortunately, the first step of this process, where systems of equations are shown to have unique solutions, does not transfer to ProbGKAT (nor GKAT). Indeed, some systems of equations do not have *any* solution [39, 53]; the lack of a procedure to construct solutions also encumbers a proof of uniqueness.

Instead, we follow the approach from [58] pioneered by Bergstra and Klop [10], and incorporate uniqueness of solutions into the axiomatisation. The *uniqueness axiom* (UA) that accomplishes this is an *axiom scheme*, which is to say it is a template for infinitely many axioms, one for each number of unknowns. In the case of a single unknown, one can show that F1 and F2 are special cases of UA, which moreover give a candidate solution.

With UA in hand, the traditional roadmap towards completeness works out. Before we get there, however, we must expend some energy to properly state this axiom scheme. Moreover, showing soundness of UA requires effort. Both of these take up the bulk of the development in this section; we derive the desired completeness property at the end.

(Salomaa) systems of equations. First, we define formally the idea of *systems of equations* for ProbGKAT automata. The constraints on each variable will be built using the following two-sorted grammar, where X is a finite set of indeterminates.

$$e_1, e_2 \in \mathtt{Exp}(X) ::= p \mid e_1 +_{\mathsf{b}} e_2 \qquad (p \in \mathtt{PExp}(X), \mathsf{b} \in \mathtt{BExp})$$
$$p_1, p_2 \in \mathtt{PExp}(X) ::= \mathsf{f} \mid \mathsf{g}x \mid p_1 \oplus_r p_2 \qquad (\mathsf{f}, \mathsf{g} \in \mathtt{Exp}, x \in X, r \in [0,1])$$

▶ **Definition 15.** *A* system of equations *is a pair* $(X, \tau : X \to \mathtt{Exp}(X))$ *consisting of a finite set* X *of indeterminates and a function* $\tau : X \to \mathtt{Exp}(X)$*. If for all* $x \in X$*, in each of* $\tau(x)$ *all subterms of the form* $\mathsf{g}x$ *satisfy* $\mathsf{E}(\mathsf{g}) = 0$*, then such system is called* Salomaa.[1]

Every finite state ProbGKAT automaton yields a Salomaa system of equations.

▶ **Definition 16.** *Let* (X, β) *be a finite state* ProbGKAT *automaton. A system of equations associated with* (X, β) *is a Salomaa system* (X, τ)*, with* $\tau : X \to \mathtt{Exp}(X)$ *defined by*

$$\tau(x) = \sum_{\alpha \in \mathsf{At}} \left(\bigoplus_{d \in \mathtt{supp}(\beta(x))_\alpha} \beta(x)_\alpha(d) \cdot \mathtt{sys}(d) \right)$$

where $\mathtt{sys} : 2 + \mathsf{Out} + \mathsf{Act} \times \mathtt{Exp} \to \mathtt{PExp}(X)$ *is given by*

$$\mathtt{sys}(\text{✗}) = 0 \quad \mathtt{sys}(\text{✓}) = 1 \quad \mathtt{sys}(v) = v \quad \mathtt{sys}(\mathsf{a}, x) = \mathsf{a}x$$

[1] In process algebra [46], Salomaa systems are usually called *guarded*. We avoid the latter name to prevent confusion with Boolean guarded choice present in (Prob)GKAT.

▶ **Example 17.** In the system associated with the automaton from Example 3, τ is given by

$$x_1 \mapsto (\mathsf{q}x_2 \oplus_{\frac{1}{2}} v) +_\alpha \Big((\mathsf{p}x_1 \oplus_{\frac{1}{2}} \mathsf{q}x_2) +_\beta 0\Big) \qquad x_2 \mapsto 1 +_\alpha (1 +_\beta 0)$$

Given a function $h : X \to \mathtt{Exp}$ that assigns a value to each indeterminate in X, we can derive a ProbGKAT expression $h^\#(e)$ for each $e \in \mathtt{Exp}(X)$ inductively, as follows: $h^\#(\mathsf{f}) = \mathsf{f}$, $h^\#(p_1 \oplus_r p_2) = h^\#(p_1) \oplus_r h^\#(p_2)$, $h^\#(\mathsf{g}x) = \mathsf{g}\,;h(x)$, $h^\#(e_1 +_\mathsf{b} e_2) = h^\#(e_1) +_\mathsf{b} h^\#(e_2)$. We can now state the notion of a *solution* to the Salomaa system. Rather than expecting both sides of equations to be strictly equal, we require them to be related by a relation, which we leave as a parameter to instantiate later.

▶ **Definition 18.** *Let $R \subseteq \mathtt{Exp} \times \mathtt{Exp}$. A* solution *up to R to a system (X, τ) is a map $h : X \to \mathtt{Exp}$ satisfying for all $x \in X$ that $\big(h(x), h^\#(\tau(x))\big) \in R$.*

▶ **Example 19.** A solution up to $\equiv$ to the system from Example 17 would satisfy

$$h(x_1) \equiv (\mathsf{q}\,;h(x_2) \oplus_{\frac{1}{2}} v) +_\alpha \Big((\mathsf{p}\,;h(x_1) \oplus_{\frac{1}{2}} \mathsf{q}\,;h(x_2)) +_\beta 0\Big) \qquad h(x_2) \equiv 1 +_\alpha (1 +_\beta 0)$$

In this case, choosing $h(x_1) = (\mathsf{p} +_\beta v)^{[\frac{1}{2}]}\,;\mathsf{q}$ and $h(x_2) = 1$ fits these constraints.

▶ **Example 20.** Let $\mathsf{r} \in [0, 1]$. The recursive specification on the left below describes a program $\mathsf{randAdd}(\mathsf{m}, \mathsf{r})$ which takes an integer m and bias r. As long as m is strictly below 10, this program flips an r-biased coin to decide between incrementing m followed by a recursive call or termination. That recursive specification can be thought of as a Salomaa system with one unknown; the program on the right is a solution up to $\equiv$.

```
def randAdd(m, r):
    if m < 10 then
        if flip(r) then
            m++;
            randAdd(m, r)
        else
            skip
    else
        skip
```

```
while flip(r) do
    if m < 10 then
        m++;
        randAdd(m, r)
    else
        skip
```

Solutions up to $\equiv$ can be characterised concretely, using Theorem 14.

▶ **Theorem 21.** *Let (X, β) be a finite state* ProbGKAT *automaton. The map $h : X \to \mathtt{Exp}$ is a solution up to $\equiv$ to the system associated with (X, β) if and only if $[-]_\equiv \circ h$ is a* ProbGKAT *automata homomorphism from (X, β) to $(\mathtt{Exp}/{\equiv}, \bar{\partial})$. We write $\bar{\partial}$ to denote the unique transition function on $\mathtt{Exp}/{\equiv}$ which makes the quotient map $[-]_\equiv : \mathtt{Exp} \to \mathtt{Exp}/{\equiv}$ a* ProbGKAT *automaton homomorphism from $(\mathtt{Exp}, \partial)$ [50, Proposition 5.8].*

Uniqueness of Solutions axiom. Informally, UA extends $\equiv$ by stating that solutions to Salomaa systems, if they exist, are unique. Formally, we define $\doteq \subseteq \mathtt{Exp} \times \mathtt{Exp}$ to be the least congruence that contains $\equiv$, and satisfies the following (quasi-equational) axiom:

$$\frac{(X, \tau) \text{ is a Salomaa system} \quad f, g : X \to \mathtt{Exp} \text{ are solutions of } (X, \tau) \text{ up to } \doteq}{f(x) \doteq g(x) \text{ for all } x \in X} \tag{UA}$$

F1 and F2 are instantiations of UA for Salomaa systems with one variable.

Behavioural pseudometric. We now develop the theory necessary to verify soundness of UA. First, note that for every ProbGKAT, we can define a function $d_X : X \times X \to \mathbb{R}^+$:

$$d_X(x,y) = \begin{cases} 2^{-n} & n \text{ is maximal such that } x \sim^{(n)} y \\ 0 & \text{if } x \sim y \end{cases}$$

The above is well-defined by Theorem 10, and is a *pseudometric*, in the following sense.

▶ **Definition 22.** *A* pseudometric space *is a pair* (X, d_X)*, where* $d_X : X \times X \to \mathbb{R}^+$ *is a* pseudometric*, which means that for all* $x, y, z \in X$ *we have*

$$d_X(x,x) = 0 \qquad d_X(x,y) = d_X(y,x) \qquad d_X(x,z) \leq d_X(x,y) + d_X(y,z)$$

Let $k \in \mathbb{R}^+$*. A mapping* $f : X \to Y$ *between pseudometric spaces* (X, d_X) *and* (Y, d_Y) *is called* k-Lipschitz *if for all* $x, y \in X$ $d_Y(f(x), f(y)) \leq k d_X(x,y)$*.*

The behavioural pseudometric satisfies the definition above, in a strong sense.

▶ **Lemma 23.** *For every* ProbGKAT *automaton,* (X, β)*,* (X, d_X) *a pseudometric space that is* ultra*, in the sense that for all* $x, y, z \in X$ *we have* $d_X(x,z) = \max\{d_X(x,y), d_X(y,z)\}$*.*

Let (X, d_X) and (Y, d_Y) be pseudometric spaces. Their *product* is a pseudometric space $(X \times Y, d_{X\times Y})$ where $d_{X\times Y}$ is defined by $d_{X\times Y}((x,y),(x',y')) = \max\{d_X(x,x'), d_Y(y,y')\}$. It is easy to show that if both pseudometric spaces are ultra, then so is their product. Going forward, we will omit subscripts when they are clear from context.

Soundness of the Uniqueness Axiom. Every Salomaa system $(X, \tau : X \to \mathtt{Exp}(X))$ with $X = \{x_1, x_2, \ldots, x_n\}$ induces a mapping $\bar{\tau} : \mathtt{Exp}^n \to \mathtt{Exp}^n$. Intuitively, this mapping takes a vector $\vec{\mathsf{e}} = (\mathsf{e}_1, \ldots, \mathsf{e}_n)$, and produces a new vector where the i-th component is the evaluation of $\tau(x_i)$ when each x_j is substituted by e_j. More formally, given this $\vec{\mathsf{e}}$, we define $e : X \to \mathtt{Exp}$ by $e(x_i) = \mathsf{e}_i$, and set $\bar{\tau}(\vec{\mathsf{e}}) = \big((e^\# \circ \tau)(x_1), \ldots, (e^\# \circ \tau)(x_n)\big)$.

To establish soundness of UA, we first show that $\bar{\tau}$ is $\frac{1}{2}$-Lipschitz on the pseudometric space $(\mathtt{Exp}^n, d)$, where d is the metric that arises from the n-fold product of $(\mathtt{Exp}, \partial)$.

▶ **Lemma 24.** *Given a Salomaa system* $(X, \tau : X \to \mathtt{Exp}(X))$*, the map* $\bar{\tau} : \mathtt{Exp}^n \to \mathtt{Exp}^n$ *from the pseudometric space* $(\mathtt{Exp}^n, d)$ *to itself is* $\frac{1}{2}$*-Lipschitz.*

Finally, we can prove the following.

▶ **Lemma 25.** UA *is satisfied by bisimilarity.*

Proof. Let (X, τ) is a Salomaa system, with $X = \{x_1, \ldots, x_n\}$, and let $f, g : X \to \mathtt{Exp}(X)$ be solutions up to $\doteqdot$ to the system. Finally, let $\vec{\mathsf{f}} = (f(x_1), \ldots, f(x_n))$ and $\vec{\mathsf{g}} = (g(x_1), \ldots, g(x_n))$. Assume that the premises are satisfied by the bisimilarity, $f(x_i) \sim (f^\# \circ \tau)(x_i)$ and $g(x_i) \sim (g^\# \circ \tau)(x_i)$ for all $1 \leq i \leq n$. In other words, we have that $d(\bar{\tau}(\vec{\mathsf{f}}), \vec{\mathsf{f}}) = 0$ and $d(\bar{\tau}(\vec{\mathsf{g}}), \vec{\mathsf{g}}) = 0$

Let $d(\bar{\tau}(\vec{\mathsf{f}}), \bar{\tau}(\vec{\mathsf{g}})) = k$ for some $k \in \mathbb{R}^+$. Then, since d is ultra,

$$d(\vec{\mathsf{f}}, \vec{\mathsf{g}}) = \max\{d(\vec{\mathsf{f}}, \bar{\tau}(\vec{\mathsf{f}})), d(\bar{\tau}(\vec{\mathsf{f}}), \vec{\mathsf{g}})\} = d(\bar{\tau}(\vec{\mathsf{f}}), \vec{\mathsf{g}}) = \max\{d(\bar{\tau}(\vec{\mathsf{f}}), \bar{\tau}(\vec{\mathsf{g}})), d(\bar{\tau}(\vec{\mathsf{g}}), \vec{\mathsf{g}})\} = k$$

By Lemma 24, we find $k = d(\bar{\tau}(\vec{\mathsf{f}}), \bar{\tau}(\vec{\mathsf{g}})) \leq \frac{1}{2} d(\vec{\mathsf{f}}, \vec{\mathsf{g}}) = \frac{1}{2} k$ which implies that $d(\vec{\mathsf{f}}, \vec{\mathsf{g}}) = 0$. Because of the definition of the product pseudometric on $(\mathtt{Exp}, \partial)$, we have $f(x_i) \sim g(x_i)$ for all $1 \leq i \leq n$. Therefore, the conclusion of the UA is satisfied by bisimilarity. ◀

Because of the above lemma and Theorem 13, both UA and the axioms of $\equiv$ are contained in $\sim$, the greatest bisimulation on $(\mathtt{Exp}, \partial)$. Recall that $\doteqdot$ is the least congruence containing those rules. Since $\sim$ on $(\mathtt{Exp}, \partial)$ is a congruence (Theorem 11), we have that $\doteqdot$ is sound.

▶ **Theorem 26** (Soundness with UA)**.** *For all* $\mathsf{e}, \mathsf{f} \in \mathtt{Exp}$ *if* $\mathsf{e} \doteqdot \mathsf{f}$ *then* $\mathsf{e} \sim \mathsf{f}$*.*

Completeness. After all the hard work is done, the proof of completeness follows via the same line of reasoning as the one for GKAT [58, 53].

▶ **Theorem 27** (Completeness). *For all* $\mathsf{e}, \mathsf{f} \in \mathtt{Exp}$ *if* $\mathsf{e} \sim \mathsf{f}$ *then* $\mathsf{e} \doteqdot \mathsf{f}$

Proof. Let $R \subseteq \mathtt{Exp} \times \mathtt{Exp}$ be a bisimulation with a transition structure $\rho : R \times \mathsf{At} \to \mathcal{D}_\omega(2 + \mathsf{Out} + \mathsf{Act} \times R)$ relating ProbGKAT automata $(\langle \mathsf{e} \rangle_\partial, \partial)$ and $(\langle \mathsf{f} \rangle_\partial, \partial)$ such that $(\mathsf{e}, \mathsf{f}) \in R$. Let π_1, π_2 be the projection homomorphisms from (R, ρ) to $(\langle \mathsf{e} \rangle_\partial, \partial)$ and $(\langle \mathsf{f} \rangle_\partial, \partial)$ respectively. Since both $\langle \mathsf{e} \rangle_\partial$ and $\langle \mathsf{f} \rangle_\partial$ are finite (by Lemma 7), so is R.

Let j, k be the inclusion homomorphisms of $(\langle \mathsf{e} \rangle_\partial, \partial)$ and $(\langle \mathsf{f} \rangle_\partial, \partial)$ in $(\mathtt{Exp}, \partial)$. We can construct two homomorphisms $[-]_\equiv \circ j \circ \pi_1$ and $[-]_\equiv \circ k \circ \pi_2$ from (R, ρ) to $(\mathtt{Exp}/\equiv, \bar{\partial})$. By Theorem 21, $j \circ \pi_1$ and $k \circ \pi_2$ are solutions up to $\equiv$ to the Salomaa system associated with (R, ρ). Since $\equiv$ is contained in $\doteqdot$, those are immediately also solutions up to $\doteqdot$.

Because of UA, we have that $(j \circ \pi_1)(\mathsf{g}, \mathsf{h}) \doteqdot (k \circ \pi_2)(\mathsf{g}, \mathsf{h})$ for all $(\mathsf{g}, \mathsf{h}) \in R$. Thus,

$$\mathsf{e} \doteqdot j(\mathsf{e}) \doteqdot (j \circ \pi_1)(\mathsf{e}, \mathsf{f}) \doteqdot (k \circ \pi_2)(\mathsf{e}, \mathsf{f}) \doteqdot k(\mathsf{f}) \doteqdot \mathsf{f}$$ ◀

7 Decidability and Complexity

To decide whether $\mathsf{e} \doteqdot \mathsf{f}$, we need to demonstrate the existence of a bisimulation between the states e and f in $(\mathtt{Exp}, \partial)$. Since bisimulations need only involve reachable states, it suffices to find this bisimulation within $\langle \mathsf{e}, \mathsf{f} \rangle_\partial$, the smallest subautomaton of $(\mathtt{Exp}, \partial)$ containing e and f, which is also the union of $\langle \mathsf{e} \rangle_\partial$ and $\langle \mathsf{f} \rangle_\partial$; this automaton is finite by Lemma 7. We thus focus on the problem of deciding bisimilarity within a single finite ProbGKAT automaton.

Our analysis in this section is facilitated by two simplifying assertions.

1. To avoid having to compare real (infinite-precision) probabilities, we limit ProbGKAT expressions to rational probabilities $r \in [0, 1] \cap \mathbb{Q}$ in this section. This restriction is compatible with the earlier operators on probabilities, which all preserve rationality.
2. Equivalence of GKAT proper is co-NP-hard [58], simply because Boolean unsatisfiability can trivially be encoded in the language of tests. We take a fixed-parameter approach, assuming that At, the set of atoms that can appear on transitions, is fixed beforehand.

Coalgebraic partition refinement. We rely on *partition refinement* [31, 32, 48], which effectively computes the *largest bisimulation* on an automaton, by approximating it from above. In the *coalgebraic* presentation of partition refinement [67], which we instantiate to our setting, automata of various types are encoded as abstract graphs. More specifically, an automaton is encoded in two maps $o : X \to O$ and $\ell : X \to \mathcal{B}(L \times X)$, where

- X is a set of *nodes* that represent (partial) states of the automaton;
- O is a set of *observable values* at each node;
- L is a set representing possible *labels* of edges between nodes;
- $\mathcal{B}(L \times X)$ is a multiset of pairs representing *edges* between nodes.

Subject to a number of coherence conditions on the encoding (omitted here), coalgebraic partition refinement yields an $\mathcal{O}(n \log |X|)$ algorithm to compute the largest bisimulation on an automaton, where $n = \sum_{x \in X} |\ell(x)|$ is the number of *edges* of the automaton.

Encoding ProbGKAT automata. Coalgebraic partition refinement provides suitable encodings for well-known transition types, as well as methods to soundly obtain encodings of composite transition types [67]. The details of these techniques are beyond the scope of this paper, but the underlying idea is fairly intuitive: composite transition types are encoded

by inserting synthetic nodes that represent partially evaluated states – not unlike how our drawings contain intermediate nodes that are the target of α-labelled arrows. More precisely, the nodes of an encoded ProbGKAT automaton (Q, t) are three-sorted:

1. every state of the automaton is a node; and
2. every "intermediate" state (the small circles in our drawings) is a node; and
3. every probabilistic edge gives rise to another node.

Nodes of the third kind separate the dashed arrows in our drawings (labelled with a probability as well as an action) into two arrows, each of which is labelled by one value.

Formally, we choose $X := Q + I + \mathsf{Act} \times Q$ as our set of nodes, where $I := \{t(q)_\alpha : q \in Q, \alpha \in \mathsf{At}\}$. We also set $L := \mathsf{At} + \mathbb{Q} + \mathsf{Act}$. The map $\ell : X \to \mathcal{B}(L \times X)$ is then defined by:[2]

$$\ell(x) := \begin{cases} \{\!|(\alpha, t(q)_\alpha) \mid \alpha \in \mathsf{At}|\!\} & x = q \in Q \\ \{\!|(d(\mathsf{p}, q), (\mathsf{p}, q)) \mid \mathsf{p} \in \mathsf{Act}, q \in Q|\!\} & x = d \in I \\ \{\!|(\mathsf{p}, q)|\!\} & x = (\mathsf{p}, q) \in \mathsf{Act} \times Q \end{cases}$$

In other words, ℓ labels the edges between nodes of the first and second kind with an atom, the edges between nodes of the second and third kind with a probability, and the edges between nodes of the third and first kind with an action.

Observables represent the probabilities assigned to acceptance, rejection, or a return value by nodes of the second kind. Formally, $O := 1 + \mathbb{Q}^{2+\mathsf{Out}}$, where $* \in 1$ means "no observable value", and values from $\mathbb{Q}^{2+\mathsf{Out}}$ assign a probability to each $\xi \in 2 + \mathsf{Out}$. We can then define $o : X \to O$ by setting $o(d)(\xi) := d(\xi)$ when $d \in I$, and $o(x) := *$ otherwise.[3]

Deciding bisimilarity. We can now leverage the encoding given above to decide bisimilarity.

▶ **Theorem 28.** *If all probabilities are rational and* At *is fixed, then bisimilarity of states in a* ProbGKAT *automaton* (Q, t) *is decidable in time* $\mathcal{O}(|Q|^2 |\mathsf{Act}| \log(|\mathsf{Act} \times Q|))$.

Proof. The results from [67] ensure that our encoding of ProbGKAT automata can be equipped with an appropriate interface that allows their algorithm to decide equivalence.

As for the complexity, we instantiate their abstract complexity result by computing the parameters. The number of nodes and edges can be bound from above fairly easily, as follows:

$$|X| = |Q| + |I| + |\mathsf{Act} \times Q| \leq |Q| + 2 \cdot |\mathsf{Act}| \cdot |Q|$$
$$n = \sum_{x \in X} |\ell(x)| \leq |Q| \cdot |\mathsf{At}| + |Q|^2 \cdot |\mathsf{Act}| + |Q| \cdot |\mathsf{Act}|$$

Since At is fixed, the claimed complexity then follows. ◀

This allows us to conclude that bisimilarity of ProbGKAT expressions is also decidable.

▶ **Corollary 29.** *If all probabilities are rational and* At *is fixed, then* ProbGKAT *equivalence of* $\mathsf{e}, \mathsf{f} \in \mathtt{Exp}$ *is decidable in time* $\mathcal{O}(n^3 \log n)$, *where* $n = \#(\mathsf{e}) + \#(\mathsf{f})$.

Proof. By Lemma 7, $\langle \mathsf{e}, \mathsf{f} \rangle_\partial$ is of size at most n, and the number of distinct actions e or f is fixed from above by n as well. The claim then follows by Theorem 28. ◀

[2] Here, $\{\!|- \mid -|\!\}$ denotes multiset comprehension, where each element occurs at most once.
[3] If the coalgebraic approach from [67] is followed to the letter, the observable map for nodes of the third kind behaves slightly differently; we simplify our encoding here for the sake of presentation.

8 Related work

Our work builds on GKAT, a strictly deterministic fragment [39] of Kleene Algebra with Tests (KAT). KAT has been used in several verification tasks, such as cache control [15], compiler optimisations [37], source-to-source translations [3], and network properties [2, 22, 21, 59, 60, 66], and was generalised to include fuzzy logics [23]. GKAT admits a Salomaa-style [52] axiomatisation of trace equivalence [58] and bisimilarity [53], both relying on the Uniqueness of Solutions axiom, and completeness without it remains open, though completeness of a fragment of GKAT was recently proved by [33].

GKAT modulo bisimilarity and Milner's interpretation of regular expressions arise as fragments of the *parametrised processes* framework [55]; this is not the case for ProbGKAT due to a different treatment of loops. The uniqueness axiom was originally introduced by Bergstra and Klop under the name Recursive Specification Principle (RSP) [10] and used in axiomatisations of process calculi [11]. The general pattern of their proofs of completeness is similar to ours, although the key challenge is the extension to the probabilistic setting.

Our paper also builds up the vast line of research on probabilistic bisimulation [40, 56, 18] and the coalgebraic approach to systems with probabilistic transitions [16, 8, 18, 61]. More concretely, we relied on relation refinement characterisation of bisimilarity [63], natural metrics on the final coalgebras for ω-accessible endofunctors [7, 69], coalgebraic completeness theorems [27, 57, 54] and minimisation algorithms for coalgebras [67, 17, 68, 29]. Axiomatisations of probabilistic bisimulation were extensively studied in the process algebra community, including a recursion-free process algebra of Bandini and Segala [6] and recursive calculi of Stark and Smolka [62] and Mislove, Ouaknine and Worrell [47]. Aceto, Ésik and Ingólfsdóttir [1] gave an alternative axiomatisation of Stark and Smolka's calculus by extending Iteration Theories [12, 20] with equational axioms.

Probabilistic Kleene Algebra (pKA) [43] relaxes the axioms of KA to accommodate reasoning about probabilistic predicate transformers; its axioms are complete w.r.t. simulation equivalence of NFAs [44]. pKA was also extended with a probabilistic choice operator and concurrency primitives [45], but completeness this system was not considered. ProbNetKAT [21, 60] is a domain-specific language for reasoning about probabilistic effects in networks based on KAT, which features a probabilistic choice operator, however, axiomatisation of the obtained language was not studied.

9 Conclusion and Future Work

We have presented ProbGKAT, a language for reasoning about uninterpreted programs with branching and loops, with both Boolean and probabilistic guards. We provided an automata-theoretic operational model and characterised bisimilarity for these automata. We gave a sound and complete axiomatisation of bisimilarity, relying on the Uniqueness of Solutions (UA) axiom, and showed bisimilarity can be efficiently decided in $O(n^3 \log n)$ time.

A first natural direction for future work is the question whether the more traditional language semantics of GKAT can be lifted to ProbGKAT and axiomatised. More broadly, we would like to investigate notions of ProbGKAT expression equivalence more permissive than bisimilarity, including the notion of *bisimulation distance* [5] and its possible axiomatisations based on *quantitative equational logic* [42, 4].

A second direction touches on the problem of completeness without UA, which is still open for (Prob)GKAT. In light of recent completeness results for the skip-free fragment of GKAT [33] modulo bisimilarity and trace equivalence, we are interested to study the skip-free fragment of ProbGKAT. The proofs in [33] do not immediately generalise to ProbGKAT as probabilities do not obviously embed into (1-free) regular expressions.

Similarly to GKAT, ProbGKAT is strictly deterministic and thus avoids known complications of combining nondeterminism with probabilistic choice [30, 65, 24]. We are interested if the recent work on combining multisets and probabilities via distributive laws [28, 38] could be applied to extending our developments with nondeterminism.

ProbGKAT can express only uninterpreted programs, hence it cannot be used to reason about programs involving mutable state. An example of a probabilistic program with state is Pólya's urn [41]. One way of adding mutable state [25] to ProbGKAT is by adding *hypotheses* [14]. Unfortunately, adding hypotheses can lead to undecidability or incompleteness [35], although there are forms of hypotheses that retain completeness [36, 19, 49] and exploring this is as an interesting direction for future work.

Action Codes

Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

Abstract

We provide a new perspective on the problem how high-level state machine models with abstract actions can be related to low-level models in which these actions are refined by sequences of concrete actions. We describe the connection between high-level and low-level actions using *action codes*, a variation of the prefix codes known from coding theory. For each action code $\mathcal{R}$, we introduce a *contraction* operator $\alpha_{\mathcal{R}}$ that turns a low-level model $\mathcal{M}$ into a high-level model, and a *refinement* operator $\varrho_{\mathcal{R}}$ that transforms a high-level model $\mathcal{N}$ into a low-level model. We establish a Galois connection $\varrho_{\mathcal{R}}(\mathcal{N}) \sqsubseteq \mathcal{M} \Leftrightarrow \mathcal{N} \sqsubseteq \alpha_{\mathcal{R}}(\mathcal{M})$, where $\sqsubseteq$ is the well-known simulation preorder. For conformance, we typically want to obtain an overapproximation of model $\mathcal{M}$. To this end, we also introduce a *concretization* operator $\gamma_{\mathcal{R}}$, which behaves like the refinement operator but adds arbitrary behavior at intermediate points, giving us a second Galois connection $\alpha_{\mathcal{R}}(\mathcal{M}) \sqsubseteq \mathcal{N} \Leftrightarrow \mathcal{M} \sqsubseteq \gamma_{\mathcal{R}}(\mathcal{N})$. Action codes may be used to construct adaptors that translate between concrete and abstract actions during learning and testing of Mealy machines. If Mealy machine $\mathcal{M}$ models a black-box system then $\alpha_{\mathcal{R}}(\mathcal{M})$ describes the behavior that can be observed by a learner/tester that interacts with this system via an adaptor derived from code $\mathcal{R}$. Whenever $\alpha_{\mathcal{R}}(\mathcal{M})$ implements (or conforms to) $\mathcal{N}$, we may conclude that $\mathcal{M}$ implements (or conforms to) $\gamma_{\mathcal{R}}(\mathcal{N})$.

Almost all results, examples, and counter-examples are formalized in Coq.

Acknowledgements As part of an MSc thesis project under supervision of the first author, Timo Maarse studied a different and more restricted type of action codes (called action refinements) [29]. It turned out, however, that for these action codes, the concretization operator is not monotone. The present paper arose from our efforts to fix this problem. We thank the anonymous reviewers for their suggestions, Paul Fiterău-Broştean for examples of the use of action codes in model learning, and Jules Jacobs for helpful discussions about Coq. The first author would like to thank Rocco De Nicola for his hospitality at IMT Lucca during the work on this paper.

1 Introduction

Labeled transition systems (LTSs) constitute one of the most fundamental modeling mechanisms in Computer Science. An LTS is a rooted, directed graph whose nodes represent *states* and whose edges are labeled with *actions* and represent *state transitions*. LTS-based formalisms such as Finite Automata [21], Finite State Machines [25], I/O automata [26], IOTSs [35], and process algebras [4] have been widely used to model and analyze a broad variety of reactive systems, and a rich body of theory has been developed for them.

In order to manage the complexity of computer-based systems, designers structure such systems into hierarchical layers. This allows them to describe and analyze systems at different levels of abstraction. Many LTS-based frameworks have been proposed to formally relate models at different hierarchical levels, e.g. [4, 14, 27, 40]. In most of these frameworks, the states of a high-level LTS correspond to sets of states of a low-level LTS via simulation or bisimulation-like relations. However, the actions are fixed and considered to be atomic. Actions used at a lower level of abstraction can be hidden at a higher level, but higher-level actions will always be available at the lower level. For this reason, Rensink & Gorrieri [18, 31] argue that these (bi)simulations relate systems at the same conceptual level of abstraction, and therefore they call them *horizontal* implementation relations. They contrast them with *vertical* implementation relations that compare systems that belong to conceptually different abstraction levels, and have different alphabets of actions.

A prototypical example of a hierarchical design is a computer network. To reduce design complexity, such a network is organized as a stack of layers or levels, each one built upon the one below it [34]. Examples are the transport layer, with protocols such as TCP and UDP, and the physical layer, concerned with transmitting raw bits over a communication channel. Now consider a host that receives a TCP packet in some state s. If P is the set of possible packets then, in an LTS model of the transport layer, state s will contain outgoing transitions labeled with action $receive(p)$, for each $p \in P$. At the physical layer, however, receipt of a packet corresponds to a sequence of $receive(b)$ actions, with b a bit in $\{0, 1\}$. Only after the final bits have arrived, the host knows which packet was actually received. Mechanisms for transforming high-level actions into sequences (or processes) of low-level actions have been addressed extensively in work on action refinements [18]. These approaches, however, are unable to describe the above scenario in a satisfactory manner and somehow assume that a host upfront correctly guesses the packet that it will receive, even before the first bit has arrived. In order to illustrate this problem, we consider the simplified example of an LTS with a distinguished initial state, displayed in Figure 1a, which accepts either input a or input b. At a lower level of abstraction, input a is implemented by three consecutive inputs 1 4 1, whereas input b is implemented by action sequence 1 4 2 (the ASCII encodings of a and b in octal format). An action refinement operator will replace the a-transition in Figure 1a by a sequence of three consecutive transitions with labels 1, 4 and 1, respectively,

and will handle the b-transition in an analogous manner. Thus, action refinement introduces a nondeterministic choice (Figure 1b), rather than the deterministic behavior that one would like to see (Figure 1c). As a consequence of this and other limitations, refinement operators have not found much practical use [18].

Based on the observation that any action can be modeled as a state change, some authors (e.g. [2, 10, 24]) prefer modeling formalisms in which the term "action" is only used informally, and Kripke structures rather than LTSs are used to model systems. These state-based approaches have the advantage that a distinction between horizontal and vertical implementation relations is no longer needed, and a single implementation relation suffices. Purely state-based approaches, however, are problematic in cases where we need to interact with a black-box system and (by definition) we have no clue about the state of this system. Black-box systems prominently occur in the areas of model-based testing [36] and model learning [37]. In these application areas, use of LTSs makes sense and there is a clear practical need for formalisms that allow engineers to relate actions at different levels of abstraction.

Van der Bijl et al. [7], for instance, observe that in model-based testing specifications are usually more abstract than the System Under Test (SUT). This means that generated test cases may not have the required level of detail, and often a single abstract action has to be translated (either manually or by an adaptor) to a sequence of concrete actions that are applied to the SUT. Van der Bijl et al. [7] study a restricted type of action refinement in which a single input is refined into a sequence of inputs, and implement this in a testing tool.

Also in model learning, typically an adaptor is placed in between the SUT and the learner, to take care of the translation between abstract and concrete actions. For example, in a case study on hand-held smartcard readers for Internet banking, Chalupar et al. [9] used abstract inputs that combine several concrete inputs in order to accelerate the learning process and reduce the size of the learned model. In particular, they introduced a single abstract input COMBINED_PIN corresponding to a USB command, followed by a 4-digit PIN code, followed by an OK command. Fiterău-Broştean et al. [12] used model learning for a comprehensive analysis of DTLS implementations, and found four serious security vulnerabilities, as well as several functional bugs and non-conformance issues. Handshakes in (D)TLS are defined over flights of messages. Hence, (D)TLS entities are often expected to produce multiple messages before expecting a response. During learning, Fiterău-Broştean et al. [12] used an adaptor that contracted multiple messages from the SUT into a single abstract output. Also in other case studies on TLS [32], Wi-Fi [33] and SSH [39, 13], multiple outputs from the SUT were contracted into a single abstract output. Verleg [39] used a single abstract input to execute the entire key re-exchange during learning higher layers of SSH.

In this article, we provide answers to two fundamental questions: (1) How can we formalize the concept of an *adaptor* that translates between abstract and concrete actions?, and (2) Suppose the behavior of an SUT is described by an unknown, concrete model $\mathcal{M}$, and suppose a learner interacts with this SUT through an adaptor and learns an abstract model $\mathcal{N}$. What can we say about the relation between $\mathcal{M}$ and $\mathcal{N}$?

We answer the first question by introducing *action codes*, a variation of the prefix codes known from coding theory [5]. Action codes describe how high-level actions are converted into sequences of low-level actions, and vice versa. This makes them different from action refinements, which specify how high-level actions can be translated into low-level processes, but do not address the reverse translation. Our notion of an action code captures adaptors that are used in practice, and in particular those described in the case studies listed above.

In order to answer the second question we introduce, for each action code $\mathcal{R}$, a *contraction* operator $\alpha_{\mathcal{R}}$ that turns a low-level model $\mathcal{M}$ into a high-level model by contracting concrete action sequences of $\mathcal{M}$ according to $\mathcal{R}$. We also introduce the left adjoint of $\alpha_{\mathcal{R}}$, the *refinement*

operator $\varrho_{\mathcal{R}}$ that turns a high-level model $\mathcal{M}$ into a low-level model by refining abstract actions of $\mathcal{N}$ according to $\mathcal{R}$. This refinement operator, for instance, maps the LTS of Figure 1a to the LTS of Figure 1c. We establish a Galois connection $\varrho_{\mathcal{R}}(\mathcal{N}) \sqsubseteq \mathcal{M} \;\Leftrightarrow\; \mathcal{N} \sqsubseteq \alpha_{\mathcal{R}}(\mathcal{M})$, where $\sqsubseteq$ denotes the simulation preorder. So if an abstract model $\mathcal{N}$ implements contraction $\alpha_{\mathcal{R}}(\mathcal{M})$, then the refinement $\varrho_{\mathcal{R}}(\mathcal{N})$ implements concrete model $\mathcal{M}$, and vice versa.

In practice, we typically want to obtain an overapproximation of concrete model $\mathcal{M}$. To this end, we introduce the right adjoint of $\alpha_{\mathcal{R}}$, the *concretization* operator $\gamma_{\mathcal{R}}$. This operator behaves like the refinement operator, but adds arbitrary behavior at intermediate points (cf. the demonic completion of [6]). We establish another Galois connection: $\alpha_{\mathcal{R}}(\mathcal{M}) \sqsubseteq \mathcal{N} \Leftrightarrow \mathcal{M} \sqsubseteq \gamma_{\mathcal{R}}(\mathcal{N})$. This connection is useful, because whenever we have established that $\alpha_{\mathcal{R}}(\mathcal{M})$ implements (or conforms to) $\mathcal{N}$, it allows us to conclude that $\mathcal{M}$ implements (or conforms to) $\gamma_{\mathcal{R}}(\mathcal{N})$.

We show that, in a setting of Mealy machines (subsuming Finite State Machines), an *adaptor* can be constructed for any action code for which a winning strategy exists in a certain 2-player game. If a learner/tester interacts with an SUT via an adaptor generated from such an action code $\mathcal{R}$, and the SUT is modeled by Mealy machine $\mathcal{M}$, then from the learner/tester perspective, the composition of adaptor and SUT will behave like $\alpha_{\mathcal{R}}(\mathcal{M})$. Thus, if a learner succeeds to learn an abstract model $\mathcal{N}$ such that $\mathcal{N} \approx \alpha_{\mathcal{R}}(\mathcal{M})$ then, using the Galois connections, the learner may conclude that $\varrho_{\mathcal{R}}(\mathcal{N}) \sqsubseteq \mathcal{M} \sqsubseteq \gamma_{\mathcal{R}}(\mathcal{N})$.

The remainder of this article is structured as follows. We start with a preliminary Section 2 that introduces basic notations and results for LTSs. Next, action codes and the contraction operator are introduced in Section 3. After describing the refinement operator, we establish our first Galois connection in Section 4. Next we define concretization and establish our second Galois connection in Sections 5. Section 6 explains how action codes can be composed, and shows that contraction and refinement commute with action code composition. Section 7 describes how adaptors can be constructed from action codes. Finally, Section 8 contains a discussion of our results and identifies directions for future research.

Almost all proofs are formalized in Coq (about 6000 lines of code) and can be accessed via `https://gitlab.science.ru.nl/twissmann/action-codes-coq` and via the ancillary files of the full version on arxiv. We mark formalized results with a clickable Coq icon pointing to the respective location in the HTML documentation. Appendix A (in the full version) contains comments on the Coq formalization and Appendix B contains full proofs (in natural language) and additional remarks.

2 Preliminaries

If Σ is a set of symbols then Σ^* denotes the set of all finite words over Σ, and Σ^+ the set of all non-empty words. We use ε to denote the empty word, so e.g. $\Sigma^* = \Sigma^+ \cup \{\varepsilon\}$. Concatenation of words $u, w \in \Sigma^*$ is notated $u \cdot w$ (or simply $u\,w$). We write $u \leq w$ if u is a prefix of w, i.e. if there is $v \in \Sigma^*$ with $u\,v = w$. We write $|w|$ to denote the length of word w.

We use $f\colon X \rightharpoonup Y$ to denote a partial map f from X to Y and write $\mathsf{dom}(f) \subseteq X$ for its domain, i.e. set of $x \in X$ on which f is defined. The *image* $\mathsf{im}(f)$ of a partial map $f\colon X \rightharpoonup Y$ is the set of elements of Y it can reach: $\mathsf{im}(f) := \{f(x) \mid x \in \mathsf{dom}(f)\} \subseteq Y$.

▶ **Definition 2.1** (). *For a set A of action labels, a* labeled transition system (LTS) *is a tuple $\mathcal{M} = \langle Q, q_0, \longrightarrow \rangle$ where Q is a set of states, $q_0 \in Q$ is a starting state, and $\longrightarrow \subseteq Q \times A \times Q$ is a transition relation. We write $\mathsf{LTS}(A)$ for the class of all LTSs with labels from A. We refer to the three components of an LTS $\mathcal{M}$ as $Q^{\mathcal{M}}$, $q_0^{\mathcal{M}}$ and $\longrightarrow_{\mathcal{M}}$, respectively, and introduce the following notation:*

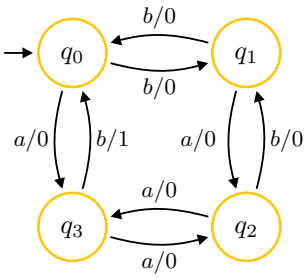

Figure 2 A Mealy machine.

- $q \xrightarrow{a} q'$ *denotes* $(q, a, q') \in \longrightarrow$; $q \xrightarrow{a}$ *denotes that there is some* q' *with* $q \xrightarrow{a} q'$;
- $q \overset{w}{\Longrightarrow} q'$ *for* $w \in A^*$ *denotes that there are finite sequences* $a_1, \ldots, a_n \in A$, $r_0, \ldots, r_n \in Q$ *such that* $w = a_1 \cdots a_n$, *and* $r_0 = q$, $r_n = q'$ *and* $r_{i-1} \xrightarrow{a_i} r_i$ *for all* $1 \leq i \leq n$;
- $q \overset{w}{\Longrightarrow}$ *denotes that there is* q' *such that* $q \overset{w}{\Longrightarrow} q'$;
- $q \in Q$ *is* reachable *if there is* $w \in A^*$ *such that* $q_0 \overset{w}{\Longrightarrow} q$.

A special class of LTSs that is frequently used in conformance testing and model learning are *Mealy machines*. Mealy machines with a finite number of states are commonly referred to as *Finite State Machines*.

▶ **Definition 2.2.** *For non-empty sets of inputs* I *and outputs* O, *a (non-deterministic)* Mealy machine $\mathcal{M} \in \mathsf{LTS}(I \times O)$ *is an LTS where the labels are pairs of an input and an output. We write* $q \xrightarrow{i/o} q'$ *to denote that* $(q, (i, o), q') \in \longrightarrow$. *Whenever we omit a symbol in predicate* $q \xrightarrow{i/o} q'$ *this is quantified existentially. Thus,* $\xrightarrow{i/o}$ *if there are* q *and* q' *s.t.* $q \xrightarrow{i/o} q'$, $q \xrightarrow{i/} q'$ *if there is an* o *s.t.* $q \xrightarrow{i/o} q'$, *and* $q \xrightarrow{i/}$ *if there is a* q' *s.t.* $q \xrightarrow{i/} q'$.

▶ **Example 2.3** (🐓). Figure 2 visualizes a simple Mealy machine with inputs $\{a, b\}$ and outputs $\{0, 1\}$. The machine always outputs 0 in response to an input, except in one specific situation. Output 1 is produced in response to input b if the previous input was a and the number of preceding inputs is odd. The machine has four states q_0, q_1, q_2 and q_3, with starting state q_0 marked by an incoming arrow. In states q_0 and q_2 the number of preceding inputs is always even, whereas in states q_1 and q_3 it is always odd. In states q_2 and q_3 the previous input is always a, whereas in states q_0 and q_1 either the previous input is b, or no input has occurred yet. Thus, only in state q_3 input b triggers output 1.

We introduce some notation and terminology for LTSs.

▶ **Definition 2.4** (🐓). *Let* $\mathcal{M} = \langle Q, q_0, \longrightarrow \rangle \in \mathsf{LTS}(A)$ *be an LTS. We say that*

- $\mathcal{M}$ *is* deterministic *if, whenever* $q \xrightarrow{a}$ *for some* q *and* a, *there is a unique* q' *with* $q \xrightarrow{a} q'$.
- $\mathcal{M}$ *is a* tree-shaped *if each state* $q \in Q$ *can be reached via a unique sequence of transitions from state* q_0.
- $q \in Q$ *is a* leaf, *notated* $q \not\rightarrow$, *if there is no* $a \in A$ *with* $q \xrightarrow{a}$.
- $\mathcal{M}$ *is* grounded *if every state* $q \in Q$ *has a path to a leaf.*

We can now define the set of traces of an LTS:

▶ **Definition 2.5** (🐓). *Let* $\mathcal{M} = \langle Q, q_0, \longrightarrow \rangle \in \mathsf{LTS}(A)$. *A word* $w \in A^*$ *is a* trace *of state* $q \in Q$ *if* $q \overset{w}{\Longrightarrow}$, *and a* trace *of* $\mathcal{M}$ *if it is a trace of* q_0. *We write* $\mathit{trace}(\mathcal{M})$ *for the set* $\{w \in A^* \mid q_0 \overset{w}{\Longrightarrow}\}$ *of all traces of* $\mathcal{M}$.

▶ **Definition 2.6** (Simulation, 🐓). *For $\mathcal{M}, \mathcal{N} \in \mathsf{LTS}(A)$, a* simulation *from $\mathcal{M}$ to $\mathcal{N}$ is a relation $S \subseteq Q^{\mathcal{M}} \times Q^{\mathcal{N}}$ such that*
1. $q_0^{\mathcal{M}}\ S\ q_0^{\mathcal{N}}$ *and*
2. *if $q_1\ S\ q_2$ and $q_1 \xrightarrow{a}_{\mathcal{M}} q_1'$ then there exists a state q_2' such that $q_2 \xrightarrow{a}_{\mathcal{N}} q_2'$ and $q_1'\ S\ q_2'$.*

We write $\mathcal{M} \sqsubseteq \mathcal{N}$ if there exists a simulation from $\mathcal{M}$ to $\mathcal{N}$.

It is a classical result that trace inclusion coincides with the simulation preorder for deterministic labeled transition systems (see e.g. [28]):

▶ **Lemma 2.7** (🐓). *For all $\mathcal{M}, \mathcal{N} \in \mathsf{LTS}(A)$ where $\mathcal{N}$ is deterministic: $\mathit{trace}(\mathcal{M}) \subseteq \mathit{trace}(\mathcal{N})$ iff $\mathcal{M} \sqsubseteq \mathcal{N}$.*

We will often consider LTSs up to isomorphism of their reachable parts:

▶ **Definition 2.8** (Isomorphism, 🐓). *For $\mathcal{M}, \mathcal{N} \in \mathsf{LTS}(A)$, an* isomorphism *from $\mathcal{M}$ to $\mathcal{N}$ is a bijection $f\colon Q_R^{\mathcal{M}} \to Q_R^{\mathcal{N}}$, where:*
1. *$Q_R^{\mathcal{M}} \subseteq Q^{\mathcal{M}}$ and $Q_R^{\mathcal{N}} \subseteq Q^{\mathcal{N}}$ are the subsets of reachable states in $\mathcal{M}$ and $\mathcal{N}$, respectively;*
2. *$f(q_0^{\mathcal{M}}) = q_0^{\mathcal{N}}$, and*
3. *$q \xrightarrow{a}_{\mathcal{M}} q'$ iff $f(q) \xrightarrow{a}_{\mathcal{N}} f(q')$, for all $q, q' \in Q_R^{\mathcal{M}}$, $a \in A$.*

We write $\mathcal{M} \cong \mathcal{N}$ if there exists an isomorphism from $\mathcal{M}$ to $\mathcal{N}$.

Note that $\cong$ is an equivalence relation on $\mathsf{LTS}(A)$, and that $\mathcal{M} \cong \mathcal{N}$ implies $\mathcal{M} \sqsubseteq \mathcal{N}$, since each isomorphism (when viewed as a relation) is trivially a simulation.

3 Action Codes

Adaptors that are used for learning and testing translate sequences of abstract actions into sequences of concrete actions, and vice versa. Action codes describe *how* an adaptor may translate between two action label alphabets, for example from A to B. Intuitively, we understand the first alphabet A as the actions at the lower, concrete level, and the second alphabet B as the actions at the higher, more abstract level. In an action code, a single abstract action $b \in B$ corresponds to a finite, non-empty sequence of concrete actions $a_1 \cdots a_n$ in A. Essentially, action codes are just a special type of *prefix codes* [5], as known from coding theory. Prefix codes have the desirable property that they are *uniquely decodable*: given a sequence of concrete actions, there is at most one corresponding sequence of abstract actions. We provide two equivalent definitions of action codes: one via tree-shaped LTSs and one via partial maps.

▶ **Definition 3.1** (Action code, 🐓). *For sets of action labels A and B, a* (tree-shaped) action code *$\mathcal{R}$ from A to B is a structure $\mathcal{R} = \langle \mathcal{M}, l \rangle$, with $\mathcal{M} = \langle R, r_0, \longrightarrow \rangle \in \mathsf{LTS}(A)$ a deterministic, tree-shaped LTS with L being the set of non-root leaves $L \subseteq R \setminus \{r_0\}$ and an injective function $l\colon L \to B$. We write $\mathsf{Code}(A, B)$ for all action codes from A to B.*

The injectivity of l and the tree-shape ensure that every abstract $b \in B$ is represented by at most one $w \in A^+$.

▶ **Example 3.2.** Figure 3 shows an action code for a fragment of the ASCII encoding in octal format, e.g., 1 1 5 encodes the letter `M`, 1 4 5 encodes the letter `e`, etc.

▶ **Example 3.3.** Figure 4 shows an action code for the activity of getting a cup of coffee or espresso, in the special case of Mealy machines, i.e. where $A = I \times O$ and $B = I' \times O'$ are sets of input/output-pairs. Rather than the full sequence of interventions that is required in order to get a drink, the abstract input/output pair only reports on the type of drink that was ordered and the number of interventions that occurred.

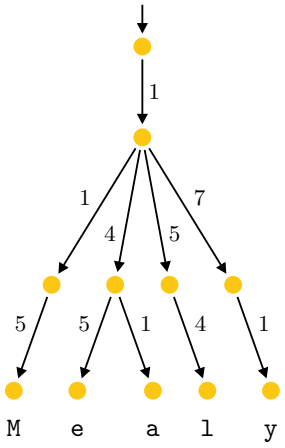

Figure 3 Action code for a fragment of ASCII.

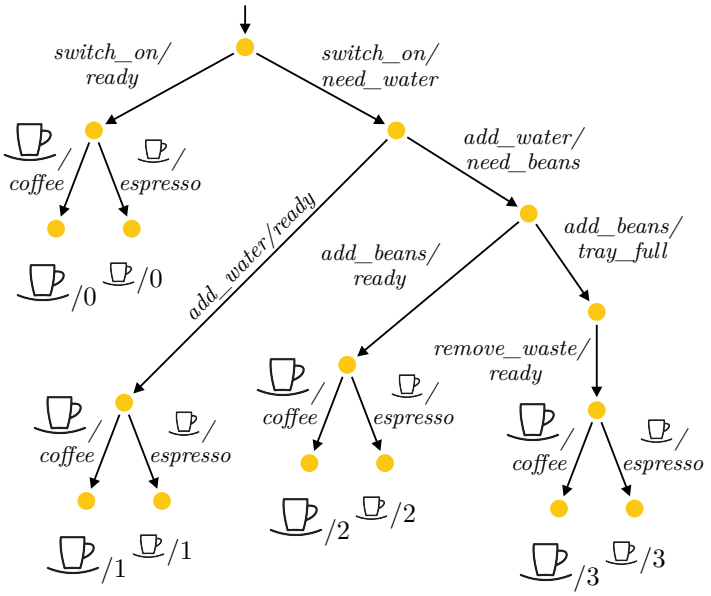

Figure 4 Action code for a coffee machine.

The definition of action codes as LTSs allows an intuitive visualization. For easier mathematical reasoning, we characterize action codes also in terms of maps:

▶ **Definition 3.4** (🐓). *A* (map-based) action code *from A to B is a partial map $f\colon B \rightharpoonup A^+$ which is* prefix-free*, by which we mean that for all $b, b' \in \mathsf{dom}(f)$,*

$$f(b) \leq f(b') \qquad \textit{implies} \qquad b = b'. \tag{1}$$

In the following, we show that these prefix-free partial maps bijectively correspond to the tree-shaped LTSs:

▶ **Lemma 3.5** (🐓). *Every tree-shaped action code $\mathcal{R} \in \mathsf{Code}(A, B)$ induces a unique map-based action code $f\colon B \rightharpoonup A^+$ with the property that for all $b \in B, w \in A^+$:*

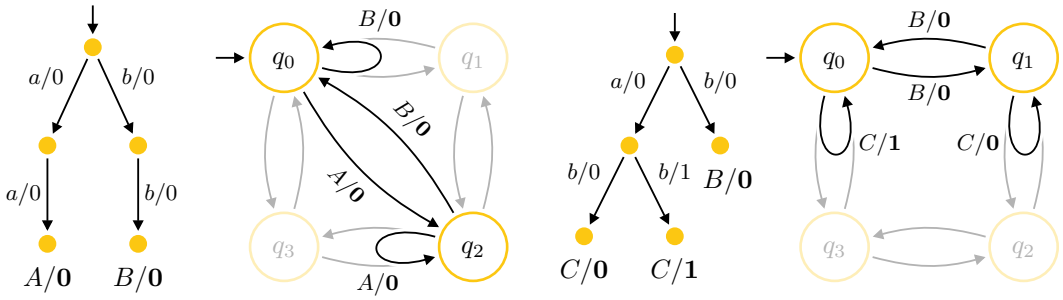
$$f(b) = w \qquad \textit{iff} \qquad \exists r \in L\colon r_0 \xRightarrow{w}_{\mathcal{R}} r, \quad l(r) = b \tag{2}$$

▶ **Lemma 3.6** (🐓). *For each map-based action code $f\colon B \rightharpoonup A^+$, there is (up to isomorphism) a unique tree-shaped action code $\mathcal{R} \in \mathsf{Code}(A, B)$ which is grounded and satisfies* (2)*.*

▶ **Example 3.7** (🐓). For the uniqueness in Lemma 3.6, we use groundedness, because for $A = \{a\}$ and any B, the action codes

$\mathcal{R} :=$  and $\mathcal{S} :=$  .

both have no non-root leaves, and so they both induce the empty partial map $f\colon B \rightharpoonup A^+$ via Lemma 3.5. This f is undefined for all $b \in B$. And indeed, $\mathcal{R}$ and $\mathcal{S}$ are not isomorphic. The issue is that while the finite $\mathcal{S}$ is grounded, the infinite $\mathcal{R}$ is not grounded. So $\mathcal{R}$ contains subtrees which do not contribute anything to the partial map f but which hinder the existence of an isomorphism.



(a) An action code $\mathcal{R}$ together with $\alpha_{\mathcal{R}}(\mathcal{M})$. **(b)** Another code $\mathcal{S}$ together with $\alpha_{\mathcal{S}}(\mathcal{M})$.

Figure 5 The resulting contraction of the LTS $\mathcal{M}$ from Figure 2 for different action codes.

Having shown the correspondence between tree-shaped and map-based action codes $\mathsf{Code}(A, B)$, we can switch between the two views in proofs. Mostly, we use the tree-shaped version for visualization and the map-based version for mathematical reasoning.

Consider a concrete $\mathcal{M} \in \mathsf{LTS}(A)$, together with an action code $\mathcal{R}$ from A to B. We can construct an abstract LTS for the action labels B by walking through $\mathcal{M}$ with seven-league boots, repeatedly choosing input sequences that correspond to runs to some leaf of $\mathcal{R}$, and then contracting this sequence to a single abstract transition.

▶ **Notation 3.8.** In the rest of the paper, we introduce operators $\alpha_{\mathcal{R}}$, $\varrho_{\mathcal{R}}$, $\gamma_{\mathcal{R}}$ on LTSs, involving an action code $\mathcal{R}$. Whenever the action code $\mathcal{R}$ is clear from the context, we omit the index and simply speak of operators α, ϱ, γ for the sake of brevity.

▶ **Definition 3.9** (Contraction, 🐓). *For each action code $\mathcal{R} \in \mathsf{Code}(A, B)$, the* contraction *operator $\alpha_{\mathcal{R}} \colon \mathsf{LTS}(A) \to \mathsf{LTS}(B)$ is defined as follows. For $\mathcal{M} \in \mathsf{LTS}(A)$, the LTS $\alpha_{\mathcal{R}}(\mathcal{M})$ has states $Q^{\alpha(\mathcal{M})} \subseteq Q^{\mathcal{M}}$ and transitions $\longrightarrow_{\alpha(\mathcal{M})}$ defined inductively by the rules (1_α) and (2_α), for all $q, q' \in Q^{\mathcal{M}}$, $b \in B$.*

$$\frac{}{q_0^{\mathcal{M}} \in Q^{\alpha(\mathcal{M})}} \quad (1_\alpha) \qquad \frac{q \in Q^{\alpha(\mathcal{M})}, \quad b \in \mathsf{dom}(\mathcal{R}), \quad q \xRightarrow{\mathcal{R}(b)}_{\mathcal{M}} q'}{q \xrightarrow{b}_{\alpha(\mathcal{M})} q', \qquad q' \in Q^{\alpha(\mathcal{M})}} \quad (2_\alpha)$$

The initial state $q_0^{\alpha(\mathcal{M})} := q_0^{\mathcal{M}}$ is the same as in $\mathcal{M}$.

▶ **Example 3.10.** Figures 5 shows two examples of action codes and the contractions obtained when we apply them to the Mealy machine of Figure 2 (with the original machine shaded in the background). The examples illustrate that by choosing different codes we may obtain completely different abstractions of the same LTS.

The next proposition asserts that we can view $\alpha_{\mathcal{R}}$ as a monotone function $\alpha_{\mathcal{R}} \colon \mathsf{LTS}(A) \to \mathsf{LTS}(B)$ between preordered classes.

▶ **Proposition 3.11** (Monotonicity, 🐓). *For every action code $\mathcal{R} \in \mathsf{Code}(A, B)$, whenever $\mathcal{M} \sqsubseteq \mathcal{N}$ for $\mathcal{M}, \mathcal{N} \in \mathsf{LTS}(A)$, then $\alpha_{\mathcal{R}}(\mathcal{M}) \sqsubseteq \alpha_{\mathcal{R}}(\mathcal{N})$ in $\mathsf{LTS}(B)$.*

4 Refinements

Now that we have introduced the contraction $\alpha_{\mathcal{R}}$ of an LTS for a code $\mathcal{R}$, it is natural to consider an operation in the other direction, which we call the *refinement* $\varrho_{\mathcal{R}}$. Intuitively, refinement replaces each abstract transition $q \xrightarrow{b} q'$ by a sequence of concrete transitions, as prescribed by $\mathcal{R}$.

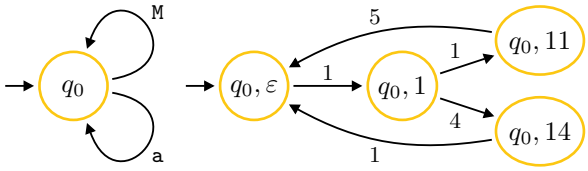


Figure 6 LTS and its refinement w.r.t $\mathcal{R}$ of Figure 3.

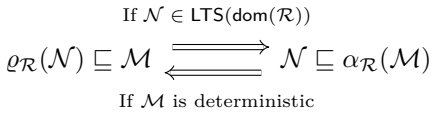

Figure 7 Theorem 4.5.

▶ **Definition 4.1** (Refinement, 🐓). *For each action code $\mathcal{R} \in \mathsf{Code}(A, B)$, we define the* refinement *operator $\varrho_{\mathcal{R}} \colon \mathsf{LTS}(B) \to \mathsf{LTS}(A)$ as follows. For $\mathcal{M} \in \mathsf{LTS}(B)$, the LTS $\varrho_{\mathcal{R}}(\mathcal{M}) \in \mathsf{LTS}(A)$ has a set of states*

$$Q^{\varrho(\mathcal{M})} := \{(q, w) \in Q^{\mathcal{M}} \times A^* \mid w = \varepsilon \text{ or (there is } b \text{ with } q \xrightarrow{b}_{\mathcal{M}} \text{ and } w \lneqq \mathcal{R}(b))\}$$

and the initial state $(q_0^{\mathcal{M}}, \varepsilon)$. The transition relation $\longrightarrow_{\varrho(\mathcal{M})}$ is defined by the following rules:

$$\frac{(q, wa) \in Q^{\varrho(\mathcal{M})}}{(q, w) \xrightarrow{a}_{\varrho(\mathcal{M})} (q, wa)} \ (1_\varrho) \qquad \frac{q \xrightarrow{b}_{\mathcal{M}} q' \quad wa = \mathcal{R}(b)}{(q, w) \xrightarrow{a}_{\varrho(\mathcal{M})} (q', \varepsilon)} \ (2_\varrho)$$

Intuitively, whenever $\varrho(\mathcal{M})$ is in state (q, w), then this corresponds to being in state q in the abstract automaton $\mathcal{M} \in \mathsf{LTS}(B)$ and having observed the actions $w \in A^*$ so far. However, we have insufficiently many actions for finding an abstract transition $q \xrightarrow{b}_{\mathcal{M}} q'$ with $w = \mathcal{R}(b)$ because w is still to short. Nevertheless, whenever $\varrho(\mathcal{M})$ admits a transition to a state (q, w) with $w \neq \varepsilon$, then we know that we can eventually complete w to a sequence corresponding to an abstract transition: there exist at least one $q \xrightarrow{b}_{\mathcal{M}} q'$ for some $b \in \mathsf{dom}(\mathcal{R})$ with $w \leq \mathcal{R}(b)$. If the abstract system $\mathcal{M}$ is non-deterministic, then there may be multiple abstract transitions that match in the final rule (2_ϱ), but the transitions produced by rule (1_ϱ) are deterministic.

▶ **Example 4.2.** Figure 6 shows an example application of a refinement operator that replaces the actions of the LTS $\mathcal{M}$ on the left by their ASCII encoding in octal format, as prescribed by the action code from Figure 3. The initial state is (q_0, ε), corresponding to q_0 in $\mathcal{M}$. Since $\mathcal{M}$ contains abstract labels `M` and `a`, with $\mathcal{R}(\mathtt{M}) = 1\,1\,5$ and $\mathcal{R}(\mathtt{a}) = 1\,4\,1$, we need to introduce additional states for having read 1, 1 1, and 1 4, because those are the sequences of A-actions before we have observed a sequence $\mathcal{R}(b) \in A^+$ for some $b \in B$.

A more visual explanation of $\varrho_{\mathcal{R}}(\mathcal{M})$ is the following: for every state $q \in Q^{\mathcal{M}}$, we consider the outgoing transitions $\{q \xrightarrow{b}_{\mathcal{M}} q' \mid b \in B, q' \in Q^{\mathcal{M}}\}$ and labels $B' \subseteq B$ that appear in it. Then, this outgoing-transition structure is replaced with (a copy of) the minimal subgraph of the tree $\mathcal{R}$ containing all leaves with labels in B'.

Like contraction, the refinement operation also preserves the simulation preorder.

▶ **Proposition 4.3** (Monotonicity, 🐓). *For all action codes $\mathcal{R} \in \mathsf{Code}(A, B)$, if $\mathcal{M} \sqsubseteq \mathcal{N}$ in $\mathsf{LTS}(B)$, then $\varrho_{\mathcal{R}}(\mathcal{M}) \sqsubseteq \varrho_{\mathcal{R}}(\mathcal{N})$ in $\mathsf{LTS}(A)$.*

As $\mathcal{R}$ is deterministic, applying $\varrho_{\mathcal{R}}$ on a deterministic LTS results in a deterministic LTS:

▶ **Proposition 4.4** (Refinement preserves determinism, 🐓). *For every action code $\mathcal{R} \in \mathsf{Code}(A, B)$, if $\mathcal{M} \in \mathsf{LTS}(B)$ is deterministic, then $\varrho_{\mathcal{R}}(\mathcal{M}) \in \mathsf{LTS}(A)$ is deterministic, too.*

▶ **Theorem 4.5** (Galois connection, 🐓). *For $\mathcal{R} \in \mathsf{Code}(A, B)$, $\mathcal{N} \in \mathsf{LTS}(B)$, and $\mathcal{M} \in \mathsf{LTS}(A)$:*
1. *If $\mathcal{N}$ is in the subclass $\mathsf{LTS}(\mathsf{dom}(\mathcal{R})) \subseteq \mathsf{LTS}(B)$, then $\varrho_{\mathcal{R}}(\mathcal{N}) \sqsubseteq \mathcal{M}$ implies $\mathcal{N} \sqsubseteq \alpha_{\mathcal{R}}(\mathcal{M})$.*
2. *If $\mathcal{M}$ is deterministic, then $\mathcal{N} \sqsubseteq \alpha_{\mathcal{R}}(\mathcal{M})$ implies $\varrho_{\mathcal{R}}(\mathcal{N}) \sqsubseteq \mathcal{M}$.*

The condition in the first direction means that $\mathcal{N} \in \mathsf{LTS}(B)$ only makes use of action labels in the subset $\mathsf{dom}(\mathcal{R}) \subseteq B$. Hence, in the proof, we can consider $\mathcal{R}$ to be a total map $\mathsf{dom}(\mathcal{R}) \to A^+$.

▶ Remark 4.6. If we wanted to support non-deterministic $\mathcal{M}$, we can consider a less-pleasant $\varrho'_{\mathcal{R}}$ that replaces every $q \xrightarrow{b} q'$ for $\mathcal{R}(a_1 \cdots a_n) = b$ with literally a sequence $q \xrightarrow{a_1} \cdots \xrightarrow{a_n} q'$. Thus, $\varrho'_{\mathcal{R}}$ would rather create a system as in Figure 1b whereas $\varrho_{\mathcal{R}}$ creates a system as in Figure 1c. However, such an operator $\varrho'_{\mathcal{R}}$ does not preserve determinism.

▶ Remark 4.7. In the proof of the Galois connection, we make use of the fact that our action codes are functional, i.e. that every $b \in B$ is encoded by at most one $w \in A^*$. We would allow multiple, then one can show that α can not have a left-adjoint (details in appendix).

In the first direction, we can even prove a stronger statement for $\mathcal{M} := \varrho_{\mathcal{R}}(\mathcal{N})$, showing a Galois insertion between $\alpha_{\mathcal{R}}$ and $\varrho_{\mathcal{R}}$:

▶ **Theorem 4.8** (Galois insertion, 🐓). *For $\mathcal{R} \in \mathsf{Code}(A, B)$, if $\mathcal{N} \in \mathsf{LTS}(B)$ is in the subclass $\mathcal{N} \in \mathsf{LTS}(\mathsf{dom}(\mathcal{R}))$, then $\mathcal{N} \cong \alpha_{\mathcal{R}}(\varrho_{\mathcal{R}}(\mathcal{N}))$.*

5 Concretizations

In this section, we consider another method of transforming an abstract system into a concrete one: the *concretization* operator. Whereas refinement is the left adjoint of contraction (Theorem 4.5), this section will establish that concretization is the right adjoint (Theorem 5.5) of contraction. Whereas for refinement we omitted transitions for which the action code $\mathcal{R}$ was not defined, for concretization we add transitions to a new *chaos* state [20] in which any action may occur. Essentially, this is the idea of *demonic completion* of [6]. In order to reduce the number of transitions to the chaos state, the concretization operator is parametric in a reflexive relation $\mathcal{I} \subseteq A \times A$ which describes whether two symbols are sufficiently similar. With this relation, we allow transitions to the chaos state only for those symbols that are not similar to any symbol for which the code is defined:

▶ **Definition 5.1** (Concretization, 🐓). *Let $\mathcal{M} \in \mathsf{LTS}(B)$ be an LTS, $\mathcal{R} \in \mathsf{Code}(A, B)$ an action code, and $\mathcal{I} \subseteq A \times A$ a reflexive relation. The* concretization $\gamma_{\mathcal{R},\mathcal{I}}(\mathcal{M}) \in \mathsf{LTS}(A)$ *consists of:*

- $Q^{\gamma(\mathcal{M})} := Q^{\mathcal{M}} \times W \cup \{\chi\}$ *with* $W := \{w \in A^* \mid w = \varepsilon \text{ or } \exists b \in \mathsf{dom}(\mathcal{R}) \colon w \lneq \mathcal{R}(b)\}$.
- $q_0^{\gamma(\mathcal{M})} := (q_0^{\mathcal{M}}, \varepsilon)$
- *Transitions are defined by the following rules, for $a \in A$, $w \in A^*$, $b \in B$:*

$$\frac{wa \in W}{(q,w) \xrightarrow{a}_{\gamma(\mathcal{M})} (q,wa)} \ (1_\gamma) \qquad \frac{q \xrightarrow{b}_{\mathcal{M}} q', \quad \mathcal{R}(b) = wa}{(q,w) \xrightarrow{a}_{\gamma(\mathcal{M})} (q',\varepsilon)} \ (2_\gamma)$$

$$\frac{\forall a' \in A, (a,a') \in \mathcal{I}\colon \quad wa' \notin W \wedge wa' \notin \mathsf{im}(\mathcal{R})}{(q,w) \xrightarrow{a}_{\gamma(\mathcal{M})} \chi} \ (3_\gamma) \qquad \frac{}{\chi \xrightarrow{a}_{\gamma(\mathcal{M})} \chi} \ (4_\gamma)$$

Intuitively, W represents the internal nodes of the tree-representation of action code $\mathcal{R}$. The transitions then try to accumulate a word $w \in A^*$ known to the action code (rule (1_γ)). As soon as we reach $w = \mathcal{R}(b)$ for some b, we use a b-transition in the original $\mathcal{M} \in \mathsf{LTS}(B)$ to jump to a new state (rule (2_γ)). The chaos state χ attracts all runs with symbols unknown to the action code. The corresponding rule (3_γ) involves the relation $\mathcal{I} \subseteq A \times A$. The rule only allows a transition to χ for a symbol $a \in A$ if there is no related symbol $a' \in A$, $(a,a') \in A$ for which the code R could make a transition. For general LTSs, we can simply consider $\mathcal{I}$ to be the identity relation on A. Once transitioned to the chaos state χ, we allow transitions for arbitrary action symbols $a \in A$ (rule (4_γ)).

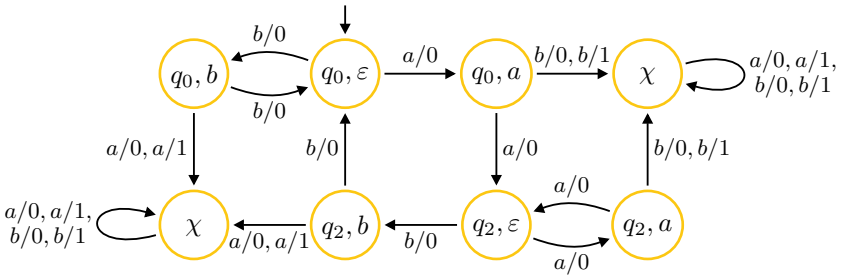

Figure 8 Concretization of the Mealy machine of Figure 5a.

▶ **Example 5.2.** For the special case of Mealy machines $A := I \times O$, we can define $\mathcal{I} \subseteq (I \times O) \times (I \times O)$ to relate (i, o) and (i', o') iff $i = i'$, i.e. two actions are related if they use the same input symbol. Then, we only have transitions to the chaos states if the code can't do any action for the same input symbol $i \in I$. Figure 8 depicts the concretization (for this $\mathcal{I}$) of the Mealy machine of Figure 5a(right) with the action code of Figure 5a(left). To increase readability, we introduced two copies of chaos state χ. Also, multiple labels next to an arrow denote multiple transitions.

Like in the refinement operator, the transition structure of γ is built in such a way that transitions for $b \in B$ in $\mathcal{M}$ correspond to runs of $\mathcal{R}(b)$ in $\gamma(\mathcal{M})$:

$$(q, \varepsilon) \xrightarrow{\mathcal{R}(b)}_{\gamma(\mathcal{M})} \bar{q} \quad \text{iff} \quad \exists q' \colon q \xrightarrow{b}_{\mathcal{M}} q' \text{ and } \bar{q} = (q', \varepsilon).$$

To make γ right adjoint to α, all runs outside the code $\mathcal{R}$ lead to the chaos state. One may think that the many transitions to the chaos state χ would make the construction $\gamma_{\mathcal{R}}$ trivial. However, only those paths lead to χ for which the action code is not defined.

The following technical condition describes that a code $\mathcal{R}$ contains sufficiently many related symbols compared to a given $\mathcal{M} \in \mathsf{LTS}(A)$:

▶ **Definition 5.3** (🐓). *A code $\mathcal{R} \in \mathsf{Code}(A, B)$ is called $\mathcal{I}$-complete for $\mathcal{M} \in \mathsf{LTS}(A)$, if for all $w \in B^*$, $u \in A^*$, $q \in Q^{\mathcal{M}}$, $a, a' \in A$:*

$$r_0 \xrightarrow{u\,a}_{\mathcal{R}} \quad \text{and} \quad (a, a') \in \mathcal{I} \quad \text{and} \quad q_0 \xrightarrow{\mathcal{R}^*(w)\ u}_{\mathcal{M}} q \xrightarrow{a'} \quad \text{implies} \quad r_0 \xrightarrow{u\,a'}_{\mathcal{R}}.$$

Intuitively, $\mathcal{I}$-completeness means that if a state $q \in \mathcal{M}$ can do a transition for $a' \in A$ which is related to similar symbol $a \in A$ defined in the action code, then $a' \in A$ itself is also defined in the action code. However, we do not compare arbitrary transitions of q in $\mathcal{M}$ with arbitrary symbols mentioned in $\mathcal{R}$, but only look at the node in $\mathcal{R}$ reached when 'executing $\mathcal{R}$' zero or more times while following the path $q_0 \Longrightarrow q$.

For example, if $\mathcal{I} \subseteq A \times A$ happens to be the identity relation, then $\mathcal{R}$ is $\mathcal{I}$-complete for any $\mathcal{M} \in \mathsf{LTS}(A)$. In the instance of $\mathcal{I} \subseteq (I \times O) \times (I \times O)$ for Mealy machines, if $\mathcal{R}$ is $\mathcal{I}$-complete for $\mathcal{M}$, then this means: whenever a state $q \in Q^{\mathcal{M}}$ has transitions $q \xrightarrow{i/o}$ and $q \xrightarrow{i/o'}$, then the code $\mathcal{R}$ is defined for either both or none of them.

▶ **Assumption 5.4.** For the rest of the present Section 5, we fix the sets A, B, an action code $\mathcal{R} \in \mathsf{Code}(A, B)$, and a reflexive relation $\mathcal{I} \subseteq A \times A$.

▶ **Theorem 5.5** (Galois connection, 🐓). *For all $\mathcal{N} \in \mathsf{LTS}(A)$, and $\mathcal{M} \in \mathsf{LTS}(B)$, such that $\mathcal{R}$ is $\mathcal{I}$-complete for $\mathcal{N}$, we have*

$$\alpha_{\mathcal{R}}(\mathcal{N}) \sqsubseteq \mathcal{M} \ (\text{in } \mathsf{LTS}(B)) \qquad \Longleftrightarrow \qquad \mathcal{N} \sqsubseteq \gamma_{\mathcal{R},\mathcal{I}}(\mathcal{M}) \ (\text{in } \mathsf{LTS}(A)).$$

▶ **Example 5.6** (🐓). If we instantiate $\mathcal{I}$ to be the identity relation Δ on A, then this means that we simply replace a' with a in rule (3_γ), and then we have above equivalence for all $\mathcal{N} \in \mathsf{LTS}(A)$ and $\mathcal{M} \in \mathsf{LTS}(B)$ (without any side-condition):

$$\alpha_{\mathcal{R}}(\mathcal{N}) \sqsubseteq \mathcal{M} \text{ (in } \mathsf{LTS}(B)) \qquad \Longleftrightarrow \qquad \mathcal{N} \sqsubseteq \gamma_{\mathcal{R},\Delta}(\mathcal{M}) \text{ (in } \mathsf{LTS}(A)).$$

▶ **Example 5.7** (🐓). Consider the instantiation of $\mathcal{I}$ for Mealy machines described in Example 5.2. Let $\mathcal{N}$ be our running example of Figure 2, let $\mathcal{R}$ be the action code from Figure 5a(left), and let $\mathcal{M}$ be the abstract Mealy machine from Figure 5a(right), i.e. $\alpha_{\mathcal{R}}(\mathcal{N}) = \mathcal{M}$. One can verify that $\mathcal{R}$ is $\mathcal{I}$-complete for $\mathcal{N}$. Therefore, application of the Galois connection gives that there is a simulation from $\mathcal{N}$ to the Mealy machine $\gamma_{\mathcal{R},\mathcal{I}}(\mathcal{M})$ of Figure 8.

It is a standard proof that the operators in a Galois connections are monotone. In that proof, one applies the Galois connection also to $\mathcal{M} := \gamma_{\mathcal{R},\mathcal{I}}(\mathcal{N})$, so we first need to show that it satisfies the technical completeness condition:

▶ **Lemma 5.8** (🐓). *$\mathcal{R}$ is always $\mathcal{I}$-complete for $\gamma_{\mathcal{R},\mathcal{I}}(\mathcal{M})$.*

▶ **Corollary 5.9** (🐓). *$\mathcal{M} \sqsubseteq \mathcal{N}$ in $\mathsf{LTS}(B)$ implies $\gamma_{\mathcal{R},\mathcal{I}}(\mathcal{M}) \sqsubseteq \gamma_{\mathcal{R},\mathcal{I}}(\mathcal{N})$ in $\mathsf{LTS}(A)$.*

▶ Remark 5.10. Monotonicity of concretization also follows by observing that the rules in Definition 5.1 all fit the *tyft* format of [19] if we view $(\cdot, w)$ as a unary operator for each sequence $w \in W$. Monotonicity then follows from the result of [19] that the simulation preorder is a congruence for any operator defined using the *tyft* format. Since contraction also can be defined using the *tyft* format, also monotonicity of contraction (Proposition 3.11) follows from the result of [19].

Like refinement, concretization preserves determinism.

▶ **Proposition 5.11** (🐓). *If $\mathcal{M} \in \mathsf{LTS}(B)$ is a deterministic LTS and Δ the identity relation on A, then $\gamma_{\mathcal{R},\Delta}(\mathcal{M})$ is deterministic, too.*

If the code $\mathcal{R} \in \mathsf{Code}(A, B)$ is defined for all labels mentioned in $\mathcal{M} \in \mathsf{LTS}(B)$, then $\gamma_{\mathcal{R}}$ is even the right inverse of $\alpha_{\mathcal{R}}$, that is, we have a Galois insertion:

▶ **Theorem 5.12** (Galois insertion, 🐓). *If $\mathcal{M} \in \mathsf{LTS}(\mathsf{dom}(\mathcal{R}))$, then $\mathcal{M} \cong \alpha_{\mathcal{R}}(\gamma_{\mathcal{R},\mathcal{I}}(\mathcal{M}))$.*

Note that $\mathsf{dom}(\mathcal{R}) \subseteq B$, and so $\mathsf{LTS}(\mathsf{dom}(\mathcal{R})) \subseteq \mathsf{LTS}(B)$. Since we may reach the chaos state χ in the concretization, it is clear that $\gamma_{\mathcal{R}}$ is not a left inverse of $\alpha_{\mathcal{R}}$ in general.

6 Action Code Composition

Since notions of abstraction can be stacked up, it is natural to consider multiple adaptors for multiple action codes. Assume an action code $\mathcal{R} \in \mathsf{Code}(A, B)$ and an action code $\mathcal{S} \in \mathsf{Code}(B, C)$. Then the composition of $\mathcal{R}$ and $\mathcal{S}$ should be an action code from A to C.

▶ **Definition 6.1** (🐓). *Given two map-based action codes $\mathcal{R}\colon B \rightharpoonup A^+$ and $\mathcal{S}\colon C \rightharpoonup B^+$, we define their* (Kleisli) composition $(\mathcal{R} * \mathcal{S})\colon C \rightharpoonup A^+$ *by*

$$(\mathcal{R} * \mathcal{S})(c) = \begin{cases} \mathcal{R}(b_1) \cdots \mathcal{R}(b_n) & \text{if } \mathcal{S}(c) = b_1 \cdots b_n \text{ with } \forall i\colon b_i \in \mathsf{dom}(\mathcal{R}) \\ \text{undefined} & \text{otherwise} \end{cases}$$

The composed action code $\mathcal{R} * \mathcal{S}$ is only defined for $c \in C$ if $\mathcal{S}$ is defined for c and additionally $\mathcal{R}$ is defined for every letter $b_i \in B$ that appears in the word $\mathcal{S}(c) \in B^+$.

▶ Remark 6.2. The defined composition is an instance of *Kleisli composition* for a monad, which is a standard concept in functional programming and category theory.

▶ **Lemma 6.3** (🐓). *Action codes are closed under composition.*

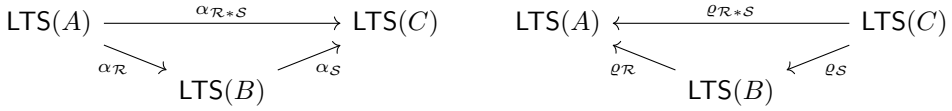
Concretely, given two map-based action codes $\mathcal{R}\colon B \rightharpoonup A^+$ *and* $\mathcal{S}\colon C \rightharpoonup B^+$*, their Kleisli composition* $(\mathcal{R} * \mathcal{S})\colon C \rightharpoonup A^+$ *is again a* prefix-free *partial map.*

Now that we can compose action codes, we can now investigate how the previously defined operators on LTSs behave for composed action codes:

▶ **Theorem 6.4** (🐓, 🐓). *Contraction and refinement commute with action code composition: for action codes* $\mathcal{R} \in \mathsf{Code}(A, B)$, $\mathcal{S} \in \mathsf{Code}(B, C)$,

1. $\alpha_{\mathcal{R}*\mathcal{S}}(\mathcal{M}) = \alpha_{\mathcal{S}}(\alpha_{\mathcal{R}}(\mathcal{M}))$ *for all* $\mathcal{M} \in \mathsf{LTS}(A)$.
2. $\varrho_{\mathcal{R}*\mathcal{S}}(\mathcal{M}) = \varrho_{\mathcal{R}}(\varrho_{\mathcal{S}}(\mathcal{M}))$, *whenever* $\mathsf{im}(\mathcal{S}) \subseteq \mathsf{dom}(\mathcal{R})^+$ *and for all* $\mathcal{M} \in \mathsf{LTS}(C)$.

For the case of refinement, the additional assumption expresses that every word produced by $\mathcal{S}$ only contains letters $b \in B$ for which $\mathcal{R}$ is defined. The equations of Theorem 6.4 equivalently mean that the following diagrams commute:



▶ Remark 6.5 (🐓). Concretization does not commute with action code composition. The reason for that is that the rules (1_γ) and (2_γ) in $\gamma_{\mathcal{R}}(\gamma_{\mathcal{S}}(\mathcal{M}))$ would also be applied to transitions for the chaos state in $\gamma_{\mathcal{S}}(\mathcal{M}) \in \mathsf{LTS}(B)$ (see appendix for details).

7 Adaptors

In this section, we describe how action codes may be used for learning and testing of black-box systems. The general architecture is shown in Figure 9. On the right we see the *system under test (SUT)*, some piece of hardware/software whose behavior can be modeled by a Mealy machine $\mathcal{M}$ with inputs I and outputs O. On the left we see the *learner/tester*, an

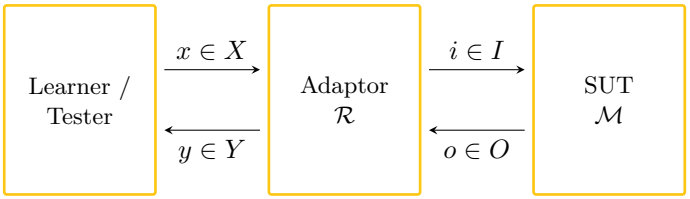


Figure 9 Using action codes for learning/testing.

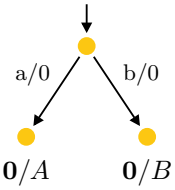

Figure 10 Example 7.4.

agent which either tries to construct a model $\mathcal{N}$ of $\mathcal{M}$ by performing experiments, or already has such a model $\mathcal{N}$ and performs experiments (tests) to find a counterexample which shows that $\mathcal{M}$ and $\mathcal{N}$ behave differently. The learner/tester uses abstract inputs X and outputs Y. In between the learner/tester and the SUT we place an *adaptor*, which uses action code $\mathcal{R}$ to translate between the abstract world of the learner/tester and the concrete world of the SUT. In order to enable the adaptor to do its job, we need to make four (reasonable) assumptions.

Our first assumption, common in model-based testing [35], is that the SUT will accept any input from I in any state, that is, we require that $\mathcal{M}$ is *input enabled*: for all $q \in Q^{\mathcal{M}}$ and $i \in I$, $q \xrightarrow{i/}_{\mathcal{M}}$. Our second assumption is that code $\mathcal{R}$ is $\mathcal{I}$-complete for $\mathcal{M}$ (for $\mathcal{I}$

denoting *same input* as in Example 5.2). This ensures that whenever the adaptor sends a concrete symbol $i \in I$ to the SUT, the adaptor will accept any output $o \in O$ that the SUT may possibly produce in response. Our third assumption is that whenever the adaptor receives an abstract input $x \in X$ from the learner/tester, it can choose concrete inputs from I that drive $\mathcal{R}$ from its initial state to a leaf with label (x, y), for some $y \in Y$. Output y can then be returned as a response to the learner/tester. Reaching such a leaf is nontrivial since the transitions taken in $\mathcal{R}$ are also determined by the outputs provided by the SUT. We may think of the situation in terms of a 2-player game where the adaptor wins if the game ends in an x-leaf, and the SUT wins otherwise. Formally, we require that $\mathcal{R}$ has finitely many states and a winning strategy for every input $x \in X$, as defined below:

▶ **Definition 7.1** (Winning). *Let $\mathcal{R} = \langle R, r_0, \longrightarrow, l\rangle \in \mathsf{Code}(I \times O, X \times Y)$ be an action code with R finite and let $x \in X$. Then*

1. *A leaf $r \in R$ is* winning for x *if $\pi_1(l(r)) = x$.*[1]
2. *An internal state $r \in R$ is* winning for x with input $i \in I$ *if $r \xrightarrow{i/}$ and, for each transition of the form $r \xrightarrow{i/o} r'$, r' is winning for x.*
3. *An internal state $r \in R$ is* winning for x *if it is winning for x with some $i \in I$.*
4. *$\mathcal{R}$ has a* winning strategy for x *if r_0 is winning for x.*

▶ **Example 7.2.** The action codes for Mealy machines that we have seen thus far (Figures 4, 5a and 5b) are winning for all the inputs that label their leaves. The action code of Figure 4 is not winning for the input  (latte macchiato), for the simple reason that this input does not label any leaf. If we remove the transition to the leaf  /2 in Figure 4, then the resulting code is no longer winning for  (espresso), although it is winning for  (coffee).

Our fourth and final assumption is that action code $\mathcal{R}$ is *determinate*. If an action code is determinate then, for each state r and abstract input x, there is at most one concrete input i such that r is winning for x with i.

▶ **Definition 7.3** (Determinate, ). *An action code $\mathcal{R}$ is* determinate *if, for each state r, whenever $r \xrightarrow{i_1/} r_1$, $r \xrightarrow{i_2/} r_2$ and from both r_1 and r_2 there is a path to a leaf labeled with input x, then $i_1 = i_2$.*

▶ **Example 7.4.** All action codes for Mealy machines that we have seen thus far (Figures 4, 5a and 5b) are determinate. Figure 10 shows an action code that is not determinate: in the root two different concrete inputs a and b are enabled that lead to leaves with the same abstract input $\mathbf{0}$. Hence (trivially), this action code does have a winning strategy for input $\mathbf{0}$.

Algorithm 1 shows pseudocode for an adaptor that implements action code $\mathcal{R}$. During learning/testing, the adaptor records the current state of the action code in a variable r. When an abstract input x arrives, it first sets r to r_0. As long as current state r is internal, the adaptor chooses an input i that is winning for x, and forwards it to the SUT. When the SUT replies with an output o, the adaptor sets r to a state r' with $r \xrightarrow{i/o} r'$. When the new r is internal the adaptor chooses again a winning input, and updates its current state after interacting with the SUT, etc. When the new r is a leaf with label (x, y) then the adaptor returns symbol y to the learner/tester and waits for the next abstract input to arrive.

[1] We use projections functions π_1 and π_2 to denote the first and second element of a pair, respectively. So $\pi_1(x, y) = x$ and $\pi_2(x, y) = y$.

Algorithm 1 Pseudocode for an adaptor that implements action code $\mathcal{R}$.

```
1: while true do
2:     x ← Receive-from-learner()
3:     r ← r_0
4:     while r is internal do                ▷ loop invariant: r is winning for x
5:         i ← unique input such that r is winning for x with i
6:         Send-to-SUT(i)
7:         o ← Receive-from-SUT()
8:         r ← unique state r' such that r --i/o--> r'        ▷ R is I-complete for M
9:     end while
10:    Send-to-learner(π_2(l(r)))
11: end while
```

From the perspective of the learner/tester, the combination of the adaptor and SUT behaves the same as the contraction $\alpha_{\mathcal{R}}(\mathcal{M})$. In the appendix, we will formalize this statement by modeling both the combination of adaptor and SUT, as well as contraction $\alpha_{\mathcal{R}}(\mathcal{M})$ as expressions in the process calculus CCS [30], and then establish the existence of *delay simulations* between these expressions. This implies that both expressions have the same traces if we remove all occurrences of the synchronizations between adaptor and SUT, which are invisible from the perspective of the learner.

▶ **Theorem 7.5.** *Let $\mathcal{M} \in \mathsf{LTS}(I \times O)$ be an input enabled Mealy machine and let $\mathcal{R} \in \mathsf{Code}(I \times O, X \times Y)$ be a finite, determinate action code that has a winning strategy for every input in X and that is output enabled for $\mathcal{M}$. Then the composition of an implementation for $\mathcal{M}$ and an adaptor for $\mathcal{R}$ is delay simulation equivalent to an implementation for $\alpha_{\mathcal{R}}(\mathcal{M})$.*

▶ Remark 7.6. Requiring the existence of a determinate action code with a winning strategy for a Mealy machine is not a severe restriction. Definition 7.1 implicitly describes a bottom-up algorithm (linear in the size of the action code) that checks whether a winning strategy exists. Checking whether an action code is determinate is also easy. A sufficient (but not necessary) condition for an action code to be determinate and have a winning strategy is that when we project the action code to the inputs (with concrete inputs labeling the transitions and abstract inputs as label for the leaves) and merge isomorphic subtrees, then the result is still an action code (defined for all the abstract inputs). This is a natural condition that can also be used for the design of determinate action codes with a winning strategy: we start from an action code for the inputs and recursively add output labels starting from the root. Whenever, for a given input i, different outputs may occur, we make a copy of the subtree after i for each possible output o. Finally, the abstract outputs need to be defined in such a way that the labeling of the leaves remains injective.

Active automata learning algorithms and tools for Mealy machines typically assume that the system under learning is *output deterministic*[2]: the output and target state of a transition are uniquely determined by its source state and input.

▶ **Definition 7.7.** *Mealy machine $\mathcal{M}$ is* output deterministic *if, for each state q and input i,*

$$q \xrightarrow{i/o} r \wedge q \xrightarrow{i/o'} r' \quad \Rightarrow \quad o = o' \wedge r = r'.$$

[2] The notion of deterministic that we use in this article is the standard one for LTSs. In the literature on Mealy machines and FSMs, machines that we call output deterministic are called deterministic, and machines that we call deterministic are called observable.

For action codes that are determinate, contraction preserves output determinism. This property makes it possible to use existing automata learning tools to learn models of an output deterministic SUT composed with a determinate adaptor.

▶ **Proposition 7.8** (🐓). *Suppose $\mathcal{M}$ is a Mealy machine and $\mathcal{R}$ is an action code. If $\mathcal{M}$ is output deterministic and $\mathcal{R}$ is determinate then $\alpha_{\mathcal{R}}(\mathcal{M})$ is output deterministic.*

8 Discussion and Future Work

Via the notion of action codes, we provided a new perspective on the fundamental question how high-level state machine models with abstract actions can be related to low-level models in which these actions are refined by sequences of concrete actions. This perspective may, for instance, help with the systematic design of adaptors during learning and testing, and the subsequent interpretation of obtained results. Our theory allows for action codes (such as in Figure 4) that are adaptive in the sense that outputs which occur in response to inputs at the concrete level may determine the sequence of concrete inputs that refines an abstract input. We are not aware of case studies in which such adaptive codes are used, but believe they may be of practical interest. One may, for instance, consider a scenario in which an abstract action AUTHENTICATE is refined by a protocol in which a user is either asked to authenticate by entering a PIN code, or by providing a fingerprint.

Close to our work are the results of Rensink and Gorrieri [31], who investigate vertical implementation relations to link models at conceptually different levels of abstraction. These relations are indexed by a refinement function that maps abstract actions into concrete processes. Within a setting of a CCS-like language, Rensink & Gorrieri [31] list a number of proof rules that should hold for any vertical implementation relation, and propose *vertical bisimulation* as a candidate vertical implementation relation for which these proof rules hold. In the setting of our paper, we can define two vertical implementation relations $\sqsubseteq_{\gamma}^{\mathcal{R}}$ and $\sqsubseteq_{\varrho}^{\mathcal{R}}$, for any action code $\mathcal{R}$, by

$$\mathcal{M} \sqsubseteq_{\gamma}^{\mathcal{R}} \mathcal{N} \;\Leftrightarrow\; \mathcal{M} \sqsubseteq \gamma_{\mathcal{R}}(\mathcal{N}) \quad \text{and} \quad \mathcal{M} \sqsubseteq_{\varrho}^{\mathcal{R}} \mathcal{N} \;\Leftrightarrow\; \mathcal{M} \sqsubseteq \varrho_{\mathcal{R}}(\mathcal{N}).$$

Then $\sqsubseteq_{\varrho}^{\mathcal{R}} \subseteq \sqsubseteq_{\gamma}^{\mathcal{R}}$ and both relations satisfy all language-independent proof rules of [31]. For instance, we have

$$\frac{\mathcal{M} \sqsubseteq \mathcal{M}' \quad \mathcal{M}' \sqsubseteq_{\gamma}^{\mathcal{R}} \mathcal{N}' \quad \mathcal{N}' \sqsubseteq \mathcal{N}}{\mathcal{M} \sqsubseteq_{\gamma}^{\mathcal{R}} \mathcal{N}}$$

(since $\gamma_{\mathcal{R}}$ is monotone and $\sqsubseteq$ is transitive). With the action code $\mathcal{R}$ of Figure 3, both implementation relations relate the LTSs of Figures 1c and 1a. However, the vertical bisimulation preorder of Rensink and Gorrieri [31] does not relate these LTSs, when using a code that maps a to 1 4 1, and b to 1 4 2. This suggests that bisimulations may not be suitable as vertical implementation relations.

Also close to our work are results of Burton et al. [8, 23], who propose a vertical implementation relation in the context of CSP. Instead of action codes, they use *extraction patterns*, a strict monotonic map $extr : Dom \to B^*$, where Dom is the prefix closure of a set $dom \subseteq A^*$ of concrete action sequences that may be regarded as complete. As a mapping from concrete to abstract sequences of actions, extraction patterns are more general than action codes. However, as extraction mappings are not required to have an inverse, establishing interesting Galois connections in this setting may be difficult. With an extraction pattern

defined in the obvious way, the LTSs of Figures 1c and 1a are related by the implementation relation of [8]. We are not aware of any other vertical implementation relation proposed in the literature that handles our basic interface refinement example correctly. We find it surprising that the fundamental problem of refining inputs actions has not been properly addressed in the literature, except in some work that apparently has not been picked up outside Newcastle-upon-Tyne and Catania.

The action refinement operator $\varrho_{\mathcal{R}}$ that we study is similar to the one proposed by [16, 17]. It improves on the one from [16, 17] by not introducing unnecessary nondeterminism, as illustrated in the example of Figure 1. However, it falls short of the approach of [16, 17] by not considering concurrency. Another difference is that in [16, 17] $\mathcal{R}(b)$ can be an arbitrary system (including choice and parallel composition), whereas in our work it must be a sequence. But then [16, 17] did not have the dual contraction operator $\alpha_{\mathcal{R}}$. It would be very interesting to combine both approaches.

Our theory is orthogonal to the one of Aarts et al. [1], which explores the use of so-called *mappers* to formalize adaptors that abstract the large action alphabets of realistic applications into small sets of actions that can be handled by a learning tool. Aarts et al. [1] also describe the relation between abstract and concrete models using a Galois connection. In practical applications of model learning, it makes sense to construct an adaptor that combines a mapper in the sense of [1] with an action code as introduced in this paper. Fiterău-Broştean et al. [11] describe a small domain specific language to specify mapper components, and from which adaptor software can be generated automatically. It would be interesting to extend this domain specific language so that it may also be used to specify action codes.

We developed our theory for LTSs and Mealy machines, using the simulation preorder as the implementation relation. It would be interesting to transfer our results to other modeling frameworks, such as IOTSs [35] timed automata [3] and Markov Decision Processes, and to other preorders and equivalences in the linear-time branching-time spectrum for LTSs [15] and IOTSs [22]. An obvious direction for future work would be to explore how action codes interact with parallel composition. Here the work of [8, 23] may serve as a basis.

Different action codes lead to different contractions, and thereby to different abstract views of a system, see for instance Figures 5a and 5b. We may try to exploit this fact during learning and testing. For instance, if a system $\mathcal{M}$ is too big for state-of-the-art learning algorithms, we may still succeed to learn partial views using cleverly selected action codes. Using our Galois connections we then could obtain various upper and lower bounds for $\mathcal{M}$. Ideally, such an approach may even succeed to uniquely identify $\mathcal{M}$. In particular, learning algorithms such as $L^{\#}$ [38] that use observation trees as their primary data structure may exploit the use of different action codes, since the refinement operator $\varrho_{\mathcal{R}}$ and contraction operator $\alpha_{\mathcal{R}}$ transform observation trees for abstract actions into observation trees for concrete actions, and vice versa. Maarse [29] quantified the quality of a contraction $\alpha_{\mathcal{R}}(\mathcal{M})$ in terms of the graph-theoretic concept of *eccentricity*. If q and q' are states in an LTS $\mathcal{M}$ then $d(q, q')$ is defined as the number of transitions in the shortest path from q to q' (or ∞ if no such path exists). For any set of states $Q \subseteq Q_{\mathcal{M}}$, the *eccentricity* $\varepsilon(Q)$ is defined as $\max_{q' \in Q_{\mathcal{M}}} \min_{q \in Q} d(q, q')$, that is, the maximal distance one needs to travel to visit a state of $\mathcal{M}$, starting from a state of Q. A good contraction has a small set of states Q and a low eccentricity $\varepsilon(Q)$: it only covers a small subset Q of the states of $\mathcal{M}$, but any state from $\mathcal{M}$ can be reached via a few transitions from a Q-state.
