Ortho-Radial Drawing in Near-Linear Time

Yi-Jun Chang
National University of Singapore, Singapore

Abstract

An *orthogonal drawing* is an embedding of a plane graph into a grid. In a seminal work of Tamassia (SIAM Journal on Computing 1987), a simple combinatorial characterization of angle assignments that can be realized as bend-free orthogonal drawings was established, thereby allowing an orthogonal drawing to be described combinatorially by listing the angles of all corners. The characterization reduces the need to consider certain geometric aspects, such as edge lengths and vertex coordinates, and simplifies the task of graph drawing algorithm design.

Barth, Niedermann, Rutter, and Wolf (SoCG 2017) established an analogous combinatorial characterization for *ortho-radial drawings*, which are a generalization of orthogonal drawings to *cylindrical grids*. The proof of the characterization is existential and does not result in an efficient algorithm. Niedermann, Rutter, and Wolf (SoCG 2019) later addressed this issue by developing quadratic-time algorithms for both testing the realizability of a given angle assignment as an ortho-radial drawing without bends and constructing such a drawing.

In this paper, we improve the time complexity of these tasks to near-linear time. We establish a new characterization for ortho-radial drawings based on the concept of a *good sequence*. Using the new characterization, we design a simple greedy algorithm for constructing ortho-radial drawings.

1 Introduction

A *plane graph* is a *planar graph* $G = (V, E)$ with a *combinatorial embedding* $\mathcal{E}$. The combinatorial embedding $\mathcal{E}$ fixes a circular ordering $\mathcal{E}(v)$ of the edges incident to each vertex $v \in V$, specifying the counter-clockwise ordering of these edges surrounding v in the drawing. An *orthogonal drawing* of a plane graph is a drawing of G such that each edge is drawn as a sequence of horizontal and vertical line segments. For example, see Figure 1 for an orthogonal drawing of K_4 with 4 bends. Alternatively, an orthogonal drawing of G can be seen as an embedding of G into a grid such that the edges of G correspond to internally disjoint paths in the grid. Orthogonal drawing is one of the most classical drawing styles studied in the field of graph drawing, and it has a wide range of applications, including VLSI circuit design [7, 40], architectural floor plan design [33], and network visualization [5, 22, 26, 30].

The topology-shape-metric framework. One of the most fundamental quality measures of orthogonal drawings is the number of *bends*. The *bend minimization* problem, which asks for an orthogonal drawing with the smallest number of bends, has been extensively studied over the past 40 years [14, 16, 17, 38, 39, 25]. In a seminal work, Tamassia [39] introduced the *topology-shape-metric* framework to tackle the bend minimization problem. Tamassia showed that an orthogonal drawing can be described combinatorially by an *orthogonal representation*, which consists of an assignment of an angle of degree in $\{90°, 180°, 270°, 360°\}$ to each corner and a designation of the *outer face*. Specifically, Tamassia [39] showed that an orthogonal representation can be realized as an orthogonal drawing with zero bends if and only if the following two conditions are satisfied:

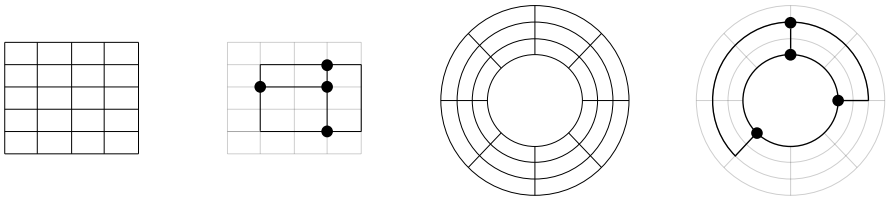

Figure 1 A grid, an orthogonal drawing, a cylindrical grid, and an ortho-radial drawing.

(O1) The sum of angles around each vertex is 360°.

(O2) The sum of angles around each face with k corners is $(k+2)\cdot 180°$ for the outer face and is $(k-2)\cdot 180°$ for the other faces.

An orthogonal representation is *valid* if it satisfies the above conditions (O1) and (O2). Given a valid orthogonal representation, an orthogonal drawing realizing the orthogonal representation can be computed in linear time [29, 39]. This result (shape → metric) allows us to reduce the task of finding a bend-minimized orthogonal drawing (topology → metric) to the conceptually much simpler task of finding a bend-minimized valid orthogonal representation (topology → shape). By focusing on orthogonal representations, we may neglect certain geometric aspects of graph drawing such as edge lengths and vertex coordinates, making the task of algorithm design easier. In particular, given a fixed combinatorial embedding, the task of finding a bend-minimized orthogonal representation can be easily reduced to the computation of a min-cost flow [39].

1.1 Ortho-radial drawing

Ortho-radial drawing is a natural generalization of orthogonal drawing to *cylindrical grids*, whose grid lines consist of concentric circles and straight lines emanating from the center of the circles. Formally, an ortho-radial drawing is defined as a planar embedding where each edge is drawn as a sequence of lines that are either a circular arc of some circle centered on the origin or a line segment of some straight line passing through the origin. We do not allow a vertex to be drawn on the origin, and we do not allow an edge to pass through the origin in the drawing. For example, see Figure 1 for an ortho-radial drawing of K_4 with two bends.

The study of ortho-radial drawing is motivated by its applications [4, 23, 42] in network visualization [41]. For example, ortho-radial drawing is naturally suitable for visualizing metro systems with radial routes and circle routes.

There are three types of faces in an ortho-radial drawing. The face that contains an unbounded region is called the *outer face*. The face that contains the origin is called the *central face*. The remaining faces are called *regular faces*. It is possible that the outer face and the central face are the same face.

Given a plane graph, an *ortho-radial representation* is defined as an assignment of an angle to each corner together with a designation of the central face and the outer face. Barth, Niedermann, Rutter, and Wolf [2] showed that an ortho-radial representation can be realized as an ortho-radial drawing with zero bends if the following three conditions are satisfied:

(R1) The sum of angles around each vertex is 360°.

(R2) The sum s of angles around each face F with k corners satisfies the following.

- $s = (k-2)\cdot 180°$ if F is a regular face.
- $s = k\cdot 180°$ if F is either the central face or the outer face, but not both.
- $s = (k+2)\cdot 180°$ if F is both the central face and the outer face.

(R3) There exists a choice of the *reference edge* $e^\star$ such that the ortho-radial representation does not contain a *strictly monotone cycle*.

Intuitively, this shows that the ortho-radial representations that can be realized as ortho-radial drawings with zero bends can be characterized similarly by examining the angle sum around each vertex and each face, with the additional requirement that the representation does not have a strictly monotone cycle.

The definition of a strictly monotone cycle is technical and depends on the choice of the reference edge $e^\star$, so we defer its formal definition to a subsequent section. The reference edge $e^\star$ is an edge in the contour of the outer face and is required to lie on the outermost circular arc used in an ortho-radial drawing. Informally, a strictly monotone cycle has a structure that is like a loop of ascending stairs or a loop of descending stairs, so a strictly monotone cycle cannot be drawn. The necessity of (R1)–(R3) is intuitive to see. The more challenging and interesting part of the proof in [2] is to show that these three conditions are actually sufficient.

1.2 Previous methods

The proof by Barth, Niedermann, Rutter, and Wolf [2] that conditions (R1)–(R3) are necessary and sufficient is only *existential* in that it does not yield efficient algorithms to check the validity of a given ortho-radial representation and to construct an ortho-radial drawing without bends realizing a given ortho-radial representation.

Checking (R1) and (R2) can be done in linear time in a straightforward manner. The difficult part is to design an efficient algorithm to check (R3). The most naive approach of examining all cycles costs exponential time. The subsequent work by Niedermann, Rutter, and Wolf [35] addressed this gap by showing an $O(n^2)$-time algorithm to decide whether a strictly monotone cycle exists for a given reference edge $e^\star$, where n is the number of vertices in the input graph. They also show an $O(n^2)$-time algorithm to construct an ortho-radial drawing without bends, for any given ortho-radial representation with a reference edge $e^\star$ that does not lead to a strictly monotone cycle.

Rectangulation. The idea behind the proof of Barth, Niedermann, Rutter, and Wolf [2] is a reduction to the easier case where each regular face is *rectangular*. For this case, they provided a proof that conditions (R1)–(R3) are necessary and sufficient, and they also provided an efficient drawing algorithm via a reduction to a flow computation given that (R1)–(R3) are satisfied. For any given ortho-radial representation with n vertices, it is possible to add $O(n)$ additional edges to turn it into an ortho-radial representation where each regular face is rectangular. A major difficulty in the proof of [2] is that they need to ensure that the addition of the edges preserves not only (R1) and (R2) but also (R3). The lack of an efficient algorithm to check whether (R3) is satisfied is precisely the reason that the proof of [2] does not immediately lead to a polynomial-time algorithm.

Quadratic-time algorithms. The above issue was addressed in a subsequent work by Niedermann, Rutter, and Wolf [35]. They provided an $O(n^2)$-time algorithm to find a strictly monotone cycle if one exists, given a fixed choice of the reference edge $e^\star$. This immediately leads to an $O(n^2)$-time algorithm to decide whether a given ortho-radial representation, with a fixed reference edge $e^\star$, admits an ortho-radial drawing. Moreover, combining this $O(n^2)$-time algorithm with the proof of [2] discussed above yields an $O(n^4)$-time drawing algorithm. The time complexity is due to the fact that $O(n)$ edge additions are needed for rectangulation, for each edge addition there are $O(n)$ candidate reference edges to consider, and to test the feasibility of each candidate edge they need to run the $O(n^2)$-time algorithm to test whether the edge addition creates a strictly monotone cycle.

The key idea behind the $O(n^2)$-time algorithm for finding a strictly monotone cycle is a structural theorem that if there is a strictly monotone cycle, then there is a unique outermost one which can be found by a *left-first* DFS starting from any edge in the outermost strictly monotone cycle. The DFS algorithm costs $O(n)$ time. Guessing an edge in the outermost monotone cycle adds an $O(n)$ factor overhead in the time complexity.

Using further structural insights on the augmentation process of [2], the time complexity of the above $O(n^4)$-time drawing algorithm can be lowered to $O(n^2)$ [35]. The reason for the quadratic time complexity is that for each of the $O(n)$ edge additions, a left-first DFS starting from the newly added edge is needed to test whether the addition of this edge creates a strictly monotone cycle.

1.3 Our new method

For both validity testing (checking whether a given angle assignment induces a strictly monotone cycle) and drawing (finding a geometric embedding realizing a given ortho-radial representation), the two algorithms in [35] naturally cost $O(n^2)$ time, as they both require performing left-first DFS $O(n)$ times.

In this paper, we present a new method for ortho-radial drawing that is not based on rectangulation and left-first DFS. We design a simple $O(n \log n)$-time greedy algorithm that simultaneously accomplishes both validity testing and drawing, for the case where the reference edge $e^\star$ is fixed. If a reference edge $e^\star$ is not fixed, our algorithm costs $O(n \log^2 n)$ time, where the extra $O(\log n)$ factor is due to a binary search over the set of candidates for the reference edge. At a high level, our algorithm tries to construct an ortho-radial drawing in a piece-by-piece manner. If at some point no progress can be made in that the current partial drawing cannot be further extended, then the algorithm can identify a strictly monotone cycle to certify the non-existence of a drawing.

Good sequences. The core of our method is the notion of a *good sequence*, which we briefly explain below. An ortho-radial representation satisfying (R1) and (R2), with a fixed reference edge $e^\star$, determines whether an edge e is a vertical edge (i.e., e is drawn as a segment of a straight line passing through the origin) or horizontal (i.e., e is drawn as a circular arc of some circle centered on the origin). Let E_{h} denote the set of horizontal edges, oriented in the clockwise direction, and let $\mathcal{S}_{\mathsf{h}}$ denote the set of connected components induced by E_{h}. Note that each component $S \in \mathcal{S}_{\mathsf{h}}$ is either a path or a cycle. The exact definition of a good sequence is technical, so we defer it to a subsequent section. Intuitively, a good sequence is an ordering of $\mathcal{S}_{\mathsf{h}} = (S_1, S_2, \ldots, S_k)$, where $k = |\mathcal{S}_{\mathsf{h}}|$, that allows us to design a simple linear-time greedy algorithm constructing an ortho-radial drawing in such a way that S_1 is drawn on the circle $r = k$, S_2 is drawn on the circle $r = k - 1$, and so on.

In general, a good sequence might not exist, even if the given ortho-radial representation admits an ortho-radial drawing. In such a case, we show that we may add *virtual edges* to transform the ortho-radial representation into one where a good sequence exists. We will design a greedy algorithm for adding virtual edges and constructing a good sequence. In each step, we add virtual vertical edges to the current graph and append a new element $S \in \mathcal{S}_{\mathsf{h}}$ to the end of our sequence. In case we are unable to find any suitable $S \in \mathcal{S}_{\mathsf{h}}$ to extend the sequence, we can extract a strictly monotone cycle to certify the non-existence of an ortho-radial drawing. A major difference between our method and the approach based on rectangulation in [2, 35] is that the cost for adding a new virtual edge is only $O(\log n)$ in our algorithm. As we will later see, in our algorithm, in order to identify new virtual edges to be added, we only need to do some simple local checks such as calculating the sum of angles, and there is no need to do a full left-first DFS to test whether a newly added edge creates a strictly monotone cycle.

Open questions. While we show a nearly linear-time algorithm for the (shape → metric)-step (i.e., from ortho-radial representations to ortho-radial drawings), essentially nothing is known about the (topology → shape)-step (from planar graphs to ortho-radial representations). While the task of finding a *bend-minimized orthogonal representation* of a given plane graph can be easily reduced to the computation of a minimum cost flow [39], such a reduction does not apply to ortho-radial representations, as network flows do not work well with the notion of strictly monotone cycles. It remains an open question as to whether a bend-minimized ortho-radial representation of a plane graph can be computed in polynomial time.

1.4 Related work

The bend minimization problem for orthogonal drawings for planar graphs of maximum degree 4 without a fixed combinatorial embedding is NP-hard [24, 25]. If the combinatorial embedding is fixed, the topology-shape-metric framework of Tamassia [39] reduces the bend minimization problem to a min-cost flow computation. The algorithm of Tamassia [39] costs $O(n^2 \log n)$ time. The time complexity was later improved to $O\left(n^{7/4}\sqrt{\log n}\right)$ [25] and then to $O\left(n^{3/2} \log n\right)$ [14]. A recent $O(n \operatorname{poly} \log n)$-time planar min-cost flow algorithm [20] implies that the bend minimization problem can be solved in $O(n \operatorname{poly} \log n)$ time if the combinatorial embedding is fixed.

If the combinatorial embedding is not fixed, the NP-hardness result of [24, 25] can be bypassed if the first bend on each edge does not incur any cost [9] or if we restrict ourselves to some special class of planar graphs. In particular, for planar graphs with maximum degree 3, it was shown that the bend-minimization can be solved in polynomial time [16]. After a series of improvements [13, 17, 19], we now know that a bend-minimized orthogonal drawing of a planar graph with maximum degree 3 can be computed in $O(n)$ time [17].

The topology-shape-metric framework [39] is not only useful in bend minimization, but it is also, implicitly or explicitly, behind the graph drawing algorithms for essentially all computational problems in orthogonal drawing and its variants, such as morphing orthogonal drawings [8], allowing vertices with degree greater than 4 [15, 31, 36], restricting the direction of edges [18, 21], drawing cluster graphs [10], and drawing dynamic graphs [11].

The study of ortho-radial drawing by Barth, Niedermann, Rutter, and Wolf [2, 35] extended the topology-shape-metric framework [39] to accommodate cylindrical grids. Before these works [2, 35], a combinatorial characterization of drawable ortho-radial representation is only known for paths, cycles, and theta graphs [28], and for the special case where the graph is 3-regular and each regular face in the ortho-radial representation is a rectangle [27].

1.5 Organization

In Section 2, we discuss the basic graph terminology used in this paper, review some results in previous works [2, 35], and state our main theorems. In Section 3, we give a technical overview of our proof. We conclude in Section 4 with discussions on possible future directions.

2 Preliminaries

Throughout the paper, let $G = (V, E)$ be a planar graph of maximum degree at most 4 with a fixed combinatorial embedding $\mathcal{E}$ in the sense that, for each vertex $v \in V$, a circular ordering $\mathcal{E}(v)$ of its incident edges is given to specify the counter-clockwise ordering of these edges surrounding v in a planar embedding. As we will discuss in the full version of the paper, we may assume that the input graph G is *simple* and *biconnected*. In this section, we introduce some basic graph terminology and review some results from the paper [3], which is a merge of the two papers [2, 35] on ortho-radial drawing.

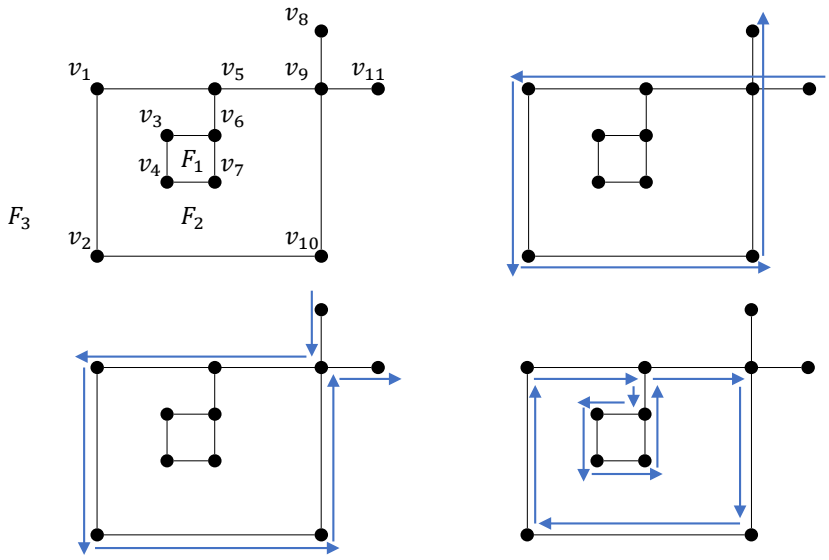

Figure 2 A non-crossing-free path, a crossing-free path, and a facial cycle.

Paths and cycles. Unless otherwise stated, all edges, paths, and cycles are assumed to be directed. We write $\overline{e}$, $\overline{P}$, and $\overline{C}$ to denote the *reversal* of an edge e, a path P, and a cycle C, respectively. We allow paths and cycles to have repeated vertices and edges. We say that a path or a cycle is *simple* if it does not have repeated vertices. Following [3], we say that a path or a cycle is *crossing-free* if it satisfies the following conditions:

- The path or the cycle does not contain repeated undirected edges.
- For each vertex v that appears multiple times in the path or the cycle, the ordering of the edges incident to v appearing in the path or the cycle respects the ordering of $\mathcal{E}(v)$ or its reversal.

Although a crossing-free path or a crossing-free cycle might touch a vertex multiple times, the path or the cycle never crosses itself. For any face F, we define the *facial cycle* C_F to be the clockwise traversal of its contour. In general, a facial cycle might not be a simple cycle as it can contain repeated edges. If we assume that G is biconnected, then each facial cycle of G must be a simple crossing-free cycle. See Figure 2 for an illustration of different types of paths and cycles. The path $(v_{11}, v_9, v_5, v_1, v_2, v_{10}, v_9, v_8)$ is not crossing-free as the path crosses itself at v_9. The path $(v_8, v_9, v_5, v_1, v_2, v_{10}, v_9, v_{11})$ is crossing-free since it respects the ordering $\mathcal{E}(v)$ for $v = v_9$. The cycle $C = (v_1, v_5, v_6, v_3, v_4, v_7, v_6, v_5, v_9, v_{10}, v_2)$ is the facial cycle of F_2. The cycle C is not a crossing-free cycle as it traverses the undirected edge $\{v_5, v_6\}$ twice, from opposite directions.

Ortho-radial representations and drawings. A *corner* is an ordered pair of undirected edges (e_1, e_2) incident to v such that e_2 immediately follows e_1 in the counter-clockwise circular ordering $\mathcal{E}(v)$. Given a planar graph $G = (V, E)$ with a fixed combinatorial embedding $\mathcal{E}$, an ortho-radial representation $\mathcal{R} = (\phi, F_\mathsf{c}, F_\mathsf{o})$ of G is defined by the following components:

- An assignment ϕ of an angle $a \in \{90°, 180°, 270°\}$ to each corner of G.
- A designation of a face of G as the central face F_c.
- A designation of a face of G as the outer face F_o.

For the special case where v has only one incident edge e, we view (e, e) as a 360° corner. This case does not occur if we consider biconnected graphs.

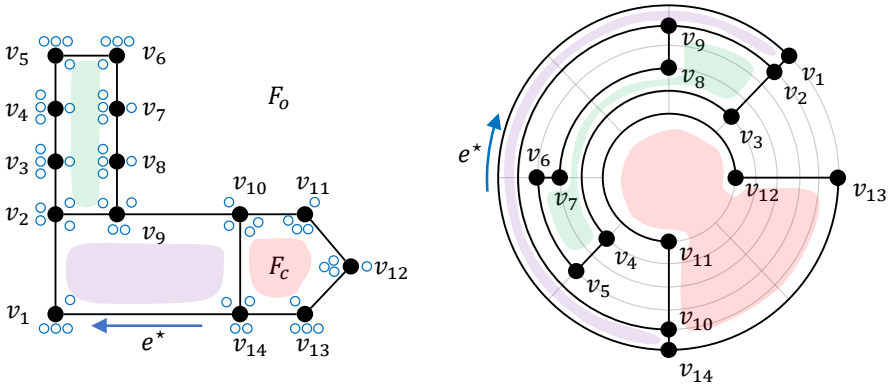

Figure 3 A drawing of an ortho-radial representation with a reference edge, where the small blue circles in the left figure denote the angles in the representation that are realized in the right figure.

An ortho-radial representation $\mathcal{R} = (\phi, F_c, F_o)$ is *drawable* if the representation can be realized as an ortho-radial drawing of G with zero bends such that the angle assignment ϕ is satisfied, the central face F_c contains the origin, the outer face F_o contains an unbounded region.

Recall that, by the definition of ortho-radial drawing, in an ortho-radial drawing with zero bends, each edge is either drawn as a line segment of a straight line passing the origin or drawn as a circular arc of a circle centered at the origin. We also consider the setting where the *reference edge* $e^\star$ is fixed. In this case, there is an additional requirement that the reference edge $e^\star$ has to lie on the outermost circular arc used in the drawing and follows the clockwise direction. If such a drawing exists, we say that $(\mathcal{R}, e^\star)$ is *drawable*. See Figure 3 for an example of a drawing of an ortho-radial representation $\mathcal{R}$ with the reference edge $e^\star = (v_{14}, v_5)$. In the figure, we use $\circ$, $\circ\circ$, and $\circ\circ\circ$ to indicate a 90°, a 180°, and a 270° angle assigned to a corner, respectively.

It was shown in [3] that $(\mathcal{R}, e^\star)$ is drawable if and only if the ortho-radial representation $\mathcal{R}$ satisfies (R1) and (R2) and the reference edge $e^\star$ does not lead to a strictly monotone cycle. Since it is straightforward to test whether (R1) and (R2) are satisfied in linear time, from now on, unless otherwise stated, we assume that (R1) and (R2) are satisfied for the ortho-radial representation $\mathcal{R}$ under consideration.

Combinatorial rotations. Consider a 2-length path $P = (u, v, w)$ that passes through v such that $u \neq w$. Given the angle assignment ϕ, P is either a 90° left turn, a straight line, or a 90° right turn. We define the *combinatorial rotation* of P as follows.

$$\mathsf{rotation}(P) = \begin{cases} -1, & P \text{ is a } 90^\circ \text{ left turn,} \\ 0, & P \text{ is a straight line,} \\ 1, & P \text{ is a } 90^\circ \text{ right turn.} \end{cases}$$

More formally, let $S = (e_1, \ldots, e_k)$ be the contiguous subsequence of edges starting from $e_1 = \{u, v\}$ and ending at $e_k = \{v, w\}$ in the circular ordering $\mathcal{E}(v)$ of the undirected edges incident to v. Then $\sum_{j=1}^{k-1} \phi(e_j, e_{j+1}) - 180^\circ$ equals the degree of the turn of P at the intermediate vertex v, so the combinatorial rotation of P is $\mathsf{rotation}(P) = \left(\sum_{j=1}^{k-1} \phi(e_j, e_{j+1}) - 180^\circ\right) / 90^\circ$.

For the special case where $u = w$, the rotation of $P = (u, v, u)$ can be a 180° left turn, in which case $\mathsf{rotation}(P) = -2$, or a 180° right turn, in which case $\mathsf{rotation}(P) = 2$. For example, consider the directed edge $e = (u, v)$ where P first goes from u to v along the right side of e and then goes from v back to u along the left side of e. Then P is considered a 180° left turn, and similarly, $\overline{P}$ is considered a 180° right turn. In particular, if $P = (u, v, u)$ is a subpath of a facial cycle C, then P is always considered as a 180° left turn, and so $\mathsf{rotation}(P) = -2$.

For a crossing-free path P of length more than 2, we define $\mathsf{rotation}(P)$ as the sum of the combinatorial rotations of all 2-length subpaths of P. Similarly, for a cycle C of length more than 2, we define $\mathsf{rotation}(C)$ as the sum of the combinatorial rotations of all 2-length subpaths of C. Same as [2, 35], based on this notion, we may restate condition (R2).

(R2′) For each face F, the combinatorial rotation of its facial cycle C_F satisfies the following:

$$\mathsf{rotation}(C_F) = \begin{cases} 4, & F \text{ is a regular face,} \\ 0, & F \text{ is either the central face or the outer face, but not both,} \\ -4, & F \text{ is both the central face and the outer face.} \end{cases}$$

For example, consider the ortho-radial representation shown in Figure 3. The path $P = (v_{10}, v_{11}, v_{12}, v_{13}, v_{14})$ has $\mathsf{rotation}(P) = -1$ since it makes two 90° left turns and one 90° right turn. The cycle $C = (v_{10}, v_{11}, v_{12}, v_{13}, v_{14})$ is the facial cycle of the central face, and it has $\mathsf{rotation}(C) = 0$.

We briefly explain the equivalence between the new and the old definitions of (R2). If F is a regular face with k corners, then in the original definition of (R2), it is required that the sum s of angles around F is $s = (k-2) \cdot 180°$. Since the facial cycle C_F traverses the contour of F in the clockwise direction, the number of 90° right turns minus the number of 90° left turns must be exactly 4. Therefore, $s = (k-2) \cdot 180°$ is the same as $\mathsf{rotation}(C_F) = 4$, as each 90° right turn contributes 1 and each 90° left turn contributes -1 in the calculation of $\mathsf{rotation}(C_F)$.

Interior and exterior regions of a cycle. Any cycle C partitions the remaining graph into two parts. If C is a facial cycle, then one part is empty. The direction of C is clockwise with respect to one of the two parts. The part with respect to which C is clockwise, together with C itself, is called the *interior* of C. Similarly, the part with respect to which C is counter-clockwise, together with C itself, is called the *exterior* of C. In particular, if a vertex v lies in the interior of C, then v must be in the exterior of $\overline{C}$.

This above definition is consistent with the notion of facial cycle in that any face F is in the interior of its facial cycle C_F. Depending on the context, the interior or the exterior of a cycle can be viewed as a subgraph, a set of vertices, a set of edges, or a set of faces. For example, consider the cycle $C = (v_1, v_2, v_{10}, v_9, v_5)$ of the plane graph shown in Figure 2. The interior of C is the subgraph induced by v_8, v_{11}, and all vertices in C. The exterior of C is the subgraph induced by v_3, v_4, v_6, v_7, and all vertices in C. The cycle C partitions the faces into two parts: The interior of C contains F_3, and the exterior of C contains F_1 and F_2.

Let C be a simple cycle oriented in such a way that the outer face F_{o} lies in its exterior. Following [3], we say that C is *essential* if the central face F_{c} is in the interior of C. Otherwise we say that C is *non-essential*. The following lemma was proved in [3].

▶ **Lemma 1** ([3]). *Let C be a simple cycle oriented in such a way that the outer face F_o lies in its exterior, then the combinatorial rotation of C satisfies the following:*

$$\mathsf{rotation}(C) = \begin{cases} 4, & C \text{ is an essential cycle,} \\ 0, & C \text{ is a non-essential cycle.} \end{cases}$$

In the above lemma, we implicitly assume that (R1) and (R2) are satisfied. The intuition behind the lemma is that an essential cycle behaves like the facial cycle of the outer face or the central face, and a non-essential cycle behaves like the facial cycle of a regular face.

Subgraphs. When we take a subgraph H of G, the combinatorial embedding, the angle assignment, the central face, and the outer face of H are inherited from G naturally. For example, suppose that $\mathcal{E}(v) = (e_1, e_2, e_3)$ with $\phi(e_1, e_2) = 90°$, $\phi(e_2, e_3) = 90°$, and $\phi(e_3, e_1) = 180°$ in G. Suppose that v is incident only to two edges e_1 and e_2 in H, then the angle assignment ϕ_H for the two corners surrounding v in H will be $\phi_H(e_1, e_2) = 90°$ and $\phi_H(e_2, e_1) = 270°$.

Each face of G is contained in exactly one face of H, A face in H can contain multiples faces of G. A face of H is said to be the central face if it contains the central face of G. Similarly, A face of H is said to be the outer face if it contains the outer face of G.

For example, consider the subgraph H induced by $\{v_2, v_3, \ldots, v_9\}$ in the ortho-radial representation in Figure 3. In H, v_9 is incident to only two edges $e_1 = \{v_8, v_9\}$ and $e_2 = \{v_2, v_9\}$, and the angle assignment ϕ_H for the two corners surrounding v_9 in H are $\phi_H(e_1, e_2) = 90°$ and $\phi_H(e_2, e_1) = 270°$. The outer face and the central face of H are the same.

Defining direction via reference paths. Following [3], for any two edges $e = (u, v)$ and $e' = (x, y)$, we say that a crossing-free path P is a reference path for e and e' if P starts at u or v and ends at x or y such that P does not contain any of the edges in $\{e, \overline{e}, e', \overline{e'}\}$. Given a reference path P for $e = (u, v)$ and $e' = (x, y)$, we define the *combinatorial direction* of e' with respect to e and P as follows.

$$\mathsf{direction}(e, P, e') = \begin{cases} \mathsf{rotation}(e \circ P \circ e'), & P \text{ starts at } v \text{ and ends at } x, \\ \mathsf{rotation}(\overline{e} \circ P \circ e') + 2, & P \text{ starts at } u \text{ and ends at } x, \\ \mathsf{rotation}(e \circ P \circ \overline{e'}) - 2, & P \text{ starts at } v \text{ and ends at } y, \\ \mathsf{rotation}(\overline{e} \circ P \circ \overline{e'}), & P \text{ starts at } u \text{ and ends at } y. \end{cases}$$

Here $P \circ Q$ denotes the concatenation of the paths P and Q. An edge e is interpreted as a 1-length path. In the definition of $\mathsf{direction}(e, P, e')$, we allow the possibility that a reference path P consists of a single vertex. If $v = x$ and $u \neq w$, then we may choose P to be the 0-length path consisting of a single vertex $v = x$, in which case $\mathsf{direction}(e, P, e')$ is simply the combinatorial rotation of the 2-length path (u, v, y). We do not consider the cases where $e = e'$ or $e = \overline{e'}$.

Consider the reference edge $e = (v_{14}, v_1)$ in the ortho-radial representation of Figure 3. We measure the direction of $e' = (v_8, v_9)$ from e with different choices of the reference path P. If $P = (v_1, v_2, v_9)$, then $\mathsf{direction}(e, P, e') = \mathsf{rotation}(e \circ P \circ \overline{e'}) - 2 = -1$. If $P = (v_{14}, v_{10}, v_9)$, then we also have $\mathsf{direction}(e, P, e') = \mathsf{rotation}(\overline{e} \circ P \circ \overline{e'}) = -1$. If we select $P = (v_1, v_2, v_3, v_4, v_5, v_6, v_7, v_8)$, then we get a different value of $\mathsf{direction}(e, P, e') = \mathsf{rotation}(e \circ P \circ e') = 3$. As we will later discuss, $\mathsf{direction}(e, P, e') \bmod 4$ is invariant under the choice of P.

In the definition of $\mathsf{direction}(e, P, e')$, the additive $+2$ in $\mathsf{rotation}(\overline{e} \circ P \circ e') + 2$ is due to the fact that the actual path that we intend to consider is $e \circ \overline{e} \circ P \circ e'$, where we make a $180°$ right turn in $e \circ \overline{e}$, which contributes $+2$ in the calculation of the combinatorial rotation. Similarly, the additive -2 in $\mathsf{rotation}(e \circ P \circ \overline{e'}) - 2$ is due to the fact that the actual path that we intend to consider is $e \circ P \circ \overline{e'} \circ e'$, where we make a $180°$ left turn in $\overline{e'} \circ e'$. There is no additive term in $\mathsf{rotation}(\overline{e} \circ P \circ \overline{e'})$ because of the cancellation of the $180°$ right turn $e \circ \overline{e}$ and the $180°$ left turn $\overline{e'} \circ e'$. The reason why $e \circ \overline{e}$ has to be a right turn and $\overline{e'} \circ e'$ has to be a left turn will be explained later.

See Figure 4 for an example of the calculation of an edge direction. The direction of $e = (u_1, u_2)$ with respect to $e^\star = (v_1, v_2)$ and the reference path $P = (v_1, v_5, v_4, u_1)$ can be calculated by $\mathsf{rotation}(\overline{e^\star} \circ P \circ e') + 2 = 1$ according to the formula above, where the additive $+2$ is due to the $180°$ right turn at $e^\star \circ \overline{e^\star}$.

Edge directions. Imagining that the origin is the south pole, in an ortho-radial drawing with zero bends, each edge e is either drawn in one of the following four directions:

- e points towards the *north* direction if e is drawn as a line segment of a straight line passing the origin, where e is directed away from the origin.
- e points towards the *south* direction if e is drawn as a line segment of a straight line passing the origin, where e is directed towards the origin.
- e points towards the *east* direction if e is drawn as a circular arc of a circle centered at the origin in the clockwise direction.
- e points towards the *west* direction if e is drawn as a circular arc of a circle centered at the origin in the counter-clockwise direction.

We say that e is a *vertical* edge if e points towards north or south. Otherwise, we say that e is a *horizontal* edge. We argue that as long as (R1) and (R2) are satisfied, the direction of any edge e is uniquely determined by the ortho-radial representation.

For the reference edge $e^\star$, it is required that $e^\star$ points east, and so $\overline{e^\star}$ points west. Consider any edge e that is neither $e^\star$ nor $\overline{e^\star}$. It is clear that the value of $\mathsf{direction}(e^\star, P, e)$ determines the direction of e in that the direction of e is forced to be east, south, west, or north if $\mathsf{direction}(e^\star, P, e) \bmod 4$ equals 0, 1, 2, or 3, respectively. For example, in the ortho-radial representation of Figure 3, the edge $e' = (v_8, v_9)$ is a vertical edge in the north direction, as we have calculated that $\mathsf{direction}(e^\star, P, e') \bmod 4 = 3$.

▶ **Lemma 2** ([3]). *For any two edges e and e', the value of $\mathsf{direction}(e, P, e') \bmod 4$ is invariant under the choice of the reference path P.*

The above lemma shows that $\mathsf{direction}(e^\star, P, e) \bmod 4$ is invariant under the choice of the reference path P, so the direction of each edge in an ortho-radial representation is well defined, even for the case that $(\mathcal{R}, e^\star)$ might not be drawable. Given the reference edge $e^\star$, we let E_h denote the set of all horizontal edges in the east direction, and let E_v denote the set of all vertical edges in the north direction.

Horizontal segments. We require that in a drawing of $(\mathcal{R}, e^\star)$, the reference edge $e^\star$ lies on the outermost circular arc used in the drawing, so not every edge in $\overline{C_{F_\circ}}$ is eligible to be a reference edge. To determine whether an edge $e \in \overline{C_{F_\circ}}$ is eligible to be a reference edge, we need to introduce some terminology.

Given the reference edge $e^\star$, the set E_v of vertical edges in the north direction and the set E_h of horizontal edges in the east direction are fixed. Let $\mathcal{S}_\mathsf{h}$ denote the set of connected components induced by E_h. Each component $S \in \mathcal{S}_\mathsf{h}$ is either a path or a cycle, and so in any drawing of $\mathcal{R}$, there is a circle C centered at the origin such that S must be drawn as C or a circular arc of C. We call each component $S \in \mathcal{S}_\mathsf{h}$ a *horizontal segment*.

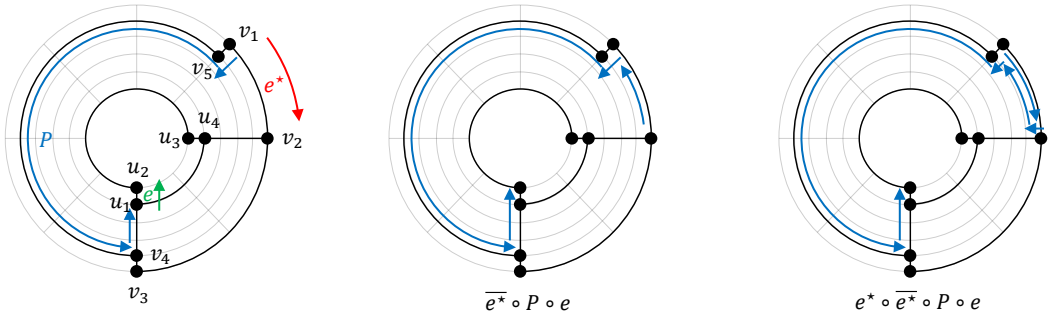

Figure 4 The calculation of $\mathsf{direction}(e^\star, P, e)$.

Each horizontal segment $S \in \mathcal{S}_\mathsf{h}$ is written as a sequence of vertices $S = (v_1, v_2, \ldots, v_s)$, where s is the number of vertices in S, such that $(v_i, v_{i+1}) \in E_\mathsf{h}$ for each $1 \leq i < s$. If S is a cycle, then we additionally have $(v_s, v_1) \in E_\mathsf{h}$, so $S = (v_1, v_2, \ldots, v_s)$ is a circular order. When S is a cycle, we use modular arithmetic on the indices so that $v_{s+1} = v_1$. We write $\mathcal{N}_\mathsf{north}(S)$ to denote the set of vertical edges $e = (x, y) \in E_\mathsf{v}$ such that $x \in S$. Similarly, $\mathcal{N}_\mathsf{south}(S)$ is the set of vertical edges $e = (x, y) \in E_\mathsf{v}$ such that $y \in S$. We assume that the edges in $\mathcal{N}_\mathsf{north}(S)$ and $\mathcal{N}_\mathsf{south}(S)$ are ordered according to the indices of their endpoints in S. The ordering is sequential if S is a path and is circular if S is a cycle. Consider the ortho-radial representation $\mathcal{R}$ given in Figure 3 as an example. The horizontal segment $S = (v_{10}, v_9, v_2)$ has $\mathcal{N}_\mathsf{south}(S) = ((v_{11}, v_{10}), (v_8, v_9), (v_3, v_2))$ and $\mathcal{N}_\mathsf{north}(S) = ((v_{10}, v_{14}), (v_2, v_1))$.

Observe that $\mathcal{N}_\mathsf{north}(S) = \emptyset$ for the horizontal segment $S \in \mathcal{S}_\mathsf{h}$ that contains $e^\star$ is a necessary condition that a drawing of $\mathcal{R}$ where $e^\star$ lies on the outermost circular arc exists. This condition can easily be checked in linear time.

Spirality. Intuitively, $\mathsf{direction}(e, P, e')$ quantifies the degree of *spirality* of e' with respect to e and P. Unfortunately, Lemma 2 does not hold if we replace $\mathsf{direction}(e, P, e') \bmod 4$ with $\mathsf{direction}(e, P, e')$. A crucial observation made in [3] is that such a replacement is possible if we add some restrictions about the positions of e, e', and P. See the following lemma.

▶ **Lemma 3** ([3]). *Let C and C' be essential cycles such that C' lies in the interior of C. Let e be an edge on C. Let e' be an edge on C'. The value of $\mathsf{direction}(e, P, e')$ is invariant under the choice of the reference path P, over all paths P in the interior of C and in the exterior of C'.*

Recall that we require a reference path to be crossing-free. This requirement is crucial in the above lemma. If we allow P to be a general path that is not crossing-free, then we may choose P in such a way that P repeatedly traverses a *non-essential* cycle many times, so that $\mathsf{direction}(e, P, e')$ can be made arbitrarily large and arbitrarily small.

Setting $e = e^\star$ and $C = \overline{C_{F_\mathsf{o}}}$ in the above lemma, we infer that $\mathsf{direction}(e^\star, P, e')$ is determined once we fix an essential cycle C' that contains e' and only consider reference paths P that lie in the exterior of C'. The condition for the lemma is satisfied because $\overline{C_{F_\mathsf{o}}}$ is the outermost essential cycle in that all other essential cycles are in the interior of $\overline{C_{F_\mathsf{o}}}$. The reason why we set $C = \overline{C_{F_\mathsf{o}}}$ and not $C = C_{F_\mathsf{o}}$ is that F_o has to be in the exterior of C. Note that the assumption that G is biconnected ensures that each facial cycle is simple.

Let C be an essential cycle and let e be an edge in C. In view of the above, following [3], we define the *edge label* $\ell_C(e)$ of e with respect to C as the value of $\mathsf{direction}(e^\star, P, e)$, for any choice of reference path P in the exterior of C'. For the special case that $e = e^\star$ and $C = \overline{C_{F_\mathsf{o}}}$,

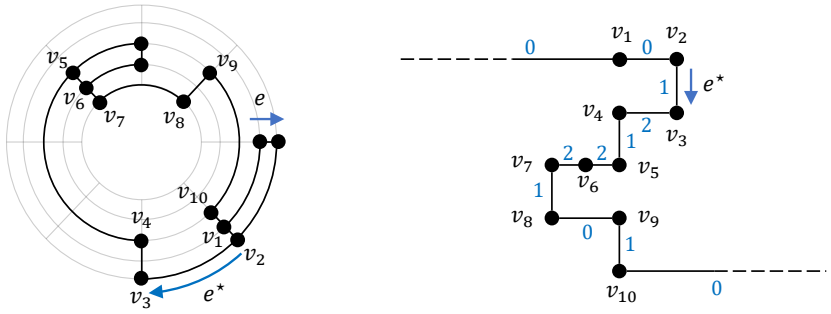

Figure 5 Changing the reference edge to e leads to a strictly monotone cycle.

we let $\ell_C(e) = 0$. Intuitively, the value $\ell_C(e)$ quantifies the degree of spirality of e from $e^\star$ if we restrict ourselves to the exterior of C. Consider the edge $e = (u_1, u_2)$ in the essential cycle $C = (u_1, u_2, u_3, u_4)$ in Figure 4 as an example. We have $\ell_C(e) = \mathsf{direction}(e^\star, P, e) = 1$, since the reference path $P = (v_1, v_5, v_4, u_1)$ lies in exterior of C.

We briefly explain the formula of $\mathsf{direction}(e, P, e')$: As discussed earlier, in the definition of $\mathsf{direction}(e, P, e')$, the additive $+2$ in $\mathsf{rotation}(\overline{e} \circ P \circ e') + 2$ is due to the fact that the actual path that we want to consider is $e \circ \overline{e} \circ P \circ e'$, where we make a 180° right turn in $e \circ \overline{e}$. The reason why $e \circ \overline{e}$ has to be a right turn is because of the scenario considered in Lemma 3, where e is an edge in C. To ensure that we stay in the interior of C in the traversal from e to e' via the path $e \circ \overline{e} \circ P \circ e'$, the 180° turn of $e \circ \overline{e}$ has to be a right turn. The remaining part of the formula of $\mathsf{direction}(e, P, e')$ can be explained similarly.

Monotone cycles. We are now ready to define the notion of strictly monotone cycles used in (R3). We say that an essential cycle C is *monotone* if all its edge labels $\ell_C(e)$ are non-negative or all its edge labels $\ell_C(e)$ are non-positive. Let C be an essential cycle that is monotone. If C contains at least one positive edge label, then we say that C is *increasing*. If C contains at least one negative edge label, then we say that C is *decreasing*. We say that C is *strictly monotone* if C is either decreasing or increasing but not both.

Intuitively, an increasing cycle is like a loop of descending stairs, and a decreasing cycle is like a loop of ascending stairs, so they are not drawable. It was proved in [3] that $(\mathcal{R}, e^\star)$ is drawable if and only if it does not contain a strictly monotone cycle. Recall again that, throughout the paper, unless otherwise stated, we assume that the given ortho-radial representation already satisfies (R1) and (R2).

▶ **Lemma 4** ([3]). *An ortho-radial representation $\mathcal{R}$, with a fixed reference edge $e^\star$ such that $\mathcal{N}_{\mathsf{north}}(S) = \emptyset$ for the horizontal segment $S \in \mathcal{S}_{\mathsf{h}}$ that contains $e^\star$, is drawable if and only if it does not contain a strictly monotone cycle.*

Consider Figure 5 as an example. The ortho-radial representation $\mathcal{R}$ is drawable with the reference edge $e^\star$. If we change the reference edge to e, then $(\mathcal{R}, e)$ become undrawable, as the essential cycle $C = (v_1, v_2, \ldots, v_{10})$ is increasing. With respect to the reference edge e, all the edge labels on the cycle C are non-negative, with some of them being positive. We are ready to state our main results.

▶ **Theorem 5.** *There is an $O(n \log n)$-time algorithm $\mathcal{A}$ that outputs either a drawing of $(\mathcal{R}, e^\star)$ or a strictly monotone cycle of $(\mathcal{R}, e^\star)$, for any given ortho-radial representation $\mathcal{R}$ of an n-vertex biconnected simple graph, with a fixed reference edge $e^\star$ such that $\mathcal{N}_{\mathsf{north}}(S) = \emptyset$ for the horizontal segment $S \in \mathcal{S}_{\mathsf{h}}$ that contains $e^\star$.*

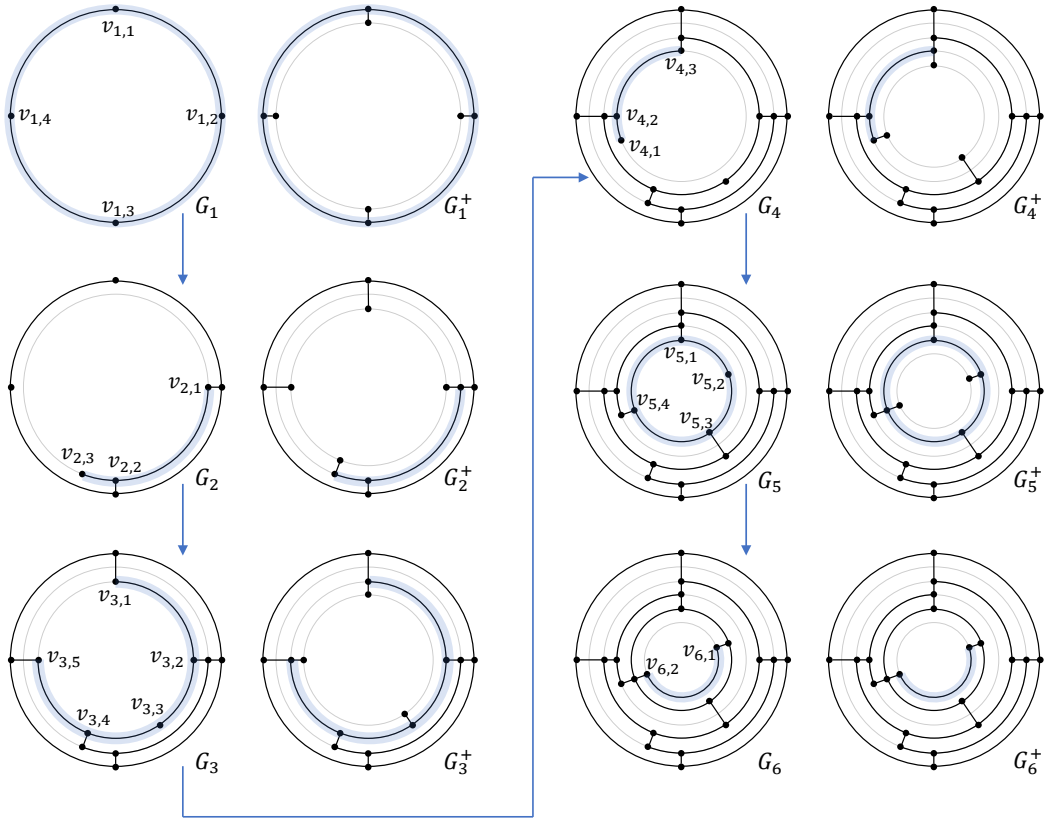

Figure 6 Constructing a good drawing for a good sequence.

The above theorem improves the previous algorithm of [35] which costs $O(n^2)$ time. If the output of $\mathcal{A}$ is a strictly monotone cycle, then the cycle certifies the non-existence of a drawing, by Lemma 4. We also extend the above theorem to the case where the reference edge is not fixed.

▶ **Theorem 6.** *There is an $O(n \log^2 n)$-time algorithm $\mathcal{A}$ that decides whether an ortho-radial representation $\mathcal{R}$ of an n-vertex biconnected simple graph is drawable. If $\mathcal{R}$ is drawable, then $\mathcal{A}$ also computes a drawing of $\mathcal{R}$.*

The proofs of Theorems 5 and 6 are left to the full version of the paper.

3 Technical overview

Let $A = (S_1, S_2, \ldots, S_k)$ be any sequence of k horizontal segments. We consider the following terminology for each $1 \leq i \leq k$, where k is the length of the sequence A.

- Let G_i be the subgraph of G induced by the horizontal edges in $S_1, S_2, \ldots, S_i$ and the set of all vertical edges whose both endpoints are in $S_1, S_2, \ldots, S_i$. Let F_i be the central face of G_i, and let C_i be the facial cycle of F_i.
- We extend the notion $\mathcal{N}_{\mathsf{south}}(S)$ to a sequence of horizontal segments: $\mathcal{N}_{\mathsf{south}}(S_1, S_2, \ldots, S_i)$ is defined as the set of all vertical edges $e = (x, y) \in E_{\mathsf{v}}$ such that $y \in C_i$ and $x \notin C_i$.
- Let G_i^+ be the subgraph of G induced by all the edges in G_i together with the edge set $\mathcal{N}_{\mathsf{south}}(S_1, S_2, \ldots, S_i)$. Let F_i^+ be the central face of G_i^+, and let C_i^+ be the facial cycle of F_i^+.

For each vertical edge $e = (x, y) \in \mathcal{N}_{\mathsf{south}}(S_1, S_2, \ldots, S_i)$, the south endpoint x appears exactly once in C_i^+. We circularly order the edges $e = (x, y) \in \mathcal{N}_{\mathsf{south}}(S_1, S_2, \ldots, S_i)$ according to the position of the south endpoint x in the circular ordering of C_i^+. Take the graph $G = G_6$ in Figure 6 as an example. In this graph, there are 6 horizontal segments, shaded in Figure 6:

$$S_1 = (v_{1,1}, v_{1,2}, v_{1,3}, v_{1,4}), \quad S_2 = (v_{2,1}, v_{2,2}, v_{2,3}), \quad S_3 = (v_{3,1}, v_{3,2}, v_{3,3}, v_{3,4}, v_{3,5}),$$
$$S_4 = (v_{4,1}, v_{4,2}, v_{4,3}), \quad S_5 = (v_{5,1}, v_{5,2}, v_{5,3}, v_{5,4}, v_{5,5}), \quad S_6 = (v_{6,1}, v_{6,2}).$$

With respect to the sequence $A = (S_1, S_2, \ldots, S_6)$, Figure 6 shows the graphs G_i and G_i^+, for all $1 \le i \le 6$. For example, for $i = 2$, we have:

$$\mathcal{N}_{\mathsf{south}}(S_1, S_2) = ((v_{3,1}, v_{1,1})(v_{3,2}, v_{2,1}), (v_{3,4}, v_{2,3}), (v_{3,5}, v_{1,4})),$$
$$\mathcal{N}_{\mathsf{north}}(S_2) = ((v_{2,1}, v_{1,2}), (v_{2,2}, v_{1,3}))$$
$$C_2 = (v_{1,1}, v_{1,2}, v_{2,1}, v_{2,2}, v_{2,3}, v_{2,2}, v_{1,3}, v_{1,4}),$$
$$C_2^+ = (v_{1,1}, v_{3,1}, v_{1,1}, v_{1,2}, v_{2,1}, v_{3,2}, v_{2,1}, v_{2,2}, v_{2,3}, v_{3,4}, v_{2,3}, v_{2,2}, v_{1,3}, v_{1,4}, v_{3,5}, v_{1,4}).$$

Here $\mathcal{N}_{\mathsf{south}}(S_1, S_2)$, C_2, and C_2^+ are circular orderings, and $\mathcal{N}_{\mathsf{north}}(S_2)$ is a sequential ordering, as S_2 is a path.

Good sequences. We say that a sequence of horizontal segments $A = (S_1, S_2, \ldots, S_k)$ is *good* if A satisfies the following conditions.

(S1) S_1 is the reversal of the facial cycle of the outer face F_o, i.e., $S_1 = \overline{C_{F_o}}$.

(S2) For each $1 < i \le k$, $\mathcal{N}_{\mathsf{north}}(S_i)$ satisfies the following requirements.

- $\mathcal{N}_{\mathsf{north}}(S_i) \neq \emptyset$.
- If S_i is a path, then $\mathcal{N}_{\mathsf{north}}(S_i)$ is a contiguous subsequence of $\mathcal{N}_{\mathsf{south}}(S_1, S_2, \ldots, S_{i-1})$.
- If S_i is a cycle, then $\mathcal{N}_{\mathsf{north}}(S_i) = \mathcal{N}_{\mathsf{south}}(S_1, S_2, \ldots, S_{i-1})$.

Clearly, if $A = (S_1, S_2, \ldots, S_k)$ is good, then $(S_1, S_2, \ldots, S_i)$ is also good for each $1 \le i < k$. In general, a good sequence that covers the set of all horizontal segments might not exist for a given $(\mathcal{R}, e^\star)$. In particular, in order to satisfy (S1), it is necessary that the cycle $\overline{C_{F_o}}$ is a horizontal segment. The sequence $A = (S_1, S_2, \ldots, S_6)$ shown in Figure 6 is a good sequence.

If $A = (S_1, S_2, \ldots, S_k)$ is good, then we can find a drawing of G_k in linear time by fixing the drawing of $S_1, S_2, \ldots, S_k$ sequentially, as the definition of a good sequence allows us to safely place S_i below $S_1, S_2, \ldots, S_{i-1}$ and above $S_{i+1}, S_{i+2}, \ldots, S_k$. The following lemma is proved formally in the full version of the paper.

▶ **Lemma 7.** *For a given good sequence $A = (S_1, S_2, \ldots, S_k)$, an ortho-radial drawing of G_k without bends can be constructed in time $O\left(\sum_{i=1}^{k} |S_i|\right)$.*

See Figure 6 for an example of a drawing of G_k produced by the algorithm of Lemma 7.

Constructing a good sequence. In order to use Lemma 7 to compute an ortho-radial drawing of $(\mathcal{R}, e^\star)$, we need to find a good sequence $A = (S_1, S_2, \ldots, S_k)$ with $G_k = G$. However, such a good sequence might not exist even if $(\mathcal{R}, e^\star)$ is drawable. We will show that as long as $(\mathcal{R}, e^\star)$ is drawable, we can always add some *virtual edges* to the graph so that such a good sequence exists and can be computed efficiently. The first step of the algorithm is a simple preprocessing step to ensure the following two properties:

- The facial cycle of the outer face is a horizontal segment.
- Each vertex is incident to a horizontal segment.

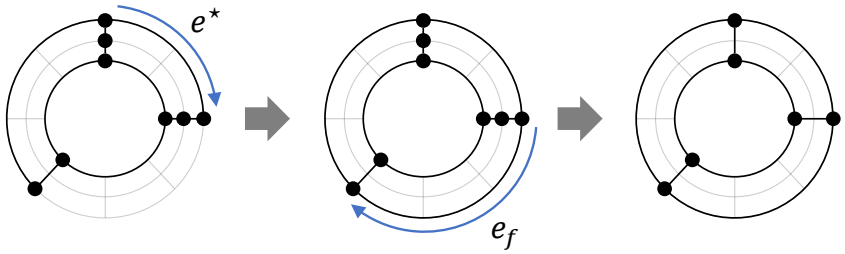

Figure 7 The preprocessing steps.

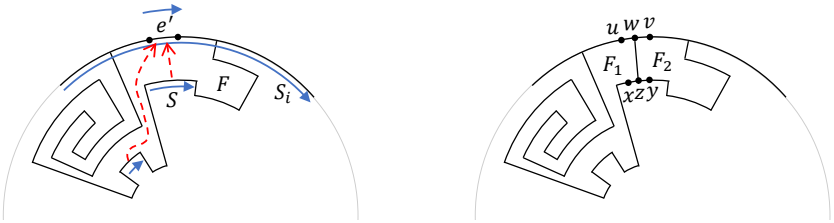

Figure 8 Adding a virtual vertical edge in a regular face.

See Figure 7 for the algorithm of the preprocessing step. The addition of the edge e_f ensures that $\overline{C_{F_o}}$ is a horizontal segment. To ensure that each vertex is on a horizontal segment, some degree-2 vertices are removed by smoothing.

The above two properties alone are not sufficient to guarantee the existence of a good sequence $A = (S_1, S_2, \ldots, S_k)$ with $G_k = G$, as there could be horizontal segment S such that $\mathcal{N}_{\mathsf{north}}(S) = \emptyset$ and $S \neq \overline{C_{F_o}}$. Such a horizontal segment S can never be added to a good sequence, as the definition of a good sequence requires all horizontal segments in the sequence to be non-empty. To deal with this issue, we consider the following eligibility criterion for adding a *virtual* vertical edge incident to such a horizontal segment S:

- Let $A = (S_1, S_2, \ldots, S_k)$ be the current good sequence. Let $S \notin A$ be a horizontal segment such that $\mathcal{N}_{\mathsf{north}}(S) = \emptyset$ and $S \neq \overline{C_{F_o}}$. Let F be the face such that $\overline{S}$ is a subpath of C_F. We say that S is *eligible* for adding a virtual edge if there exists an edge $e' \in C_F$ with $e' \in S_i$ for some $1 \leq i \leq k$ such that either $\mathsf{rotation}(e' \circ \cdots \circ \overline{S}) = 2$ or $\mathsf{rotation}(\overline{S} \circ \cdots \circ e') = 2$ along the cycle C_F.

See Figure 8 for an illustration of adding a virtual edge. In the figure, there are two horizontal segments along the contour of F that are eligible for adding a virtual edge due to $e' \in S_i$. The rotation criterion for eligibility is to ensure that the new faces created due to the virtual edge still satisfy (R2). The condition $\mathcal{N}_{\mathsf{north}}(S) = \emptyset$ ensures that immediately after adding the virtual edge, we may append S to the end of the sequence A.

Our algorithm to construct a good sequence is a simple greedy algorithm: We repeatedly find horizontal segments that can be appended to the current good sequence and repeatedly add virtual edges, until no further such operations can be done. A straightforward implementation of the greedy algorithm, which checks all remaining horizontal segments in each step, takes $O(n^2)$ time. In the full version of the paper, we will present a more efficient implementation that costs only $O(n \log n)$ time.

Extracting a strictly monotone cycle. In the full version of the paper, we prove that if the above greedy algorithm stops with a good sequence $A = (S_1, S_2, \ldots, S_k)$ that does not cover all horizontal segments, then a strictly monotone cycle of the original graph G, without any

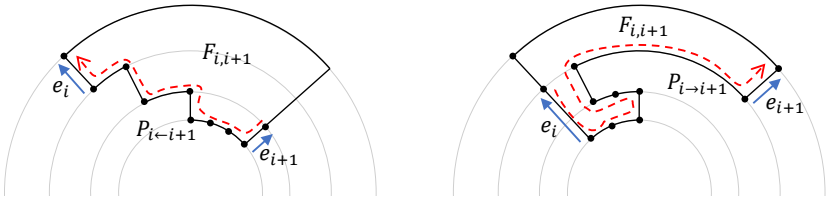

Figure 9 Face types $(*, \sqcup)$ and $(\sqcup, *)$.

virtual edges, can be found to certify the non-existence of a drawing. Let $(e_1, e_2, \ldots, e_s)$ be the circular ordering of $\mathcal{N}_{\mathsf{south}}(A)$. Note that $\{e_1, e_2, \ldots, e_s\}$ is the set of all edges connecting a vertex in G_k and a vertex not in G_k. The proof is achieved by a careful analysis of the structure of the faces involving $\{e_1, e_2, \ldots, e_s\}$. We show that the fact that no more progress can be made in the greedy algorithm forces the parts of the contours of these faces that are not in G_k to form ascending or descending patterns in a consistent manner, so we are able to extract a strictly monotone cycle in G by considering the edges in these facial cycles.

Face types. For each $1 \leq i \leq s$, we write $F_{i,i+1}$ to denote the unique face F such that C_F contains both e_i and $\overline{e_{i+1}}$. Note that $v_{s+1} = v_1$ because $(e_1, e_2, \ldots, e_s)$ is a circular ordering. Consider the face $F_{i,i+1}$, for some $1 \leq i \leq s$. We define $P_{i\leftarrow i+1}$ as the subpath of $C_{F_{i,i+1}}$ starting at $\overline{e_{i+1}}$ and ending at e_i. We write $P_{i\rightarrow i+1} = \overline{P_{i\leftarrow i+1}}$. We write $Z_{i\leftarrow i+1} = (z_1, z_2, \ldots)$ to denote the string of numbers such that z_l is the rotation of the subpath of $P_{i\leftarrow i+1}$ consisting of the first l edges. Similarly, we let $Z_{i\rightarrow i+1} = (z_1, z_2, \ldots)$ be the string of numbers such that z_l is the rotation of the subpath of $P_{i\rightarrow i+1}$ consisting of the first l edges. We define the types $(*, \sqcup)$, $(\sqcup, *)$, $(\sqcup, \sqcup)$, and $(-)$, as follows.

- $F_{i,i+1}$ is of type $(*, \sqcup)$ if $0 \circ 1^c \circ 2$, for some $c \geq 1$, is a prefix of $Z_{i\leftarrow i+1}$.
- $F_{i,i+1}$ is of type $(\sqcup, *)$ if $0 \circ (-1)^c \circ (-2)$, for some $c \geq 1$, is a prefix of $Z_{i\rightarrow i+1}$.
- $F_{i,i+1}$ is of type $(\sqcup, \sqcup)$ if $F_{i,i+1}$ is both of type $(\sqcup, *)$ and of type $(*, \sqcup)$.
- $F_{i,i+1}$ is of type $(-)$ if $Z_{i\leftarrow i+1} = 0 \circ 1^c \circ 2$ for some $c \geq 1$.

In other words, $F_{i,i+1}$ is of type $(-)$ if the subpath of the facial cycle of $F_{i,i+1}$ that connects the south endpoints of e_{i+1} and e_i is a horizontal straight line in the west direction. By considering $P_{i\rightarrow i+1} = \overline{P_{i\leftarrow i+1}}$, equivalently, $F_{i,i+1}$ is of type $(-)$ if $Z_{i\rightarrow i+1} = 0 \circ (-1)^c \circ (-2)$ for some $c \geq 1$.

Consider the good sequence $A = (S_1, S_2)$ of Figure 6 as an example, where we let $\mathcal{N}_{\mathsf{south}}(S_1, S_2) = (e_1, e_2, e_3, e_4)$, where $e_1 = (v_{3,1}, v_{1,1})$, $e_2 = (v_{3,2}, v_{2,1})$, $e_3 = (v_{3,4}, v_{2,3})$, and $e_4 = (v_{3,5}, v_{1,4})$. The facial cycle of the face $F_{1,2}$ is $(v_{3,1}, v_{1,1}, v_{2,1}, v_{3,2})$. We have $P_{1\rightarrow 2} = (v_{1,1}, v_{3,1}, v_{3,2}, v_{2,1})$ and $Z_{1\rightarrow 2} = (0, -1, -2)$, so $F_{1,2}$ is of type $(-)$.

Intuitively, the face $F_{i,i+1}$ is of type $(\sqcup, *)$ if $P_{i\rightarrow i+1}$ makes two 90° left turns before making any right turns, and the first 90° left turn is made at x_i. These two 90° left turns form a $\sqcup$-shape. Similarly, the face $F_{i,i+1}$ is of type $(*, \sqcup)$ if $P_{i\leftarrow i+1}$ makes two 90° right turns before making any left turns, and the first 90° right turn is made at x_{i+1}. These two 90° right turns form a $\sqcup$-shape. See Figure 9 for illustrations of faces of types $(*, \sqcup)$ and $(\sqcup, *)$. In the left part of the figure, we have $Z_{i\leftarrow i+1} = (0, 1, 1, 1, 2, 1, 2, 1, 2)$, so $F_{i,i+1}$ is of type $(*, \sqcup)$. In the right part of the figure, we have $Z_{i\rightarrow i+1} = (0, -1, -1, -2, -3, -3, -2, -1, -2)$, so $F_{i,i+1}$ is of type $(\sqcup, *)$. We show that one of the following holds, which intuitively implies the existence of a strictly monotone cycle.

- All faces $F_{i,i+1}$ are of type $(-)$ and $(\sqcup, *)$, and at least one face $F_{i,i+1}$ is of type $(\sqcup, *)$.
- All faces $F_{i,i+1}$ are of type $(-)$ and $(*, \sqcup)$, and at least one face $F_{i,i+1}$ is of type $(*, \sqcup)$.

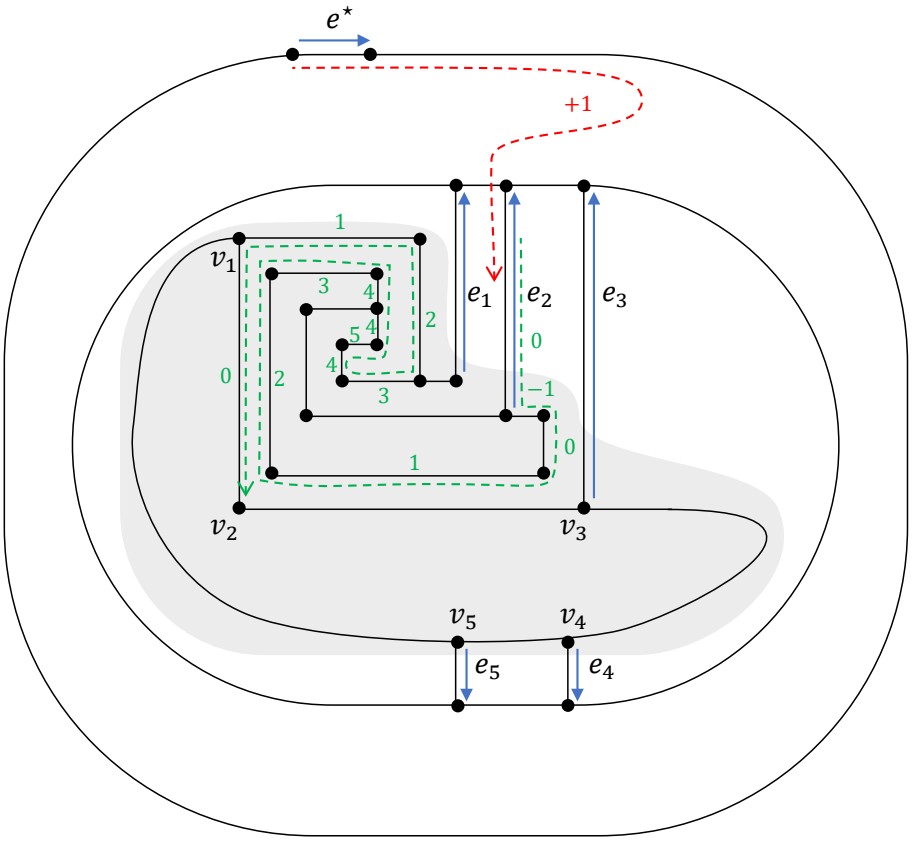

Figure 10 Extracting a strictly monotone cycle $C = (v_1, v_2, \ldots, v_5)$.

Consider Figure 10 for an example of extracting a strictly monotone cycle. In the figure, the shaded part corresponds to the part of the graph that is not in G_k. In this example, $\mathcal{N}_{\mathsf{south}}(A) = (e_1, e_2, \ldots, e_5)$. The faces $F_{5,1}$, $F_{1,2}$, and $F_{2,3}$ are of type $(*, \sqcup)$. The faces $F_{3,4}$ and $F_{4,5}$ are of type $(-)$. The cycle $C = (v_1, v_2, \ldots, v_5)$ is strictly monotone, as it is increasing. We can calculate that $\ell_C((v_1, v_2)) = 1$ by first going from $e^\star$ to $\overline{e_2}$ via a crossing-free path P and then going from $\overline{e_2}$ to (v_1, v_2) along the path $P_{2\to 3}$, as (v_1, v_2) is an intermediate edge of $P_{2\to 3}$. The first part has rotation 1 and the second part has rotation 0, so the overall rotation is 1. Similarly, we can calculate that $\ell_C(e) = 0$ for each remaining edge e in C.

4 Conclusions

In this paper, we presented a near-linear time algorithm to decide whether a given ortho-radial representation is drawable, improving upon the previous quadratic-time algorithm [35]. If the representation is drawable, then our algorithm outputs an ortho-radial drawing realizing the representation. Otherwise, our algorithm outputs a strictly monotone cycle to certify the non-existence of such a drawing. Given the broad applications of the topology-shape-metric framework in orthogonal drawing, we anticipate that our new ortho-radial drawing algorithm will be relevant and useful in future research in this field.

While there has been extensive research in orthogonal drawing, much remains unknown about the computational complexity of basic optimization problems in ortho-radial drawing. In particular, the problem of finding an ortho-radial representation that minimizes the number of bends has only been addressed by a practical algorithm [34] that has no provable guarantees. It remains an intriguing open question to determine to what extent bend minimization is polynomial-time solvable for ortho-radial drawing. To the best of our knowledge, even deciding whether a given plane graph admits an ortho-radial drawing *without bends* is not known to be polynomial-time solvable.

Given an ortho-radial representation, can we find an ortho-radial drawing with the smallest number of layers (i.e., the number of concentric circles) in polynomial time? As discussed in the full version of the paper, if a good sequence is given, then our algorithm can output a layer-minimized drawing. For the general case where a good sequence might not exist, our algorithm does not have the layer-minimization guarantee, as there is some flexibility in the choice of virtual edges to add, and selecting different virtual edges results in different good sequences. There was a series of work in finding *compact* orthogonal drawings according to various complexity measures [1, 6, 12, 32, 37]. To what extent the ideas developed in these works can be applied to ortho-radial drawings?

Approximation Algorithms for Network Design in Non-Uniform Fault Models

Chandra Chekuri

Rhea Jain
Department of Computer Science, University of Illinois, Urbana-Champaign, Urbana, IL, USA

Abstract

Classical network design models, such as the Survivable Network Design problem (SNDP), are (partly) motivated by robustness to faults under the assumption that any subset of edges upto a specific number can fail. We consider *non-uniform* fault models where the subset of edges that fail can be specified in different ways. Our primary interest is in the flexible graph connectivity model [1, 3, 4, 8], in which the edge set is partitioned into *safe* and *unsafe* edges. Given parameters $p, q \geq 1$, the goal is to find a cheap subgraph that remains p-connected even after the failure of q unsafe edges. We also discuss the bulk-robust model [6, 2] and the relative survivable network design model [19]. While SNDP admits a 2-approximation [32], the approximability of problems in these more complex models is much less understood even in special cases. We make two contributions.

Our first set of results are in the flexible graph connectivity model. Motivated by a conjecture that a constant factor approximation is feasible when p and q are fixed, we consider two special cases. For the s-t case we obtain an approximation ratio that depends only on p, q whenever $p + q > pq/2$ which includes $(p, 2)$ and $(2, q)$ for all $p, q \geq 1$. For the global connectivity case we obtain an $O(q)$ approximation for $(2, q)$, and an $O(p)$ approximation for $(p, 2)$ and $(p, 3)$ for any $p \geq 1$, and for $(p, 4)$ when p is even. These are based on an augmentation framework and decomposing the families of cuts that need to be covered into a small number of uncrossable families.

Our second result is a poly-logarithmic approximation for a generalization of the bulk-robust model when the "width" of the given instance (the maximum number of edges that can fail in any particular scenario) is fixed. Via this, we derive corresponding approximations for the flexible graph connectivity model and the relative survivable network design model. We utilize a recent framework due to Chen et al. [17] that was designed for handling group connectivity.

1 Introduction

The Survivable Network Design Problem (SNDP) is an important problem in combinatorial optimization that generalizes many well-known problems related to connectivity and is also motivated by practical problems related to the design of fault-tolerant networks. The input to this problem is an undirected graph $G = (V, E)$ with non-negative edge costs $c : E \to \mathbb{R}_+$ and a collection of source-sink pairs $(s_1, t_1), \ldots, (s_h, t_h)$, each with an integer connectivity requirement r_i. The goal is to find a minimum-cost subgraph H of G such that

H has r_i connectivity for each pair (s_i, t_i). We focus on edge-connectivity requirements in this paper.[1] SNDP contains as special cases classical problems such as s-t shortest path, minimum spanning tree (MST), minimum k-edge-connected subgraph (k-ECSS), Steiner tree, Steiner forest and several others. It is NP-Hard and APX-Hard to approximate. There is a 2-approximation via the iterated rounding technique [32].

A pair (s, t) that is k-edge-connected in G is robust to the failure of *any* set of $k-1$ edges. In various settings, the set of edges that can fail can be correlated and/or exhibit non-uniform aspects. We are interested in network design in such settings, and discuss a few models of interest that have been studied in the (recent) past. We start with the flexible graph connectivity model (flex-connectivity for short) that was the impetus for our work.

Flexible graph connectivity. In this model, first introduced by Adjiashvili [1] and studied in several recent papers [3, 4, 5, 8, 7], the input is an edge-weighted undirected graph $G = (V, E)$ where the edge set E is partitioned to *safe* edges $\mathcal{S}$ and *unsafe* edges $\mathcal{U}$. The assumption, as the names suggest, is that unsafe edges can fail while safe edges cannot. We say that a vertex-pair (s, t) is (p, q)-flex-connected in a subgraph H of G if s and t are p-edge-connected after deleting from H any subset of at most q unsafe edges. The input, as in SNDP, consists of G and h source-sink pairs; the i'th pair now specifies a (p_i, q_i)-flex-connectivity requirement. The goal is to find a min-cost subgraph H of G such that for each i, s_i and t_i are (p_i, q_i)-flex-connected in H. We refer to this as the Flex-SNDP problem. Note that Flex-SNDP generalizes SNDP in two ways[2].

Bulk-robust network design. This fairly general non-uniform model was introduced by Adjiashvili, Stiller and Zenklusen [6]. Here an explicit *scenario* set $\Omega = \{F_1, F_2, \ldots, F_m\}$ is given as part of the input where each $F_j \subseteq E$. The goal is to find a min-cost subgraph H of G such that each of the given pairs (s_i, t_i) remains connected in $H - F_j$ for each $j \in [m]$. We consider a slight generalization of this problem in which each scenario is now a pair $(F_j, \mathcal{K}_j)$ where $\mathcal{K}_j$ is a set of source-sink pairs. As earlier, the goal is to find a min-cost subgraph H of G such that for each $j \in [m]$, each pair (s_i, t_i) in $\mathcal{K}_j$ is connected in $H - F_j$. The *width* of the failure scenarios is $\max_{1 \le j \le \ell} |F_j|$. We use Bulk-SNDP to refer to this problem.

The advantage of the bulk-robust model is that one can specify arbitrarily correlated failure patterns, allowing it to capture many well studied problems in network design. We observe that SNDP and Flex-SNDP problem can be cast as special cases of Bulk-SNDP model where the width is $\max_i(r_i - 1)$ in the former case, and $\max_i(p_i + q_i - 1)$ in the latter case. The slight generalization on Bulk-SNDP described above also allows us to model a new problem recently proposed by Dinitz, Koranteng, and Kortsarz [19] called **Relative Survivable Network Design** (RSNDP). This problem allows one to ask for higher connectivity even when the underlying graph G has small cuts. The input is an edge-weighted graph $G = (V, E)$ and source-sink pairs (s_i, t_i) each with requirement r_i; the goal is to find a min-cost subgraph H of G such that for each $F \subseteq E$ with $|F| < r_i$, (s_i, t_i) is connected in $H - F$ if s_i and t_i are connected in $G - F$. It is easy to see that RSNDP is a special case of Bulk-SNDP with width at most $\max_i(r_i - 1)$. A disadvantage of Bulk-SNDP is that scenarios have to be explicitly listed, while the other models discussed specify failure scenarios implicitly. However, when connectivity requirements are small/constant, one can reduce to Bulk-SNDP by explicitly listing the failure sets.

---

[1] In the literature the term EC-SNDP and VC-SNDP are used to distinguish edge and vertex connectivity requirements. We use SNDP in place of EC-SNDP.

[2] If all edges are safe ($E = \mathcal{S}$), then $(p, 0)$-flex-connectivity is equivalent to p-edge-connectivity. Similarly, if all edges are unsafe ($E = \mathcal{U}$), then $(1, q-1)$-flex-connectivity is equivalent to q-edge-connectivity.

While SNDP admits a 2-approximation, the approximability of network design in the preceding models is not well-understood. The known results mostly focus on two special cases: (i) the single pair case where there is only one pair (s,t) with a connectivity requirement and (ii) the spanning or global connectivity case when all pairs of vertices have identical connectivity requirement. Even in the single pair case, there are results that show that problems in the non-uniform models are hard to approximate to poly-logarithmic or almost-polynomial factors when the connectivity requirement is not bounded [6, 5]. Further, natural LP relaxations in some cases can also be shown to have large integrality gaps [16]. Motivated by these negative results and practical considerations, we focus our attention on Flex-SNDP when the max connectivity requirement p, q are small, and similarly on Bulk-SNDP when the width is small. Other network design problems with similar hardness results have admitted approximation ratios that depend on the max connectivity requirement (for example, VC-SNDP [12, 18, 38] and (s,t) case of Bulk-Robust [6]).

1.1 Our contribution

We are mainly motivated by Flex-SNDP and insights for it via Bulk-SNDP. We make two broad contributions. Our first set of results is on special cases of Flex-SNDP for which we obtain constant factor approximations. Our second contribution is a poly-logarithmic approximation for Flex-SNDP, Bulk-SNDP, and RSNDP when the requirements are small.

We use the terminology (p,q)-Flex-ST to refer to the single-pair problem with requirement (p,q). We use the term (p,q)-FGC to refer to the spanning/global-connectivity problem where all pairs of vertices have the (p,q)-flex-connectivity requirement (the term FGC is to be consistent with previous usage [3, 8]).

(p,q)-FGC. Adjiashvili et al. [3] considered $(1,1)$-FGC and obtained a constant factor approximation that was subsequently improved to 2 by Boyd et al. [8]. [8] obtained several results for (p,q)-FGC including a 4-approximation for $(p,1)$-FGC, a $(q+1)$-approximation for $(1,q)$-FGC, and a $O(q \log n)$-approximation for (p,q)-FGC. The first non-trivial case of small p, q for which we did not know a constant factor is $(2,2)$-FGC. We prove several results that, as a corollary, yield constant factor approximation for small values of p, q.

▶ **Theorem 1.** *For any $q \geq 0$ there is a $(2q+2)$-approximation for $(2,q)$-FGC. For any $p \geq 1$ there is a $(2p+4)$-approximation for $(p,2)$-FGC, and a $(4p+4)$-approximation for $(p,3)$-FGC. Moreover, for all* even *$p \geq 2$ there is an $(6p+4)$-approximation for $(p,4)$-FGC.*

▶ Remark 2. In independent work Bansal et al. [7] obtained an $O(1)$-approximation for $(p,2)$-FGC for any $p \geq 1$ (6 when p is even and 20 when p is odd). More broadly, they obtain constant factor approximations for a special class of augmentation problems and demonstrate several interesting applications.

(p,q)-Flex-ST. Adjiashivili et al. [4] considered $(1,q)$-Flex-ST and $(p,1)$-Flex-ST and obtained several results. They described a q-approximation for $(1,q)$-Flex-ST and a $(p+1)$-approximation for $(p,1)$-Flex-ST; when p is a fixed constant they obtain a 2-approximation. Also implicit in [6] is an $O(q(p+q)\log n)$-approximation algorithm for (p,q)-Flex-ST that runs in $n^{O(p+q)}$-time. No constant factor approximation was known when $p, q \geq 2$ with $(2,2)$-Flex-ST being the first non-trivial case. We prove a constant factor approximation for this and several more general settings via the following theorem.

▶ **Theorem 3.** *For all p, q where $(p+q) > pq/2$, there is an $O((p+q)^{O(p)})$-approximation algorithm for (p,q)-Flex-ST that runs in $n^{O(p+q)}$ time. In particular, there is an $O(1)$ approximation for $(p,2)$ and $(2,q)$-Flex-ST when p, q are fixed constants.*

Flex-SNDP, Bulk-SNDP, and RSNDP. We show that these problems admit poly-logarithmic approximation algorithms when the width/connectivity requirements are small.

▶ **Theorem 4.** *There is a randomized algorithm that yields an $O(k^4 \log^7 n)$-approximation for Bulk-SNDP on instances with width at most k, and runs in expected polynomial time.*

▶ **Corollary 5.** *There is a randomized algorithm that yields an $O(q(p+q)^3 \log^7 n)$- approximation for Flex-SNDP when $(p_i, q_i) \leq (p, q)$ for all pairs (s_i, t_i), and runs in expected $n^{O(q)}$-time.*

▶ **Corollary 6.** *There is a randomized algorithm that yields an $O(k^4 \log^7 n)$-approximation for RSNDP where k is the maximum connectivity requirement, and runs in expected polynomial time.*

As far as we are aware of, no previous approximation algorithms were known for SNDP versions of flexible graph connectivity (with both $p, q \geq 2$) or bulk-robustness.

1.2 Overview of techniques and related work

Network design has substantial literature. We describe closely related work and results to put ours in context.

SNDP and related connectivity problems. SNDP is a canonical problem in network design for connectivity that captures many problems. We refer the reader to some older surveys [28, 36] on approximation algorithms for connectivity problems, and several recent papers with exciting progress on TSP and weighted Tree and Cactus augmentation. Frank's books is an excellent source for polynomial-time solvable exact algorithms [23]. For SNDP, the augmentation approach was pioneered in [41], and was refined in [25]. These led to $2H_k$ approximation where k is the maximum connectivity requirement. Jain's iterated rounding approach [32] obtained a 2-approximation. The nice structural results that underpin the algorithms for SNDP have been extended to *element* connectivity introduced in [33]; consequently, Elem-SNDP also admits a 2-approximation [21]. VC-SNDP has posed non-trivial technical challenges; the problem is not constant factor approximable when the maximum connectivity requirement is large [12]. In a breakthrough result, [18], Chuzhoy and Khanna gave an $O(k^3 \log n)$ approximation via a reduction to element connectivity, where k is the maximum connectivity. Nutov [38] improves this to an $O(k^2)$ approximation for the single-source VC-SNDP case; however, there has been no further progress in obtaining an $f(k)$-approximation for the general VC-SNDP problem.

Flexible Graph Connectivity. Flexible graph connectivity has been a topic of recent interest, although the model was introduced earlier in the context of a single pair [1]. Adjiashvili, Hommelsheim and Mühlenthaler [3] introduced FGC (which is the same as $(1,1)$-FGC) and pointed out that it generalizes the well-known MST and 2-ECSS problems. Several approximation algorithms for various special cases of FGC and Flex-ST were obtained by Adjiashvili et al.[3] and Boyd et al. [8], as described in Section 1.1.

Adjiashvili et al. [5] also showed hardness results in the single pair setting. They prove that $(1,k)$-Flex-ST in directed graphs is at least as hard as directed Steiner tree which implies poly-logarithmic factor inapproximability [31]. They prove that $(k,1)$-Flex-ST in

directed graphs is at least as hard to approximate as directed Steiner forest (which has almost polynomial factor hardness [20]). The hardness results are when k is part of the input and large, and show that approximability of network design in this model is substantially different from the edge-connectivity model.

Bulk-Robust Network Design. This model was initiated in [6]. They obtained an $O(\log n + \log m)$ approximation for the Bulk-Robust spanning tree problem (as a special case of the more general matroid basis problem). The authors show that the *directed* single pair problem (Bulk-Robust shortest path) is very hard to approximate. The hardness reduction motivated the definition of width. The authors obtain an $O(k^2 \log n)$-approximation for Bulk-Robust shortest path via a nice reduction to the Set Cover problem and the use of the augmentation approach that we build upon here. For the special case of $k = 2$ the authors obtain an $O(1)$-approximation. Adjiashvili [2] showed that if the graph is planar then one can obtain an $O(k^2)$-approximation for both Bulk-Robust shortest path and spanning tree problems – he uses the augmentation approach from [6] and shows that the corresponding covering problem in each augmentation phase corresponds to a Set Cover problem that admits a constant factor approximation. As far as we are aware, there has not been any progress on the general setting beyond the spanning tree and shortest path cases.

Relative Network Design. This model was introduced in very recent work [19]. The authors obtain a 2-approximation for the spanning case via nice use of the iterated rounding technique even though the requirement function is not skew-supermodular. They also obtain a simple 2-approximation when the maximum requirement is 2. They obtain a $\frac{27}{4}$-approximation for the (s,t)-case when the maximum demand is 3.

Survivable Network Design for Group Connectivity. As we remarked, one part of this work builds on the recent framework of Chen et al. [17]. Their main motivation was to address the approximability of the survivable network design problem with group connectivity requirements. We refer the reader to [24, 30, 31, 14, 13, 17] and pointers to the extensive work on the approximability of these problems.

Our Techniques. As we remarked, the non-uniform models have been difficult to handle for existing algorithmic techniques. The structures that underpins the known algorithms for SNDP (primal-dual [41] and iterated rounding [32]) are skew-supermodularity of the requirement function and submodularity of the cut function in graphs. Since non-uniform models do not have such clean structural properties, these known techniques cannot be applied directly. Another technique for network design, based on several previous works, is augmentation. In the augmentation approach we start with an initial set of edges F_0 that partially satisfy the connectivity constraints. We then augment F_0 with a set F in the graph $G - F_0$; the augmentation is typically done to increase the connectivity by one unit for pairs that are not yet satisfied. We repeat this process in several stages until all connectivity requirements are met. The utility of the augmentation approach is that it allows one to reduce a higher-connectivity problem to a series of problems that solve a potentially simpler $\{0,1\}$-connectivity problem. An important tool in this area is a 2-approximation for covering an *uncrossable* function (a formal definition is given in Section 3) [41].

In trying to use the augmentation approach for Flex-SNDP and its special cases, we see that the resulting functions are usually not uncrossable. To prove Theorems 1 and 3, we overcome this difficulty by decomposing the family of cuts to be covered in the augmentation

problem into a sequence of cleverly chosen uncrossable subfamilies. Our structural results hold for certain range of values of p and q and hint at additional structure that may be available to exploit in future work. Boyd et al. also show a connection to *capacitated* network design (also implicitly in [5]) which has been studied in several works [25, 9, 10, 11]. This model generalizes standard edge connectivity by allowing each edge e to have an integer capacity $u_e \geq 1$. One can reduce capacitated network design to standard edge connectivity by replacing each edge e with u_e parallel edges, blowing up the approximation factor by $\max_e u_e$. Boyd et al. show that $(1,k)$-Flex-SNDP and $(k,1)$-Flex-SNDP can be reduced to Cap-SNDP with maximum capacity k. While this reduction does not extend when $p, q \geq 2$, it provides a useful starting point that we exploit for Theorem 3.

We use a completely different algorithmic approach to prove Theorem 4. We rely on a recent novel framework of Chen, Laekhanukit, Liao, and Zhang [17] to tackle survivable network design in group connectivity setting. They used the seminal work of Räcke [39] on probabilistic approximation of capacitated graphs via trees, and the group Steiner tree rounding techniques of Garg, Konjevod and Ravi [24], and subsequent developments [27]. We adapt their ideas to handle the augmentation problem for Flex-SNDP and Bulk-SNDP. We refer the reader to Section 4 since the framework is technical.

Organization. Section 2 sets up the relevant background on the LP relaxations for Flex-SNDP and Bulk-SNDP. Section 3 outlines the proofs of Theorems 1 and 3. Section 4 outlines the proofs of Theorems 4 and the resulting corollaries 5 and 6. This paper combines and extends results from two preliminary versions; [16] for the first set of results discussed in Section 3, and [15] for the second set of results discussed in Section 4. A full version of this paper will be made publicly available in the near future.

2 Preliminaries

Throughout the paper we will assume that we are given an undirected graph $G = (V, E)$ along with a cost function $c : E \to \mathbb{R}_{\geq 0}$. When we say that H is a subgraph of $G = (V, E)$ we implicitly assume that H is an edge-induced subgraph, i.e. $H = (V, F)$ for some $F \subseteq E$. For any subset of edges $F \subseteq E$ and any set $S \subseteq V$ we use the notation $\delta_F(S)$ to denote the set of edges in F that have exactly one endpoint in S. We may drop F if it is clear from the context. For all discussion of flex-connectivity, we will let $\mathcal{S}$ denote the set of safe edges and $\mathcal{U}$ denote the set of unsafe edges.

Flex-SNDP LP Relaxation. We describe an LP relaxation for (p, q)-Flex-SNDP problem. Recall that we are given a set of h terminal pairs $(s_i, t_i) \subseteq V \times V$ and the goal is to choose a min-cost subset of the edges F such that in the subgraph $H = (V, F)$, s_i and t_i are (p, q)-flex-connected for any $i \in [h]$. Let $\mathcal{C} = \{S \subset V \mid \exists i \in [h] \text{ s.t. } |S \cap \{s_i, t_i\}| = 1\}$ be the set of all vertex sets that separate some terminal pair. For a set of edges F to be feasible for the given (p, q)-Flex-SNDP instance, we require that for all $S \in \mathcal{C}$, $|\delta_F(S) \setminus B| \geq p$ for any $B \subseteq \mathcal{U}$ with $|B| \leq q$. We can write cut covering constraints expressing this condition, but these constraints are not adequate by themselves. To improve this LP, we consider the connection to capacitated network design: we give each safe edge a capacity of $p + q$, each unsafe edge a capacity of p, and require $p(p + q)$ connectivity for the terminal pairs; it is not difficult to verify that this is a valid constraint. These two sets of constraints yield the following LP relaxation with variables $x_e \in [0, 1]$, $e \in E$.

$$\begin{aligned}
\min \sum_{e\in E} c(e)x_e & \\
\text{subject to} \sum_{e\in\delta(S)-B} x_e \geq p & \qquad S\in\mathcal{C}, B\subseteq\mathcal{U}, |B|\leq q \\
(p+q)\sum_{e\in\delta(S)\cap\mathcal{S}} x_e + p\sum_{e\in\delta(S)\cap\mathcal{U}} x_e \geq p(p+q) & \qquad S\in\mathcal{C} \\
x_e\in[0,1] & \qquad e\in E
\end{aligned}$$

The following lemma borrows ideas from [8, 10].

▶ **Lemma 7.** *The Flex-SNDP LP relaxation can be solved in $n^{O(q)}$ time. For (p,q)-FGC, it can be solved in polynomial time.*

Proof. We show a polynomial time separation oracle for the given LP. Suppose we are given some vector $x\in[0,1]^{|E|}$. We first check if the capacitated min-cut constraints are satisfied. This can be done in polynomial time by giving every safe edge a weight of $p+q$ and every unsafe edge a weight of p, and checking that the min-cut value is at least $p(p+q)$. If it is not, we can find the minimum cut and output the corresponding violated constraint. Suppose all capacitated constraints are satisfied. Then, for each $B\subseteq\mathcal{U}, |B|\leq q$ we remove B and check that for each $s,t\in T$, the s-t min-cut value in the graph $G-B$ with edge-capacities given by x is at least p. Since there are at most $n^{O(q)}$ such possible sets B, we get our desired separation oracle.

In the FGC case, if there is a remaining unsatisfied constraint, then there must must be some $S\subset V$ and some $B\subseteq\mathcal{U}$, $|B|\leq q$, such that $\sum_{e\in\delta(S)-B} x_e < p$. In particular, $\sum_{e\in\mathcal{S}\cap\delta(S)-B} x_e < p$ and $\sum_{e\in\mathcal{U}\cap\delta(S)-B} x_e < p$. We claim that the total weight (according to weights $(p+q)$ for safe edges and p for unsafe edges) going across $\delta(S)$ is at most $2p(p+q)$: at most $(p+q)p$ from $\mathcal{S}\cap(\delta(S)-B)$, at most p^2 from $\mathcal{U}\cap(\delta(S)-B)$, and at most pq from B. Recall that the min-cut of the graph according the weights has already been verified to be at least $p(p+q)$. Hence, any violated cut from the first set of constraints corresponds to 2-approximate min-cut. It is known via Karger's theorem that there are at most $O(n^4)$ 2-approximate min-cuts in a graph, and moreover they can also be enumerated in polynomial time [34, 35]. We can enumerate all 2-approximate min-cuts and check each of them to see if they are violated. To verify whether a candidate cut S is violated we consider the unsafe edges in $\delta(S)\cap\mathcal{U}$ and sort them in decreasing order of x_e value. Let B' be a prefix of this sorted order of size $\min\{q, |\delta(S)\cap\mathcal{U}|\}$. It is easy to see that that $\delta(S)$ is violated iff it is violated when $B=B'$. Thus, we can verify all candidate cuts efficiently. ◀

Bulk-SNDP LP Relaxation. We can similarly define an LP relaxation for the Bulk-SNDP problem. As above, we have a variable $x_e\in[0,1]$ for each edge $e\in E$.

$$\begin{aligned}
\min \sum_{e\in E} c(e)x_e & \\
\text{subject to} \sum_{e\in\delta(S)\setminus F_j} x_e \geq 1 & \qquad \forall (F_j,\mathcal{K}_j)\in\Omega, S \text{ separates a terminal pair in } \mathcal{K}_j \\
x_e\in[0,1] &
\end{aligned}$$

Note that the LP has a separation oracle that runs in time polynomial in n and m: for each scenario $(F_j,\mathcal{K}_j)$, we can remove F_j from the graph and check that the minimum (u,v)-cut is at least 1 for each $(u,v)\in\mathcal{K}_j$.

Augmentation. The results of this paper rely on the augmentation framework. We first discuss Flex-SNDP. Suppose $G = (V, E), \{s_i, t_i\}_{i \in [h]}$ is an instance of (p, q)-Flex-SNDP. We observe that $(p, 0)$-Flex-SNDP instance can be solved via 2-approximation to EC-SNDP. Hence, we are interested in $q \geq 1$. Let F_1 be a feasible solution for the $(p, q-1)$-Flex-SNDP instance. This implies that for any cut S that separates a terminal pair we have $|\delta_{F_1 \cap \mathcal{S}}(S)| \geq p$ or $|\delta_{F_1}(S)| \geq p + q - 1$. We would like to augment F_1 to obtain a feasible solution to satisfy the (p, q) requirement. Define a function $f : 2^{|V|} \to \{0, 1\}$ where $f(S) = 1$ iff (i) S separates a terminal pair and (ii) $|\delta_{F_1 \cap \mathcal{S}}(S)| < p$ *and* $|\delta_{F_1}(S)| = p + q - 1$. We call S a *violated* cut with respect to F_1. Since F_1 satisfies $(p, q-1)$ requirement, if $|\delta_{F_1 \cap \mathcal{S}}| < p$ it must be the case that $|\delta_{F_1}(S)| \geq p + q - 1$. The following lemma is simple.

▶ **Lemma 8.** *Suppose $F_2 \subseteq E \setminus F_1$ is a feasible cover for f, that is, $\delta_{F_2}(S) \geq f(S)$ for all S. Then $F_1 \cup F_2$ is a feasible solution to (p, q)-Flex-SNDP.*

The augmentation problem is then to find a min-cost subset of edges to cover f in $G - F_1$. The key observation is that the augmentation problem does not distinguish between safe and unsafe edges and hence we can rely on traditional connectivity augmentation ideas. Note that if we instead tried to augment from $(p-1, q)$ to (p, q)-flex-connectivity, we would still need to distinguish between safe and unsafe edges. The following lemma shows that the LP relaxation for the original instance provides a valid cut-covering relaxation for the augmentation problem.

▶ **Lemma 9.** *Let $x \in [0, 1]^{|E|}$ be a feasible LP solution for a given instance of (p, q)-Flex-Steiner. Let F_1 be a feasible solution that satisfies $(p, q-1)$ requirements for the terminal. Then, for any violated cut $S \subseteq V$ in (V, F_1), we have $\sum_{e \in \delta(S) \setminus F_1} x_e \geq 1$.*

Adjiashvili et al [6] also define a corresponding augmentation problem for the bulk robust network design model as follows: given an instance to Bulk-SNDP, let $\Omega_\ell = \bigcup_{j \in [m]} \{(F, \mathcal{K}_j) : |F| \leq \ell \text{ and } F \subseteq F_j\}$. Let $H_\ell \subseteq E$ be a subset of edges that satisfy the constraints defined by the scenarios in Ω_ℓ. Then, a solution to the augmentation problem from $\ell - 1$ to ℓ is a set of edges H' such that $H_{\ell-1} \cup H'$ satisfies the constraints defined by scenarios in Ω_ℓ. It is not difficult to verify that any solution to the original instance Ω is also a solution to any of the augmentation problems, and any solution satisfying all scenarios in Ω_k also satisfies all scenarios in Ω, where k is the width of the Bulk-SNDP instance.

3 Uncrossability-Based Approximation Algorithms

In this section, we prove Theorem 1 and Theorem 3. Recall that we are given a graph $G = (V, E)$ with cost function on the edges $c : E \to \mathbb{R}_{\geq 0}$ and a partition of the edge set E into safe edges $\mathcal{S}$ and unsafe edges $\mathcal{U}$. In the (p, q)-FGC problem, our goal is to find the cheapest set of edges such that every cut has either p safe edges or $p + q$ total edges. The (p, q)-Flex-ST problem is similar, except that we are also given $s, t \in V$ as part of the input and we focus only on cuts separating s from t.

We start by providing some necessary background on uncrossable/ring families and submodularity of the cut function. We then prove a simple $O(q)$-approximation for $(2, q)$-FGC by directly applying existing algorithms for covering uncrossable functions. Next, we devise a framework for augmentation when the requirement function is not uncrossable. Finally, we prove our results for special cases of (p, q)-FGC and (p, q)-Flex-ST using this framework.

Uncrossable functions and families. Uncrossable functions are a general class of requirement functions that are an important ingredient in network design [41, 26, 28, 36].

▶ **Definition 10.** *A function $f : 2^V \to \{0,1\}$ is* uncrossable *if for every $A, B \subseteq V$ such that $f(A) = f(B) = 1$, one of the following is true: (i) $f(A \cup B) = f(A \cap B) = 1$, (ii) $f(A - B) = f(B - A) = 1$. A family of cuts $\mathcal{C} \subset 2^V$ is an uncrossable* family *if the indicator function $f_{\mathcal{C}} : 2^V \to \{0,1\}$ with $f(S) = 1$ iff $S \in \mathcal{C}$, is uncrossable.*

For a graph $G = (V, E)$, a requirement function $f : 2^V \to \{0,1\}$, and a subset of edges $A \subseteq E$, we say a set $S \subseteq V$ is violated with respect to A, f if $f(S) = 1$ and $\delta_A(S) = \emptyset$. The following important result gives a 2-approximation algorithm for the problem of covering an uncrossable requirement function.

▶ **Theorem 11** ([41]). *Let $G = (V, E)$ be an edge-weighted graph and let $f : 2^V \to \{0,1\}$ be an uncrossable function. Suppose there is an efficient oracle that for any $A \subseteq E$ outputs all the minimal violated sets of f with respect to A. Then there is an efficient 2-approximation for the problem of finding a minimum cost subset of edges that covers f.*

A special case of uncrossable family of sets is a *ring family*. We say that an uncrossable family $\mathcal{C} \subseteq 2^V$ is a ring family if the following conditions hold: (i) if $A, B \in \mathcal{C}$ and A, B properly intersect[3] then $A \cap B$ and $A \cup B$ are in $\mathcal{C}$ and (ii) there is a unique minimal set in $\mathcal{C}$. We observe that if $\mathcal{C}$ is an uncrossable family such that there is a vertex s contained in every $A \in \mathcal{C}$ then $\mathcal{C}$ is automatically a ring family. Theorem 11 can be strengthened for this case. There is an optimum algorithm to find a min-cost cover of a ring family – see [37, 38, 22].

In order to use Theorem 11 in the augmentation framework, we need to be able efficiently find all the minimal violated sets of the family. As above, we let F_1 denote a feasible solution for the $(p, q-1)$-Flex-SNDP instance. For any fixed p, q, we can enumerate all minimal violated sets in $n^{O(p+q)}$ time by trying all possible subsets of $p + q - 1$ edges in F_1. In the context of (p, q)-FGC, the total number of violated cuts in the augmentation problem is bounded by $O(n^4)$. See [8] and the proof of Lemma 7 for details.

For the following sections on (p, q)-FGC, we let $\mathcal{C}$ denote the family of violated cuts. Note that such families are symmetric, since $\delta(S) = \delta(V - S)$. For any two sets $A, B \in \mathcal{C}$, if $A \cup B = V$ then by symmetry, $V - A, V - B \in \mathcal{C}$. In this case, $V - A = B - A$ and $V - B = A - B$, so A and B uncross. Therefore, when proving uncrossability of A and B, we assume without loss of generality that $(A \cup B) \neq V$.

Submodularity and posimodularity of the cut function. It is well-known that the cut function of an undirected graph is symmetric and submodular. Submodularity implies that for all $A, B \subseteq V$, $|\delta(A)| + |\delta(B)| \geq |\delta(A \cap B)| + |\delta(A \cup B)|$. Symmetry and submodularity also implies posimodularity: for all $A, B \subseteq V$, $|\delta(A)| + |\delta(B)| \geq |\delta(A - B)| + |\delta(B - A)|$.

3.1 An $O(q)$-approximation for $(2, q)$-FGC

The following lemma shows that the augmentation problem for increasing flex-connectivity from $(2, q-1)$ to $(2, q)$, for any $q \geq 1$ corresponds to covering an uncrossable function.

▶ **Lemma 12.** *The set of all violated cuts when augmenting from $(2, q-1)$-FGC to $(2, q)$-FGC is uncrossable.*

[3] A, B properly intersect if $A \cap B \neq \emptyset$ and $A - B, B - A \neq \emptyset$.

The preceding lemma yields a $2(q+1)$-approximation for $(2,q)$-FGC as follows. We start with a 2-approximation for $(2,0)$-FGC that can be obtained by using an algorithm for 2-ECSS. Then for we augment in q-stages to go from a feasible solution to $(2,0)$-FGC to $(2,q)$-FGC. The cost of augmentation in each stage is at most OPT where OPT is the cost of an optimum solution to $(2,q)$-FGC. We can use the known 2-approximation algorithm in each augmentation stage since the family is uncrossable. Recall from Section 2 that the violated cuts can be enumerated in polynomial time, and hence the primal-dual 2-approximation for covering an uncrossable function can be implemented in polynomial-time. This leads to the claimed approximation and running time.

3.2 Identifying Uncrossable Subfamilies

We have seen that the augmentation problem from $(2,q-1)$-FGC to $(2,q)$-FGC leads to covering an uncrossable function. Boyd et al. [8] showed that augmenting from $(p,0)$-FGC to $(p,1)$-FGC also leads to an uncrossable function for any $p \geq 1$. However this approach fails for most cases of augmenting from $(p,q-1)$ to (p,q) (see [16] for examples). However, in certain cases, we can take a more sophisticated approach where we consider the violated cuts in a small number of stages. In each stage, we choose a subfamily of the violated cuts that is uncrossable. In such cases, we can obtain a $2k$-approximation for the augmentation problem, where k is the upper bound on the number of stages.

Suppose we want to augment from $(p,q-1)$ to (p,q) (for either FGC or the Flex-ST setting). Let $G=(V,E)$ be the original input graph, and let F be the set of edges we have already included. Recall that a cut $\emptyset \neq A \subsetneq V$ is violated iff $|\delta_F(A)| = p+q-1$, $|\delta_{F\cap\mathcal{S}}(A)| < p$, and in the Flex-ST case, A separates s from t. Instead of attempting to cover all violated sets at once, we do so in stages. In each stage we consider the violated cuts based on the number of safe edges. We begin by covering all violated sets with no safe edges, then with one safe edge, and iterate until all violated sets are covered. This is explained in Algorithm 1 below.

Algorithm 1 Augmenting from $(p,q-1)$ to (p,q) in stages.

$F' \leftarrow F$
for $i = 0,\ldots,p-1$ **do**
  $\mathcal{C}_i \leftarrow \{S : S \text{ is violated and } |\delta_{F'\cap\mathcal{S}}(S)| = i\}$
  $F'_i \leftarrow$ approximation algorithm to cover cuts in $\mathcal{C}_i$
  $F' \leftarrow F' \cup F'_i$
end for
return F'

3.3 Approximating (p,q)-FGC for $q \leq 4$

In this section, we show that the above approach works to augment from $(p,q-1)$-FGC to (p,q)-FGC whenever $q \leq 3$ and also for $q=4$ when p is even. The only unspecified part Algorithm 1 is to cover cuts in $\mathcal{C}_i$ in the i'th stage. If we can prove that $\mathcal{C}_i$ forms an uncrossable family then we can obtain a 2-approximation in each stage. First, we prove a generic and useful lemma regarding cuts in $\mathcal{C}_i$.

For the remaining lemmas, we let $F_i \subseteq E$ denote the set of edges F' at the start of iteration i. In other words, F_i is a set of edges such that for all $\emptyset \neq A \subsetneq V$, if $|\delta_{F_i}(A)| = p+q-1$, then $|\delta_{F_i\cap\mathcal{S}}(A)| \geq i$.

▶ **Lemma 13.** *Fix an iteration $i \in \{0, \ldots, p-1\}$. Let $\mathcal{C}_i$ be as defined in Algorithm 1. Then, if $A, B \in \mathcal{C}_i$ and*
1. $|\delta_{F_i}(A \cap B)| = |\delta_{F_i}(A \cup B)| = p + q - 1$, *or*
2. $|\delta_{F_i}(A - B)| = |\delta_{F_i}(B - A)| = p + q - 1$

then A and B uncross, i.e. $A \cap B, A \cup B \in \mathcal{C}_i$ or $A - B, B - A \in \mathcal{C}_i$.

Note that the preceding lemma holds for the high-level approach. Now we focus on cases where we can prove that $\mathcal{C}_i$ is uncrossable.

▶ **Lemma 14.** *Fix an iteration $i \in \{0, \ldots, p-1\}$. Let $\mathcal{C}_i$ be as defined in Algorithm 1. Then, for $q \leq 3$, $\mathcal{C}_i$ is uncrossable.*

Proof. Suppose $A, B \subseteq V$ such that $\delta_{F_i}(A)$ and $\delta_{F_i}(B)$ both have exactly i safe and $p + q - 1 - i$ unsafe edges. Suppose for the sake of contradiction that they do not uncross. By Lemma 13, one of $\delta_{F_i}(A \cap B)$ and $\delta_{F_i}(A \cup B)$ must have at most $p + q - 2$ edges, and the same holds for $\delta_{F_i}(A - B)$ and $\delta_{F_i}(B - A)$. Without loss of generality, suppose $\delta_{F_i}(A \cap B)$ and $\delta_{F_i}(A - B)$ each have at most $p + q - 2$ edges. By the assumptions on F_i, they must both have at least p safe edges, hence they each have at most $q - 2$ unsafe edges. Note that $\delta_{F_i}(A) \subseteq \delta_{F_i}(A - B) \cup \delta_{F_i}(A \cap B)$, hence $\delta_{F_i}(A)$ can have at most $2(q - 2)$ unsafe edges. When $q \leq 3$, $2(q-2) < q$, which implies that $\delta_{F_i}(A)$ has strictly more than $p-1$ safe edges, a contradiction. Notice that $\delta_{F_i}(A) \subseteq \delta_{F_i}(B-A) \cup \delta_{F_i}(A \cup B)$, $\delta_{F_i}(B) \subseteq \delta_{F_i}(A-B) \cup \delta_{F_i}(A \cup B)$, and $\delta_{F_i}(B) \subseteq \delta_{F_i}(B - A) \cup \delta_{F_i}(A \cap B)$; therefore the same argument follows regardless of which pair of sets each have strictly less than $p + q - 2$ edges. ◀

▶ **Corollary 15.** *For any $p \geq 2$ there is a $(2p + 4)$-approximation for $(p, 2)$-FGC and a $(4p + 4)$-approximation for $(p, 3)$-FGC.*

Can we extend the preceding lemma for $q = 4$? It turns out that it does work when p is even but fails for odd $p \geq 3$.

▶ **Lemma 16.** *Fix an iteration $i \in \{0, \ldots, p-2\}$. Let $\mathcal{C}_i$ be as defined in Algorithm 1. Then, for $q = 4$, $\mathcal{C}_i$ is uncrossable. Furthermore, if p is an* even *integer, $\mathcal{C}_{p-1}$ is uncrossable.*

The preceding lemma leads to a $(6p + 4)$-approximation for $(p, 4)$-FGC when p is even by augmenting from a feasible solution to $(p, 3)$, since we pay an additional cost of $2p \cdot OPT$. The preceding lemma also shows that the bottleneck for odd p is in covering $\mathcal{C}_{p-1}$. It may be possible to show that $\mathcal{C}_{p-1}$ separates into a constant number of uncrossable families leading to an $O(p)$-approximation for $(p, 4)$-FGC for all p. The first non-trivial case is when $p = 3$.

3.4 An $O(1)$-Approximation for Flex-ST

In this section, we provide a constant factor approximation for (p, q)-Flex-ST for all fixed p, q that satisfy $2(p + q) > pq$. We follow the general approach outlined in 3.2 with some modifications. In particular, we start with a stronger set of edges F than in the FGC case above. Let $E' \subseteq E$ denote a feasible solution to $(p, q - 1)$-Flex-ST.

Recall from Section 1 the capacitated network design problem, in which each edge has an integer capacity $u_e \geq 1$. Consider an instance of the $(p(p + q))$-Cap-ST problem on G where every safe edge is given a capacity of $p + q$ and every unsafe edge is given a capacity of p. Our goal is to find the cheapest set of edges that support a flow of $(p(p + q))$ from s to t. It is easy to see that any solution to (p, q)-Flex-ST is also a feasible solution for this capacitated problem: every s-t cut either has at least p safe edges or at least $p + q$ total edges, and either case gives a capacity of at least $p(p + q)$. As mentioned in Section 1, there exists a

$2\max_e(u_e) = 2(p+q)$ approximation for this problem. Let $E'' \subseteq E$ be such a solution, and note that $\text{cost}(E'') \leq 2(p+q) \cdot OPT$, where OPT denotes the cost of an optimal solution to (p,q)-Flex-ST.

Let $F = E' \cup E''$. We redefine $\mathcal{C}$ to limit ourselves to the set of violated cuts containing s, i.e. $\mathcal{C} = \{A \subset V : s \in A, t \notin A, |\delta_{F\cap\mathcal{S}}(A)| < p, |\delta_{F\cap\mathcal{U}}(A)| = p+q-1\}$. By symmetry, it suffices to only consider cuts containing s, since covering a set also covers its complement. Following the discussion in Section 3.2, we use Algorithm 1 to cover violated cuts in stages based on the number of safe edges. However, unlike the spanning case, the sets $\mathcal{C}_i$ are not uncrossable in the single pair setting, even for $(2,2)$-Flex-ST. In this case, we aim to further partition $\mathcal{C}_i$ into subfamilies that we can cover efficiently.

For the remaining lemmas, we let $F_i \subseteq E$ denote the set of edges F' at the start of iteration i. In other words, F_i is a set of edges such that for all cuts A separating s from t, if $|\delta_{F_i}(A)| = p+q-1$, then $|\delta_{F_i\cap\mathcal{S}}(A)| \geq i$. We begin with a structural lemma.

▶ **Lemma 17.** *Fix an iteration $i \in \{0,\ldots,p-1\}$. Let $\mathcal{C}_i$ be as defined in Algorithm 1. Let $A, B \in \mathcal{C}_i$. Then, either*
1. *$A \cup B, A \cap B \in \mathcal{C}_i$, i.e. A and B uncross, or*
2. *$\max(\delta_{F_i\cap\mathcal{S}}(A\cap B), \delta_{F_i\cap\mathcal{S}}(A\cup B)) \geq p$.*

Consider a flow network on the graph (V, F_i) with safe edges given a capacity of $(p+q)$ and unsafe edges given a capacity of p. Since $E'' \subseteq F_i$, F_i satisfies the $p(p+q)$-Cap-ST requirement. Therefore, the minimum capacity s-t cut and thus the maximum s-t flow value is at least $p(p+q)$. Since capacities are integral, there is some integral max flow f. By flow decomposition, we can decompose f into a set $\mathcal{P}$ of $|f|$ paths, each carrying a flow of 1, and we can find $\mathcal{P}$ in polynomial time.

For each $\mathcal{Q} \subseteq \mathcal{P}$ where $|\mathcal{Q}| = i$, we define a subfamily of violated cuts $\mathcal{C}_i^{\mathcal{Q}}$ as follows. Let $\mathcal{Q} = P_1, \ldots, P_i$. Then, $A \in \mathcal{C}_i$ is in $\mathcal{C}_i^{\mathcal{Q}}$ iff there exist distinct edges $e_1, \ldots, e_i \in \mathcal{S}$ satisfying:
1. $\forall j \in [i]$, $\delta_{F_i}(A) \cap P_j = \{e_j\}$,
2. $\delta_{F_i\cap\mathcal{S}}(A) = \{e_1, \ldots, e_i\}$.

Informally, $\mathcal{C}_i^{\mathcal{Q}}$ is the set of all violated cuts that intersect the paths of $\mathcal{Q}$ exactly once and on a distinct safe edge each.

▶ **Lemma 18.** *Suppose $pq < 2p + 2q$. If $A \in \mathcal{C}_i$, then there exists some $\mathcal{Q} \subseteq \mathcal{P}$, $|\mathcal{Q}| = i$, such that $A \in \mathcal{C}_i^{\mathcal{Q}}$.*

The above lemma shows that $\cup_{\mathcal{Q}\subseteq\mathcal{P},|\mathcal{Q}|=i}\mathcal{C}_i^{\mathcal{Q}} = \mathcal{C}_i$. Therefore, it suffices to cover each $\mathcal{C}_i^{\mathcal{Q}}$.

▶ **Lemma 19.** *For any $\mathcal{Q} \subseteq \mathcal{P}$, $|\mathcal{Q}| = i$, $\mathcal{C}_i^{\mathcal{Q}}$ is a ring family.*

We combine the above lemmas to obtain a constant factor approximation for covering $\mathcal{C}_i$.

▶ **Lemma 20.** *Suppose $2(p+q) > pq$ and p, q are fixed. Then, there exists an algorithm that runs in $n^{O(p+q)}$ time to cover all cuts in $\mathcal{C}_i$ with cost at most $\binom{p^2+2pq}{i} \cdot OPT$.*

The above lemma gives us Theorem 3 as a corollary. At the beginning of each augmentation step, before running Algorithm 1, we compute a solution to the $(p(p+q))$-Cap-ST problem, which we can do with cost at most $(p+q) \cdot OPT$. Summing over q augmentation iterations gives us the desired $(p+q)^{O(p)}$ approximation ratio.

▶ Remark 21. The approximation factor in Theorem 3 can be optimized slightly. For example, the algorithm we describe gives a 5-approximation for $(2,2)$-Flex-ST. We omit the details of this optimization in this paper and instead focus on showing constant factor for fixed p, q.

4 Approximating the Augmentation Problem for (p, q)-Flex-SNDP

In this section, we prove Theorem 4 and the resulting Corollaries 5 and 6. We begin with some background on Räcke's capacity-based probabilistic tree embeddings and Tree Rounding algorithms for Group Steiner tree. We then present the algorithm and analysis for Bulk-SNDP.

4.1 Räcke Tree Embeddings

The results in this section use Räcke's capacity-based probabilistic tree embeddings. We borrow the notation from [17]. Given $G = (V, E)$ with capacity $x : E \to \mathbb{R}^+$ on the edges, a capacitated tree embedding of G is a tree $\mathcal{T}$, along with two mapping functions $\mathcal{M}_1 : V(\mathcal{T}) \to V(G)$ and $\mathcal{M}_2 : E(\mathcal{T}) \to 2^{E(G)}$ that satisfy some conditions. $\mathcal{M}_1$ maps each vertex in $\mathcal{T}$ to a vertex in G, and has the additional property that it gives a one-to-one mapping between the leaves of $\mathcal{T}$ and the vertices of G. $\mathcal{M}_2$ maps each edge $(a, b) \in E(\mathcal{T})$ to a path in G between $\mathcal{M}_1(a)$ and $\mathcal{M}_1(b)$. For notational convenience we view the two mappings as a combined mapping $\mathcal{M}$. For a vertex $u \in V(G)$ we use $\mathcal{M}^{-1}(u)$ to denote the leaf in $\mathcal{T}$ that is mapped to u by $\mathcal{M}_1$. For an edge $e \in E(G)$ we use $\mathcal{M}^{-1}(e) = \{f \in E(\mathcal{T}) \mid e \in \mathcal{M}_2(f)\}$. It is sometimes convenient to view a subset $S \subseteq V(G)$ both as vertices in G and also corresponding leaves of $\mathcal{T}$.

The mapping $\mathcal{M}$ induces a capacity function $y : E(\mathcal{T}) \to \mathbb{R}_+$ as follows. Consider $f = (a, b) \in E(\mathcal{T})$. $\mathcal{T} - f$ induces a partition (A, B) of $V(T)$ which in turn induces a partition/cut (A', B') of $V(G)$ via the mapping $\mathcal{M}$: A' is the set of vertices in G that correspond to the leaves in A and similarly B'. We then set $y(f) = \sum_{e \in \delta(A')} x(e)$, in other words $y(f)$ is the capacity of cut (A', B') in G. The mapping also induces loads on the edges of G. For each edge $e \in G$, we let $\mathrm{load}(e) = \sum_{f \in E(\mathcal{T}) : e \in M(f)} y(f)$. The relative load or *congestion* of e is $\mathrm{rload}(e) = \mathrm{load}(e)/x(e)$. The congestion of G with respect to a tree embedding $(\mathcal{T}, \mathcal{M})$ is defined as $\max_{e \in E(G)} \mathrm{rload}(e)$. Given a probabilistic distribution $\mathcal{D}$ on trees embeddings of (G, x) we let $\beta_{\mathcal{D}} = \max_{e \in E(G)} \mathbf{E}_{(\mathcal{T}, \mathcal{M}) \sim \mathcal{D}} \mathrm{rload}(e)$ denote the maximum expected congestion. Räcke showed the following fundamental result on probabilistic embeddings of a capacitated graph into trees.

▶ **Theorem 22** ([39]). *Given a graph G and $x : E(G) \to \mathbb{R}^+$, there exists a probability distribution $\mathcal{D}$ on tree embeddings such that $\beta_{\mathcal{D}} = O(\log |V(G)|)$. All trees in the support of $\mathcal{D}$ have height at most $O(\log(nC))$, where C is the ratio of the largest to smallest capacity in x. Moreover, there is randomized polynomial-time algorithm that can sample a tree from the distribution $\mathcal{D}$.*

In the rest of the paper we use β to denote the guarantee provided by the preceding theorem where $\beta = O(\log n)$ for a graph on n nodes. In order to use these probabilistic embeddings to route flow, we need the following corollary, where we use $\mathrm{maxflow}^z_H(A, B)$ to denote the maxflow between two disjoint vertex subsets A, B in a capacitated graph H with capacities given by $z : E(H) \to \mathbb{R}_+$.

▶ **Corollary 23.** *Let $\mathcal{D}$ be the distribution guaranteed in Theorem 22. Let $A, B \in V(G)$ be two disjoint sets. Then*

- **(i)** *for any tree $(\mathcal{T}, \mathcal{M})$ in $\mathcal{D}$, $\mathrm{maxflow}^x_G(A, B) \leq \mathrm{maxflow}^y_{\mathcal{T}}(\mathcal{M}^{-1}(A), \mathcal{M}^{-1}(B))$ and*
- **(ii)** $\frac{1}{\beta} \mathbf{E}_{(\mathcal{T}, \mathcal{M}) \sim \mathcal{D}}[\mathrm{maxflow}^y_{\mathcal{T}}(\mathcal{M}^{-1}(A), \mathcal{M}^{-}(B))] \leq \mathrm{maxflow}^x_G(A, B)$.

4.2 Group Steiner Tree, Set Connectivity and Tree Rounding

The group Steiner tree problem was introduced in [40] and studied in approximation by Garg, Konjevod and Ravi [24]. The input is an edge-weighted graph $G = (V, E)$, a root vertex $r \in V$, and k groups $S_1, S_2, \ldots, S_k$ where each $S_i \subseteq V$. The goal is to find a min-weight subgraph H of G such there is a path in H from r to each group S_i (that is, to some vertex in S_i). The approximability of this problem has attracted substantial attention. Garg et al. [24] described a randomized algorithm to round a fractional solution to a cut-based LP relaxation when G is a tree – it achieves a $O(\log n \log k)$-approximation.

Set Connectivity is a generalization of group Steiner tree problem. Here we are given pairs of sets $(S_1, T_1), (S_2, T_2), \ldots, (S_k, T_k)$ and the goal is to find a min-cost subgraph H such that there is an (S_i, T_i) path in H for each i. Chalermsook, Grandoni and Laekhanukit [13] studied Survivable Set Connectivity problem, motivated by earlier work in [29]. Here each pair (S_i, T_i) has a connectivity requirement r_i which implies that one seeks r_i edge-disjoint paths between S_i and T_i in the chosen subgraph H; [13] obtained a bicriteria-approximation via Räcke tree and group Steiner tree rounding. The recent work of Chen et al [17] uses related but more sophisticated ideas to obtain the first true approximation for this problem. They refer to the problem as Group Connectivity problem and obtain an $O(r^3 \log r \log^7 n)$-approximation where $r = \max_i r_i$ connectivity requirement (see [17] for more precise bounds).

Oblivious tree rounding. In [13] a randomized oblivious algorithm based on the group Steiner tree rounding from [24] is described. This is useful since the sets to be connected during the course of their algorithm are implicitly generated. We encapsulate their result in the following lemma. The tree rounding algorithm in [13, 17] is phrased slightly differently since they combine aspects of group Steiner rounding and the congestion mapping that comes from Räcke trees. We separate these two explicitly to make the idea more transparent. We refer to the algorithm from the lemma below as TreeRounding.

▶ **Lemma 24** ([13, 17]). *Consider an instance of Set Connectivity on an n-node tree $T = (V, E)$ with height h and let $x : E \to [0, 1]$. Suppose $A, B \subseteq V$ are disjoint sets and suppose $K \subseteq E$ such that x restricted to K supports a flow of $f \leq 1$ between A and B. There is a randomized algorithm that is oblivious to A, B, K (hence depends only on x and value f) that outputs a subset $E' \subseteq E$ such that (i) The probability that $E' \cap K$ connects A to B is at least a fixed constant ϕ and (ii) For any edge $e \in E$, the probability that $e \in E'$ is $\min\{1, O(\frac{1}{f} h \log^2 n) x(e)\}$.*

4.3 Rounding Algorithm for the Augmentation Problem

We adapt the algorithm and analysis in [17] to Bulk-SNDP. Let β be the expected congestion given by Theorem 22. Consider an instance of Bulk-SNDP specified by a graph $G : (V, E)$ with cost function $c : E \to \mathbb{R}_{\geq 0}$ and a set of scenarios $\Omega = \{(F_j, \mathcal{K}_j) : j \in [m]\}$. Assume we have a partial solution H satisfying all scenarios in $\Omega_{\ell-1}$. We augment H to satisfy scenarios in Ω_ℓ.

We start by obtaining a solution $\{x_e\}_{e \in E \setminus H}$ for the LP relaxation. Let $E' = E \setminus H$. We define $\text{LARGE} = \{e \in E' : x_e \geq \frac{1}{4\ell\beta}\}$, and $\text{SMALL} = \{e \in E' : x_e < \frac{1}{4\ell\beta}\}$. The LP has paid for each $e \in \text{LARGE}$ a cost of at least $c(e)/(4\ell\beta)$, hence adding all of them to H will cost $O(\ell\beta \cdot \text{OPT}_{\text{LP}})$. If $\text{LARGE} \cup H$ is a feasible solution to the augmentation problem, then we are done since we obtain a solution of cost $O(\ell \log n \cdot \text{OPT}_{\text{LP}})$. Thus, the interesting case is when $\text{LARGE} \cup H$ is *not* a feasible solution.

Following [17] we employ a Räcke tree based rounding. A crucial step is to set up a capacitated graph appropriately. We can assume, with a negligible increase in the fractional cost, that for each edge $e \in E'$, $x(e) = 0$ or $x(e) \geq \frac{1}{n^3}$; this can be ensured by rounding down to 0 the fractional value of any edge with very small value, and compensating for this loss by scaling up the fractional value of the other edges by a factor of $(1 + 1/n)$. It is easy to check that the new solution satisfies the cut covering constraints, and we have only increased the cost of the fractional solution by a $(1 + 1/n)$-factor. In the subsequent steps we can ignore edges with $x_e = 0$ and assume that there are no such edges.

Consider the original graph $G = (V, E)$ where we set a capacity for each $e \in E$ as follows. If $e \in \text{LARGE} \cup H$ we set $\tilde{x}_e = \frac{1}{4\ell\beta}$. Otherwise we set $\tilde{x}_e = x_e$. Since the ratio of the largest to smallest capacity is $O(n^3)$, the height of any Räcke tree for G with capacities $\tilde{x}$ is at most $O(\log n)$. Then, we repeatedly sample Räcke trees. For each tree, we sample edges by the rounding algorithm given by Chalermsook et al in [13] (see Section 4.2 for details). A formal description of the algorithm is provided below where t' and t are two parameters that control the number of trees sampled and the number of times we run the tree rounding algorithm in each sampled tree. We will analyze the algorithm by setting both t and t' to $\Theta(\ell \log n)$.

Algorithm 2 Approximating the Bulk-SNDP Augmentation Problem from $\ell - 1$ to ℓ.

$H \leftarrow$ partial solution satisfying scenarios in Ω_ℓ
$\{x\}_{e \in E} \leftarrow$ fractional solution to the LP
$\text{LARGE} \leftarrow \{e \in E' : x_e \geq \frac{1}{4\ell\beta}\}$
$\text{SMALL} \leftarrow \{e \in E' : x_e < \frac{1}{4\ell\beta}\}$
$H \leftarrow H \cup \text{LARGE}$
if H is a feasible solution satisfying scenarios in $\Omega_{\ell+1}$ **then return** H
else

$$\tilde{x}_e \leftarrow \begin{cases} \frac{1}{4\ell\beta} & e \in H \\ x_e & \text{otherwise} \end{cases}$$

end if
$\mathcal{D} \leftarrow$ Räcke tree distribution for $(G, \tilde{x})$
for $i = 1, \ldots t'$ **do**
  Sample a tree $(\mathcal{T}, \mathcal{M}, y) \sim \mathcal{D}$
  for $j = 1, \ldots, t$ **do**
    $H' \leftarrow$ output of oblivious TreeRounding algorithm on $(G, \mathcal{T})$
    $H \leftarrow H \cup \mathcal{M}(H')$
  end for
end for
return H

4.4 Analysis

For the remainder of of this analysis, we denote as H the partial solution after buying edges in LARGE. We will assume, following earlier discussion, that H does not satisfy all requirements specified by scenarios in Ω_ℓ. This implies that there must be some F such that $|F| \leq \ell$, $F \subseteq F_i$ for some $i \in [m]$, and $\exists (u, v) \in \mathcal{K}_i$ such that u and v are disconnected in $(V, H \setminus F)$. Since H satisfies all scenarios in $\Omega_{\ell-1}$, it must be the case that F has exactly ℓ edges. We call such an F a violating set. There are at most $\binom{|H|}{\ell}$ violating edge sets, and since $|H| \leq n^2$, this is upper bounded by $O(n^{2\ell})$. We say that a set of edges $H' \subseteq E \setminus H$ is a feasible augmentation for violating edge set F if $\forall i \in [m]$ such that $F \subseteq F_i$, $\forall (u, v) \in \mathcal{K}_i$, there is a path from u to v in $(H \cup H') \setminus F$. The following is a simple observation.

▷ Claim 25. $H' \subseteq E \setminus H$ is a feasible solution to the augmentation problem iff for each violating edge set F, H' is a feasible augmentation for F.

The preceding observation allows us to focus on a fixed violating edge set F, and ensure that the algorithm outputs a set H' that is a feasible augmentation for F with high probability. We observe that the algorithm is oblivious to F. Thus, if we obtain a high probability bound for a fixed F, since there are $O(n^{2\ell})$ violating edge sets, we can use the union bound to argue that H' is feasible solution for *all* violating edge sets. For the remainder of this section, until we do the final cost analysis, we work with a fixed violating edge set F. For ease of notation, we let $\mathcal{K}_F = \bigcup_{i \in [m]: F \subseteq F_i} \mathcal{K}_i$ be the set of terminal pairs that need to be connected in $(H \cup H') \setminus F$.

Consider a tree $(\mathcal{T}, \mathcal{M}, y)$ in the Räcke distribution for the graph G with capacities $\tilde{x}$. We let $\mathcal{M}^{-1}(F)$ denote the set of all tree edges corresponding to edges in F, i.e. $\mathcal{M}^{-1}(F) = \cup_{e \in F} \mathcal{M}^{-1}(e)$. We call $(\mathcal{T}, \mathcal{M}, y)$ *good* with respect to F if $y(\mathcal{M}^{-1}(F)) \leq \frac{1}{2}$; equivalently, F blocks a flow of at most $\frac{1}{2}$ in $\mathcal{T}$.

▶ **Lemma 26.** *For a violating edge set F, a randomly sampled Räcke tree $(\mathcal{T}, \mathcal{M}, y)$ is good with respect to F with probability at least $\frac{1}{2}$.*

Given the preceding lemma, a natural approach is to sample a good tree $\mathcal{T}$ and hope that $\mathcal{T} \setminus M^{-1}(F)$ still has good flow between each terminal pair. However, since we rounded down all edges in $\text{LARGE} \cup H$, it is possible that $\mathcal{M}^{-1}(F)$ contains an edge whose removal would disconnect a terminal pair in $\mathcal{T}$, even if $\mathcal{T}$ is good. See [17] for a more detailed discussion and example.

We note that our goal is to find a set of edges $H' \subseteq E$ such that each terminal pair in $\mathcal{K}_F$ has a path in $(H' \cup H) \setminus F$; these paths must exist in the original graph, even if they do not exist in the tree. Therefore, instead of looking directly at paths in $\mathcal{T}$, we focus on obtaining paths through components that are already connected in $(V(G), H \setminus F)$. The rest of the argument is to show that sufficiently many iterations of TreeRounding on any good tree $\mathcal{T}$ for F will yield a feasible set H' for F.

4.5 Shattered Components, Set Connectivity and Rounding

Let $\mathbb{Q}_F$ be the set of connected components in the subgraph induced by $H \setminus F$. We use vertex subsets to denote components. Let $\mathcal{T}$ be a good tree for F. We say that a connected component $Q \in \mathbb{Q}_F$ is *shattered* if it is disconnected in $\mathcal{T} \setminus \mathcal{M}^{-1}(F)$, else we call it *intact*. For each $(u, v) \in \mathcal{K}_F$, let $Q_u \in \mathbb{Q}_F$ be the component containing u, and $Q_v \in \mathbb{Q}_F$ be the component containing v. Note that Q_u may be the same as Q_v for some $(u, v) \in \mathcal{K}_F$, but if F is a violating edge set then there is at least one pair $(u, v) \in \mathcal{K}_F$ such that $Q_u \neq Q_v$. Now, we define a Set Connectivity instance that is induced by F and $\mathcal{T}$. Consider two disjoint vertex subsets $A, B \subset V$. We say that (A, B) partitions the set of shattered components if each shattered component Q is fully contained in A or fully contained in B. Formally let

$$Z_F = \{(A \cup Q_u, B \cup Q_v) : (A, B) \text{ partitions the shattered components}, (u, v) \in \mathcal{K}_F\}.$$

In other words, Z_F is set of all partitions of shattered components that separate some pair $(u, v) \in \mathcal{K}_F$. Since the leaves of $\mathcal{T}$ are in one to one correspondence with $V(G)$ we can view Z_F as inducing a Set Connectivity instance in $\mathcal{T}$; technically we need to consider the pairs $\{(\mathcal{M}^{-1}(A), \mathcal{M}^{-1}(B)) \mid (A, B) \in Z_F\}$; however, for simplicity we conflate the leaves of $\mathcal{T}$ with $V(G)$. We claim that it suffices to find a feasible solution that connects the pairs defined by Z_F in the tree $\mathcal{T}$.

▶ **Lemma 27.** *Let $E' \subseteq \mathcal{T} \setminus \mathcal{M}^{-1}(F)$. Suppose there exists a path in $E' \subseteq \mathcal{T} \setminus \mathcal{M}^{-1}(F)$ connecting A to B for all $(A,B) \in Z_F$. Then, there is an u-v path for each $(u,v) \in \mathcal{K}_F$ in $(\mathcal{M}(E') \cup H) \setminus F$.*

Routing flow. We now argue that $(\mathcal{T}, \mathcal{M}, y)$ routes sufficient flow for each pair in Z_F without using the edges in $\mathcal{M}^{-1}(F)$; in other words y is fractional solution (modulo a scaling factor) to the Set Connectivity instance Z_F in the graph/forest $\mathcal{T} \setminus \mathcal{M}^{-1}(F)$. We can then appeal to TreeRounding lemma to argue that it will connect the pairs in Z_F without using any edges in F.

▶ **Lemma 28.** *Let $(A,B) \in Z_F$. Let $S \subset V_{\mathcal{T}}$ such that $A \subseteq S$ and $B \subseteq V_{\mathcal{T}} \setminus S$. Then $y(\delta_{\mathcal{T} \setminus \mathcal{M}^{-1}(F)}(S)) \geq \frac{1}{4\ell\beta}$.*

Bounding Z_F. A second crucial property is a bound on $|Z_F|$, the number of pairs in the Set Connectivity instance induced by F and a good tree $\mathcal{T}$ for F.

▶ **Lemma 29.** *For a good tree $\mathcal{T}$, $|Z_F| \leq 2^{2\ell\beta}|\mathcal{K}_F|$.*

4.6 Correctness and Cost

The following two lemmas show that by taking a union bound over all violating edge sets F and applying the Tree Rounding lemma 24, one can show that the algorithm outputs a feasible augmentation solution with probability at least $\frac{1}{2}$.

▶ **Lemma 30.** *Suppose $\mathcal{T}$ is good for a violating edge set F. Then after $t = O(\ell log n)$ rounds of TreeRounding with flow parameter $\frac{1}{4\ell\beta}$, the probability that H' is* not *a feasible augmentation for F is at most $(1-\phi)^t|Z_F| \leq 1/4$.*

▶ **Lemma 31.** *The algorithm outputs a solution H' such that $H \cup H'$ is a feasible augmentation to the given instance with probability at least $\frac{1}{2}$.*

Now we analyze the expected cost of the edges output by the algorithm for augmentation with respect to $\mathrm{OPT}_{\mathrm{LP}}$, the cost of the fractional solution.

▶ **Lemma 32.** *The total expected cost of the algorithm is $O(\ell^3 \log^7 n) \cdot OPT_{LP}$.*

Combining the correctness and cost analysis we obtain the following.

▶ **Lemma 33.** *There is a randomized $O(\ell^3 \log^7 n)$-approximation algorithm for the Bulk-SNDP Augmentation problem from $\ell - 1$ to ℓ. The algorithm runs in time polynomial in n and α, where α is the amount of time it takes to solve the LP.*

To prove Theorem 4, we start with a solution from $\ell = 0$ and iteratively solve k augmentation problems. Since the LP for Bulk-SNDP can be solved in polynomial time (see Section 2), we obtain a polynomial time $O(k^4 \log^7 n)$-approximation algorithm.

For Flex-SNDP, recall that $(p,0)$-Flex-SNDP is equivalent to EC-SNDP where every terminal pair has connectivity requirement $r_i = p$. Therefore, we can start with a 2-approximate solution to $(p,0)$-Flex-SNDP and apply Lemma 33 q times. In this case, the maximum width is $p+q$, so we get an overall approximation ratio of $O(q(p+q)^3 \log^7 n)$. Recall from Section 2 that the LP can be solved in $n^{O(q)}$ time, giving us Corollary 5.

Finally, for Relative SNDP, there is an LP relaxation described in [19] that can be solved in polynomial time, even when k is not fixed. We can modify Algorithm 2 for RSNDP by solving this LP relaxation instead and following the same rounding algorithm. This, along with the reduction to Bulk-SNDP discussed in Section 1, completes the proof of Corollary 6.

Abstract

We consider the design of sublinear space and query complexity algorithms for estimating the cost of a minimum spanning tree (MST) and the cost of a minimum traveling salesman (TSP) tour in a metric on n points. We start by exploring this estimation task in the regime of $o(n)$ space, when the input is presented as a stream of all $\binom{n}{2}$ entries of the metric in an arbitrary order (a metric stream). For any $\alpha \geq 2$, we show that both MST and TSP cost can be α-approximated using $\tilde{O}(n/\alpha)$ space, and moreover, $\Omega(n/\alpha^2)$ space is necessary for this task. We further show that even if the streaming algorithm is allowed p passes over a metric stream, it still requires $\tilde{\Omega}(\sqrt{n/\alpha p^2})$ space.

We next consider the well-studied semi-streaming regime. In this regime, it is straightforward to compute MST cost exactly even in the case where the input stream only contains the edges of a weighted graph that induce the underlying metric (a graph stream), and the main challenging problem is to estimate TSP cost to within a factor that is strictly better than 2. We show that in graph streams, for any $\varepsilon > 0$, any one-pass $(2-\varepsilon)$-approximation of TSP cost requires $\Omega(\varepsilon^2 n^2)$ space. On the other hand, we show that there is an $\tilde{O}(n)$ space two-pass algorithm that approximates the TSP cost to within a factor of 1.96.

Finally, we consider the query complexity of estimating metric TSP cost to within a factor that is strictly better than 2 when the algorithm is given access to an $n \times n$ matrix that specifies pairwise distances between n points. The problem of MST cost estimation in this model is well-understood and a $(1+\varepsilon)$-approximation is achievable by $\tilde{O}(n/\varepsilon^{O(1)})$ queries. However, for estimating TSP cost, it is known that an analogous result requires $\Omega(n^2)$ queries even for $(1,2)$-TSP, and for general metrics, no algorithm that achieves a better than 2-approximation with $o(n^2)$ queries is known. We make progress on this task by designing an algorithm that performs $\tilde{O}(n^{1.5})$ distance queries and achieves a strictly better than 2-approximation when either the metric is known to contain a spanning tree supported on weight-1 edges or the algorithm is given access to a minimum spanning tree of the graph. Prior to our work, such results were only known for the special cases of graphic TSP and $(1,2)$-TSP.

In terms of techniques, our algorithms for metric TSP cost estimation in both streaming and query settings rely on estimating the *cover advantage* which intuitively measures the cost needed to turn an MST into an Eulerian graph. One of our main algorithmic contributions is to show that this quantity can be meaningfully estimated by a sublinear number of queries in the query model. On one hand, the fact that a metric stream reveals pairwise distances for all pairs of vertices provably helps algorithmically. On the other hand, it also seems to render useless techniques for proving space lower bounds via reductions from well-known hard communication problems. Our main technical contribution in lower bounds is to identify and characterize the communication complexity of new problems that can serve as canonical starting point for proving metric stream lower bounds.

1 Introduction

The minimum spanning tree (MST) problem and the metric traveling salesman (TSP) problem are among the most well-studied combinatorial optimization problems with a long and rich history. The two problems are intimately connected to one another, as many approximation algorithms for metric TSP use a minimum spanning tree as a starting point for efficiently constructing an approximate solution. In particular, any algorithm for estimating the MST cost to within a factor of α immediately implies an algorithm for estimating the metric TSP cost to within a factor of 2α. In this work, we consider the design of sublinear space and query complexity algorithms for estimating the cost of a minimum spanning tree (MST) and the cost of a minimum metric traveling salesman (TSP) tour in an n-vertex weighted undirected graph G. An equivalent view of both problems is that we are given an $n \times n$ matrix w specifying pairwise distances between them, where the entry $w[u, v]$ corresponds to the weight of the shortest path from u to v in G. It is clear that any algorithm that works with a weighted graph as input also works when the input is presented as the complete metric. However, the converse is not true. For instance, no single-pass streaming algorithm can obtain a finite approximation to the diameter (or even determine the connectivity) of a graph in $o(n)$ space when the graph is presented as a sequence of edges (a *graph stream*). But if instead we are presented a stream of n^2 entries of the metric matrix w (a *metric stream*), there is a trivial $\tilde{O}(1)$ space algorithm for this problem – simply track the largest entry seen.

1.1 Our Results

In the first part of this work, we explore the power and limitations of graph and metric streams for MST and TSP cost estimation. We start by exploring this estimation task in the regime of $o(n)$ space in the streaming model. It is easy to show that no finite approximation to MST/TSP cost is achievable in this regime when the input stream simply contains the edges of a weighted graph that induce the underlying metric (a graph stream). However, we show that this state of affairs changes completely if the input is instead presented as all entries of the shortest-path-distance metric induced by the input graph (a metric stream).

▶ **Theorem 1.** *For any $\alpha > 1$, there is a randomized one-pass α-approximation streaming algorithm for MST cost estimation in metric streams using $\tilde{O}(n/\alpha)$ space.*

Note that this also immediately gives a one-pass $\tilde{O}(n/\alpha)$-space algorithm for TSP cost estimation for any $\alpha \geq 2$ by simply doubling the MST cost estimate. The result above is in sharp contrast to what is achievable in graph streams. Using a simple reduction from the Index problem, we can show the following lower bound for graph streams.

▶ **Theorem 2.** *For any $\alpha > 1$, any randomized p-pass α-approximation streaming algorithm for MST cost estimation in graph streams requires $\tilde{\Omega}(n/p)$ space.*

We next show that there are limits to the power of metric streams, and in particular, any non-trivial approximation of MST cost still requires polynomial space even if we allow multiple passes over the stream.

▶ **Theorem 3.** *For any $\alpha > 1$, any randomized one-pass α-approximation streaming algorithm for MST cost estimation in metric streams requires $\Omega(n/\alpha^2)$ space.*

▶ **Theorem 4.** *For any $\alpha > 1$, any randomized p-pass α-approximation streaming algorithm for MST cost estimation requires $\tilde{\Omega}(\sqrt{n/\alpha p^2})$ space.*

Table 1 summarizes our results for MST (and TSP) cost estimation in the regime of $o(n)$ space.

Table 1 Summary of results for MST-cost estimation streaming algorithms.

Stream Type	MST estimation		
	# of passes	Approximation ratio	Upper or Lower bounds
Metric Stream	1	1	$\tilde{O}(n)$ (trivial)
	1	α	$\tilde{O}(n/\alpha)$ (Theorem 1), $\tilde{\Omega}(n/\alpha^2)$ (Theorem 3)
	p	α	$\tilde{\Omega}(\sqrt{n/\alpha p^2})$ (Theorem 4)
Graph Stream	1	1	$\tilde{\Theta}(n)$ (trivial)
	p	any	$\Omega(n/p)$ (Theorem 2)

We next consider the well-studied semi-streaming regime when the streaming algorithm is allowed to use $\tilde{O}(n)$ space. In this regime, it is straightforward to design a deterministic one-pass streaming algorithm to compute MST cost exactly even in graph streams, and this in turn, immediately gives an $\tilde{O}(n)$ space algorithm to estimate TSP cost to within a factor of 2. Thus in the semi-streaming regime, the key challenging problem is to estimate TSP cost to within a factor that is strictly better than 2. A special case of this problem, *graphic TSP cost* estimation, where the input metric corresponds to the shortest-path distances induced by an unweighted undirected graph, was studied in [4], and the authors gave an $\tilde{O}(n)$ space randomized one-pass streaming algorithm that achieves an (11/6)-approximation even in the setting of graph streams. This ratio was recently improved[1] by Behnezhad, Roghani, Rubinstein, and Saberi to 1.83 [2]. However, no analogous result is known for general TSP. We show that there is in fact a good reason for this state of affairs:

▶ **Theorem 5.** *For any $0 < \epsilon < 1$, any randomized one-pass $(2-\varepsilon)$-approximation streaming algorithm for TSP cost estimation in graph streams requires $\Omega(\epsilon^2 n^2)$ space.*

However, we show that the situation changes considerably once we allow two passes and indeed there is now a deterministic $\tilde{O}(n)$ space algorithm that achieves better than a 2-approximation to TSP cost.

▶ **Theorem 6.** *There is a deterministic two-pass 1.96-approximation algorithm for TSP cost estimation in graph streams using $\tilde{O}(n)$ space.*

We note that an interesting remaining question here is if a similar result is achievable using one pass when the input is a metric stream. As a step towards understanding the power of metric streams in semi-streaming regime, we show that any one-pass algorithm that computes TSP cost exactly requires $\Omega(n^2)$ space. Table 2 summarizes our results for TSP cost estimation in the regime of semi-streaming space.

[1] In their paper, they give an $\tilde{O}(n)$-time 1.83-approximation algorithm, which can be easily turned into a one-pass streaming algorithm with space $\tilde{O}(n)$ with the same approximation ratio.

Table 2 Summary of results for TSP-cost estimation streaming algorithms. The statements and proofs for entries marked by (∗) is deferred to the full version.

Stream Type	TSP estimation		
	# of passes	Approximation ratio	Upper or Lower bounds
Metric Stream	1	1	$\Omega(n^2)$*
	1	$2-\varepsilon$	Open
Graph Stream	1	2	$\tilde{\Theta}(n)$ (trivial)
	1	$2-\varepsilon$	$\tilde{\Omega}(\varepsilon^2 n^2)$ (Theorem 5)
	2	1.96	$\tilde{O}(n)$ (Theorem 6)

The second part of our paper focuses on the design of sublinear query complexity algorithms for TSP cost estimation. The related problem of estimating the MST cost using sublinear queries was first studied in the graph adjacency-list model by Chazelle, Rubinfeld, and Trevisan [3]. The authors gave an $\tilde{O}(dW/\varepsilon^2)$-time algorithm to estimate the MST cost to within a factor of $(1+\varepsilon)$ in a graph where the average degree is d, and all edge costs are integers in $\{1,\ldots,W\}$. For certain parameter regimes this gives a sublinear time algorithm for estimating the MST cost, but in general, this run-time need not be sublinear. In fact, it is not difficult to show that in general, even checking if a graph is connected requires $\Omega(n^2)$ queries in the graph adjacency-list model, and hence no finite approximation to MST cost can be achieved in $o(n^2)$ queries. However, the situation changes if one restricts attention to the *metric* MST problem where the edge weights satisfy the triangle inequality, and the algorithm is given access to an $n \times n$ matrix w specifying pairwise distances between vertices. Czumaj and Sohler [6] showed that for any $\varepsilon > 0$, there exists an $\tilde{O}(n/\varepsilon^{O(1)})$ query algorithm that returns a $(1+\varepsilon)$-approximate estimate of the metric MST cost. This result immediately implies an $\tilde{O}(n/\varepsilon^{O(1)})$ time algorithm to estimate the TSP cost to within a factor of $(2+\varepsilon)$ for any $\varepsilon > 0$. In sharp contrast to this result, so far no $o(n^2)$ query algorithms are known to approximate metric TSP cost to a factor that is strictly better than 2. In this work, we consider sublinear query algorithms for TSP cost when the algorithm is given query access to the $n \times n$ distance matrix w. *We will assume throughout the paper that all entries of w are positive integers.*

For the special case of graphic TSP, where the metric corresponds to shortest path distances of some underlying connected unweighted graph, the algorithm of Chen, Kannan, and Khanna [4] combined with the recent result of Behnezhad [1] (which builds on the work of Yoshida et al. [8] and Onak et al. [7]), gives an $\tilde{O}(n)$-query (27/14)-approximation algorithm for estimating graphic TSP cost. The authors in [4] also show that there exists an $\varepsilon_0 > 0$, such that any algorithm that estimates the cost of graphic TSP (or even $(1,2)$-TSP) to within a $(1+\varepsilon_0)$-factor, necessarily requires $\Omega(n^2)$ queries. Later on, Behnezhad, Roghani, Rubinstein, and Saberi [2] improved the graphic TSP result by giving an $\tilde{O}(n)$-query 1.83-approximation, and they also gave an $\tilde{O}(n)$-query $(1.5+\varepsilon)$-approximation algorithm for $(1,2)$-TSP. This leaves open the following question: Is there an $o(n^2)$ query algorithm to estimate TSP cost to a factor strictly better than 2 when the metric is *arbitrary*?

We make progress on this question by designing an $\tilde{O}(n^{1.5})$-query algorithm that achieves a strictly better than 2-approximation when either the metric is known to contain a spanning tree supported on weight-1 edges or the algorithm is given access to a minimum spanning tree of the graph. Prior to our work, such results were only known for the special cases of graphic TSP and $(1,2)$-TSP.

▶ **Theorem 7.** *There is a randomized algorithm, that, given access to an n-point metric w with the promise that w contains a minimum spanning tree supported only on weight-1 edges, estimates with high probability the metric TSP cost to within a factor of $(2-\varepsilon_0)$ for some universal constant $\varepsilon_0 > 0$, by performing $\tilde{O}(n^{1.5})$ queries to w.*

We note that the setting of Theorem 7 captures as a special case graphic TSP but is considerably more general, and hence difficult.

▶ **Theorem 8.** *There is a randomized algorithm, that, given access to an n-point metric w and an arbitrary minimum spanning tree of the complete graph with edge weights given by w, estimates with high probability the metric TSP cost to within a factor of $(2-\varepsilon_0)$ for some universal constant $\varepsilon_0 > 0$, by performing $\tilde{O}(n^{1.5})$ queries to w.*

In what follows, we give an overview of the techniques underlying our results.

1.2 Technical Overview

1.2.1 Overview of Algorithmic Techniques

Our streaming algorithm for MST estimation (Theorem 1) utilizes a rather natural idea. We sample $O(n/\alpha)$ vertices and maintain a MST T' over them. For the remaining vertices, we maintain an estimate of the cost of connecting them to the nearest vertex in T'. We show that these estimates can be suitably combined to obtain an α-approximation of MST cost. In this subsection we focus on providing a high-level overview of the algorithms for TSP estimation.

It is well-known that $\mathsf{MST} \leq \mathsf{TSP} \leq 2 \cdot \mathsf{MST}$ holds for any graph/metric, since we can construct a TSP-tour by doubling all edges of a MST (and then shortcut the obtained walk into a tour). Since the MST cost of a graph/metric can be exactly computed by a one-pass $\tilde{O}(n)$ space algorithm (the greedy algorithm) in the streaming model, and can be approximated to within a factor of $(1+\varepsilon)$ by performing $\tilde{O}(n)$ queries in the query model [6], to obtain a factor $(2-\varepsilon)$ approximation for TSP, it suffices to establish either $\mathsf{TSP} \geq (1+\varepsilon) \cdot \mathsf{MST}$ or $\mathsf{TSP} \leq (2-\varepsilon) \cdot \mathsf{MST}$ holds. From the approach due to [5], the minimum weight of a perfect matching on the set of all odd-degree vertices in an MST can immediately gives us the answer. However, obtaining a good approximation to the minimum weight of such a perfect matching appears hard to do, both for semi-streaming algorithms and for a query algorithm that performs $o(n^2)$ queries, even if we are given an MST at the start. To get around this issue, we consider an alternative measure, called the *cover advantage*, that turns out to be more tractable in both models.

Cover Advantage. Let T be a MST of the input graph/metric. For an edge $f \in E(T)$ and an edge $e \notin E(T)$, we say that f is *covered* by e, iff f belongs to the unique tree-path in T connecting the endpoints of e. For a set E' of edges, we denote by $\mathsf{cov}(E', T)$ the set of all edges in $E(T)$ that are covered by at least one edge in E'. The *cover advantage* of E', denoted by $\mathsf{adv}(E')$, is defined to be the total weight of all edges in $\mathsf{cov}(E', T)$ minus the total weight of all edges in E'. Intuitively, if a single-edge set $\{e\}$ where $e = (u, v)$ has cover advantage c, then we can construct a tour by starting from some Euler-tour of T and replacing the segment corresponding to the tree path of T connecting u to v by the single edge e, and thereby "saving a cost of c" from $2 \cdot \mathsf{MST}$, the cost of the Euler-tour obtained by doubling MST edges. Generalizing this idea, we show that if there exists a set E' with cover advantage bounded away from 0 (at least $\varepsilon \cdot \mathsf{MST}$), then $\mathsf{TSP} \leq (2-\varepsilon/2) \cdot \mathsf{MST}$. Conversely, if there does not exist any set E' with cover advantage close to $\mathsf{MST}/2$ (say

at least $(1/2 - \varepsilon/2) \cdot \mathsf{MST}$), then $\mathsf{TSP} \geq (1 + \varepsilon) \cdot \mathsf{MST}$. In fact, we show that the same hold for a more restricted notion called *special cover advantage*, which is defined to be the maximum cover advantage of any subset E' of edges that have at least one endpoint being a special vertex in T (a vertex v is called a *special vertex* of T iff $\deg_T(v) \neq 2$). Therefore, to obtain a better-than-factor-2 approximation for TSP, it suffices to obtain a constant-factor approximation for the maximum cover advantage or the maximum special cover advantage.

Estimating maximum cover advantage in the streaming setting. We construct a one-pass streaming algorithm $O(1)$-estimating the maximum cover advantage, which leads to a two-pass algorithm in Theorem 6 where in the first pass we only compute an MST of the input graph. We store edges with substantial cover advantage with respect to the MST in a greedy manner. Since all edges appear in the stream, it can be shown that, if we end up not discovering a large cover advantage, then the real maximum cover advantage is indeed small (bounded away from $\mathsf{MST}/2$).

Estimating maximum cover advantage in the query model. The task of obtaining a constant-factor approximation to maximum cover advantage turns out to be distinctly more challenging in the query model, even if we are given explicit access to an MST of the metric. The design of sublinear query algorithms for estimating cover advantage is indeed our central algorithmic contribution. We design an $\tilde{O}(n^{1.5})$-query algorithm for estimating the maximum cover advantage when either an MST is explicitly given or we can assume that the MST is supported on weight-1 edges. Note that the latter case generalizes graphic TSP studied in [4].

The algorithms for these two cases share several similarities. To illustrate the ideas behind them, it might be instructive to consider the following two examples. In the first example, we are given an MST T on V that has at most $O(\sqrt{n})$ leaves. We can simply query the distances between all pairs $u, v \in V$ where u is a special vertex of T, and then use the obtained information to compute the maximum special cover advantage, which takes $\tilde{O}(n^{1.5})$ queries since there can be at most $O(\sqrt{n})$ special vertices (or in fact we can even query the distances between all pairs of special vertices in T and compute the minimum weight perfect matching on them). In the second example, we are given an MST T on V which is a star graph centered at a vertex $r \in V$, and all edges have weight 1. Note that, since all edge weights are integers, in this case the distances between every pair of vertices in $V \setminus \{r\}$ is either 1 or 2, and it is not hard to see that the maximum cover advantage is exactly the size of a maximum weight-1 matching on $V \setminus \{r\}$. Therefore, we can adapt the algorithm from [1] to obtain an $O(1)$-approximation of the maximum weight-1 matching size, using $\tilde{O}(n)$ queries. Note that, in this case we obtain an estimate of the maximum cover advantage without computing a set of edges that achieves it.

Taking a step back, we observe that, in the first example where the number of special vertices is small, the cover advantage can be computed in a local and exhaustive manner, while in the second example where the number of special vertices is large, the cover advantage has to be estimated in a global and "superficial" manner. Intuitively, our query algorithms interpolate between these two approaches in an organic manner.

We now provide more details of our query algorithms in the two special cases. We first consider the special case where we are given the structure of an MST.

When MST is given. We root the given MST T at an arbitrary vertex. For each vertex $v \in V$, we say that it is *light* iff the subtree of T rooted at v, denoted by T_v, contains at most $\sqrt{n}$ vertices, and we call T_v a *light subtree* of T. On the one hand, the cover advantages

that are local at some light subtree (achieved by edges with both endpoints in the same light subtree) can be efficiently estimated in an exhaustive manner. On the other hand, if we peel off all light subtrees from T, then the remaining subtree, that we denote by T', contains at most $\sqrt{n}$ leaves, and therefore the special cover advantage achieved by any set of edges with at least one endpoint being a special vertex of T' can also be computed in an exhaustive manner. The only type of cover advantages that is not yet computed are the one achieved by edges with endpoints in different light subtrees. We then observe that the light subtrees hanged at T are similar to the edges of a star graph hanged at its root, and eventually manage to adapt the algorithm from [1] in a delicate way to estimate the cover advantage by edges of this type in a global manner.

When MST consists of only weight-1 edges. This special case appears trickier since we do not know the structure of an MST at the start, and there may not even be a unique MST. To circumvent this, we need to utilize the following technical result of [4]: Let G_1 be the graph on V induced by all weight-1 edges in the given metric, then if G_1 contains a size-s matching consisting of only edges in 2-edge-connected components of G_1, then $\mathsf{TSP} \leq 2n - \Omega(s)$. This result allows us to construct a local procedure that explores some neighborhood of the unknown graph G_1 up to a certain size, such that in the end we either reconstruct a size-$\sqrt{n}$ subgraph of the (locally) unique MST, or certify that a set of $\Omega(\sqrt{n})$ vertices belong to some 2-edge-connected components of G_1, which will be later collected to estimate the maximum weight-1 matching size.

We then use this local procedure on a set of vertices randomly sampled from V. Let T be an MST. Intuitively, if the total size of light subtrees of T is non-negligible, then with high probability some of the sampled vertices will lie in light subtrees of T, and we can obtain an estimate of the local cover advantage within subtrees. If the total size of light subtrees is negligible, then T', the subtree obtained from T by peeling off all light subtrees, has roughly the same size as T, which means that T is close to the first instructive example mentioned before – a tree with only $O(\sqrt{n})$ special vertices. Then we can apply the local procedure to $\Omega(\sqrt{n})$ sampled vertices, to almost reconstruct the whole tree T, and the rest of the algorithm is similar to the algorithm in the first special case.

1.2.2 Overview of Lower Bound Techniques

As our algorithmic results illustrate that metric streams are more powerful than graph streams, it is perhaps not surprising that proving space lower bounds for metrics streams turns out to be a more challenging task that requires new tools. To illustrate this point, it might be instructive to consider the following simplified versions of metric and graph streams. Let G be a graph.

- Unweighted Graph Stream: a sequence that contains all edges of $E(G)$, and the same edge may appear more than once in the stream;
- Unweighted Metric Stream: a sequence that contains, for each pair u, v of $V(G)$, a symbol $f(u, v)$ indicating whether or not the edge (u, v) belongs to $E(G)$.

Note that in unweighted metric streams, the non-edge information between pairs of vertices is also explicitly given (as the edge information), as opposed to being given implicitly in the unweighted graph stream. This seemingly unimportant distinction, unexpectedly, makes proving lower bounds for several problems much harder in unweighted metric streams than unweighted graph streams.

For example, consider the problem of deciding whether the input graph is a clique. On the one hand, to prove a space lower bound for streaming algorithms in unweighted graph streams, we consider the following two-player one-way communication game: Alice is given a

graph G_A and Bob is given a graph G_B on a common vertex set V, and Alice and Bob want to decide if $G_A \cup G_B$ is the complete graph on V. It is easy to show that this communication game has back-and-forth communication complexity $\Omega(n^2)$. In fact, Alice's input graph G_A can be viewed as a vector $x^A \in \{0,1\}^{\binom{V}{2}}$ and Bob's input graph G_B can be viewed as a vector $x^B \in \{0,1\}^{\binom{V}{2}}$, where the coordinate $x^A_{(u,u')}$ indexed by the pair u, u' of vertices in V indicates whether or not the edge (u, u') appears in graph G_A, and similarly $x^B_{(u,u')}$ indicates whether or not the edge (u, u') appears graph G_B. It is then easy to see that the two players need to detect whether or not the bitwise-OR of vectors x^A and x^B is the all-one vector, which requires $\Omega(n^2)$-bits information exchange even in the back-and-forth communication model. On the other hand, in the corresponding two-player one-way communication game for unweighted metric streams, Alice and Bob are each given a set of edge/non-edge information, with the promise that the edge/non-edge information between each pair of vertices appears in at least one of the player's input. There is a one-bit protocol: Alice simply sends to Bob a signal indicating whether or not in her input there is non-edge information between any pair of vertices, and Bob outputs "Not a Clique" iff either he sees Alice's "non-edge" signal or he sees a non-edge information in his input.

The distinction that all non-edge information is explicitly given in the unweighted stream seems to fail all reductions from standard problems (like Disjointness and Index) to prove lower bounds. Therefore, in the lower bound proofs of Theorem 3 and Theorem 4, we identify new "primitive" graph-theoretic problems, prove communication lower bounds for them, and then reduce them to MST-estimation problems. Here we briefly provide some ideas for the proof of Theorem 4.

We consider the special type of metrics, in which the distance between every pair of vertices is either 1 or a large enough real number. Intuitively, the problem of estimating the MST cost is equivalent to the problem of estimating the number of connected components of the graph induced by all weight-1 edges, which is essentially a graph-theoretic problem in unweighted metric streams.

As a first step, we consider the following problem: given an unweighted metric stream, decide whether the underlying graph is a perfect matching or a perfect matching minus one edge. Unlike the previous clique-identification problem, we show that the corresponding two-player communication game for this problem has communication complexity $\Omega(n)$ in the back and forth communication model, even if the complete edge/non-edge information is split between Alice and Bob. The proof is by analyzing the information complexity of any protocol for the problem, We construct several similar input combinations for Alice and Bob, among which some cross-combination lead to different answers, and then lower bound the mutual information between the protocol transcript and the players' inputs.

However, this perfect matching vs perfect matching minus one edge problem is not sufficient for our purpose, since a perfect matching graph on n vertices has $n/2$ connected components, while a perfect matching minus one edge graph on n vertices has $n/2 - 1$ connected components, and the ratio between $n/2$ and $n/2 - 1$ are too small to provide a space lower bound for α-approximation of the number of connected components. To fix this issue, we next consider a generalization of this problem, called the *Clique or Independent Set* problem ($\mathsf{COI}_{a,b}$) parametrized by two integers a, b. In this problem, we are required to decide whether the input graph is the disjoint union of b cliques of size a each (Yes case) or it is a disjoint union of $(b-1)$ cliques of size a each and an independent set of size a (No case). Note that if $a = 2$ and $b = n/2$ then this problem is exactly the perfect matching vs perfect matching minus one edge problem. Now if we let $a \gg b$, then the ratio between numbers of connected components in Yes case and in No case is $(a + b - 1)/b = \Omega(a/b)$, which is

enough for giving a space lower bound for $o(a/b)$-approximation streaming algorithms for MST estimation. For the proof of the communication lower bound of problem $\mathsf{COI}_{a,b}$, we first consider the special case $\mathsf{COI}_{a,2}$ and show that the communication complexity is $\tilde{\Omega}(1)$ via a Hellinger distance analysis on transcript distributions on certain input combinations, and then use a direct sum type argument to show that the communication complexity of $\mathsf{COI}_{a,b}$ is $\tilde{\Omega}(b)$. Both steps use techniques similar to the ones used in the proof of communication lower bound for the perfect matching vs perfect matching minus one edge problem. Now for a given approximation ratio $\alpha > 1$, setting $a = \Theta(\sqrt{\alpha n})$ and $b = \Theta(\sqrt{n/\alpha})$ yields the desired communication lower bound, which then implies the space lower bounds for streaming algorithms.

1.3 Organization

Due to the limit of space, in the remainder of the paper we only present the proof sketches of one of our algorithmic results, which best illustrates the utilization of cover advantage. We first introduce the notion of cover advantage in Section 2. We then we sketch the proof of Theorem 6 in Section 3 and sketch the proof of Theorem 8 in Section 4. The proofs of all other theorems are deferred to the full version (in the appendix).

2 Cover Advantage

In this section, we introduce the notion of cover advantage, which is a key notion that captures the gap between the MST cost and the TSP cost. Our TSP cost estimation algorithms in both streaming and query settings will crucially utilize this notion. Due to the limit of space, the proofs of some lemmas presented in this section are deferred to the full version.

At a high-level, the TSP estimation algorithms in this paper are based on converting an MST T of the input graph/metric into a spanning Eulerian subgraph. A trivial approach is to simply double all edges in T obtaining a 2-approximation. A more clever approach due to Christofides [5] instead makes T Eulerian by adding a minimum weight perfect matching on odd-degree vertices in T, obtaining a 3/2-appproximation. However, computing a good approximation to the minimum weight perfect matching on a set of vertices appears hard to do either in the semi-streaming setting or with sublinear number of queries. We instead identify the more tractable notion, called the cover advantage, that can be efficiently implemented in the semi-streaming and query model.

We say that an edge f of tree T is *covered* by an edge e that may or may not belong to T, iff $f \in E(P_e^T)$; and we say that f is covered by a set E' of edges, iff it is covered by some edge of E'. We denote by $\mathsf{cov}(e)$ the set of all edges of T that are covered by e, and define $\mathsf{cov}(E') = \bigcup_{e \in E'} \mathsf{cov}(e)$.

Let T' be a subtree of T. For each edge $e \notin E(T)$, we define $\mathsf{cov}(e, T') = \mathsf{cov}(e) \cap E(T')$. Similarly, for a set E' of edges, we define $\mathsf{cov}(E', T') = \bigcup_{e \in E'} \mathsf{cov}(e, T')$. Clearly, $\mathsf{cov}(E', T') = \mathsf{cov}(E') \cap E(T')$.

We define the *cover advantage* of a set E' of edges on a subtree T' of T, denoted by $\mathsf{adv}(E', T')$, to be $\mathsf{adv}(E', T') = w(\mathsf{cov}(E', T')) - w(E')$. The *optimal cover advantage* of a subtree T', denoted by $\mathsf{adv}(T')$, is defined to be the maximum cover advantage of any set E' of edges that have at least one endpoint lying in $V(T')$ on T'. The *optimal special cover advantage* of a subtree T', denoted by $\mathsf{adv}^*(T')$, is defined to be the maximum cover advantage of any set E' of edges that have at least one endpoint being a special vertex of T' (a vertex v is a special vertex of T' iff $\deg_{T'}(v) \neq 2$). Clearly, by definition, $\mathsf{adv}(T') \geq \mathsf{adv}^*(T') \geq 0$.

The next two lemmas show that the optimal cover advantage and the optimal special cover advantage of any subtree can be computed using a small number of queries.

▶ **Lemma 9.** *There is an algorithm, that given a subtree T' of T, computes the optimal cover advantage of T' as well as a set E' of edges achieving the optimal cover advantage of T', by performing at most $O(n \cdot |V(T')|)$ queries.*

▶ **Lemma 10.** *There is an algorithm, that given a subtree T' of T, computes the optimal special cover advantage of T' as well as a set E' of edges achieving the optimal special cover advantage of T', by performing $O(n \cdot k_{T'})$ queries, where $k_{T'}$ is the number of special vertices in T'.*

The following lemma is crucial to our algorithms. It shows that the high cover advantage of edge-disjoint subtrees of an MST translates into a TSP tour whose cost is bounded away from 2 times the MST cost.

▶ **Lemma 11.** *Let T be an MST on a set V of vertices, and let $\mathcal{T}$ be a set of edge-disjoint subtrees of T. Then $\mathsf{TSP} \leq 2 \cdot \mathsf{MST} - \frac{1}{2} \cdot \sum_{T' \in \mathcal{T}} \mathsf{adv}(T')$.*

Proof. We introduce some definitions before providing the proof.

Let E' be a set of edges that do not belong to $E(T)$. We define the multi-graph $H_{T,E'}$ as follows. Its vertex set is $V(H_{T,E'}) = V$. Its edge set is the union of (i) the set E'; and (ii) the set $E_{[T,E']}$ that contains, for each edge $f \in E(T)$, 2 copies of f iff f is covered by an even number of edges in E', 1 copy of f iff f is covered by an odd number of edges in E'. Equivalently, graph $H_{T,E'}$ can be obtained from the following iterative algorithm. Throughout, we maintain a graph $\hat{H}$ on the vertex set V, that initially contains two copies of each edge of $E(T)$. We will maintain the invariant that, over the course of the algorithm, for each edge f of $E(T)$, graph $\hat{H}$ contains either one copy or two copies of f. We then process edges of E' one-by-one (in arbitrary order) as follows. Consider now an edge $e \in E'$ and the tree-path P_e^T. We add one copy of edge e to $\hat{H}$. Then for each edge $f \in E(P_e^T)$, if currently the graph $\hat{H}$ contains 2 copies of f, then we remove one copy of it from $\hat{H}$; if currently the graph $\hat{H}$ contains 1 copy of f, then we add one copy of it into $\hat{H}$. Clearly after each iteration of processing some edge of E', the invariant still holds. It is also easy to see that the resulting graph we obtain after processing all edges of E' is exactly the graph $H_{T,E'}$ defined above.

We prove the following observation.

▶ **Observation 12.** *For any set E', graph $H_{T,E'}$ is Eulerian.*

Proof. Consider the algorithm that produces the graph $H_{T,E'}$. Initially, graph $\hat{H}$ contains 2 copies of each edge of T, and is therefore Eulerian. It is easy to see that, in the iteration of processing the edge $e \in E'$, we only modify the degrees of vertices in the cycle $e \cup P_e^T$. Specifically, for each vertex in the cycle $e \cup P_e^T$, either its degree is increased by 2 (if a copy is added to both of its incident edges in the cycle), or its degree is decreased by 2 (if a copy is removed from both of its incident edges in the cycle), or its degree remains unchanged (if a copy is removed from one of its incident edges, and a copy is added to the other incident edge). Therefore, the graph $\hat{H}$ remains Eulerian after this iteration, and it follows that the resulting graph $H_{T,E'}$ is Eulerian. ◀

We now provide the proof of Lemma 11. Denote $\mathcal{T} = \{T_1, \ldots, T_k\}$. For each index $1 \leq i \leq k$, let E_i^* be the set of edges that achieves the maximum cover advantage on T_i. Denote $E^* = \bigcup_{1 \leq i \leq k} E_i^*$, and then we let E' be the random subset of E^* that includes

each edge of E^* independently with probability $1/2$. We will show that the expected total weight of all edges in $E(H_{T,E'})$ is at most $2 \cdot \mathsf{MST}(G) - \frac{1}{2} \cdot \sum_{1 \le i \le k} \mathsf{adv}(T_i)$. Note that this implies that there exists a subset E^{**} of E^*, such that the weight of graph $H_{T,E^{**}}$ is at most $2 \cdot \mathsf{MST}(G) - \frac{1}{2} \cdot \sum_{1 \le i \le k} \mathsf{adv}(T_i)$. Combined with Observation 12 and the fact that TSP is upper bounded by the total cost of any connected Eulerian graph, this implies $\mathsf{TSP} \le 2 \cdot \mathsf{MST}(G) - \frac{1}{2} \cdot \sum_{1 \le i \le k} \mathsf{adv}(T_i)$, completing the proof of Lemma 11.

We now show that $\mathbb{E}[w(H_{T,E'})] \le 2 \cdot \mathsf{MST}(G) - \frac{1}{2} \cdot \sum_{1 \le i \le k} \mathsf{adv}(T_i)$. From the definition of graph $H_{T,E'}$, $E(H_{T,E'}) = E' \cup E_{[T,E']}$. On one hand, from the construction of set E', $\mathbb{E}[w(E')] = w(E^*)/2$. On the other hand, for each edge $f \in \mathsf{cov}(E^*)$, with probability $1/2$ graph $H_{T,E'}$ contains 1 copy of it, and with probability $1/2$ graph $H_{T,E'}$ contains 2 copies of it. Therefore, $\mathbb{E}[w(E_{[T,E']})] = 2 \cdot w(E(T)) - w(\mathsf{cov}(E^*))/2$. Note that subtrees $\{T_i\}_{1 \le i \le k}$ are edge-disjoint, so the edge sets $\{\mathsf{cov}(E^*, T_i)\}_{1 \le i \le k}$ are mutually disjoint. Altogether,

$$\begin{aligned}
\mathbb{E}[w(H_{T,E'})] &= 2 \cdot \mathsf{MST} - \frac{w(\mathsf{cov}(E^*)) - w(E^*)}{2} \\
&\le 2 \cdot \mathsf{MST} - \frac{1}{2} \cdot \sum_{1 \le i \le k} \Big(w(\mathsf{cov}(E^*, T_i)) - w(E^*_i) \Big) \\
&\le 2 \cdot \mathsf{MST} - \frac{1}{2} \cdot \sum_{1 \le i \le k} \Big(w(\mathsf{cov}(E^*_i, T_i)) - w(E^*_i) \Big) \\
&= 2 \cdot \mathsf{MST} - \frac{1}{2} \cdot \sum_{1 \le i \le k} \mathsf{adv}(T_i).
\end{aligned}$$

◀

Complementing Lemma 11, the next lemma shows that, if the special cover advantage is low, then the TSP cost is close to 2 times the MST cost.

▶ **Lemma 13.** *Let T' be any subtree of an MST T. Then $\mathsf{TSP} \ge 2 \cdot w(T') - 2 \cdot \mathsf{adv}^*(T')$.*

Proof. Let π^* be the optimal TSP-tour that visits all vertices of V, so $\mathsf{TSP} = w(\pi^*)$. Let π be the tour obtained from π^* by deleting all vertices of $T \setminus T'$, so π is a tour that visits all vertices of $V(T')$, and, from triangle inequality, $w(\pi^*) \ge w(\pi)$. We now show that $E(\pi)$ can be partitioned into two subsets $E(\pi) = E_0 \cup E_1$, such that $E(T') \subseteq \mathsf{cov}(E_0)$ and $E(T') \subseteq \mathsf{cov}(E_1)$.

Let V' be the set of all odd-degree vertices in T', so $|V'|$ is even. Denote $V' = \{v_1, v_2, \ldots, v_{2k}\}$, where the vertices are index according to the order in which they appear in π. For each $1 \le i \le 2k$, we define edge $e_i = (v_i, v_{i+1})$ and define E^i_π to be the set of all edges traversed by π between vertices v_i and v_{i+1}. Clearly, $\mathsf{cov}(e_i) \subseteq \mathsf{cov}(E^i_\pi)$. We define $E_0 = \bigcup_{0 \le i \le k-1} E^{2i}_\pi$ and $E_1 = \bigcup_{0 \le i \le k-1} E^{2i+1}_\pi$.

Consider now the tour π' induced by edges of $e_1, \ldots, e_{2k}$. Clearly, π' is a tour that visits all vertices of V'. We define sets $F_0 = \{e_{2i} \mid 0 \le i \le k-1\}$ and $F_1 = \{e_{2i+1} \mid 0 \le i \le k-1\}$, so $E(\pi') = F_0 \cup F_1$. We now show that $E(T') \subseteq \mathsf{cov}(F_0)$ and $E(T') \subseteq \mathsf{cov}(F_1)$. Note that this implies that $E(T') \subseteq \mathsf{cov}(E_0)$ and $E(T') \subseteq \mathsf{cov}(E_1)$, since

$$\mathsf{cov}(F_0) = \Big(\bigcup_{0 \le i \le k-1} \mathsf{cov}(e_{2i}) \Big) \subseteq \Big(\bigcup_{0 \le i \le k-1} \mathsf{cov}(E^{2i}_\pi) \Big) \subseteq \mathsf{cov}\Big(\bigcup_{0 \le i \le k-1} E^{2i}_\pi \Big) = \mathsf{cov}(E_0),$$

and similarly $\mathsf{cov}(F_1) \subseteq \mathsf{cov}(E_1)$.

In fact, note that F_0 is a perfect matching on V'. Since V' is the set of odd-degree vertices of T', the graph on $V(T')$ induced by edges of $E(T') \cup F_0$ is Eulerian. Therefore, every edge of T' appears in at least two sets of $\{\mathsf{cov}(e') \mid e' \in E(T') \cup M_o\}$. Note that for each $e' \in E(T')$, $\mathsf{cov}(e') = \{e'\}$. Therefore, every edge $e \in E(T')$ appears in at least one set of $\{\mathsf{cov}(e') \mid e' \in F_0\}$, i.e., $E(T') \subseteq \mathsf{cov}(F_0)$. Similarly, we get that $E(T') \subseteq \mathsf{cov}(F_1)$.

From triangle inequality, $w(F_0) + w(F_1) \leq w(E_0) + w(E_1) = w(\pi)$. Note that edges of F_0 and F_1 have both endpoint in V', and moreover, from the definition of V', all vertices of V' are special vertices of T'. Since $E(T') \subseteq \mathsf{cov}(F_0)$, from the definition of $\mathsf{adv}^*(T')$, we get that $\mathsf{adv}^*(T') \geq w(\mathsf{cov}(F_0, T')) - w(F_0) = w(T') - w(F_0)$, and similarly $\mathsf{adv}^*(T') \geq w(T') - w(F_1)$. Therefore, $\mathsf{TSP} = w(\pi^*) \geq w(\pi) = w(E_0) + w(E_1) \geq w(F_0) + w(F_1) \geq 2 \cdot (w(T') - \mathsf{adv}^*(T'))$. ◀

The last two lemmas show that the total cover advantage and the total special cover advantage of a set of edge-disjoint subtrees of an MST can be efficiently and accurately estimated.

▶ **Lemma 14.** *There is an algorithm, that, given a constant $0 < \varepsilon < 1$ and a set $\mathcal{T}$ of edge-disjoint subtrees of T, with high probability, either correctly reports that $\sum_{T' \in \mathcal{T}} \mathsf{adv}(T') \geq \varepsilon \cdot \mathsf{MST}$, or correctly reports that $\sum_{T' \in \mathcal{T}} \mathsf{adv}(T') \leq 2\varepsilon \cdot \mathsf{MST}$, by performing $\tilde{O}((n/\varepsilon^2) \cdot \max\{|V(T')|\}_{T' \in \mathcal{T}})$ queries.*

▶ **Lemma 15.** *There is an algorithm, that, given a constant $0 < \varepsilon < 1$ and a set $\mathcal{T}$ of edge-disjoint subtrees of T, with high probability, either correctly reports that $\sum_{T' \in \mathcal{T}} \mathsf{adv}^*(T') \geq \varepsilon \cdot \mathsf{MST}$, or correctly reports that $\sum_{T' \in \mathcal{T}} \mathsf{adv}^*(T') \leq 2\varepsilon \cdot \mathsf{MST}$, by performing $\tilde{O}((n/\varepsilon^2) \cdot \max\{k_{T'} \mid T' \in \mathcal{T}\})$ queries, where $k_{T'}$ is the number of special vertices in T'.*

3 A Two-Pass Algorithm for TSP Estimation in Graph Streams

In this section, we present a deterministic 2-pass 1.96-approximation algorithm for TSP estimation in graph streams, which uses $\tilde{O}(n)$ space, thus proving Theorem 6. Our algorithm will utilize the notion of cover advantage, introduced in Section 2. This result is in a sharp contrast to Theorem 5 which showed that any single-pass algorithm requires $\Omega(n^2)$ space to obtain a better than 2-approximation.

Algorithm. Let $\alpha, \beta \in (0, 1)$ be two constants whose values will be set later. In the first pass, we simply compute a minimum spanning tree T and its cost $\mathsf{MST} = \sum_{e \in E(T)} w(e)$. Throughout the second pass, we maintain a subset E_{temp} of edges, that is initialized to be $\emptyset$, and will only grow over the course of the algorithm. Upon the arrival of each edge e, we compare $w(e)$ with $w(\mathsf{cov}(e) \setminus \mathsf{cov}(E_{\mathsf{temp}})) = \sum_{f \in \mathsf{cov}(e) \setminus \mathsf{cov}(E_{\mathsf{temp}})} w(f)$. We add the edge e to set E_{temp} iff $w(e) \leq \alpha \cdot w(\mathsf{cov}(e) \setminus \mathsf{cov}(E_{\mathsf{temp}}))$. Let E^* be the set E_{temp} at the end of the algorithm. We then compute $w(\mathsf{cov}(E^*)) = \sum_{e \in \mathsf{cov}(E^*)} w(e)$. If $w(\mathsf{cov}(E^*)) \geq \beta \cdot \mathsf{MST}$, then we output $(2 - \frac{(1-\alpha)\cdot\beta}{2}) \cdot \mathsf{MST}$ as an estimate of TSP; otherwise we output $2 \cdot \mathsf{MST}$. We use the parameters $\alpha = 0.715$ and $\beta = 0.285$, so $(2 - \frac{(1-\alpha)\cdot\beta}{2}) \approx \frac{2}{2\alpha(1-\beta)} \approx 1.96$.

Proof of Correctness. The correctness of the algorithm is guaranteed by the following two claims.

▷ Claim 16. If $w(\mathsf{cov}(E^*)) \geq \beta \cdot \mathsf{MST}$, then $\mathsf{TSP} \leq (2 - \frac{(1-\alpha)\cdot\beta}{2}) \cdot \mathsf{MST}$.

Proof. Let E' be the random subset of E^* that includes each edge of E^* independently with probability $1/2$. We will show that the expected total weight of all edges in graph $E(H_{T,E'})$ is at most $(2 - \frac{(1-\alpha)\cdot\beta}{2}) \cdot \mathsf{MST}$, namely $\mathbb{E}[w(E(H_{T,E'}))] \leq (2 - \frac{(1-\alpha)\cdot\beta}{2}) \cdot \mathsf{MST}$. Note that this implies that there exists a subset E^{**} of E^*, such that $w(E(H_{T,E^{**}})) \leq (2 - \frac{(1-\alpha)\cdot\beta}{2}) \cdot \mathsf{MST}$. Combined with Observation 12, this implies that there is an Eulerian tour of the same cost (using only edges of graph $H_{T,E^{**}}$). Therefore, there is a TSP-tour of at most the same cost, completing the proof of Claim 16.

We now show that $\mathbb{E}[w(E(H_{T,E'}))] \leq (2 - \frac{(1-\alpha)\cdot\beta}{2}) \cdot \mathsf{MST}$. From the definition of graph $H_{T,E'}$, $E(H_{T,E'}) = E' \cup E_{[T,E']}$. On one hand, from the definition of the random subset E', $\mathbb{E}[w(E')] = w(E^*)/2$. On the other hand, for each edge $f \in \mathsf{cov}(E^*)$, with probability $1/2$ graph $H_{T,E'}$ contains 1 copy of it, and with probability $1/2$ graph $H_{T,E'}$ contains 2 copies of it. Therefore, $\mathbb{E}[w(E_{[T,E']})] = 2 \cdot w(E(T)) - w(\mathsf{cov}(E^*))/2 = 2 \cdot \mathsf{MST} - w(\mathsf{cov}(E^*))/2$. Altogether, $\mathbb{E}[w(E(H_{T,E'}))] = 2 \cdot \mathsf{MST} - (w(\mathsf{cov}(E^*)) - w(E^*))/2$. The following observation follows immediately from the algorithm.

▶ **Observation 17.** $w(E^*) \leq \alpha \cdot w(\mathsf{cov}(E^*))$.

From Observation 17,

$$\mathbb{E}[w(E(H_{T,E'}))] \leq 2 \cdot \mathsf{MST} - \frac{(1-\alpha) \cdot w(\mathsf{cov}(E^*))}{2} \leq \left(2 - \frac{(1-\alpha)\cdot\beta}{2}\right) \cdot \mathsf{MST}.$$

This concludes the proof of Claim 16. ◁

We next show that, if we do not find a sufficiently large cover, i.e., the value of $w(\mathsf{cov}(E^*))$ is not sufficiently large compared with MST, then TSP must be bounded away from MST.

▷ Claim 18. If $w(\mathsf{cov}(E^*)) < \beta \cdot \mathsf{MST}$, then $\mathsf{TSP} \geq 2\alpha(1-\beta) \cdot \mathsf{MST}$.

Proof. Recall that set $V_1(T)$ contains all vertices with odd degree in T. Let M be a minimum-cost perfect matching on $V_1(T)$, so $\mathsf{TSP} \geq 2 \cdot w(M)$. We use the following observations. The proof of Observation 19 is straightforward and is deferred to the full version.

▶ **Observation 19.** $\mathsf{cov}(M) = E(T)$.

▶ **Observation 20.** *For each* $e \in M$, $w(\mathsf{cov}(e) \setminus \mathsf{cov}(E^*)) < w(e)/\alpha$.

Proof. We denote by Q_e the shortest-path in G connecting the endpoints of e (where G is the graph underlying the stream). Since Q_e is a subgraph of G, all edges of Q_e will appear in the graph stream of G. Note that $w(Q_e) = w(e)$ and $\mathsf{cov}(e) \subseteq \mathsf{cov}(E(Q_e))$.

We will show that, for every edge $e' \in E(Q_e)$, $w(\mathsf{cov}(e') \setminus \mathsf{cov}(E^*)) < w(e')/\alpha$. Note that the observation follows from this assertion, as

$$w(\mathsf{cov}(e) \setminus \mathsf{cov}(E^*)) \leq w(\mathsf{cov}(E(Q_e)) \setminus \mathsf{cov}(E^*)) \leq \sum_{e' \in E(Q_e)} w(\mathsf{cov}(e') \setminus \mathsf{cov}(E^*)) < \frac{w(Q_e)}{\alpha} = \frac{w(e)}{\alpha}.$$

Consider now any edge $e' \in E(Q_e)$, and assume for contradiction that $w(\mathsf{cov}(e') \setminus \mathsf{cov}(E^*)) \geq w(e')/\alpha$. Note that set E_{temp} only grows over the course of the algorithm that computes set E^*, and so does the set $\mathsf{cov}(E_{\mathsf{temp}})$. Therefore, when e' arrives in the stream, $w(\mathsf{cov}(e') \setminus \mathsf{cov}(E_{\mathsf{temp}})) \geq w(e')/\alpha$ must hold. Then according to the algorithm, the edge e' should be added to E_{temp} right away, which means that edge e' will eventually belong to E^*, leading to $\mathsf{cov}(e') \subseteq \mathsf{cov}(E^*)$ and $w(\mathsf{cov}(e') \setminus \mathsf{cov}(E^*)) = 0$, a contradiction to the assumption that $w(\mathsf{cov}(e') \setminus \mathsf{cov}(E^*)) \geq w(e')/\alpha$. ◀

From Observation 19 and Observation 20, we get that

$$(1-\beta) \cdot \mathsf{MST} \leq \mathsf{MST} - w(\mathsf{cov}(E^*)) = w(\mathsf{cov}(M) \setminus \mathsf{cov}(E^*)) \leq \sum_{e \in M} w(\mathsf{cov}(e) \setminus \mathsf{cov}(E^*)) < w(M)/\alpha.$$

Therefore, $w(M) \geq \alpha(1-\beta) \cdot \mathsf{MST}$. Since $\mathsf{TSP} \geq 2 \cdot w(M)$, we conclude that $\mathsf{TSP} \geq 2\alpha(1-\beta) \cdot \mathsf{MST}$. ◁

4 An $(2-\varepsilon_0)$-Approximation Query Algorithm with a given MST

In this section, we provide a proof sketch of Theorem 8, by showing an algorithm that, given access of a minimum spanning tree of a metric, obtains an $(2-\varepsilon_0)$-approximation of TSP (for $\varepsilon_0 = 2^{-100}$) by performing $\tilde{O}(n^{1.5})$ queries. Note that it suffices for the algorithm to correctly claim either $\mathsf{TSP} \geq (1+\varepsilon_0)\cdot\mathsf{MST}$ or $\mathsf{TSP} \leq (2-\varepsilon_0)\cdot\mathsf{MST}$.

Let T be the input MST and let it be rooted at an arbitrary vertex. We first divide T into a top part and a bottom part as follows. We say that a vertex v is *maximally light*, iff T_v (the subtree of T rooted at v) contains at most $\sqrt{n}$ vertices, but its parent node does not. Let T' be the tree obtained from T by deleting from it, for each maximally light vertex v, all edges and vertices of T_v, and we call T' the top part of T, and call $T \setminus T'$ the bottom part of T. It is easy to show that T' has at most $O(\sqrt{n})$ leaves and therefore at most $O(\sqrt{n})$ special vertices. Moreover, we can efficiently partition T' into a set $\mathcal{P}$ of $O(\sqrt{n})$ vertex-disjoint paths, such that, for each path $P \in \mathcal{P}$, either P contains a single vertex of T, or the total number of vertices in T that has an ancestor in P is at most $\sqrt{n}$. For each path $P \in \mathcal{P}$, we call the subtree of T induced by all vertices of P and all their descendants in T a *segment*. Let $\mathcal{S}$ be the set of all segments.

The algorithm consists of four steps, that are summarized as follows.

1. We compute the special cover advantage of T' using Lemma 10. If $\mathsf{adv}^*(T') \geq 10\varepsilon_0\cdot\mathsf{MST}$, then we claim $\mathsf{TSP} \leq (2-\varepsilon_0)\cdot\mathsf{MST}$.
2. We estimate the total cover advantage of all segments using Lemma 14. If the algorithm reports that $\sum_{S\in\mathcal{S}} \mathsf{adv}(S) \geq 10\varepsilon_0\cdot\mathsf{MST}$, then we claim $\mathsf{TSP} \leq (2-\varepsilon_0)\cdot\mathsf{MST}$.
3. (informal) We estimate the cover advantage involving $T\setminus T'$, with the help of the algorithm in [1]. If the estimation is at least $10\varepsilon_0\cdot\mathsf{MST}$, then we claim $\mathsf{TSP} \leq (2-\varepsilon_0)\cdot\mathsf{MST}$.
4. If we did not terminate and claim $\mathsf{TSP} \leq (2-\varepsilon_0)\cdot\mathsf{MST}$ in any of the previous step, then we claim $\mathsf{TSP} \geq (1+\varepsilon_0)\cdot\mathsf{MST}$.

We first count the total number of queries performed by the algorithm. First, the algorithm from Lemma 10 performs $\tilde{O}(n^{1.5})$ queries, since the number of special vertices in T' is at most $O(\sqrt{n})$. Second, in Step 2, the algorithm from Lemma 14 performs in total $\tilde{O}(n^{1.5})$ queries, since each segment contains $O(\sqrt{n})$ vertices. Lastly, in Step 3 the algorithm performs $\tilde{O}(n^{1.5})$ queries. Altogether, the algorithm performs in total $\tilde{O}(n^{1.5})$ queries.

We now show that the algorithm indeed returns a $(2-\varepsilon_0)$-approximation of TSP. That is, the claim made by the algorithm is correct.

- If in Step 1, the algorithm from Lemma 10 reported $\mathsf{adv}^*(T') \geq 10\varepsilon_0\cdot\mathsf{MST}$. Then from Lemma 11, $\mathsf{TSP} \leq 2\cdot\mathsf{MST} - (10\varepsilon_0)\cdot\mathsf{MST}/2 = (2-5\varepsilon_0)\cdot\mathsf{MST}$ and the claim is correct.
- If in Step 2, the algorithm from Lemma 14 reported $\sum_{S\in\mathcal{S}} \mathsf{adv}(S) \geq 10\varepsilon_0\cdot\mathsf{MST}$. From Lemma 11, $\mathsf{TSP} \leq 2\cdot\mathsf{MST} - (10\varepsilon_0)\cdot\mathsf{MST}/2 = (2-5\varepsilon_0)\cdot\mathsf{MST}$ and the claim is correct.
- If in Step 2, the estimate of the cover advavtage in $T\setminus T'$ is at least $10\varepsilon_0\cdot\mathsf{MST}$, from Lemma 11, we can derive that $\mathsf{TSP} \leq (2-5\varepsilon_0)\cdot\mathsf{MST}$ and the claim is correct.

We assume from now on the algorithm did not terminate and claim $\mathsf{TSP} \leq (2-\varepsilon_0)\cdot\mathsf{MST}$ in the first three steps. We will show that in this case, $\mathsf{TSP} \geq (1+\varepsilon_0)\cdot\mathsf{MST}$.

Let π be an optimal TSP-tour, so $\mathsf{TSP} = w(\pi)$. Intuitively, if the tour π "continuously travels within the top part of T", then the report in Step 1 guarantees that its total cost must be bounded away from MST; if the tour π "continuously travels within the same segments", then the report in Step 2 guarantees that its total cost must be bounded away from MST. Therefore, we only need to consider the case where the tour "constantly jumping between the top and the bottom parts of T and across different segments".

Note that, since the cover advantage that we discovered in Steps 1-2 are low, for every edge $e = (u, v)$, the weight $w(e)$ should be rougly equal to the total weight of the unique u-v path in T. Therefore, if we replace each edge of π with the corresponding path in T, then the total weight of the resulting edge set should be close to TSP. But since the tour jumps between the top and the bottom parts of T and across different segments, the "segment-connecting" edges in T must be covered many times by π, and this can be used to show that $w(\pi)$ is bounded away from MST.

Specifically, we let E'_π the obtained edge set after replacing each edge of $E(\pi)$ with edges in the corresponding path in T, so E'_π may contain many copies of the same edge. For each edge e that has more than 2 copies contained in E'_π, if E'_π contains an odd number of copies of e, then we delete all but one copies from E'_π; if E'_π contains an even number of copies of e, then we delete all but two copies from E'_π. Denote by E' the resulting set of edges, so each edge has at most 2 copies contained in E'. It is easy to verify that the graph induced by edges of E' (with multiplicity) is connected and Eulerian.

Let E'' be the subset of E' that contains all bridges in the graph induced by edges of E' (ignoring multiplicities), and it is easy to verify that each edge has two copies contained in E'. Then from the report of Steps 1-2 of the algorithm, we can show that $w(E') - w(E(\pi)) \geq O(\varepsilon_0) \cdot \mathsf{MST}$ and $w(E') \geq \mathsf{MST} + w(E'')$. Therefore, if $w(E'') \geq \Omega(\varepsilon_0) \cdot \mathsf{MST}$ then we are done. If $w(E'') \leq O(\varepsilon_0) \cdot \mathsf{MST}$, then we can show that the total cost of all edges with at least one endpoints in $T \setminus T'$ must be large, and from the report of Step 3 of the algorithm, we can conclude that $w(E(\pi))$ is bounded away from MST.

5 Future Directions

In this work, we studied the problems of MST and TSP cost estimation in the streaming and query settings. For TSP cost estimation, we introduced and utilized a novel notion called *cover advantage* that may prove useful for solving this problem in other computational models also. In the streaming setting, an interesting open problem is to obtain a one-pass $o(n^2)$-space $(2-\varepsilon)$-approximate estimation of TSP cost in the metric stream. In the query model, we believe a major open problem is to obtain an $o(n^2)$-query $(2-\varepsilon)$-approximate estimation of TSP-cost in general metrics.

University of Amsterdam, The Netherlands

Abstract

Lasso and Ridge are important minimization problems in machine learning and statistics. They are versions of linear regression with squared loss where the vector $\theta \in \mathbb{R}^d$ of coefficients is constrained in either ℓ_1-norm (for Lasso) or in ℓ_2-norm (for Ridge). We study the complexity of quantum algorithms for finding ε-minimizers for these minimization problems. We show that for Lasso we can get a quadratic quantum speedup in terms of d by speeding up the cost-per-iteration of the Frank-Wolfe algorithm, while for Ridge the best quantum algorithms are linear in d, as are the best classical algorithms. As a byproduct of our quantum lower bound for Lasso, we also prove the first classical lower bound for Lasso that is tight up to polylog-factors.

1 Introduction

1.1 Linear regression with norm constraints

One of the simplest, most useful and best-studied problems in machine learning and statistics is *linear regression*. We are given N data points $\{(x_i, y_i)\}_{i=0}^{N-1}$ where $x \in \mathbb{R}^d$ and $y \in \mathbb{R}$, and want to fit a line through these points that has small error. In other words, we want to find a vector $\theta \in \mathbb{R}^d$ of coefficients such that the inner product $\langle \theta, x \rangle = \sum_{j=1}^{d} \theta_j x_j$ is a good predictor for the y-variable. There are different ways to quantify the error ("loss") of such a θ-vector, the most common being the squared error $(\langle \theta, x \rangle - y)^2$, averaged over the N data points (or over an underlying distribution $\mathcal{D}$ that generated the data). If we let X be the $N \times d$ matrix whose N rows are the x-vectors of the data, then we want to find a $\theta \in \mathbb{R}^d$ that minimizes $\|X\theta - y\|_2^2$. This minimization problem has a well-known closed-form solution: $\theta = (X^T X)^+ X^T y$, where the superscript "+" indicates the Moore-Penrose pseudoinverse.

In practice, unconstrained least-squares regression sometimes has problems with overfitting and often yields solutions θ where all entries are non-zero, even when only a few of the d coordinates in the x-vector really matter and one would really hope for a sparse vector θ [42, see Chapters 2 and 13]. This may be improved by "regularizing" θ via additional constraints. The most common constraints are to require that the ℓ_1-norm or ℓ_2-norm of θ is at most some bound B.[1] Linear regression with an ℓ_1-constraint is called *Lasso* (due to Tibshirani [43]), while with an ℓ_2-constraint it is called *Ridge* (due to Hoerl and Kennard [29]).

Both Lasso and Ridge are widely used for robust regression and sparse estimation in ML problems and elsewhere [44, 15]. Consequently, there has been great interest in finding the fastest-possible algorithms for them. For reasons of efficiency, algorithms typically aim at finding not the exactly optimal solution but an ε-minimizer, i.e., a vector θ whose loss is only an additive ε worse than the minimal-achievable loss. The best known results on the time complexity of classical algorithms for Lasso are an upper bound of $\tilde{\mathcal{O}}(d/\varepsilon^2)$ [28] and a lower bound of $\Omega(d/\varepsilon)$ [16] (which we actually improve to a tight lower bound in this paper, see below); for Ridge the best bound is $\tilde{\Theta}(d/\varepsilon^2)$ [28], which is tight up to logarithmic factors.[2]

1.2 Our results

We focus on the *quantum* complexity of Lasso and Ridge, investigating to what extent quantum algorithms can solve these problems faster. Table 1 summarizes the results. The upper bounds are on time complexity (total number of elementary operations and queries to entries of the input vectors) while the lower bounds are on query complexity (which itself lower bounds time complexity).

Table 1 Classical and quantum upper and lower bounds for Lasso and Ridge.

	Upper bound	**Lower bound**
Lasso	Classical [28]: $\tilde{\mathcal{O}}(d/\varepsilon^2)$ Quantum [*this work*]: $\tilde{\mathcal{O}}(\sqrt{d}/\varepsilon^2)$	Classical [*this work*]: $\tilde{\Omega}(d/\varepsilon^2)$ Quantum [*this work*]: $\Omega(\sqrt{d}/\varepsilon^{1.5})$
Ridge	Classical [28]: $\tilde{\mathcal{O}}(d/\varepsilon^2)$	Classical [28]: $\Omega(d/\varepsilon^2)$ Quantum [*this work*]: $\Omega(d/\varepsilon)$

1.2.1 Lasso

We design a quantum algorithm that finds an ε-minimizer for Lasso in time $\tilde{\mathcal{O}}(\sqrt{d}/\varepsilon^2)$. This gives a quadratic quantum speedup over the best-possible classical algorithm in terms of d, while the ε-dependence remains the same as in the best known classical algorithm.

[1] For ease of presentation we will set $B = 1$. However, one can also set B differently or even do a binary search over its values, finding a good θ for each of those values and selecting the best one at the end. Instead of putting a hard upper bound B on the norm, one may also include it as a penalty term in the objective function itself, by just minimizing the function $\|X\theta - y\|_2^2 + \lambda \|\theta\|$, where λ is a Lagrange multiplier and the norm of θ could be ℓ_1 or ℓ_2 (and could also be squared). This amounts to basically the same thing as our setup.

[2] For such bounds involving additive error ε to be meaningful, one has to put certain normalization assumptions on X and y, which are given in the body of the paper. The $\tilde{\mathcal{O}}$ and $\tilde{\Theta}$-notation hides polylogarithmic factors. It is known that $N = \mathcal{O}((\log d)/\varepsilon^2)$ data points suffice for finding an ε-minimizer, which explains the absence of N as a separate variable in these bounds.

Our quantum algorithm is based on the Frank-Wolfe algorithm, a well-known iterative convex optimization method [22]. Frank-Wolfe, when applied to a Lasso instance, starts at the all-zero vector θ and updates this in $\mathcal{O}(1/\varepsilon)$ iterations to find an ε-minimizer. Each iteration looks at the gradient of the loss function at the current point θ and selects the best among $2d$ directions for changing θ (each of the d coordinates can change positively or negatively, whence $2d$ directions). The new θ will be a convex combination of the previous θ and this optimal direction of change. Note that Frank-Wolfe automatically generates *sparse* solutions: only one coordinate of θ can change from zero to nonzero in one iteration, so the number of nonzero entries in the final θ is at most the number of iterations, which is $\mathcal{O}(1/\varepsilon)$.

Our quantum version of Frank-Wolfe does not reduce the number of iterations, which remains $\mathcal{O}(1/\varepsilon)$, but it does reduce the cost per iteration. In each iteration it selects the best among the $2d$ possible directions for changing θ by using a version of quantum minimum-finding on top of a quantum approximation algorithm for entries of the gradient (which in turn uses amplitude estimation). Both this minimum-finding and our approximation of entries of the gradient will result in approximation errors throughout. Fortunately Frank-Wolfe is a very robust method which still converges if we carefully ensure those quantum-induced approximation errors are sufficiently small.

Our quantum algorithm assumes coherent quantum query access to the entries of the data points (x_i, y_i), as well as a relatively small QRAM (quantum-readable classical-writable classical memory). We use a variant of a QRAM data structure developed by Prakash and Kerenidis [37, 33], to store the nonzero entries of our current solution θ in such a way that we can (1) quickly generate θ as a quantum state, and (2) quickly incorporate the change of θ incurred by a Frank-Wolfe iteration.[3] Because our θ is $\mathcal{O}(1/\varepsilon)$-sparse throughout the algorithm, we only need $\tilde{\mathcal{O}}(1/\varepsilon)$ bits of QRAM.

We also prove a lower bound of $\Omega(\sqrt{d}/\varepsilon^{1.5})$ quantum queries for Lasso, showing that the d-dependence of our quantum algorithm is essentially optimal, while our ε-dependence might still be slightly improvable. Our lower bound strategy "hides" a subset of the columns of the data matrix X by letting those columns have slightly more $+1$s than -1, and observes that an approximate minimizer for Lasso allows us to recover this hidden set. We then use the composition property of the adversary lower bound [12] together with a worst-case to average-case reduction to obtain a quantum query lower bound for this hidden-set-finding problem, and hence for Lasso.

Somewhat surprisingly, no tight *classical* lower bound was known for Lasso prior to this work. To the best of our knowledge, the previous-best classical lower bound was $\Omega(d/\varepsilon)$, due to Cesa-Bianchi, Shalev-Shwartz, and Shamir [16]. As a byproduct of our quantum lower bound, we use the same set-hiding approach to prove for the first time the optimal (up to logarithmic factors) lower bound of $\tilde{\Omega}(d/\varepsilon^2)$ queries for classical algorithms for Lasso.

1.2.2 Ridge

What about Ridge? Because ℓ_2 is a more natural norm for quantum states than ℓ_1, one might hope that Ridge is more amenable to quantum speedup than Lasso. Unfortunately this turns out to be wrong: we prove a quantum lower bound of $\Omega(d/\varepsilon)$ queries for Ridge, using a similar strategy as for Lasso. This shows that the classical linear dependence of the runtime on d cannot be improved on a quantum computer. Whether the ε-dependence can be improved remains an open question.

[3] Each iteration will actually change all nonzero entries of θ because the new θ is a convex combination of the old θ and a vector with one nonzero entry. Our data structure keeps track of a global scalar, which saves us the cost of separately adjusting all nonzero entries of θ in the data structure in each iteration.

1.3 Related work

As already cited in Table 1, Hazan and Koren [28] obtained an optimal classical algorithm for Ridge, and the best known classical algorithm for Lasso. Cesa-Bianchi, Shalev-Shwartz, and Shamir [16] provided a non-optimal classical lower bound for Lasso, and their idea inspired us to hide a subset among the column of the data matrix and to use a Lasso solver to find that subset (our lower bound also benefited from the way composition of the adversary bound was used in [8]).

Du, Hsieh, Liu, You, and Tao [20] also showed a quantum upper bound for Lasso based on quantizing parts of Frank-Wolfe, though their running time $\tilde{\mathcal{O}}(N^{3/2}\sqrt{d})$ is substantially worse than ours. The main goal of their paper was to establish differential privacy, not so much to obtain the best-possible quantum speedup for Lasso. They also claim an $\Omega(\sqrt{d})$ lower bound for quantum algorithms for Lasso [20, Corollary 1], without explicit dependence on ε, but we do not fully understand their proof, which goes via a claimed equivalence with quantum SVMs. Bellante and Zanero [11] recently and independently used similar techniques as we use here for our Lasso upper bound (KP-trees and amplitude estimation) to give a polynomial quantum speedup for the classical matching-pursuit algorithm, which is a heuristic algorithm for the NP-hard problem of linear regression with a sparsity constraint, i.e., with an ℓ_0-regularizer.

Another quantum approach for solving (unregularized) least-squares linear regression is based on the linear-systems algorithm of Harrow, Hassidim, and Lloyd [27]. In this type of approach, the quantum algorithm very efficiently generates a solution vector θ *as a quantum state* $\frac{1}{\|\theta\|_2}\sum_i \theta_i |i\rangle$ (which is incomparable to our goal of returning θ as a classical vector). Chakraborty, Gilyén, and Jeffery [18] used the framework of block-encodings to achieve this. Subsequently Gilyén, Lloyd, and Tang [25] obtained a "dequantized" classical algorithm for (unregularized) least-squares linear regression assuming length square sampling access to the input data, which again is incomparable to our setup. The quantum algorithm was very recently improved with an ℓ_2-regularizer by Chakraborty, Morolia, and Peduri [19], thought still producing the final output as a quantum state rather than as a classical solution.

Norm-constrained linear regression is a special case of convex optimization. Quantum algorithms for various convex optimization problems have received much attention recently. For example, there has been a sequence of quantum algorithms for solving linear and semidefinite programs starting with Brandão and Svore [14, 5, 13, 6, 3]. There have also been some polynomial speedups for matrix scaling [7, 26] and for boosting in machine learning [9, 30], as well as some general speedups for converting membership oracles for a convex feasible set to separation oracles and optimization oracles [17, 4, 2]. On the other hand Garg, Kothari, Netrapalli, and Sherif [24] showed that the number of iterations for first-order algorithms for minimizing non-smooth convex functions cannot be significantly improved on a quantum computer; recently they generalized this result to higher-order algorithms [23]. Finally, there has also been work on quantum speedups for *non-convex* problems, for instance on escaping from saddle points [45].

2 Preliminaries

Throughout the paper, d will always be the dimension of the ambient space $\mathbb{R}^d$, and log without a base will be the binary logarithm. It will be convenient for us to index entries of vectors starting from 0, so the entries x_i of a d-dimensional vector x are indexed by $i \in \{0,\dots,d-1\} = \mathbb{Z}_d$. $\mathcal{U}_N = \mathcal{U}\{0,\dots,N-1\}$ is the discrete uniform distribution over integers $0,1,2,\dots,N-1$.

2.1 Computational model and quantum algorithms

Our computational model is a classical computer (a classical random-access machine) that can invoke a quantum computer as a subroutine. The input is stored in quantum-readable read-only memory (a QROM), whose bits can be queried. The classical computer can also write bits to a quantum-readable classical-writable classical memory (a QRAM). The classical computer can send a description of a quantum circuit to the quantum computer; the quantum computer runs the circuit (which may include queries to the input bits stored in QROM and to the bits stored by the computer itself in the QRAM), measures the full final state in the computational basis, and returns the measurement outcome to the classical computer. In this model, an algorithm has time complexity T if it uses at most T elementary classical operations and quantum gates, quantum queries to the input bits stored in QROM, and quantum queries to the QRAM. The query complexity of an algorithm only measures the number of queries to the input stored in QROM. We call a (quantum) algorithm *bounded-error* if (for every possible input) it returns a correct output with probability at least $9/10$.

We will represent real numbers in computer memory using a number of bits of precision that is polylogarithmic in d, N, and $1/\varepsilon$ (i.e., $\tilde{\mathcal{O}}(1)$ bits). This ensures all numbers are represented throughout our algorithms with negligible approximation error and we will ignore those errors later on for ease of presentation.

The following is a modified version of quantum minimum-finding, which in its basic form is due to Høyer and Dürr [21]. Our proof of the more general version below is given in our full version on arXiv, and is based on a result from [5]. We also use some other Grover-based quantum algorithms as subroutines, described in our full version.

▶ **Theorem 1** (min-finding with an approximate unitary). *Let $\delta_1, \delta_2, \varepsilon \in (0,1)$, $v_0, \ldots, v_{d-1} \in \mathbb{R}$. Suppose we have a unitary $\tilde{A}$ that maps $|j\rangle|0\rangle \to |j\rangle|\Lambda_j\rangle$ such that for every $j \in \mathbb{Z}_d$, after measuring the state $|\Lambda_j\rangle$, with probability $\geq 1-\delta_2$ the first register λ of the measurement outcome satisfies $|\lambda - v_j| \leq \varepsilon$. There exists a quantum algorithm that finds an index j such that $v_j \leq \min_{k\in\mathbb{Z}_d} v_k + 2\varepsilon$ with probability $\geq 1-\delta_1 - 1000\log(1/\delta_1)\cdot\sqrt{2d\delta_2}$, using $1000\sqrt{d}\cdot\log(1/\delta_1)$ applications of $\tilde{A}$ and $\tilde{A}^\dagger$, and $\tilde{\mathcal{O}}(\sqrt{d})$ elementary gates. In particular, if $\delta_2 \leq \delta_1^2/(2000000d\log(1/\delta_1))$, that finds such a j with probability $\geq 1-2\delta_1$.*

2.2 Expected and empirical loss

Let sample set $S = \{(x_i, y_i)\}_{i=0}^{N-1}$ be a set of i.i.d. samples from $\mathbb{R}^d \times \mathbb{R}$, drawn according to an unknown distribution $\mathcal{D}$. A *hypothesis* is a function $h : \mathbb{R}^d \to \mathbb{R}$, and $\mathcal{H}$ denotes a set of hypotheses. To measure the performance of the prediction, we use a convex loss function $\ell : \mathbb{R}^2 \to \mathbb{R}$. The *expected loss* of h with respect to $\mathcal{D}$ is denoted by $L_{\mathcal{D}}(h) = \mathbb{E}_{(x,y)\sim\mathcal{D}}[\ell(h(x), y)]$, and the *empirical loss* of h with respect to S is denoted by $L_S(h) = \frac{1}{N}\sum_{i\in\mathbb{Z}_N} \ell(h(x_i), y_i)$.

▶ **Definition 2.** *Let $\varepsilon > 0$. An $h \in \mathcal{H}$ is an ε-minimizer over $\mathcal{H}$ w.r.t. $\mathcal{D}$ if*

$$L_{\mathcal{D}}(h) - \min_{h'\in\mathcal{H}} L_{\mathcal{D}}(h') \leq \varepsilon.$$

▶ **Definition 3.** *Let $\varepsilon > 0$. An $h \in \mathcal{H}$ is an ε-minimizer over $\mathcal{H}$ w.r.t. sample set S if*

$$L_S(h) - \min_{h'\in\mathcal{H}} L_S(h') \leq \varepsilon.$$

2.3 Linear regression problems and their classical and quantum setup

In linear regression problems, the hypothesis class is the set of linear functions on $\mathbb{R}^d$. The goal is to find a vector θ for which the corresponding hypothesis $\langle \theta, x \rangle$ provides a good prediction of the target y. One of the most natural choices for regression problems is the squared loss

$$\ell(\hat{y}, y) = (\hat{y} - y)^2.$$

We can instantiate the expected and empirical losses as a function of θ using squared loss:

$$L_{\mathcal{D}}(\theta) = \mathbb{E}_{(x,y)\sim\mathcal{D}}[\ell(\langle \theta, x \rangle, y)] = \mathbb{E}_{(x,y)\sim\mathcal{D}}[(\langle \theta, x \rangle - y)^2],$$

$$L_S(\theta) = \frac{1}{N} \sum_{i \in \mathbb{Z}_N} \ell(\langle \theta, x \rangle, y_i) = \frac{1}{N} \sum_{i \in \mathbb{Z}_N} (\langle \theta, x \rangle - y_i)^2.$$

We also write the empirical loss as $L_S(\theta) = \frac{1}{N}\|X\theta - y\|_2^2$, where matrix entry X_{ij} is the jth entry of the vector x_i, and y is the N-dimensional vector with entries y_i. As we will see below, if the instances in the sample set are chosen i.i.d. according to $\mathcal{D}$, and N is sufficiently large, then $L_S(\theta)$ and $L_{\mathcal{D}}(\theta)$ are typically close by the law of large numbers.

In the quantum case, we assume the sample set S is stored in a QROM, which we can access by means of queries to the oracles $O_X : |i\rangle |j\rangle |0\rangle \to |i\rangle |j\rangle |X_{ij}\rangle$ and $O_y : |i\rangle |0\rangle \to |i\rangle |y_i\rangle$.

2.3.1 Lasso

The *least absolute shrinkage and selection operator*, or *Lasso*, is a special case of linear regression with a norm constraint on the vector θ: it restricts solutions to the unit ℓ_1-ball, which we denote by B_1^d. For the purpose of normalization, we require that every sample (x, y) satisfies $\|x\|_\infty \leq 1$ and $|y| \leq 1$.[4] The goal is to find a $\theta \in B_1^d$ that (approximately) minimizes the expected loss. Since the expected loss is not directly accessible, we instead find an approximate minimizer of the empirical loss. Mohri, Rostamizadeh, and Talwalkar [34] showed that with high probability, an approximate minimizer for *empirical* loss is also a good approximate minimizer for *expected* loss.

▶ **Theorem 4** ([34], Theorem 11.16). *Let $\mathcal{D}$ be an unknown distribution over $[-1,1]^d \times [-1,1]$ and $S = \{(x_i, y_i)\}_{i=0}^{N-1}$ be a sample set containing N i.i.d. samples from $\mathcal{D}$. Then, for each $\delta > 0$, with probability $\geq 1 - \delta$ over the choice of S, the following holds for all $\theta \in B_1^d$:*

$$L_{\mathcal{D}}(\theta) - L_S(\theta) \leq 4\sqrt{\frac{2\log(2d)}{N}} + 4\sqrt{\frac{\log(1/\delta)}{2N}}.$$

This theorem implies that if $N = c\log(d/\delta)/\varepsilon^2$ for sufficiently large constant c, then finding (with error probability $\leq \delta$) an ε-minimizer for the *empirical* loss L_S, implies finding (with error probability $\leq 2\delta$ taken both over the randomness of the algorithm and the choice of the sample S) a 2ε-minimizer for the *expected* loss $L_{\mathcal{D}}$.

[4] Note that if $\theta \in B_1^d$ and $\|x\|_\infty \leq 1$, then $|\langle \theta, x \rangle| \leq 1$ by Hölder's inequality.

2.3.2 Ridge

Another special case of linear regression with a norm constraint is *Ridge*, which restricts solutions to the unit ℓ_2-ball B_2^d. For the purpose of normalization, we now require that every sample (x, y) satisfies $\|x\|_2 \leq 1$ and $|y| \leq 1$. Similarly to the Lasso case, Mohri, Rostamizadeh, and Talwalkar [34] showed that with high probability, an approximate minimizer for the empirical loss is also a good approximate minimizer for the expected loss.

▶ **Theorem 5** ([34], Theorem 11.11). *Let $\mathcal{D}$ be an unknown distribution over $B_2^d \times [-1, 1]$ and $S = \{(x_i, y_i)\}_{i=0}^{N-1}$ be a sample set containing N i.i.d. samples from $\mathcal{D}$. Then, for each $\delta > 0$, with probability $\geq 1 - \delta$ over the choice of S, the following holds for all $\theta \in B_2^d$:*

$$L_{\mathcal{D}}(\theta) - L_S(\theta) \leq 8\sqrt{\frac{1}{N}} + 4\sqrt{\frac{\log(1/\delta)}{2N}}.$$

2.4 The KP-tree data structure and efficient state preparation

Kerenidis and Prakash [37, 33] gave a quantum-accessible classical data structure to store a vector θ with support t (i.e., t nonzero entries) to enable efficient preparation of the state

$$|\theta\rangle = \sum_{j \in \mathbb{Z}_d} \sqrt{\frac{|\theta_j|}{\|\theta\|_1}} |j\rangle |sign(\theta_j)\rangle .$$

We modify their data structure such that for arbitrary $a, b \in \mathbb{R}$ and $j \in \mathbb{Z}_d$, we can efficiently update a data structure for the vector θ to a data structure for the vector $a\theta + be_j$, without having to individually update all nonzero entries of the vector. We only give the definition here; for more details and analysis, see our full version on arXiv.

▶ **Definition 6** (KP-tree). *Let $\theta \in \mathbb{R}^d$ have support t. Define a KP-tree KP_θ of θ as:*

- *KP_θ is a rooted binary tree with depth $\lceil \log d \rceil$ and with $\mathcal{O}(t \log d)$ vertices.*
- *The root stores a scalar $A \in \mathbb{R} \setminus \{0\}$ and the support t of θ.*
- *Each edge of the tree is labelled by a bit.*
- *For each $j \in supp(\theta)$, there is one corresponding leaf storing $\frac{\theta_j}{A}$. The number of leaves is t.*
- *The bits on the edges of the path from the root to the leaf corresponding to the j^{th} entry of θ, form the binary description of j.*
- *Each intermediate node stores the sum of its children's absolute values.*

For $\ell \in \mathbb{Z}_{\lceil \log d \rceil}$ and $j \in \mathbb{Z}_{2^\ell}$, we define $KP_\theta(\ell, j)$ as the value of the j^{th} node in the ℓ^{th} layer, i.e., the value stored in the node that we can reach by the path according to the binary representation of j from the root. Also, we let $KP_\theta(0, 0)$ be the sum of all absolute values stored in the leaves. If there is no corresponding j^{th} node in the ℓ^{th} layer (that is, we cannot reach a node by the path according to the binary representation of j from the root), then $KP_\theta(\ell, j)$ is defined as 0. Note that both the numbering of the layer and the numbering of nodes start from 0. In the special case where θ is the all-0 vector, the corresponding tree will just have a root node with $t = 0$.

3 Quantum Algorithm for Lasso

3.1 The classical Frank-Wolfe algorithm

Below is a description of the Frank-Wolfe algorithm with approximate linear solvers. For now this is for an arbitrary convex objective function L and arbitrary compact convex domain $\mathcal{X}$ of feasible solutions; for Lasso we will later instantiate these to the quadratic loss function and

ℓ_1-ball, respectively. Frank-Wolfe finds an ε-approximate solution to a convex optimization problem, using $O(1/\varepsilon)$ iterations. It is a first-order method: each iteration assumes access to the gradient of the objective function at the current point. The algorithm considers the linearization of the objective function, and moves towards a minimizer of this linear function without ever leaving the domain $\mathcal{X}$ (in contrast to for instance projected gradient descent).

Algorithm 1 The Frank-Wolfe algorithm with approximate linear subproblems.

input : number of iterations $T > 0$; convex differentiable function L; compact convex domain $\mathcal{X}$;
Let C_L be the curvature constant of L;
Let θ^0 be an arbitrary point in $\mathcal{X}$;
for $t \leftarrow 0$ **to** T **do**
  $\tau_t = \frac{2}{t+2}$;
  find $s \in \mathcal{X}$ such that $\langle s, \nabla L(\theta^t)\rangle \leq \min_{s' \in \mathcal{X}} \langle s', \nabla L(\theta^t)\rangle + \frac{\tau_t C_L}{4}$;
  $\theta^{t+1} = (1-\tau_t)\theta^t + \tau_t s$;
end
output : θ^T;

The convergence rate of the Frank-Wolfe algorithm is affected by the "non-linearity" of the objective function L, as measured by the curvature constant C_L:

▶ **Definition 7.** *The curvature constant C_L of a convex and differentiable function $L : \mathbb{R}^d \to \mathbb{R}$ with respect to a convex domain $\mathcal{X}$ is defined as*

$$C_L \equiv \sup_{\substack{x,s \in \mathcal{X}, \gamma \in [0,1], \\ y = x + \gamma(s-x)}} \frac{2}{\gamma^2}(L(y) - L(x) - \langle \nabla L(x), (y-x)\rangle).$$

Next we give an upper bound for the curvature constant of the empirical loss function for Lasso.

▶ **Theorem 8.** *Let $S = \{(x_i, y_i)\}_{i=0}^{N-1}$ with all entries of x_i and y_i in $[-1, 1]$. Then the curvature constant C_{L_S} of L_S w.r.t. B_1^d is ≤ 8.*

Proof. We know

$$L_S(\theta) = \frac{1}{N}\|X\theta - y\|_2^2 = \frac{(X\theta - y)^T(X\theta - y)}{N} = \frac{\theta^T X^T X\theta - y^T X\theta - \theta^T X^T y + y^T y}{N},$$

which implies the Hessian of L_S is $\nabla^2 L_S(z) = \frac{2X^T X}{N}$, independent of z. By replacing sup by max because the domain is compact, we have

$$\begin{aligned} C_{L_S} &= \max_{\substack{x,s \in \mathcal{X}, \gamma \in [0,1], \\ y = x + \gamma(s-x)}} \frac{2}{\gamma^2}(L_S(y) - L_S(x) - \langle \nabla L_S(x), (y-x)\rangle) \\ &= \max_{x,s \in \mathcal{X}, \gamma \in [0,1]} \langle (s-x), \nabla^2 L_S \cdot (s-x)\rangle = \max_{x,s \in \mathcal{X}} \frac{2}{N}\|X(s-x)\|_2^2. \end{aligned}$$

Each coefficient of X is at most 1 in absolute value, and $s - x \in 2B_1^d$, hence each entry of the vector $X(s-x)$ has magnitude at most 2. Therefore $\max_{x,y \in B_1^d} \frac{2}{N}\|X(s-x)\|_2^2$ is at most 8. ◀

The original Frank-Wolfe algorithm [22] assumed that the minimization to determine the direction-of-change s was done exactly, without the additive error term $\tau_t C_{L_S}/4$ that we wrote in Algorithm 1. However, the following theorem, due to Jaggi [31], shows that solving approximate linear subproblems is sufficient for the Frank-Wolfe algorithm to converge at an $O(C_{L_S}/T)$ rate, which means one can find an ε-approximate solution with $T = O(C_{L_S}/\varepsilon)$ iterations.

▶ **Theorem 9** ([31], Theorem 1). *For each iteration $t \geq 1$, the corresponding θ^t of Algorithm 1 satisfies*

$$L_S(\theta^t) - \min_{\theta' \in B_1^d} L_S(\theta') \leq \frac{3C_{L_S}}{t+2}.$$

3.2 Approximating the quadratic loss function and entries of its gradient

In this subsection, we give a quantum algorithm to estimate the quadratic loss function $L_S(\theta)$ and entries of its gradient, given query access to entries of the vectors in $S = \{(x_i, y_i)\}_{i=0}^{N-1}$ and given a KP-tree for $\theta \in B_1^d$. One can estimate these numbers with additive error β in time roughly $1/\beta$.

We start with estimating entries of the gradient of the loss function at a given θ:

▶ **Theorem 10.** *Let $\theta \in B_1^d$, and $\beta, \delta > 0$. Suppose we have a KP-tree KP_θ of vector θ and can make quantum queries to $O_{KP_\theta} : |\ell, k\rangle |0\rangle \to |\ell, k\rangle |KP_\theta(\ell, k)\rangle$. One can implement $\tilde{U}_{\nabla L_S} : |j\rangle |0\rangle \to |j\rangle |\Lambda\rangle$ such that for all $j \in \mathbb{Z}_d$, after measuring the state $|\Lambda\rangle$, with probability $\geq 1-\delta$ the first register λ of the outcome will satisfy $|\lambda - \nabla_j L_S(\theta)| \leq \beta$, by using $\tilde{\mathcal{O}}(\frac{\log(1/\delta)}{\beta})$ applications of O_X, $O_X^\dagger$, O_y, $O_y^\dagger$, O_{KP_θ}, $O_{KP_\theta}^\dagger$, and elementary gates.*

Next we show how to estimate the value of the loss function itself at a given θ:

▶ **Theorem 11.** *Let $\theta \in B_1^d$, and $\beta, \delta > 0$. Suppose we have a KP-tree KP_θ of vector θ and can make quantum queries to $O_{KP_\theta} : |\ell, k\rangle |0\rangle \to |\ell, k\rangle |KP_\theta(\ell, k)\rangle$. Then we can implement $\tilde{U}_{L_S} : |0\rangle \to |\Lambda\rangle$ such that after measuring the state $|\Lambda\rangle$, with probability $\geq 1-\delta$ the first register λ of the outcome will satisfy $|\lambda - L_S(\theta)| \leq \beta$, by using $\tilde{\mathcal{O}}(\frac{\log(1/\delta)}{\beta})$ applications of O_X, $O_X^\dagger$, O_y, $O_y^\dagger$, O_{KP_θ}, $O_{KP_\theta}^\dagger$, and elementary gates.*

If we have multiple vectors $\theta^0, \ldots, \theta^{m-1}$, then we can apply the previous theorem conditioned on the index of the vector we care about:

▶ **Corollary 12.** *Let $\theta^0, \theta^1, \ldots, \theta^{m-1} \in B_1^d$, and $\beta, \delta > 0$. Suppose for all $h \in \mathbb{Z}_m$, we have a KP-tree KP_{θ^h} of vector θ^h and can make quantum queries to $O_{KP_\theta} : |h, \ell, k\rangle |0\rangle \to |h, \ell, k\rangle |KP_{\theta^h}(\ell, k)\rangle$. Then we can implement $\tilde{U}_{L_S} : |h\rangle |0\rangle \to |h\rangle |\Lambda\rangle$ such that for all $h \in \mathbb{Z}_m$, after measuring the state $|\Lambda\rangle$, with probability $\geq 1-\delta$ the first register λ of the outcome will satisfy $|\lambda - L_S(\theta^h)| \leq \beta$, by using $\tilde{\mathcal{O}}(\frac{\log(1/\delta)}{\beta})$ applications of O_X, $O_X^\dagger$, O_y, $O_y^\dagger$, O_{KP_θ}, $O_{KP_\theta}^\dagger$, and elementary gates.*

3.3 Quantum algorithms for Lasso with respect to S

In this subsection, we will show how to find an approximate minimizer for Lasso with respect to a given sample set S. The following algorithm simply applies the Frank-Wolfe algorithm to find an ε-minimizer for Lasso with respect to the sample set S given C, a guess for the curvature constant C_{L_S} (which our algorithm does not know in advance). Note that to find an $s \in B_1^d$ such that $\langle s, \nabla L_S(\theta^t)\rangle \leq \min_{s' \in \mathcal{X}} \langle s', \nabla L_S(\theta^t)\rangle + \tau_t C_{L_S}/4$, it suffices to only check

$s \in \{\pm e_0, \ldots, \pm e_{d-1}\}$ because the domain is B_1^d and ∇L_S is a linear function in θ. Also, by Theorem 8, the curvature constant C_{L_S} of loss function L_S is at most 8 because (x_i, y_i) is in $[-1,1]^d \times [-1,1]$ for all $i \in \mathbb{Z}_N$.

Algorithm 2 The algorithm for Lasso with a guess C for the value of the curvature constant.

input : a positive value C; additive error ε;
Let θ^0 be the d-dimensional all-zero vector;
Let $T = 6 \cdot \lceil \frac{C}{\varepsilon} \rceil$;
for $t \leftarrow 0$ **to** T **do**
  $\tau_t = \frac{2}{t+2}$;
  Let $s \in \{\pm e_0, \ldots, \pm e_{d-1}\}$ be such that $\langle \nabla L_S(\theta^t), s \rangle \leq \min_{j' \in \mathbb{Z}_d} -|\nabla_{j'} L_S(\theta^t)| + \frac{C}{8t+16}$;
  $\theta^{t+1} = (1-\tau_t)\theta^t + \tau_t s$;
end
output : θ^T;

It is worth mentioning that Algorithm 2 also outputs an ε-minimizer if its input C equals the curvature constant C_{L_S} approximately instead of exactly. For example, suppose we only know that the curvature constant C_{L_S} is between C and $2C$, where C is the input in Algorithm 2. Then the output of Algorithm 2 is still an ε-minimizer. We can see this by first observing that the error we are allowed to make for the linear subproblem in iteration t is $\frac{C_{L_S}}{4t+8} \geq \frac{C}{8t+16}$, and hence by Theorem 9, after $T = 6 \cdot \lceil \frac{C}{\varepsilon} \rceil$ iterations, the output θ^T is a $\frac{3C}{(T+2)} = \frac{3C}{6 \cdot \lceil C/\varepsilon \rceil + 2}$-minimizer for L_S. Because $\frac{3C}{6 \cdot \lceil C/\varepsilon \rceil + 2} \leq \varepsilon$, the output θ^T is therefore an ε-minimizer.

In the Lasso case, we do not know how to find a positive number C such that $C_{L_S} \in [C, 2C]$, but we know $C_{L_S} \leq 8$ by Theorem 8. Hence we can try different intervals of possible values for C_{L_S}: we apply Algorithm 2 with different input $C = 8, 4, 2, 1, 1/2, \ldots, 2^{-\lceil \log(1/\varepsilon) \rceil}$, and then we collect all outputs of Algorithm 2 with those different inputs, as candidates. After that, we compute the objective values of all those candidates, and output the one with minimum objective value. If $C_{L_S} \in (\varepsilon, 8]$, then at least one of the values we tried for C will be within a factor of 2 of the actual curvature constant C_{L_S}. Hence one of our candidates is an ε-minimizer.

However, we also need to deal with the case that $C_{L_S} \leq \varepsilon$. In this case, we consider the "one-step" version of the Frank-Wolfe algorithm, where the number of iterations is 1. But now we do not estimate $\langle \nabla L_S(\theta^t), s \rangle$ anymore (i.e., we do not solve linear subproblems anymore). We find that the only possible directions are the vertices of the ℓ_1-ball, and θ^0 is the all-zero vector, implying that θ^1, the output of one-step Frank-Wolfe, must be in $I = \{\pm e_0/3, \ldots, \pm e_{d-1}/3\}$ by the update rule of Frank-Wolfe. Besides, $C_{L_S} \leq \varepsilon$ implies that θ^1 is a $\frac{3C_{L_S}}{1+2} \leq \varepsilon$-minimizer for Lasso. Hence we simply output a $v = \arg\min_{v' \in I} L_S(v')$ if $C_{L_S} \leq \varepsilon$.

Combining the above arguments gives the following algorithm:

▶ **Theorem 13.** *Let $S = \{(x_i, y_i)\}_{i=0}^{N-1}$ be the given sample set stored in QROM. For each $\varepsilon \in (0, 0.5)$, there exists a bounded-error quantum algorithm that finds an ε-minimizer for Lasso w.r.t. sample set S using $\tilde{\mathcal{O}}(\frac{\sqrt{d}}{\varepsilon^2})$ time and $\tilde{\mathcal{O}}(\frac{1}{\varepsilon})$ QRAM and classical space.*

Proof. We will implement Algorithm 3 in $\tilde{\mathcal{O}}(\frac{\sqrt{d}}{\varepsilon^2})$ time and $\tilde{\mathcal{O}}(\frac{1}{\varepsilon})$ QRAM space. Below we analyze its different components.

Algorithm 3 The algorithm for Lasso.

input : ε;
Let $v \in \{\pm e_0/3, \ldots, \pm e_{d-1}/3\}$ be such that $L_S(v) - \min_{j\in\mathbb{Z}_d} L_S(\pm e_j/3) \le \varepsilon/10$;
Let candidate set $A = \{v\}$;
for $C \leftarrow 8, 4, 2, 1, \frac{1}{2}, \ldots, 2^{-\lceil\log(1/\varepsilon)\rceil-1}$ **do**
  RUN Algorithm 2 with inputs C and $\varepsilon/10$;
  ADD the output of Algorithm 2 to A;
end
output : $\arg\min_{w\in A} L_S(w)$;

3.3.1 Analysis of Algorithm 2

We first show that we can implement Algorithm 2 in $\tilde{\mathcal{O}}(\frac{\sqrt{d}}{\varepsilon^2})$ time. Because $C_{L_S} \le 8$ (Theorem 8), the number of iterations for Algorithm 2 with input $C = C_{L_S}$ is at most $6 \cdot \lceil\frac{8}{\varepsilon}\rceil$. However, as we mentioned above, we don't know how large C_{L_S} is exactly, so we try all possible inputs (of Algorithm 2) in Algorithm 3. Note that for every input $C \in \{8, 4, 2, 1, \frac{1}{2}, \ldots, 2^{-\lceil\log(1/\varepsilon)\rceil-1}\}$ and for every number of iterations $t \in \{1, \ldots, 6 \cdot \lceil\frac{C}{\varepsilon}\rceil\}$, $\frac{C}{4t+8}$ is at least $\frac{\varepsilon}{10}$, so it suffices to ensure that in each iteration in each of our runs of Algorithm 2, the additive error for the approximate linear subproblem is $\le \frac{\varepsilon}{10}$.

Suppose we have KP_{θ^t} for each iteration t of Algorithm 2, and suppose we can make queries to $O_{KP_{\theta^t}}$, then by Theorem 10, one can implement $\tilde{U}_{\nabla L_S} : |j\rangle|0\rangle \to |j\rangle|\Lambda\rangle$ such that for all $j \in \mathbb{Z}_d$, after measuring the state $|\Lambda\rangle$, with probability $\ge 1 - \frac{\varepsilon^2}{2d\cdot 10^{20}\cdot\log^6(1/\varepsilon)}$ the first register λ of the measurement outcome will satisfy $|\lambda - \nabla_j L_S(\theta)| \le \frac{\varepsilon}{20}$, by using $\tilde{\mathcal{O}}(\frac{\log(d/\varepsilon)}{\varepsilon})$ time and queries to $O_{KP_{\theta^t}}$, $O^\dagger_{KP_{\theta^t}}$. Then by Theorem 1, with failure probability at most $\frac{\varepsilon}{10000\log(1/\varepsilon)}$, one can find $s \in \{\pm e_0, \ldots, \pm e_{d-1}\}$ such that $\langle\nabla L_S(\theta^t), s\rangle \le \min_{j'\in\mathbb{Z}_d} -|\nabla_{j'} L_S(\theta^t)| + 2\cdot\frac{\varepsilon}{20}$, by using $\tilde{\mathcal{O}}(\sqrt{d}\cdot\log(1/\varepsilon))$ applications of $\tilde{U}_{\nabla L_S}$ and $\tilde{U}^\dagger_{\nabla L_S}$, and $\tilde{\mathcal{O}}(\sqrt{d})$ elementary gates.

For each iteration t in Algorithm 2, we also maintain KP_{θ^t} and hence we can make quantum queries to $O_{KP_{\theta^t}}$. The cost for constructing KP_{θ^0} and the cost for updating KP_{θ^t} to $KP_{\theta^{t+1}}$ is $\tilde{\mathcal{O}}(1)$ for both time and space by (shown in our full version). Moreover, the total number of iterations T is at most $6\cdot\lceil\frac{8}{\varepsilon}\rceil$ in Algorithm 2 because $C_{L_S} \le 8$, and hence the space cost for maintaining KP_{θ^t} and implementing $O_{KP_{\theta^t}}$ is $\tilde{\mathcal{O}}(\frac{1}{\varepsilon})$ bits. Hence we can implement Algorithm 2 with failure probability at most $\lceil\frac{8}{\varepsilon}\rceil\cdot\frac{6\varepsilon}{10000\log(1/\varepsilon)}$ using $\tilde{\mathcal{O}}(\frac{\sqrt{d}}{\varepsilon^2})$ time and $\tilde{\mathcal{O}}(\frac{1}{\varepsilon})$ bits of QRAM and classical space.

3.3.2 Analysis of Algorithm 3

Now we show how to implement Algorithm 3 with failure probability at most 1/10 using $\tilde{\mathcal{O}}(\frac{\sqrt{d}}{\varepsilon^2})$ time. By Corollary 12, one can implement $\tilde{U}_{L_S} : |j\rangle|0\rangle \to |j\rangle|\Lambda\rangle$ such that for all $j \in \mathbb{Z}_d$, after measuring the state $|\Lambda\rangle$, with failure probability at most $\frac{1}{2d\cdot 10^{16}}$ the first register λ of the outcome will satisfy $|\lambda - L_S(e_j/3)| \le \varepsilon/20$ using $\tilde{\mathcal{O}}(\frac{1}{\varepsilon})$ time. Then by Theorem 1, with failure probability at most $0.0001 + 1000\cdot\log(1000)\sqrt{\frac{2d}{2d\cdot 10^{16}}} \le \frac{2}{1000}$ we can find $v \in \{\pm e_0/3, \ldots, \pm e_{d-1}/3\}$ such that $L_S(v) - \min_{j\in\mathbb{Z}_d} L_S(\pm e_j/3) \le 2\cdot\varepsilon/20 = \varepsilon/10$ by using $\tilde{\mathcal{O}}(\sqrt{d})$ applications of $\tilde{U}_{L_S}$ and $\tilde{U}^\dagger_{L_S}$ and $\tilde{\mathcal{O}}(\sqrt{d})$ elementary gates, hence $\tilde{\mathcal{O}}(\frac{\sqrt{d}}{\varepsilon})$ time.

Because Algorithm 3 runs Algorithm 2 $\lceil\log(1/\varepsilon)\rceil$ times and each run fails with probability at most $\lceil\frac{8}{\varepsilon}\rceil\cdot\frac{6\varepsilon}{10000\log(1/\varepsilon)}$, the candidate set A, with failure probability $\lceil\frac{8}{\varepsilon}\rceil\cdot\frac{6\varepsilon}{10000\log(1/\varepsilon)}\cdot\lceil\log(1/\varepsilon)\rceil + \frac{2}{1000} \le \frac{1}{20}$, contains an $\frac{\varepsilon}{10}$-minimizer. To output $\arg\min_{w\in A} L_S(w)$, we use

Theorem 11 to evaluate $L_S(w)$ for all $w \in A$ with additive error $\frac{\varepsilon}{10}$ with failure probability at most $\frac{1}{40\log(1/\varepsilon)}$, and hence we find an $\varepsilon/10$-minimizer among A with probability at least $1 - 1/20 - \lceil \log(1/\varepsilon) \rceil \cdot \frac{1}{40\log(1/\varepsilon)} \geq 0.9$. Because the candidate set A contains an $\frac{\varepsilon}{10}$-minimizer for Lasso, the $\frac{\varepsilon}{10}$-minimizer among A is therefore an ε-minimizer for Lasso. The QRAM and classical space cost for each run is at most $\tilde{\mathcal{O}}(\frac{1}{\varepsilon})$ because the space cost for Algorithm 2 is $\tilde{\mathcal{O}}(\frac{1}{\varepsilon})$. Hence the total cost for implementing Algorithm 3 is $\tilde{\mathcal{O}}(\frac{\sqrt{d}}{\varepsilon^2})$ time and $\tilde{\mathcal{O}}(\frac{1}{\varepsilon})$ bits of QRAM and classical space. ◀

3.4 Quantum algorithms for Lasso with respect to $\mathcal{D}$

In the previous subsection, we showed that we can find an ε-minimizer for Lasso with respect to sample set S. Here we show how we can find an ε-minimizer for Lasso with respect to distribution $\mathcal{D}$. First sample a set S of $N = \tilde{\mathcal{O}}((\log d)/\varepsilon^2)$ i.i.d. samples from $\mathcal{D}$, which is the input that will be stored in QROM, and then find an $\varepsilon/2$-minimizer for Lasso with respect to S by Theorem 13. By Theorem 4, with high probability, an $\varepsilon/2$-minimizer for Lasso with respect to S will be an ε-minimizer for Lasso with respect to distribution $\mathcal{D}$. Hence we obtain the following corollary:

▶ **Corollary 14.** *Let $S = \{(x_i, y_i)\}_{i=0}^{N-1}$ be the given sample set, sampled i.i.d. from $\mathcal{D}$. For arbitrary $\varepsilon > 0$, if $N = \tilde{\mathcal{O}}(\frac{\log d}{\varepsilon^2})$, then there exists a bounded-error quantum algorithm that finds an ε-minimizer for Lasso w.r.t. distribution $\mathcal{D}$ using $\tilde{\mathcal{O}}(\frac{\sqrt{d}}{\varepsilon^2})$ queries to O_X, O_y and elementary gates, and using $\tilde{\mathcal{O}}(\frac{1}{\varepsilon})$ space (QRAM and classical bits).*

In our full version on arXiv we show that we can also avoid the usage of QRAM in the above corollary with $\tilde{\mathcal{O}}(1/\varepsilon)$ extra overhead.

▶ **Corollary 15.** *Let $S = \{(x_i, y_i)\}_{i=0}^{N-1}$ be the given sample set, sampled i.i.d. from $\mathcal{D}$. For arbitrary $\varepsilon > 0$, if $N = \tilde{\mathcal{O}}(\frac{\log d}{\varepsilon^2})$, then there exists a bounded-error quantum algorithm that finds an ε-minimizer for Lasso w.r.t. $\mathcal{D}$ using $\tilde{\mathcal{O}}(\frac{\sqrt{d}}{\varepsilon^3})$ queries to O_X, O_y and elementary gates, and using $\tilde{\mathcal{O}}(\frac{1}{\varepsilon})$ classical bits.*

4 Quantum query lower bounds for Lasso

In this section we prove a quantum lower bound of $\Omega(\sqrt{d}/\varepsilon^{1.5})$ queries for Lasso. To show such a lower bound, we define a certain set-finding problem, and show how it can be solved by an algorithm for Lasso. After that, we show that the worst-case set-finding problem can be seen as the composition of two problems, which have query complexities $\Omega(\sqrt{d/\varepsilon})$ and $\Omega(1/\varepsilon)$, respectively. Then the composition property of the quantum adversary bound implies a $\Omega(\sqrt{d/\varepsilon} \cdot 1/\varepsilon) = \Omega(\sqrt{d}/\varepsilon^{1.5})$ query lower bound for Lasso.

4.1 Finding a hidden set W using a Lasso solver

Let $p \in (0, 1/2)$, $W \subset \mathbb{Z}_d$, and $\overline{W} = \mathbb{Z}_d \setminus W$. Define the distribution $\mathcal{D}_{p,W}$ over $(x, y) \in \{-1, 1\}^d \times \{-1, 1\}$ as follows. For each $j' \in \overline{W}$, $x_{j'}$ is generated according to $\Pr[x_{j'} = 1] = \Pr[x_{j'} = -1] = 1/2$, and for each $j \in W$, x_j is generated according to $\Pr[x_j = 1] = 1/2 + p$. And y is generated according to $\Pr[y = 1] = 1$. The goal of the distributional set-finding problem $\mathrm{DSF}_{\mathcal{D}_{p,W}}$ with respect to $\mathcal{D}_{p,W}$ is to output a set $\tilde{W}$ such that $|\tilde{W} \Delta W| \leq w/200$, given M samples from $\mathcal{D}_{p,W}$. One can think of the $M \times d$ matrix of samples as "hiding" the set W: the columns corresponding to $j \in W$ are likely to have more 1s than -1s, while the columns corresponding to $j \in \overline{W}$ have roughly as many 1s as -1s. A Lasso-solver can help us to find the hidden set W approximately. Precisely, algorithms that find an $\varepsilon/8000$-minimizer for Lasso with respect to $\mathcal{D}_{p,W}$ can also find a set $\tilde{W} \subset \mathbb{Z}_d$ such that $|W \Delta \tilde{W}| \leq w/200$.

▶ **Theorem 16.** *Let $\varepsilon \in (2/d, 1/100)$, w be eitehr $\lfloor 1/\varepsilon \rfloor$ or $\lfloor 1/\varepsilon \rfloor - 1$, $p = 1/(2\lfloor 1/\varepsilon \rfloor)$, and $W \subset \mathbb{Z}_d$ be a set of size w. Let θ be an $\varepsilon/8000$-minimizer for Lasso w.r.t. $\mathcal{D}_{p,W}$. Then the set $\tilde{W}$ that contains the indices of the entries of θ whose absolute value is $\geq \varepsilon/3$ satisfies $|W \Delta \tilde{W}| \leq w/200$.*

4.2 Worst-case quantum query lower bound for the set-finding problem

Here we will define the worst-case set-finding problem and then provide a quantum query lower bound for it. Before we step into the query lower bound for the worst-case set-finding problem, we have to introduce the lower bounds for the following problems first.

consider the *exact set-finding problem*: given input $x = x_0 \dots x_{d-1} \in \{0,1\}^d$ with at most w 1s, find the set W of all indices j with $x_j = 1$ (equivalently, learn x). To see the query lower bound for this problem, we consider the identity function where both domain and codomain are $\mathcal{Z} = \{z \in \{0,1\}^d : |z| = w\}$, and give a lower bound for computing this. If we can compute the identity function, then we can simply check the output string $x_0, x_1, \dots, x_{d-1}$ and collect all indices j with $x_j = 1$.

▶ **Theorem 17.** *Let w be an integer satisfying $0 < w \leq d/2$, $W \subset \mathbb{Z}_d$ with size w, and $x \in \{0,1\}^d$ such that $x_j = 1$ if $j \in W$ and $x_{j'} = 0$ if $j' \in \overline{W}$. Suppose we have query access to x. Then every quantum bounded-error algorithm to find W makes at least $\frac{1}{8}\sqrt{dw}$ queries.*

Using the same method, we give a lower bound for the *approximate* set-finding problem $\mathrm{ASF}_{d,w}$, which is to find a set $\tilde{W} \subset \mathbb{Z}_d$ such that $|W \Delta \tilde{W}| \leq w/200$. The intuition is that if we could find such a $\tilde{W}$ then we can "correct" it to W itself using a small number of Grover searches, so finding a good approximation $\tilde{W}$ is not much easier than finding W itself.

▶ **Theorem 18.** *Let w be an integer satisfying $0 < w \leq d/2$, $W \subset \mathbb{Z}_d$ with size w, and $x \in \{0,1\}^d$ such that $x_j = 1$ if $j \in W$ and $x_{j'} = 0$ if $j' \in \overline{W}$. Suppose we have query access to x. Then every bounded-error quantum algorithm that outputs $\tilde{W} \subset \mathbb{Z}_d$ satisfying $|W \Delta \tilde{W}| \leq w/200$ makes $\Omega(\sqrt{dw})$ queries.*

Next we consider the *Hamming-weight distinguisher problem* $\mathrm{HD}_{\ell,\ell'}$: given a $z \in \{0,1\}^N$ of Hamming weight ℓ or ℓ', distinguish these two cases. The adversary bound gives the following bound (a special case of Nayak and Wu [35] based on the polynomial method [10]).

▶ **Theorem 19.** *Let $N \in 2\mathbb{Z}_+$, $z \in \{0,1\}^N$, and $p \in (0, 0.5)$ be multiple of $1/N$. Suppose we have query access to z. Then every bounded-error quantum algorithm that computes $HD_{\frac{N}{2},N(\frac{1}{2}+p)}$ makes $\Omega(1/p)$ queries.*

The above theorem implies a lower bound of $\Omega(1/p)$ queries for $\mathrm{HD}_{\frac{N}{2},N(\frac{1}{2}+p)}$. One can also think of the input bits as ± 1 and in this case, the goal is to distinguish whether the entries add up to 0 or to $2pN$. For convenience, we abuse the notation $\mathrm{HD}_{\frac{N}{2},N(\frac{1}{2}+p)}$ also for the problem with ± 1 inputs. Now we are ready to prove a lower bound for the *worst-case set-finding problem* $\mathrm{WSF}_{d,w,p,N}$: given a matrix $X \in \{-1,1\}^{N \times d}$ where each column-sum is either $2pN$ or 0, the goal is to find a set $\tilde{W} \subset \mathbb{Z}_d$ such that $|\tilde{W} \Delta W| \leq w/200$, where W is the set of indices for those columns whose entries add up to $2pN$ and $w = |W|$. One can see that this problem is actually a composition of the approximate set-finding problem and the Hamming-weight distinguisher problem. Composing the relational problem $\mathrm{ASF}_{d,w}$ with d valid inputs of $\mathrm{HD}_{\frac{N}{2},N(\frac{1}{2}+p)}$, exactly w of which evaluate to 1, we can see that the d-bit string given by the values of $\mathrm{HD}_{\frac{N}{2},N(\frac{1}{2}+p)}$ on these d inputs, is a valid input for $\mathrm{ASF}_{d,w}$. In other words, the set of valid inputs for $\mathrm{WSF}_{d,w,p,N}$, or equivalently, the set of valid inputs for the composed problem $\mathrm{ASF}_{d,w} \circ (\mathrm{HD}_{\frac{N}{2},N(\frac{1}{2}+p)})^d$ is

$$\{(x^{(1)},\dots,x^{(d)}) \in \mathcal{P}^d : |\mathrm{HD}_{\frac{N}{2},N(\frac{1}{2}+p)}(x^{(1)}) \dots \mathrm{HD}_{\frac{N}{2},N(\frac{1}{2}+p)}(x^{(d)})| = w\},$$

where $\mathcal{P} = \{x \in \{0,1\}^N : |x| \in \{N/2, N/2 + pN\}\}$. The next theorem by Belovs and Lee shows that the quantum query complexity of the composed problem $\mathrm{ASF}_{d,w} \circ (\mathrm{HD}_{\frac{N}{2},\frac{N+2pN}{2}})^d$ is at least the product of the complexities of the two composing problems:

▶ **Theorem 20** ([12], Corollary 27). *Let $f \subseteq S \times T$, with $S \subseteq \{0,1\}^d$, be a relational problem with bounded-error quantum query complexity L. Assume that f is efficiently verifiable, that is given some $t \in T$ and oracle access to $x \in S$, there exists a bounded-error quantum algorithm that verifies whether $(x,t) \in f$ using $o(L)$ queries to x. Let $D \subseteq \{0,1\}^N$ and $g : D \to \{0,1\}$ be a Boolean function whose bounded-error quantum query complexity is Q. Then the bounded-error quantum query complexity of the relational problem $f \circ g^d$, restricted to inputs $x \in \{0,1\}^{dN}$ such that $g^d(x) \in S$, is $\Omega(LQ)$.*

Applying Theorem 20 with the lower bounds of Theorem 19 and Theorem 18, we obtain:

▶ **Corollary 21.** *Let $N \in 2\mathbb{Z}_+$ and $p \in (0, 0.5)$ be an integer multiple of $1/N$. Given a matrix $X \in \{-1,+1\}^{N\times d}$ such that there exists a set $W \subseteq \mathbb{Z}_d$ with size w and*

- *For every $j \in W$, $\sum_{i\in\mathbb{Z}_N} X_{ij} = 2pN$.*
- *For every $j' \in \overline{W}$, $\sum_{i\in\mathbb{Z}_N} X_{ij'} = 0$.*

Suppose we have query access to X. Then every bounded-error quantum algorithm that computes $\tilde{W}$ such that $|W \Delta \tilde{W}| \le w/200$, uses $\Omega(\sqrt{dw}/p)$ queries to O_X.

4.3 Worst-case to average-case reduction for the set-finding problem

Our goal is to prove a lower bound for Lasso algorithms that have high success probability w.r.t. the distribution $\mathcal{D}_{p,W}$, yet the lower bound of the previous subsection is for *worst-case* instances. In this subsection, we will connect these by providing a worst-case to average-case reduction for the set-finding problem. After that, by simply combining with the query lower bound for the worst-case set-finding problem and the reduction from the distributional set-finding problem to Lasso, we obtain an $\Omega(\sqrt{d}/\varepsilon^{1.5})$ query lower bound for Lasso.

▶ **Theorem 22.** *Let $N \in 2\mathbb{Z}_+$, $p \in (0, 0.5)$ be an integer multiple of $1/N$, w be a natural number between 2 to $d/2$, and M be a natural number. Suppose $X \in \{-1,+1\}^{N\times d}$ is a valid input for $\mathrm{WSF}_{d,w,p,N}$, and let $W \subset \mathbb{Z}_d$ be the set of the w indices of the columns of X whose entries add up to $2pN$. Let $R \in \mathbb{Z}_N^{M\times d}$ be a matrix whose entries are i.i.d. samples from $\mathcal{U}_N$, and define $X' \in \{-1,1\}^{M\times d}$ as $X'_{ij} = X_{R_{ij}j}$. Then the M vectors $(X'_i, 1)$, where X'_i is the ith row of X' and $i \in \mathbb{Z}_M$, are i.i.d. samples from $\mathcal{D}_{p,W}$.*

Proof. Every entry of R is a sample from $\mathcal{U}_N$, so $X_{R_{ij}j}$ is uniformly chosen from the entries of the jth column of X. Moreover, because every valid input W for $\mathrm{WSF}_{d,w,p,N}$ satisfies that for every $j \in W$, $\Pr_{i\sim\mathcal{U}_N}[X_{ij} = 1] = 1/2 + p$ and for every $j' \in \overline{W}$, $\Pr_{i\sim\mathcal{U}_N}[X_{ij'} = 1] = 1/2$, we know $(X'_i, 1)$ is distributed as $D_{p,W}$. ◀

The above theorem tells us that we can convert an instance of $\mathrm{WSF}_{d,w,p,N}$ to an instance of $\mathrm{DSF}_{\mathcal{D}_{p,W}}$. Note that we can produce matrix R offline and therefore we can construct the oracle $O_{X'} : |i\rangle|j\rangle|0\rangle \to |i\rangle|j\rangle|X_{R_{ij}j}\rangle$ using 1 query to $O_X : |i\rangle|j\rangle|0\rangle \to |i\rangle|j\rangle|X_{ij}\rangle$ (and some other elementary gates, which is irrelevant to the number of queries). Also observe that if $M = 10^{12} \cdot \lceil \log d \rceil \cdot \lfloor 1/\varepsilon \rfloor^2 = \mathcal{O}((\log d)/\varepsilon^2)$ and hence $S' = \{(X'_i, 1)\}_{i=0}^{M-1}$ is a sample

set with M i.i.d. samples from $\mathcal{D}_{p,W}$, then by Theorem 4, with probability $\geq 9/10$, an $\varepsilon/16000$-minimizer for Lasso with respect to S' is also an $\varepsilon/8000$-minimizer for Lasso with respect to distribution $\mathcal{D}_{p,W}$. By Theorem 16, an $\varepsilon/8000$-minimizer for Lasso with respect to distribution $\mathcal{D}_{p,W}$ can be used to output a set $\tilde{W} \subset \mathbb{Z}_d$ such that $|\tilde{W} \Delta W| \leq w/200$, where W is the set of indices for those columns of X whose entries add up to $2pN$. Hence we have a reduction from the worst-case set-finding problem to Lasso. By the reduction above and by plugging $w = \lfloor 1/\varepsilon \rfloor$ and $p = 1/(2\lfloor 1/\varepsilon \rfloor)$ in Corollary 21 (and N an arbitrary natural number such that $pN \in \mathbb{N}$), we obtain a lower bound of $\Omega(\sqrt{d}/\varepsilon^{1.5})$ queries for $\mathrm{WSF}_{d,w,p,N}$, and hence the main result of this section: a lower bound of $\Omega(\sqrt{d}/\varepsilon^{1.5})$ for Lasso.

▶ **Corollary 23.** *Let $\varepsilon \in (2/d, 1/100)$, $w = \lfloor 1/\varepsilon \rfloor$, $p = 1/(2\lfloor 1/\varepsilon \rfloor)$, and $W \subset \mathbb{Z}_d$ with size w. Every bounded-error quantum algorithm that computes an ε-minimizer for Lasso w.r.t. $\mathcal{D}_{p,W}$ uses $\Omega(\sqrt{d}/\varepsilon^{1.5})$ queries.*

4.4 Classical lower bound for Lasso

In the full version of this paper on arXiv we show how this quantum lower bound approach can be modified to prove, for the first time, a lower bound of $\tilde{\Omega}(d/\varepsilon^2)$ on the classical query complexity of Lasso. This lower bound is optimal up to logarithmic factors.

5 Quantum query lower bound for Ridge

Recall that Ridge's setup assumes the vectors in the sample set are normalized in ℓ_2 rather than ℓ_∞ as in Lasso. We modify the distribution to $\mathcal{D}'_{p,W}$ over $(x, y) \in \{-1/\sqrt{d}, 1/\sqrt{d}\}^d \times \{-1, 1\}$ as follows. Let $p \in (0, 1/4)$, $W \subset \mathbb{Z}_d$, and $\overline{W} = \mathbb{Z}_d \setminus W$. For each $j' \in \overline{W}$, $x_{j'}$ is generated according to $\Pr[x_{j'} = -1/\sqrt{d}] = 1/2 + p$; for each $j \in W$, x_j is generated according to $\Pr[x_j = 1/\sqrt{d}] = 1/2 + p$; y is generated according to $\Pr[y = 1] = 1$. Now again we want to solve a distributional set-finding problem with respect to $\mathcal{D}'_{p,W}$, given M samples from $\mathcal{D}'_{p,W}$. Similar to the Lasso case, one can think of the $M \times d$ matrix of samples as "hiding" the set W: the columns corresponding to $j \in W$ are likely to have more $1/\sqrt{d}$'s than $-1/\sqrt{d}$'s, while the columns corresponding to $j \in \overline{W}$ are likely to have more $-1/\sqrt{d}$'s than $1/\sqrt{d}$'s.

In this section let $\theta^* = \sum_{j \in \mathbb{Z}_d} \frac{e_j}{\sqrt{d}} (-1)^{[j \in \overline{W}]}$ and note that for every $\theta \in \mathbb{R}^d$,

$$\begin{aligned}
L_{\mathcal{D}'_{p,W}}(\theta) =& \mathbb{E}_{(x,y)\sim\mathcal{D}'_{p,W}}[\langle \theta, x\rangle^2] - 2\mathbb{E}_{(x,y)\sim\mathcal{D}'_{p,W}}[\langle \theta, x\rangle] + 1 \\
=& (\mathbb{E}_{(x,y)\sim\mathcal{D}'_{p,W}}[\langle \theta, x\rangle^2] - \mathbb{E}_{(x,y)\sim\mathcal{D}'_{p,W}}[\langle \theta, x\rangle]^2) \\
&+ \mathbb{E}_{(x,y)\sim\mathcal{D}'_{p,W}}[\langle \theta, x\rangle]^2 - 2\mathbb{E}_{(x,y)\sim\mathcal{D}'_{p,W}}[\langle \theta, x\rangle] + 1 \\
=& \|\theta\|_2^2 \cdot (1 - 4p^2)/d + (\mathbb{E}_{(x,y)\sim\mathcal{D}'_{p,W}}[\langle \theta, x\rangle] - 1)^2 \\
=& \|\theta\|_2^2 \cdot (1 - 4p^2)/d + (2p\langle \theta, \theta^*\rangle - 1)^2,
\end{aligned}$$

where the third equality holds because $\langle \theta, x\rangle$ is a sum of independent random variables and hence its variance is the sum of the variances of the terms $\theta_i x_i$ (which are $\theta_i^2(1 - 4p^2)/d$).

Next we show that θ^* is the minimizer for Ridge with respect to $\mathcal{D}'_{p,W}$.

▶ **Theorem 24.** *Let $w = \lfloor d/2 \rfloor$ and $W \subset \mathbb{Z}_d$ be a set of size w, and let $\varepsilon \in (1000/d, 1/10000)$ and $p = 1/\lfloor 1/\varepsilon \rfloor$. Then $\theta^* = \sum_{j \in \mathbb{Z}_d} \frac{e_j}{\sqrt{d}} (-1)^{[j \in \overline{W}]}$ is the minimizer for Ridge w.r.t. $\mathcal{D}'_{p,W}$.*

Proof. Let $\theta = \sum_{j\in\mathbb{Z}_d} \theta_j e_j \in B_2^d$ be a minimizer. We want to show $\theta_j = \theta_j^*$ for every $j \in \mathbb{Z}_d$. Note that if $\theta_j \cdot (-1)^{[j\in\overline{W}]} < 0$, then we can flip the sign of θ_j to get a smaller objective value, that is,

$$\begin{aligned} L_{\mathcal{D}'_{p,W}}(\theta') - L_{\mathcal{D}'_{p,W}}(\theta) &= (\|\theta'\|_2^2 - \|\theta\|_2^2)\cdot(1-4p^2)/d + (2p\langle\theta',\theta^*\rangle - 1)^2 - (2p\langle\theta,\theta^*\rangle - 1)^2 \\ &= (2p\langle\theta'-\theta,\theta^*\rangle)(2p\langle\theta'+\theta,\theta^*\rangle - 2) \\ &= (-4p\theta_j\cdot(-1)^{[j\in\overline{W}]})(2p\langle\theta'+\theta,\theta^*\rangle - 2) < 0, \end{aligned}$$

where $\theta' = \sum_{k\in\mathbb{Z}_d\setminus\{j\}} \theta_k e_k - \theta_j e_j$, and the last inequality is because $-4p\theta_j\cdot(-1)^{[j\in\overline{W}]} > 0$ and $2p\langle\theta'+\theta,\theta^*\rangle \le 2p\|\theta'+\theta\|_2\cdot\|\theta^*\|_2 \le 4p \le 1$. Since θ was assumed a minimizer, for all $j\in\mathbb{Z}_d$ the sign of θ_j must be $(-1)^{[j\in\overline{W}]}$.

Second, we show that we must have $|\theta_0| = |\theta_1| = \cdots = |\theta_{d-1}|$. Suppose, towards a contradiction, that this is not the case. Consider $\theta' = \sum_{j\in\mathbb{Z}_d} ue_j\cdot(-1)^{[j\in\overline{W}]}$, where $u = \sqrt{\sum_{j\in\mathbb{Z}_d}|\theta_j|^2/d}$. We have

$$\begin{aligned} L_{\mathcal{D}'_{p,W}}(\theta') - L_{\mathcal{D}'_{p,W}}(\theta) &= (2p\langle\theta'-\theta,\theta^*\rangle)(2p\langle\theta'+\theta,\theta^*\rangle - 2) \\ &= (2p/\sqrt{d})\cdot(du - \sum_{j\in\mathbb{Z}_d}|\theta_j|)\cdot(2p\langle\theta'+\theta,\theta^*\rangle - 2) < 0. \end{aligned}$$

The last inequality holds because again $2p\langle\theta'+\theta,\theta^*\rangle \le 4p \le 1$ and in addition,

$$d\cdot\sum_{j\in\mathbb{Z}_d}|\theta_j|^2 > (\sum_{j\in\mathbb{Z}_d}|\theta_j|)^2$$

by the Cauchy–Schwarz inequality (which is strict if the $|\theta_j|$ are not all equal). Hence if θ is indeed a minimizer, then its entries must all have the same magnitude.

Now we know a minimizer θ must be in the same direction as θ^*, we just don't know yet that the magnitudes of its entries are $1/\sqrt{d}$. Suppose $\|\theta\|_2 = u \le 1$ and $\theta = u\cdot\theta^*$, then

$$L_{\mathcal{D}'_{p,W}}(\theta) = \|\theta\|_2^2\cdot(1-4p^2)/d + (2p\langle\theta,\theta^*\rangle - 1)^2 = (u^2(1-4p^2)/d + (2pu-1)^2).$$

The discriminant of $f(u) = u^2(1-4p^2)/d + (2pu-1)^2$ is less than 0, and $u = \frac{2p}{4p^2+(1-4p^2)/d}$ is the global minimizer of $f(u)$. Note that $u = \frac{2p}{4p^2+(1-4p^2)/d} > 1$, and hence $f(1) \le f(u)$ for every $u \le 1$. Therefore we know θ^* is the minimizer for Ridge with respect to $\mathcal{D}'_{p,W}$. ◀

Next we show that the inner product between the minimizer and an approximate minimizer for Ridge will be close to 1.

▶ **Theorem 25.** *Let $w = \lfloor d/2\rfloor$, $W \subset \mathbb{Z}_d$ be a set of size w, $\varepsilon \in (1000/d, 1/10000)$, and $p = 1/\lfloor 1/\varepsilon\rfloor$. Suppose $\theta \in B_2^d$ is an $\varepsilon/1000$-minimizer for Ridge w.r.t. $\mathcal{D}'_{p,W}$. Then $\langle\theta,\theta^*\rangle \ge 0.999$.*

Proof. Because θ is an $\varepsilon/1000$-minimizer, we have

$$\begin{aligned} &0.001\varepsilon \ge L_{\mathcal{D}'_{p,W}}(\theta) - L_{\mathcal{D}'_{p,W}}(\theta^*) = (1-4p^2)\cdot(\|\theta\|_2^2 - 1)/d + (2p\langle\theta,\theta^*\rangle - 1)^2 - (2p-1)^2 \\ &\implies 2p\langle\theta,\theta^*\rangle \ge 1 - \sqrt{1-4p+4p^2+0.001\varepsilon - (1-4p^2)\cdot(\|\theta\|_2^2-1)/d}. \end{aligned}$$

Letting $z = 4p - 4p^2 - 0.001\varepsilon + (1-4p^2)\cdot(\|\theta\|_2^2 - 1)/d$, we have

$$\begin{aligned} 2p\langle\theta,\theta^*\rangle \geq& 1-\sqrt{1-z} \geq 1-(1-z/2) = z/2 \\ =& 2p - 2p^2 + (1-4p^2)\cdot(\|\theta\|_2^2-1)/d - 0.001\varepsilon, \end{aligned}$$

where the second inequality holds because $z \in (0,1)$. Dividing both sides by $2p$, we have

$$\langle\theta,\theta^*\rangle \geq 1 - p + (1-4p^2)\cdot(\|\theta\|_2^2-1)/(2pd) - 0.0005\varepsilon/p.$$

Because $\theta \in B_2^d$, $p = 1/\lfloor 1/\varepsilon \rfloor$, and $\varepsilon \in (1000/d, 1/10000)$, we get $\langle\theta,\theta^*\rangle \geq 0.999$. ◀

Combining the above theorem with the following theorem, we can see how to relate the entries of an approximate minimizer for Ridge with respect to $\mathcal{D}'_{p,W}$ to the elements of the hidden set W.

▶ **Theorem 26.** *Suppose $\theta \in B_2^d$ satisfies $\langle\theta,\theta^*\rangle \geq 1 - 0.001$. Then $\#\{j \in \mathbb{Z}_d \mid \theta_j \cdot \theta^*_j \leq 0\} \leq d/500$.*

Proof. If $\theta_j \cdot \theta^*_j \leq 0$ then $|\theta_j - \theta^*_j| \geq |\theta^*_j| = \frac{1}{\sqrt{d}}$, hence using Theorem 25 we have

$$\begin{aligned} \frac{1}{d}\#\{j \in \mathbb{Z}_d \mid \theta_j\cdot\theta^*_j \leq 0\} \leq \|\theta-\theta^*\|_2^2 &= \|\theta\|_2^2 + \|\theta^*\|_2^2 - 2\langle\theta,\theta^*\rangle \\ &\leq 2 - 2(1-0.001) = 1/500. \end{aligned}$$

◀

We know $\theta^* = \sum_{j\in\mathbb{Z}_d} \frac{e_j}{\sqrt{d}}(-1)^{[j\in\overline{W}]}$, so by looking at the signs of entries of θ, we can find an index set $\tilde{W} = \{j \in \mathbb{Z}_d : \theta_j > 0\}$ satisfying that $|W\Delta\tilde{W}| \leq d/500 \leq w/200$ because $w = \lfloor d/2 \rfloor$. Therefore, once we have an $\varepsilon/1000$-minimizer for Ridge with respect to $\mathcal{D}'_{p,W}$, we can solve $\mathrm{DSF}_{\mathcal{D}'_{p,W}}$.

With the reduction from $\mathrm{DSF}_{\mathcal{D}'_{p,W}}$ to Ridge, we here show (similar to Lasso) a lower bound for the *worst-case symmetric set-finding problem* $\mathrm{WSSF}_{d,w,p,N}$: given a matrix $X \in \{-1/\sqrt{d}, 1/\sqrt{d}\}^{N\times d}$ where each column-sum is either $2pN/\sqrt{d}$ or $-2pN/\sqrt{d}$, the goal is to find a set $\tilde{W} \subset \mathbb{Z}_d$ such that $|\tilde{W}\Delta W| \leq w/200$, where W is the set of indices for those columns whose entries add up to $2pN/\sqrt{d}$ and $w = |W|$. This problem is again a composition of the approximate set finding problem in Section 4.2 and the Hamming-weight distinguisher problem $\mathrm{HD}_{\ell,\ell'}$ with $\ell = \frac{N}{2} - pN$ and $\ell' = \frac{N}{2} + pN$ up to a scalar $1/\sqrt{d}$. Following the proof of Theorem 19, we prove a lower bound of $\Omega(1/p)$ queries for this problem.

▶ **Theorem 27.** *Let $N \in 2\mathbb{Z}_+$, $z \in \{0,1\}^N$, and $p \in (0, 0.5)$ be an integer multiple of $1/N$. Suppose we have query access to z. Then every bounded-error quantum algorithm that computes $HD_{\frac{N}{2}-pN,\frac{N}{2}+pN}$ makes $\Omega(1/p)$ queries.*

Again we think of the input bits as ± 1 and abuse the notation $\mathrm{HD}_{\frac{N}{2}-pN,\frac{N}{2}+pN}$ for the problem with ± 1 input. Also, by the composition property of the adversary bound from Belovs and Lee [12] (Theorem 20), we have a lower bound of $\Omega(\sqrt{dw}/p)$ for $\mathrm{WSSF}_{d,w,p,N}$ from the $\Omega(\sqrt{dw})$ lower bound for $\mathrm{ASF}_{d,w}$ and the $\Omega(1/p)$ lower bound for $\mathrm{HD}_{\frac{N}{2}-pN,\frac{N}{2}+pN}$.

▶ **Corollary 28.** *Let $N \in 2\mathbb{Z}_+$ and $p \in (0, 0.5)$ be an integer multiple of $1/N$. Given a matrix $X \in \{-1/\sqrt{d}, +1/\sqrt{d}\}^{N\times d}$ such that there exists a set $W \subseteq \mathbb{Z}_d$ with size w and*

- *For every $j \in W$, $\sum_{i\in\mathbb{Z}_N} X_{ij} = 2pN/\sqrt{d}$.*
- *For every $j' \in \overline{W}$, $\sum_{i\in\mathbb{Z}_N} X_{ij'} = -2pN/\sqrt{d}$.*

Then every bounded-error quantum algorithm that computes $\tilde{W}$ such that $|W\Delta\tilde{W}| \leq w/200$, takes $\Omega(\sqrt{dw}/p)$ queries.

The final step for proving a lower bound for Ridge, using the same arguments as in Section 4.3, is to provide a worst-case to average-case reduction for the symmetric set-finding problem. We follow the same proof in Theorem 22 and immediately get the following theorem:

▶ **Theorem 29.** *Let $N \in 2\mathbb{Z}_+$, $p \in (0, 0.5)$ be an integer multiple of $1/N$, w be a natural number between 2 to $d/2$, and M be a natural number. Suppose $X \in \{-1/\sqrt{d}, +1/\sqrt{d}\}^{N\times d}$ is a valid input for $WSSF_{d,w,p,N}$, and let $W \subset \mathbb{Z}_d$ be the set of the w indices of the columns of X whose entries add up to $2pN/\sqrt{d}$. Let $R \in \mathbb{Z}_N^{M\times d}$ be a matrix whose entries are i.i.d. samples from $\mathcal{U}_N$, and define $X' \in \{-1/\sqrt{d}, 1/\sqrt{d}\}^{M\times d}$ as $X'_{ij} = X_{R_{ij}j}$. Then the vectors $(X'_i, 1)$, where X'_i is the ith row of X' and $i \in \mathbb{Z}_M$, are i.i.d. samples from $\mathcal{D}'_{p,W}$.*

By setting $M = 10^{10} \cdot \lceil \log d \rceil \cdot \lfloor 1/\varepsilon \rfloor^2 = \mathcal{O}((\log d)/\varepsilon^2)$ and letting $S' = \{(X'_i, 1)\}_{i=0}^{M-1}$ be a sample set with M i.i.d. samples from $\mathcal{D}'_{p,W}$, with probability $\geq 9/10$, an $\varepsilon/2000$-minimizer for Ridge with respect to S' is also an $\varepsilon/1000$-minimizer for Ridge with respect to distribution $\mathcal{D}'_{p,W}$ from Theorem 5. By Theorem 26 and Theorem 25, an $\varepsilon/1000$-minimizer for Ridge with respect to distribution $\mathcal{D}'_{p,W}$ gives us a set $\tilde{W} \subset \mathbb{Z}_d$ such that $|\tilde{W} \Delta W| \leq w/200$, where W is the set of indices for those columns of X whose entries add up to $2pN/\sqrt{d}$. Hence we have a reduction from the worst-case symmetric set-finding problem to Ridge. By this reduction and by plugging $w = \lfloor d/2 \rfloor$ and $p = 1/\lfloor 1/\varepsilon \rfloor$ in Corollary 28 (and N an arbitrary natural number such that $pN \in \mathbb{N}$), we obtain a lower bound of $\Omega(d/\varepsilon)$ queries for $\mathrm{WSSF}_{d,w,p,N}$, and hence for Ridge as well, which is the main result of this section.

▶ **Corollary 30.** *Let $\varepsilon \in (2/d, 1/1000)$, $w = \lfloor d/2 \rfloor$, $p = 1/\lfloor 1/\varepsilon \rfloor$, and $W \subset \mathbb{Z}_d$ with size w. Every bounded-error quantum algorithm that computes an ε-minimizer for Ridge w.r.t. $\mathcal{D}'_{p,W}$ uses $\Omega(d/\varepsilon)$ queries.*

6 Future work

We mention a few directions for future work:

- While the d-dependence of our quantum bounds for Lasso is essentially optimal, the ε-dependence is not: upper bound $\sqrt{d}/\varepsilon^2$ vs lower bound $\sqrt{d}/\varepsilon^{1.5}$. Can we shave off a $1/\sqrt{\varepsilon}$ factor from our upper bound, maybe using a version of accelerated gradient descent [36] with $O(1/\sqrt{\varepsilon})$ iterations instead of Frank-Wolfe's $O(1/\varepsilon)$ iterations? Or can we somehow improve our lower bound by embedding harder query problems into Lasso?
- Similar question for Ridge: the linear d-dependence of our quantum bounds is tight, but we should improve the ε-dependence of our upper and/or lower bounds. The most interesting outcome would be a quantum algorithm for Ridge with better ε-dependence than the optimal classical complexity of $\tilde{\Theta}(d/\varepsilon^2)$; currently we do not know of any quantum speedup for Ridge.
- Can we speed up some other methods for (smooth) convex optimization? In particular, can we find a classical iterative method where quantum algorithms can significantly reduce the number of iterations, rather than just the cost per iteration as we did here?
- There are many connections between Lasso and Support Vector Machines [32], and there are recent quantum algorithms for optimizing SVMs [38, 41, 39, 1, 40]. We would like to understand this connection better.

New PRGs for Unbounded-Width/Adaptive-Order Read-Once Branching Programs

Abstract

We give the first pseudorandom generators with sub-linear seed length for the following variants of read-once branching programs (roBPs):

1. First, we show there is an explicit PRG of seed length $O(\log^2(n/\varepsilon)\log(n))$ fooling *unbounded-width unordered* permutation branching programs with a single accept state, where n is the length of the program. Previously, [Lee-Pyne-Vadhan RANDOM 2022] gave a PRG with seed length $\Omega(n)$ for this class. For the ordered case, [Hoza-Pyne-Vadhan ITCS 2021] gave a PRG with seed length $\widetilde{O}(\log n \cdot \log 1/\varepsilon)$.
2. Second, we show there is an explicit PRG fooling *unbounded-width unordered* regular branching programs with a single accept state with seed length $\widetilde{O}(\sqrt{n \cdot \log(1/\varepsilon)} + \log(1/\varepsilon))$. Previously, no non-trivial PRG (with seed length less than n) was known for this class (even in the ordered setting). For the ordered case, [Bogdanov-Hoza-Prakriya-Pyne CCC 2022] gave an HSG with seed length $\widetilde{O}(\log n \cdot \log 1/\varepsilon)$.
3. Third, we show there is an explicit PRG fooling width w *adaptive* branching programs with seed length $O(\log n \cdot \log^2(nw/\varepsilon))$. Here, the branching program can choose an input bit to read depending on its current state, while it is guaranteed that on any input $x \in \{0,1\}^n$, the branching program reads each input bit exactly once. Previously, no PRG with a non-trivial seed length is known for this class.

   We remark that there are some functions computable by constant-width adaptive branching programs but not by sub-exponential-width unordered branching programs.

In terms of techniques, we indeed show that the Forbes-Kelly PRG (with the right parameters) from [Forbes-Kelly FOCS 2018] already fools all variants of roBPs above. Our proof adds several new ideas to the original analysis of Forbes-Kelly, and we believe it further demonstrates the versatility of the Forbes-Kelly PRG.

1 Introduction

One central question in complexity theory is whether randomness is necessary for efficient computation. In the time setting, the question is essentially asking whether $\mathsf{P} = \mathsf{BPP}$. While it is commonly believed that $\mathsf{P} = \mathsf{BPP}$ [23, 16], it is known that establishing this would imply breakthrough lower bounds in complexity theory [13, 17], which seems to be out of reach for current techniques. Therefore, most previous works are devoted to derandomizing sub-classes of BPP. In particular, the class of randomized log-space algorithms (BPL) has attracted a lot of attention, since not only it contains many interesting problems, but also it is indeed possible to give unconditional derandomizations of BPL [22, 27].

A leading approach to derandomize BPL is to construct explicit PRGs for ordered read-once branching programs (see below for a formal definition) with short seed length.

▶ **Definition 1.** *An ordered read-once branching program (roBP) B of length n and width w computes a function $B\colon \{0,1\}^n \to \{0,1\}$. The program has $(n+1)$ layers of states $V_0 \cup V_1 \cup \cdots \cup V_n$ where V_i contains all states in the i-th layer. Being width-w means that $|V_i| \le w$ for every $i \in [n]$. On an input $x \in \{0,1\}^n$, the branching program computes as follows. It starts at a fixed start state $s \in V_0$. Then for every $i = 1, 2, \ldots, n$, it reads the next input bit x_i and updates its state according to a transition function $B_i\colon V_{i-1} \times \{0,1\} \to V_i$ by taking $v_i = B_t(v_{i-1}, x_i)$. Note that the transition function B_i can differ at each time step.*

When we use the program to compute a decision problem, we specify a set $V_{\mathsf{acc}} \subseteq [w]$ of accepting states in the final layer. Let v_n be the final state reached by the branching program on input x. If $v_n \in V_{\mathsf{acc}}$, the branching program accepts, denoted by $B(x) = 1$. Otherwise, the program rejects, denoted by $B(x) = 0$.

Next, we recall the definition of a pseudorandom generator (PRG).

▶ **Definition 2.** *Let $\mathcal{F}$ be a class of functions $f\colon \{0,1\}^n \to \{0,1\}$. An ε-PRG for $\mathcal{F}$ is a function $G\colon \{0,1\}^s \to \{0,1\}^n$ such that for every $f \in \mathcal{F}$,*

$$\left| \Pr_{x \in \{0,1\}^n}[f(x) = 1] - \Pr_{x \in \{0,1\}^s}[f(G(x)) = 1] \right| \le \varepsilon.$$

We say that G ε-fools $\mathcal{F}$ if it is an ε-PRG for $\mathcal{F}$. The input length s is the seed length of the PRG G. We say a generator is explicit*, if given as input a seed $x \in \{0,1\}^s$, the output is computable in space $O(s)$.*

In a seminal work, Nisan constructed an explicit PRG that ε-fools length-n width-w ordered roBPs with seed length $O(\log n \cdot \log(nw/\varepsilon))$. Since then, many PRGs with improved seed lengths were constructed for sub-classes of ordered roBPs (see [5, 10, 20] and the references therein), but Nisan's PRG remains the state-of-the-art even for width-4 general roBPs.

Nisan's PRG (and [15, 9]) crucially relies on the following "communication" argument: The first half of the roBP can only communicate $\log w$ bits (describing the state reached at the end of the first half) to the second half. Due to this, it is possible to reuse all but $\log w$ bits from the seed that is used to generate the first half of the pseudorandom input, when generating the second half of the pseudorandom input. Recursively applying the idea gives the $\log n \log(nw/\varepsilon)$ seed length of Nisan's PRG.

However, some researchers have the feeling that this type of argument is inherently limited to having seed length at least $\log^2 n$ [6, 26, 28][1], and different approaches are required to

[1] For example, in [26], "This paradigm seems unlikely to yield pseudorandom generators for general logspace computations that have a seed length of $O(\log^{1.99} n)$."

overcome this $\log^2 n$ barrier. The search for a different paradigm for designing PRGs has motivated the study of models stronger than normal roBPs, with the hope that studying them would inspire us to find new techniques. In particular, two interesting models, unordered roBPs and unbounded-width roBPs, were introduced recently. It turns out that designing PRGs for both models requires inherently new techniques or analysis compared to Nisan's original PRG (or the INW PRG [15]).

Unordered roBPs. Let $\mathcal{B}$ be a class of ordered roBPs. We say a function $g\colon \{0,1\}^n \to \{0,1\}$ is computable by an unordered $\mathcal{B}$ roBP, if there is a function $f\colon \{0,1\}^n \to \{0,1\}$ and a permutation π on $[n]$ such that f is computable by a roBP in $\mathcal{B}$ and $g(x_1,\ldots,x_n) = f(x_{\pi(1)}, x_{\pi(2)}, \ldots, x_{\pi(n)})$.

It is known that Nisan's PRG fails to fool unordered roBPs [29]. After a long line of previous works [4, 14, 26, 28, 11, 19, 7], Forbes and Kelly [8] constructed $O(\log^2 n \log(nw/\varepsilon))$-seed-length PRGs fooling length-n width-w unordered roBPs with error ε.

Unbounded-width roBPs. Another recent line of works studied roBPs with unbounded width [12, 25, 24, 3, 18]. Of course, a general roBP with unbounded width can compute any function (even with a single accept state), so we must restrict our attention to sub-classes of such roBPs. The following two sub-classes of roBPs are the most studied ones in the literature.

▶ **Definition 3.** *Let B be an ordered roBP with length n and width w. We say that B is a regular roBP, if for every $t \in [n]$ and every $v \in [w]$, there are exactly 2 pairs $(u,b) \in [w]\times\{0,1\}$ such that $B_t(u,b) = v$. We say that B is a permutation roBP, if for every $t \in [n]$ and every $b \in \{0,1\}$, $B_t(\cdot,b)$ is a permutation on $[w]$.*

In [12], an $\widetilde{O}(\log n \cdot \log 1/\varepsilon)$-seed length PRG with error ε is constructed for ordered unbounded-width permutation roBP with length-n and a single accept state. A later work [25] (building on a prior work [1]) constructed an $\widetilde{O}(\log n \cdot \sqrt{\log(n/\varepsilon)} + \log(1/\varepsilon))$-seed length weighted PRG for the same class.[2]

1.1 Our Results

In this work, we consider two even stronger models of roBPs: (1) roBPs that are *both* unordered and have unbounded width and (2) roBPs that can read input in an adaptive order (that is, the next bit to read can depend on the current state).

1.1.1 Unordered and Unbounded-width roBPs

Given the recent developments on unordered roBPs and on unbounded-width roBPs, a natural question is whether one can construct non-trivial PRGs for unordered *and* unbounded-width (permutation or regular) roBPs. A prior, it is even unclear whether such a class admits *non-explicit* PRGs with short seed length, since the usual probabilistic argument for the existence of PRGs with short seed length does not apply here [12].

Our first result is a $\mathrm{polylog}(n/\varepsilon)$-seed-length PRG for unordered unbounded-width permutation roBPs with a single accept state, significantly improving the previous $\Omega(n)$-seed length PRGs from [18].

[2] A weighted PRG for a class of functions $\mathcal{F}$ is a pair of functions $G\colon \{0,1\}^s \to \{0,1\}^n$ and $\rho\colon \{0,1\}^s \to \mathbb{R}$ such that $\mathbf{E}_{x\in\{0,1\}^s}[\rho(x)f(G(x))]$ is ε-close to $\mathbf{E}_{x\in\{0,1\}^n}[f(x)]$.

▶ **Theorem 4** (Unbounded width permutation BP). *For all integers n and $\varepsilon > 0$, there is an explicit ε-PRG $G\colon \{0,1\}^s \to \{0,1\}^n$ with seed length*

$$s = O(\log n \cdot \log^2(n/\varepsilon))$$

that fools unordered unbounded-width permutation branching programs with a single accept state.

Our second result is a $\widetilde{O}(\sqrt{n}\log(1/\varepsilon))$-seed-length PRG for unordered unbounded-width regular roBPs with a single accept state. No (even non-explicit) non-trivial PRG is known for this class even in the ordered setting; Bogdanov, Hoza, Prakriya, and Pyne [3] has constructed $\widetilde{O}(\log n \cdot \log(1/\varepsilon))$-seed-length HSG for the ordered case.[3]

▶ **Theorem 5** (Unbounded width regular BP). *For all integers n and $\varepsilon > 0$, there is an explicit ε-PRG $G\colon \{0,1\}^s \to \{0,1\}^n$ with seed length*

$$s = O\left(\sqrt{n \log\left(\frac{n}{\varepsilon}\right)} \cdot \log n\right)$$

that fools unordered unbounded-width regular branching programs with a single accept state.

In terms of techniques, we indeed prove that the Forbes-Kelly PRG suffices for the two theorems above. Our analysis carefully modifies the original analysis from [8]. In fact, we prove that a single round of Forbes-Kelly pseudorandom restriction fools unordered unbounded-width regular roBPs (see Theorem 10). Iterating this restriction $O(\log(n/\varepsilon))$ times proves Theorem 4. Unfortunately, it is unclear whether the same iterative construction fools unordered unbounded-width regular roBPs since they are not closed under restrictions. Still, doing the pseudorandom restriction exactly once with the right parameters proves Theorem 5.

1.1.2 Adaptive roBPs

While an unordered roBP can read its input in any order, it cannot change the ordering based on the input it has read so far (*i.e.*, the order is input oblivious). We also consider an even stronger variant of roBPs, called adaptive roBPs, which are programs that can decide the next bit to read given its current state. We formally define them as follows.

▶ **Definition 6.** *An adaptive read-once branching program B of length n and width w computes a function $B\colon \{0,1\}^n \to \{0,1\}$. The program has states $V_0 \cup V_1 \cup \cdots \cup V_n$ where V_i consists of the w states in the i-th layer. On an input $x \in \{0,1\}^n$, the branching program B computes as follows. It starts at a fixed start state $v_0 \in [w]$. Then for every $t = 1, 2, \ldots, n$, it reads the bit $x_{\mathsf{pos}(t-1,v_{t-1})}$ and updates its state according to a transition function $B_t\colon V_{t-1} \times \{0,1\} \to V_t$ by taking $v_t = B_t(v_{t-1}, x_{\mathsf{pos}(t-1,v_{t-1})})$. Here, $\mathsf{pos}\colon V_0 \cup \cdots \cup V_{n-1} \to [n]$ is a function specifying the index of the next bit to read given the current state v_{t-1}. We require that on every input $x \in \{0,1\}^n$, B reads each bit in x exactly once.*

We remark that adaptive roBPs are strictly stronger than unordered roBPs as shown by an example function $f : \{0,1\} \times \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ as

$$f(b,x,y) = \mathbf{1}[b=0] \cdot \mathbf{1}[x=y] + \mathbf{1}[b=1] \cdot \mathbf{1}[x=y^R].$$

[3] A hitting set generator (HSG) $H\colon \{0,1\}^s \to \{0,1\}$ for a class of functions $\mathcal{F}$ satisfies the following: for every $f \in \mathcal{F}$ such that $\Pr_{x\in\{0,1\}^n}[f(x)=1] > \varepsilon$, there exists $z \in \{0,1\}^s$ such that $f(H(z)) = 1$. Note that a PRG is automatically an HSG, while the converse may not hold.

Here, y^R denotes the reversed string of y. Observe that there is a constant-width adaptive roBP for f. The program first reads b. If $b = 0$, the program reads and compares x and y bit by bit. Otherwise, the program compares x and y^R bit by bit. Moreover, it is easy to see (via a communication complexity argument) that every unordered roBP for f requires exponential width.

Our third result gives $O(\text{polylog}(nw/\varepsilon))$-seed-length PRG for adaptive roBPs. To the best of our knowledge, no explicit PRGs with seed length less than n was known prior to our work.

▶ **Theorem 7.** *For every $n, w \geq 1$ and $\varepsilon > 0$, there is an explicit ε-PRG $G : \{0,1\}^s \to \{0,1\}^n$ fooling width-w adaptive roBPs with seed length $s = O(\log n \cdot \log^2(nw/\varepsilon))$.*

We prove Theorem 7 by adapting the argument in [8]. The key observation allowing us to do so is the following. Suppose B satisfies the read-once promise. Then, for every vertex $v \in V_i$, if we denote by Pre_v (resp. Post_v) the set of possible variables read in any path from the starting state to v (resp. v to the accepting state). It must be the case that Pre_v and Post_v are disjoint for every v. By a delicate argument (Claim 15), we show that this disjointness property is sufficient for applying the key technique of Forbes-Kelley proof: decomposing the branching program by high/low-degree Fourier terms.

Moreover, when the width w of the adaptive roBP is small, we can show that the branching program has bounded Fourier growth (following [7]). In particular, we show that the L-th level Fourier mass of a width-w adaptive roBP is bounded by $O(\log(nw))^{2Lw}$. As shown in [8], for programs with bounded Fourier growth, we can further improve the seed length by a $\log(n)$ factor. Formally, we show

▶ **Theorem 8.** *For every $n, w \geq 1$ and $\varepsilon > 0$, there is an explicit ε-PRG $G : \{0,1\}^s \to \{0,1\}^n$ fooling width-w adaptive roBPs with seed length $s = \widetilde{O}(w \log^2(n/\varepsilon))$.*

Theorem 8 is a direct corollary of the new Fourier growth bound. We briefly comment on how we get the Fourier growth of $O(\log n)^{2Lw}$ for adaptive roBP. Roughly speaking, given a width-w, length-n adaptive roBP B, we construct a related witdh-$2w$, length-n^2 *oblivious* roBP B', such that the Fourier spectrum of B is "dominated" by that of B'. The idea is simple: we duplicate each input of B for n times and get n^2 bits. Now, it is easy to construct a width-$2w$ oblivious roBP running on the n^2 bits to simulate B. (Essentially, the n^2 bits allow us to make n passes over the input, we can use each pass to implement one step of transition of B.)

Although B' has n^2 input bits, we can exploit the promise that B is read-once, and prove the following nice property: For any input $z \in \{0,1\}^{n^2}$, $B'(z)$ depends only on n bits of z (that is to say, there is a subset of n bits from z, such that flipping all other bits of z cannot change the output). This allows us to connect the Fourier weights of B' and B. The details can be found in Appendix A.

2 Preliminaries

For a Boolean predicate P, we use $\mathbf{1}_{\{P\}}$ to denote the indicator of P, which takes value 1 if P holds, value 0 otherwise. We often use U_n to denote the uniform distribution over $\{0,1\}^n$ (when n is clear from the context, we will just write U for simplicity), and $U(X)$ to denote the uniform distribution over a set X. For two strings $\alpha, \beta \in \{0,1\}^n$, we use $\alpha \wedge \beta$ and $\alpha + \beta$ to denote their bit-wise AND and bit-wise XOR, respectively. Similarly, for two distributions D_1, D_2, we use $D_1 \wedge D_2$ (resp. $D_1 + D_2$) to denote the distributions obtained by drawing $\alpha \sim D_1$ and $\beta \sim D_2$ and outputting $\alpha \wedge \beta$ (resp. $\alpha + \beta$).

We always work with the $\{-1,1\}^n$ basis for Boolean function analysis. For a function $f\colon \{-1,1\}^n \to \mathbb{R}$, recall that its Fourier characters indexed by $\alpha \subseteq [n]$, is defined by

$$\widehat{f}(\alpha) = \mathop{\mathbb{E}}_{x\in\{-1,1\}^n}\left[f(x)\cdot\prod_{i\in\alpha} x_i\right].$$

We often use greek letters (such as α, β, γ) to index Fourier characters.

We will need k-wise independent and γ-almost k-wise independent distributions throughout the paper, which look locally uniform and thus fool functions that only depend on a few bits.

▶ **Definition 9.** *Let D be a distribution over $\{0,1\}^n$. We say D is k-wise independent if, for every $f\colon \{0,1\}^n \to [-1,1]$ that depends on at most k bits, we have*

$$\mathop{\mathbb{E}}_{D} f(D) = \mathop{\mathbb{E}}_{U} f(U).$$

If D merely satisfies

$$\left|\mathop{\mathbb{E}}_{D} f(D) - \mathop{\mathbb{E}}_{U} f(U)\right| \le \gamma$$

for every such f, we say that D is γ-almost k-wise independent.

It is possible to sample from a k-wise independent distribution using $O(k\cdot\log n)$ random bits ([30]) and from a γ-almost k-wise independent distribution using $O(k+\log\log n+\log 1/\gamma)$ random bits ([21, 2]).

3 PRGs for Unbounded-width Branching Programs

In this section, we will prove the following theorem, which shows that one round of pseudorandom restriction fools regular branching programs with unbounded width and a single accept state.

▶ **Theorem 10.** *Let B be an unbounded-width regular branching program of length n with starting state $s \in V_0$ and a single accept state $t \in V_n$. Let D, U denote a $2k$-wise independent distribution and a uniform distribution over $\{0,1\}^n$, respectively. Let $T^{(a)}$ denote a $2k$-wise independent distribution over $[a]^n$, and let distribution T be defined as $T_i = \mathbf{1}_{\{T_i^{(a)}=1\}}$ for all $i \in [n]$. Then*

$$|\mathbf{E}[B(U)] - \mathbf{E}[B(D + T \wedge U)]| \le n\cdot(1-1/a)^{k/2}.$$

Since the class of permutation BPs is closed under restrictions, we can iteratively apply Theorem 10 to it with $k = \log(n)$ and $a = 2$. The immediate consequence is that we get a PRG for unordered unbounded-width permutation branching programs.

▶ **Corollary 11** (Restating Theorem 4)**.** *For all integers n and $\varepsilon > 0$, there is an explicit ε-PRG $G\colon \{0,1\}^s \to \{0,1\}^n$ with seed length*

$$s = O(\log n\cdot\log^2(n/\varepsilon))$$

that fools unordered unbounded-width permutation branching programs with a single accept state.

However, when it comes to regular branching programs, this class is no longer closed under restrictions. Hence we can only apply Theorem 10 once and set $k = \widetilde{O}(\sqrt{n})$ and $a = \widetilde{O}(\sqrt{n})$. It remains an interesting open problem to apply iterative restriction for unbounded-width regular branching programs.

▶ **Corollary 12** (Restating Theorem 5). *For all integers n and $\varepsilon > 0$, there is an explicit ε-PRG $G\colon \{0,1\}^s \to \{0,1\}^n$ with seed length*

$$s = O\left(\left(\sqrt{n \log\left(\frac{n}{\varepsilon}\right)} + \log\left(\frac{1}{\varepsilon}\right)\right) \cdot \log n\right)$$

that fools unordered unbounded-width regular branching programs with a single accept state.

We will prove Theorem 10 in Subsection 3.1 and Subsection 3.2. In Subsection 3.3, we prove Corollary 11 and Corollary 12.

3.1 Fourier Decomposition of Regular BPs

Recall that V_i is the set of nodes in the i-th level of our branching program. $s \in V_0$ is the starting point and $t \in V_n$ is the unique accepting state. $x \in \{0,1\}^n$ is the input to our branching program B. In order to work with $\{-1,1\}$ basis, we let $y_i = (-1)^{x_i}$ for all $i \in [n]$.

For any two nodes $a \in V_i$ and $b \in V_j$. We define the indicator $P_{a,b} : \{-1,+1\}^n \to \{0,1\}$,

$$P_{a,b}(y) = \begin{cases} 1 & \text{Starting from } a, \text{ we reach at node } b \text{ on inputs } x_{i+1}, \ldots, x_j; \\ 0 & \text{Otherwise.} \end{cases}$$

Its Fourier expansion is as follows:

$$P_{a,b}(y) = \sum_{\alpha \subseteq \{i+1, i+2, \ldots, j\}} \widehat{P}_{a,b}(\alpha) \cdot \chi_\alpha(y)$$

where the Fourier characters are defined as

$$\chi_\alpha(y) = \prod_{i \in \alpha} y_i.$$

This naturally extends $P_{a,b}$ to $\mathbb{R}^n \to \mathbb{R}$.

Furthermore, we define

$$\bar{P}^{[k]}_{a,b}(y) = \sum_{\substack{\alpha \subseteq \{i+1, i+2, \ldots, j\} \\ |\alpha| = k,\ j \in \alpha}} \widehat{P}_{a,b}(\alpha) \cdot \chi_\alpha(y)$$

which is the sum all the degree k terms that contain y_j.

We also define

$$P^{(k)}_{a,b}(y) = \sum_{\substack{\alpha \subseteq \{i+1, i+2, \ldots, j\} \\ |\alpha| = k,\ i+1 \in \alpha}} \widehat{P}_{a,b}(\alpha) \cdot \chi_\alpha(y)$$

which is the sum all the degree k terms that contain y_{i+1}.

▶ **Fact 13.** *Let D, T, U be the distributions defined in Theorem 10, and let G be a distribution defined as*

$$G_i = \begin{cases} (-1)^{D_i} & T_i = 0, \\ 0 & T_i = 1. \end{cases} \quad \forall i \in [n].$$

Then, we have $\mathbf{E}[B(U)] = \widehat{P}_{s,t}(\varnothing)$ and $\mathbf{E}[B(D + T \wedge U)] = \mathbf{E}_{y \sim G}[P_{s,t}(y)]$.

Proof. Notice that when $y_i = (-1)^{x_i}$ for all i, $B(x) = P_{s,t}(y)$. The first fact holds because for all $\alpha \neq \varnothing$, we have $\mathbf{E}_{y\sim U(\{\pm 1\}^n)}[\chi_\alpha(y)] = 0$. Hence $\mathbf{E}[B(U)] = \mathbf{E}_{y\sim U(\{\pm 1\}^n)}[P_{s,t}(y)] = \widehat{P}_{s,t}(\varnothing)$.

For the second fact, conditioned on an instantiation of T, we define an intermediate distribution G' as

$$G'_i = \begin{cases} (-1)^{D_i} & T_i = 0, \\ (-1)^{U_i} & T_i = 1. \end{cases}.$$

we know that $\mathbf{E}[B(D + T \wedge U)] = \mathbf{E}_{y\sim G'}[P_{s,t}(y)]$.

- When $T_i = 1$, we have $\mathbf{E}_{y\sim G'}[y_i \mid T_i = 1] = \mathbf{E}_{y\sim G}[y_i \mid T_i = 1] = 0$ since y_i is sampled uniformly and independently from $\{\pm 1\}$.
- When $T_i = 0$, we always have $G_i = G'_i = (-1)^{D_i}$.

Hence for all α, we know that

$$\mathbf{E}_{y\sim G'}[\chi_\alpha(y)] = \mathbf{E}_{y\sim G'}\left[\prod_{i\in\alpha} y_i\right] = \mathbf{E}_T\left[\prod_{\substack{i\in\alpha \\ T_i=1}} \mathbf{E}_{y\sim G'}\left[y_i \mid T_i = 1\right] \cdot \mathbf{E}_{y\sim G'}\left[\prod_{\substack{i\in\alpha \\ T_i=0}} y_i \,\middle|\, T\right]\right]$$

$$= \mathbf{E}_T\left[\prod_{\substack{i\in\alpha \\ T_i=1}} \mathbf{E}_{y\sim G}\left[y_i \mid T_i = 1\right] \cdot \mathbf{E}_{y\sim G}\left[\prod_{\substack{i\in\alpha \\ T_i=0}} y_i \,\middle|\, T\right]\right] = \mathbf{E}_{y\sim G}[\chi_\alpha(y)].$$

As a result, $\mathbf{E}_{y\sim G'}[P_{s,t}(y)] = \mathbf{E}_{y\sim G}[P_{s,t}(y)]$. This finishes the proof. ◀

3.2 Bounding the Error

In the error analysis, we follow the approach of Forbes and Kelley [8]. By Fact 13, the result we wish to prove is equivalent to

$$\left|\mathbf{E}_{y\sim G}[P_{s,t}(y)] - \widehat{P}_{s,t}(\varnothing)\right| \leq n \cdot (1 - 1/a)^{k/2}.$$

In the analysis of [8], they considered the decomposition,

$$L_k(y) = \sum_{\substack{\alpha\subseteq\{1,2,\ldots,n\} \\ 0<|\alpha|<k}} \widehat{P}_{s,t}(\alpha) \cdot \chi_\alpha(y),$$

$$P_{s,t}(y) - \widehat{P}_{s,t}(\varnothing) = L_k(y) + \sum_{i=1}^{n} \sum_{m\in V_i} \bar{P}^{[k]}_{s,m}(y) \cdot P_{m,t}(y).$$

Here $L_k(y)$ are the low-degree terms, and $\bar{P}^{[k]}_{s,m}(y) \cdot P_{m,t}(y)$ are the terms that reaches degree k exactly at node $m \in V_i$. The intuition is that the $2k$-wise independent distribution D fools $L_k(y)$ while the high-degree terms are fooled by $T \wedge U$.

However, in order to work for unbounded-width regular branching programs, we have to consider a different decomposition. Let $L_k(y)$ be the same as before. We have

$$P_{s,t}(y) - \widehat{P}_{s,t}(\varnothing) = L_k(y) + \sum_{i=1}^{n} \sum_{m\in V_i} P_{s,m}(y) \cdot P^{(k)}_{m,t}(y).$$

Observe that we are using $P^{(k)}_{m,t}(y)$ instead of $\bar{P}^{[k]}_{m,t}(y)$. The benefit of this decomposition is that now for all y, we have

$$\sum_{m\in V_i} P_{s,m}(y)^2 \leq 1,$$

since from s only one state m can be reached under input y. In contrast, in the original decomposition, $\sum_{m\in V_i} P_{m,t}(y)^2$ could be very large. This difference will be essential in our analysis.

Now we are ready to prove Theorem 10.

Proof of Theorem 10. By our decomposition, we know

$$\left|\mathbf{E}_{y\sim G}[P_{s,t}(y)] - \widehat{P}_{s,t}(\varnothing)\right| \le |\mathbf{E}_{y\sim G}[L_k(y)]| + \sum_{i=1}^{n}\sum_{m\in V_i}\left|\mathbf{E}_{y\sim G}\left[P_{s,m}(y)\cdot P^{(k)}_{m,t}(y)\right]\right|. \tag{1}$$

Since G is k-wise independent, we know $\mathbf{E}_{y\sim G}\left[L_k(y)\right] = 0$. Now we bound the second term. We will need the following fact: For any two (not necessarily independent) sequences of random variables $\{f_m\}_{m\in V_i}, \{g_m\}_{m\in V_i}$, we have

$$\mathbf{E}\left[\sum_{m\in V_i} f_m g_m\right] \le \mathbf{E}\left[\sum_{m\in V_i} f_m^2\right]^{1/2} \mathbf{E}\left[\sum_{m\in V_i} g_m^2\right]^{1/2}.$$

This is the Cauchy-Schwarz Inequality for random variables.

Let $f_m = |P_{s,m}(y)|$ and $g_m = |P^{(k)}_{m,t}(y)|$. We have

$$\sum_{m\in V_i}\left|\mathbf{E}_{y\sim G}\left[P_{s,m}(y)P^{(k)}_{m,t}(y)\right]\right| \le \mathbf{E}_{y\sim G}\left[\sum_{m\in V_i}\left(P_{s,m}(y)\right)^2\right]^{1/2} \mathbf{E}_{y\sim G}\left[\sum_{m\in V_i} P^{(k)}_{m,t}(y)^2\right]^{1/2}$$

We bound these two separately.

We first bound $\mathbf{E}_{y\sim G}\left[\sum_{m\in V_i} P^{(k)}_{m,t}(y)^2\right]$. Suppose

$$P^{(k)}_{m,t}(y) = \sum_{\alpha} c_\alpha \chi_\alpha(y).$$

By $2k$-wise independence of G, we know for all $\alpha \neq \beta$ and $|\alpha| + |\beta| \le 2k$, the cross term

$$\mathbf{E}_{y\sim G}[\chi_\alpha(y)\chi_\beta(y)] = 0.$$

For the square terms, notice that for all $T_i = 1$, we have $y_i = 0$. When $T_i = 0$, $y_i = (-1)^{D_i}$. $T_i = 1$ happens with probability $1/a$. D, T are $2k$-wise independent. Hence when $|\alpha| = k$, we have[4]

$$\begin{aligned}\mathbf{E}_{y\sim G}[\chi_\alpha(y)^2] &= \mathbf{E}_{y\sim D}[\chi_\alpha(y)^2\cdot \mathbf{1}_{\{\forall i\in\alpha, T_i=0\}}]\\ &= \left(1-\frac{1}{a}\right)^k \cdot \mathbf{E}_{y\sim U}[\chi_\alpha(y)^2]\\ &= \left(1-\frac{1}{a}\right)^k.\end{aligned}$$

Hence,

$$\begin{aligned}\mathbf{E}_{y\sim G}\left[\left(P^{(k)}_{m,t}(y)\right)^2\right] &= \mathbf{E}_{y\sim G}\left[\sum_{|\alpha|=k} c_\alpha^2\chi_\alpha(y)^2\right]\\ &= \left(1-\frac{1}{a}\right)^k \sum_{|\alpha|=k} c_\alpha^2 \le \left(1-\frac{1}{a}\right)^k \mathbf{E}_{y\sim U}\left[\left(P_{m,t}(y)\right)^2\right].\end{aligned}$$

[4] For brevity, we use $y\sim U$ to mean that $y\sim U(\{-1,1\}^n)$.

The last step follows from Parseval identity. Summing over all $m \in V_i$ for a fixed i, we get

$$\sum_{m\in V_i} \mathbf{E}_{y\sim G}\left[\left(P^{(k)}_{m,t}(y)\right)^2\right] \le \left(1-\frac{1}{a}\right)^k \sum_{m\in V_i} \mathbf{E}_{y\sim U}\left[\left(P_{m,t}(y)\right)^2\right]$$
$$= \left(1-\frac{1}{a}\right)^k \sum_{m\in V_i} \mathbf{E}_{y\sim U}\left[P_{m,t}(y)\right] = \left(1-\frac{1}{a}\right)^k.$$

The last step is because now $y \sim U$, and the branching program is regular so that $\sum_{m\in V_i} \mathbf{E}_{y\sim U}[P_{m,t}(y)] = 1$.[5]

- On the other hand, as we mentioned, for any y, s can reach a single vertex in V_i, hence

$$\sum_{m\in V_i} \mathbf{E}_{y\sim G}\left[P_{s,m}(y)^2\right] \le 1.$$

Putting these two together, we get

$$|\mathbf{E}_{y\sim G}[P_{s,t}(y)] - \widehat{P}_{s,t}(\varnothing)| \le \sum_{i=1}^{n} \mathbf{E}_{y\sim G}\left[\sum_{m\in V_i}\left(P_{s,m}(y)\right)^2\right]^{1/2} \cdot \mathbf{E}_{y\sim G}\left[\sum_{m\in V_i} P^{(k)}_{m,t}(y)^2\right]^{1/2}$$
$$\le \left(1-\frac{1}{a}\right)^{k/2} n. \qquad \blacktriangleleft$$

3.3 Applications

Finally, we prove Corollary 11 and Corollary 12 in the rest of this section.

Proof of Corollary 11. Let $\{D^{(i)}\}_{i\in[\ell]}, \{T^{(i)}\}_{i\in[\ell]}$ be ℓ independent copies of $2k$-wise independent dsitributions defined in Theorem 10 with $k = \log\left(\frac{n}{\varepsilon}\right) + \log\log(\frac{n}{\varepsilon}) + 1$ and $a = 2$.

We construct pseudorandom distributions $G^{(0)}, G^{(1)}, \ldots, G^{(\ell)}$ with $\ell = \Theta(\log(n/\varepsilon))$. We let G_0 be the set of all one strings in $\{0,1\}^n$ and set

$$G^{(i+1)} = D^{(i)} + T^{(i)} \wedge G^{(i)}.$$

Let branching program $B^{(i)}$ be defined as $B^{(\ell)} = B$ and

$$B^{(i)}(x) = B^{(i+1)}(D^{(i)} + T^{(i)} \wedge x).$$

Since any restriction of a permutation branching program is still a permutation branching program. For any realization of $D^{(i)}$ and $T^{(i)}$, Theorem 10 says that,

$$\left|\mathbf{E}[B^{(i+1)}(U)] - \mathbf{E}[B^{(i)}(U)]\right| = \left|\mathbf{E}_{x\sim D^{(i)}+T^{(i)}\wedge U}[B^{(i)}(x)] - \mathbf{E}[B^{(i)}(U)]\right|$$
$$\le \left(1-\frac{1}{2}\right)^{\log\left(\frac{n}{\varepsilon}\right)+\log\log\left(\frac{n}{\varepsilon}\right)+1} n \le \frac{\varepsilon/2}{\log(\frac{n}{\varepsilon})}.$$

From a standard Chernoff bound, with probability at least $1-\varepsilon/2$, $T^{(1)} \wedge T^{(2)} \wedge \cdots \wedge T^{(\ell)} = 0000\ldots0$. This implies that $\left|\mathbf{E}[B^{(0)}(U)] - \mathbf{E}_{x\sim G^{(0)}}[B^{(0)}(x)]\right| \le \varepsilon/2$ since $B^{(0)}$ does not depend on its input when $T^{(1)} \wedge T^{(2)} \wedge \cdots \wedge T^{(\ell)} = 0000\ldots0$.

[5] This is the only place we use the regularity of the program.

On the other hand, by definition, we know $\mathbf{E}_{B^{(0)},x\sim G^{(0)}}[B^{(0)}(x)] = \mathbf{E}_{x\sim G^{(\ell)}}[B(x)]$. Hence a hybrid argument proves that

$$\begin{aligned}|\mathbf{E}_{x\sim G^{(\ell)}}[B(x)] - \mathbf{E}[B(U)]| &= \left|\mathbf{E}_{x\sim G^{(0)}}[B^{(0)}(x)] - \mathbf{E}[B^{(0)}(U)]\right| + \left|\mathbf{E}[B^{(0)}(U)] - \mathbf{E}[B^{(\ell)}(U)]\right| \\ &\le \varepsilon/2 + \sum_{i=1}^{\ell}\left|\mathbf{E}[B^{(i-1)}(U)] - \mathbf{E}[B^{(i)}(U)]\right| \\ &\le \varepsilon.\end{aligned}$$

◀

Proof of Corollary 12. For regular branching programs, let D and T be $2k$-wise independent distributions defined in Theorem 10 with $k = 2\sqrt{n\log\left(\frac{n}{\varepsilon}\right)} + \log\left(\frac{1}{\varepsilon}\right) + 2$ and $a = \sqrt{\frac{n}{\log\left(\frac{n}{\varepsilon}\right)}}$. We let D' be another independent copy of D.

We construct pseudorandom distribution $G = D + T \wedge D'$. From Theorem 10, we know that

$$|\mathbf{E}_{x\sim D+T\wedge U}[B(x)] - \mathbf{E}[B(U)]| \le n\cdot\left(1-\frac{1}{a}\right)^k \le \varepsilon/2.$$

Let $N = |\{i \mid T_i = 1\}|$. Since T is $2k$-wise independent,

$$\begin{aligned}\mathbf{E}[N^k] &\le \sum_{i_1,i_2,\ldots,i_k\in[n]} \Pr[T_{i_1} = T_{i_2} = \cdots = T_{i_k} = 1] \\ &= n^k \cdot \Pr_{i_1,i_2,\ldots,i_k\in[n]}[T_{i_1} = T_{i_2} = \cdots = T_{i_k} = 1] \\ &= n^k \cdot \prod_{j=1}^{k} \Pr[T_{i_j} = 1 \mid T_{i_1} = T_{i_2} = \cdots = T_{i_{j-1}} = 1] \\ &\le n^k \cdot \prod_{j=1}^{k} (\Pr[i_j \in \{i_1, i_2, \ldots, i_{j-1}\}] + \Pr[T_{i_j} = 1 \mid i_j \notin \{i_1, i_2, \ldots, i_{j-1}\}]) \\ &\le n^k \cdot \left(\frac{k}{n} + \frac{1}{a}\right)^k\end{aligned}$$

From Markov inequality, we get that $\Pr[N \ge 2k] \le 2\cdot(1/2)^k + 2\cdot(n/(2ak))^k$. By the $2k$ wise independence of D',

$$|\mathbf{E}_{x\sim G}[B(x)] - \mathbf{E}_{x\sim D+T\wedge U}[B(x)]| \le 2\cdot(1/2)^k + 2\cdot(n/(2ak))^k \le \varepsilon/2.$$

The seed length is $3k(\log n + \log a) = O\left(\left(\sqrt{n\log\left(\frac{n}{\varepsilon}\right)} + \log\left(\frac{1}{\varepsilon}\right)\right)\cdot\log n\right)$. ◀

▶ Remark 14. We believe the seed length in Corollary 11 can be improved to $O(\log^2 n\cdot\log(n/\varepsilon))$ following the sharper analysis in Section 7.1 of [8]. However, for the simplicity of presentation, we choose to only present it for the seed length of $O(\log n\cdot\log^2(n/\varepsilon))$.

4 PRGs for Adaptive Branching Programs

In this section, we prove our results for adaptive roBPs.

4.1 Decomposition of roBPs

As before, We use $B : \{0,1\}^n \to \{0,1\}$ to denote the adaptive branching program we are analyzing and use $P : \{\pm1\}^n \to \{0,1\}$ to denote the function computed by BP over $\{\pm1\}$ basis. For every input $x \in \{0,1\}^n$, define $y \in \{\pm1\}^n$ as $y_i = (-1)^{x_i}$ for every $i \in [n]$, and

define $P(y) = B(x)$. For any state v in the program, we denote by pos_v the index of the variable queried on state v. We have two outgoing edges from v, one marked with $x_{\mathsf{pos}_v} = 0$ and another with $x_{\mathsf{pos}_v} = 1$.

For any state v in the program, we denote by Pre_v the set of variables read in any path from the starting state to v, and by Post_v the set of variables read in any path from v to the accepting state. We observe that Pre_v and Post_v are disjoint as otherwise there exists a path from the starting state to the accepting state (and passes through v) and reads the same variable twice.

Formally, suppose there exists a vertex v and an index $i \in \mathsf{Pre}_v \cap \mathsf{Post}_v$. We choose a computation path π from starting vertex v_0 to v that queries the set $S \subseteq [n]$ of variables, and a path π' from v to the final layer that queries the set $T \subseteq [n]$, where $i \in S$.

We can construct an input $x \in \{0,1\}^n$ that guides the program to follow the computational path of $\pi \circ \pi'$. Each time the program reads a variable x_j, if x_j has been queried before, this clearly violates the read-once requirement. Otherwise, we can set x_j to make the program follow the path of $\pi \circ \pi'$. However, since know x_i is queried at least twice along the path, there must be some point, where the "read-once" requirement is violated.

Define $P : \{-1,1\}^n \to \{0,1\}$ as the function computed by the program. For a state v in the branching program, we denote by $P_{\to v}$ the event that the path from the starting state passes through v. Note that $P_{\to v}$ can be described as a branching program on the variables Pre_v. We denote by $P_{v\to}$ the sub-program of P starting at v. Note that $P_{v\to}$ can be described as a branching program on the variables Post_v.

4.1.1 Fourier Decomposition for Adaptive BP

Recall that the Fourier representation of any function $f : \{\pm 1\}^n \to \mathbb{R}$ is $\sum_{\alpha\subseteq[n]} \widehat{f}(\alpha)\chi_\alpha(y)$ where $\chi_\alpha(y) = \prod_{i\in\alpha} y_i$ and $\widehat{f}(\alpha) = \mathbf{E}_{y\sim\{\pm1\}^n}[f(y)\cdot\chi_\alpha(y)]$. Furthermore, we have that $\mathbf{E}_{y\sim\{\pm1\}^n}[f(y)^2] = \sum_\alpha \widehat{f}(\alpha)^2$ and $\mathbf{E}_{y\sim\{\pm1\}^n}[f(y)] = \widehat{f}(\emptyset)$.

Let $k \in \mathbb{N}$. Let α be a set of size $\ell > k$. We express $\widehat{P}(\alpha)$ as a sum of products of Fourier coefficients, where the Fourier coefficients come from sub-programs of B. In particular, we have the following claim.

▷ Claim 15. We have

$$\widehat{P}(\alpha) = \sum_{v:|\mathsf{Pre}_v\cap\alpha|=k,\mathsf{pos}_v\in\alpha} \widehat{P_{\to v}}(\alpha\cap\mathsf{Pre}_v)\cdot\widehat{P_{v\to}}(\alpha\cap\mathsf{Post}_v).$$

Proof. By definition

$$\widehat{P}(\alpha) = \mathbf{E}_{y\sim\{\pm1\}^n}[P(y)\cdot\chi_\alpha(y)] = \mathbf{E}_{y\sim\{\pm1\}^n}[P(y)\cdot\mathbf{1}_{\{B \text{ on } y \text{ reads all the variables in } \alpha\}}\cdot\chi_\alpha(y)]$$

where the second equality holds due to the following reason. For any $\beta \subseteq \alpha$ let X_β be the set of strings on which the program reads β and doesn't read $\alpha \setminus \beta$. We note that if $x \in X_\beta$ for some set β which is a strict subset of α, then also $x' := x \oplus e_i$ for $i \in \alpha \setminus \beta$ is in X_β, since the path for both x and x' will be the same (as the path doesn't query x_i). We see that the inputs in X_β can be partitioned to pairs, and each pair contributed 0 to $\mathbf{E}_{y\sim\{\pm1\}^n}[\chi_\alpha(y)]$.

For any x for which $B(x)$ reads all the variables in α, there is a unique state v along the path such that B reads exactly k variables in α before v, and B reads the $k+1$ variable from α immediately on the edge that goes out from v.

Thus, we can partition these paths according to the state v. We observe that v is the state immediately before reading the $k+1$ variable in α if $|\mathsf{Pre}_v \cap \alpha| = k$ and if $\mathsf{pos}_v \in \alpha$. This gives

$$\begin{aligned}\widehat{P}(\alpha) &= \mathbf{E}_{y\sim\{\pm1\}^n}\left[\sum_{v:|\mathsf{Pre}_v\cap\alpha|=k,\mathsf{pos}_v\in\alpha} P_{\to v}(y)P_{v\to}(y)\cdot\chi_\alpha(y)\cdot\mathbf{1}_{\{B \text{ reads all the variables in } \alpha\}}\right]\\ &= \sum_{v:|\mathsf{Pre}_v\cap\alpha|=k,\mathsf{pos}_v\in\alpha} \mathbf{E}_{y\sim\{\pm1\}^n}\left[P_{\to v}(y)P_{v\to}(y)\cdot\chi_\alpha(y)\right]\cdot\mathbf{1}_{\{B \text{ reads all the variables in } \alpha\}}\big]\\ &= \sum_{v:|\mathsf{Pre}_v\cap\alpha|=k,\mathsf{pos}_v\in\alpha} \mathbf{E}_{y\sim\{\pm1\}^n}[P_{\to v}(y)P_{v\to}(y)\cdot\chi_\alpha(y)]\end{aligned}$$

where the last equality follows from the same argument as before by observing that $P_{\to v}(y)P_{v\to}(y)$ is equivalent to the indicator of a program B' that checks that we passed through v and reached the accept state of B.

Now, for every state $v : |\mathsf{Pre}_v \cap \alpha| = k, \mathsf{pos}_v \in \alpha$, we get

$$\begin{aligned}&\mathbf{E}_x[P_{\to v}(y)P_{v\to}(y)\cdot\chi_\alpha(y)]\\ &= \mathbf{E}_{y\in\{0,1\}^{\mathsf{Pre}_v}}[P_{\to v}(y)\chi_{\alpha\cap\mathsf{Pre}_v}(y)]\cdot\mathbf{E}_{y\in\{0,1\}^{\mathsf{Post}_v}}[P_{v\to}(y)\chi_{\alpha\cap\mathsf{Post}_v}(y)]\\ &= \widehat{P_{\to v}}(\alpha\cap\mathsf{Pre}_v)\cdot\widehat{P_{v\to}}(\alpha\cap\mathsf{Post}_v),\end{aligned}$$

which completes the proof. ◁

By summing over all sets of size larger than k we get

$$\begin{aligned}&\sum_{\alpha:|\alpha|>k}\widehat{P}(\alpha)\chi_\alpha(y)\\ &= \sum_{\alpha,v:|\mathsf{Pre}_v\cap\alpha|=k,\mathsf{pos}_v\in\alpha}\widehat{P_{\to v}}(\alpha\cap\mathsf{Pre}_v)\chi_{\alpha\cap\mathsf{Pre}_v}(y)\cdot\widehat{P_{v\to}}(\alpha\cap\mathsf{Post}_v)\chi_{\alpha\cap\mathsf{Post}_v}(y)\\ &= \sum_v\left(\sum_{\alpha':\alpha'\subseteq\mathsf{Pre}_v,|\alpha'|=k}\widehat{P_{\to v}}(\alpha')\chi_{\alpha'}(y)\right)\cdot\left(\sum_{\alpha'':\alpha''\subseteq\mathsf{Post}_v,\mathsf{pos}_v\in\alpha''}\widehat{P_{\to v}}(\alpha'')\chi_{\alpha''}(y)\right).\end{aligned}$$

For each v we denote

$$H_v(y) := \sum_{\alpha':\alpha'\subseteq\mathsf{Pre}_v,|\alpha'|=k}\widehat{P_{\to v}}(\alpha')\chi_{\alpha'}(y)$$

and

$$G_v(y) := \sum_{\alpha'':\alpha''\subseteq\mathsf{Post}_v,\mathsf{pos}_v\in\alpha''}\widehat{P_{\to v}}(\alpha'')\chi_{\alpha''}(y).$$

We observe that $G_v(y)$ is the pos_v-Laplacian[6] of $P_{v\to}$. As such, $G_v(y)$ is a bounded function, i.e., $|G_v(y)| \le 1$ for all $y \in \{\pm1\}^n$.

▶ **Lemma 16.** *For any read-once adaptive branching program B, let P be the function computed by B. We have*

$$P(y) = \mathbf{E}[P(U)] + L(y) + \sum_{v\in V} H_v(y)\cdot G_v(y)$$

where $L(y) = \sum_{1\le|\alpha|\le k}\widehat{P}(\alpha)\chi_\alpha(y)$.

[6] Given a function $f : \{\pm1\}^n \to \mathbb{R}$ and index $i \in [n]$. The i-Laplacian of f is defined as a new function $\mathsf{L}_i f(y) := \frac{f(y)-f(y+e_i)}{2}$, where e_i denotes the i-th unit vector. Observe that $\mathsf{L}_i f(y) = \sum_{S:i\in S}\widehat{f}(S)\chi_S(y)$.

Proof. Any function can be written in the Fourier representation, i.e.

$$P(y) = \sum_{\alpha \subseteq [n]} \widehat{P}(\alpha) \cdot \chi_\alpha(y).$$

Now, we can partition this sum to the sum of sets of size at least k and the sum of sets of size smaller than k,

$$P(y) = \mathbf{E}[P] + L(y) + H(y)$$

where

$$\mathbf{E}[P] = \widehat{P}(\emptyset), \qquad L(y) = \sum_{1 \le |\alpha| \le k} \widehat{P}(\alpha)\chi_\alpha(y) \qquad \text{and} \qquad H(y) = \sum_{|\alpha| > k} \widehat{P}(\alpha)\chi_\alpha(y).$$

We decompose $H(y)$ by the above decomposition. ◀

4.2 Forbes-Kelley PRG fools Adaptive roBP

In this section, we prove that the Forbes-Kelley PRG fools adaptive roBP. First, the following lemma is the analog of [8, Lemma 6.3] for adaptive roBP.

▶ **Lemma 17.** *Let B be a read-once adaptive branching program of size s. Suppose D, T, and U are independently drawn from a $2(k+1)$-wise independent distribution, a $(k+1)$-wise independent distribution, and the uniform distribution over $\{\pm 1\}^n$, respectively. Then,*

$$|\mathbf{E}[P(U)] - \mathbf{E}[P(D + T \wedge U)]| \le s \cdot 2^{-k/2}.$$

Since we are working over ± 1 basis, $T \wedge U$ is a coordinate-wise operation defined as $(T \wedge U)_i = -1$ if and only if $T_i = U_i = -1$, and $D + (T \wedge U)$ is defined as $(D + (T \wedge U))_i = D_i \times (T \wedge U)_i$.

Proof. We use the Decomposition Lemma (Lemma 16):

$$|\mathbf{E}[P] - \mathbf{E}[P(D + T \wedge U)]| \le |\mathbf{E}[L(D + T \wedge U)]| + \sum_{v \in V} |\mathbf{E}[(H_v \cdot G_v)(D + T \wedge U)]|. \tag{2}$$

The first summand in the RHS of Eq. (2) equals zero since $D + T \wedge U$ fools any χ_α for $|\alpha| \le k$. Namely,

$$\mathbf{E}[L(D + T \wedge U)] = \sum_{0 < |\alpha| \le k} \widehat{P}(\alpha) \cdot \mathbf{E}[\chi_\alpha(D + T \wedge U)] = 0.$$

We bound the second summand in the RHS of Eq. (2) term by term. For each $v \in V$:

$$\begin{aligned}
&|\mathbf{E}_{D,T,U}[(H_v \cdot B_{v\to})(D + T \wedge U)]| \\
&\le \mathbf{E}_{D,T}\left[|\mathbf{E}_U[(H_v \cdot B_{v\to})(D + T \wedge U)]|\right] \\
&= \mathbf{E}_{D,T}\left[|\mathbf{E}_U[H_v(D + T \wedge U)]| \cdot |\mathbf{E}_U[G_v(D + T \wedge U)]|\right] && (3) \\
&\le \mathbf{E}_{D,T}\left[|\mathbf{E}_U[H_v(D + T \wedge U)]|\right] && (4) \\
&\le 2^{-k/2}. && \text{(Claim 18)}
\end{aligned}$$

Here, (3) follows by observing that, for every fixed T and D, $H_v(D + T \wedge U)$ and $G_v(D + T \wedge U)$ are independent. (4) is due to that $B_{v\to}$ is bounded. Finally, the last line utilizes a claim that is to be introduced and proved next.

Overall, we get

$$|\mathbf{E}[B(U)] - \mathbf{E}[B(D + T \wedge U)]| \le \sum_{i, v \in V_i} 2^{-k/2} = s \cdot 2^{-k/2},$$

as desired. ◀

The following claim has been used in the proof of Lemma 17. We show its proof now.

▷ Claim 18. Let $H_v : \{\pm 1\}^m \to \mathbb{R}$ be a function whose Fourier spectrum is k-homogeneous, i.e.,

$$H_v(y) = \sum_{\alpha \subseteq [m]:|\alpha|=k} \widehat{H_v}(\alpha) \cdot \chi_\alpha(y).$$

Let D, T, and U denote a $2k$-wise independent distribution, a k-wise independent distribution, and uniform distribution over $\{0,1\}^n$. Then,

$$\mathbf{E}_{D,T}\left[|\mathbf{E}_U[H_v(D + T \wedge U)]|\right] \leq 2^{-k/2} \cdot \sqrt{\sum_\alpha \widehat{H_v}(\alpha)^2}$$

Proof. We verify the claim by direction calculation.

$$\begin{aligned}
&\left(\mathbf{E}_{D,T}\left[|\mathbf{E}_U[H_v(D + T \wedge U)]|\right]\right)^2 \\
&\leq \mathbf{E}_{D,T}\left[\mathbf{E}_U[H_v(D + T \wedge U)]^2\right] \\
&= \mathbf{E}_{D,T,U,U'}\left[H_v(D + T \wedge U) \cdot H_v(D + T \wedge U')\right] \\
&= \sum_{\alpha,\alpha'} \widehat{H_v}(\alpha) \cdot \widehat{H_v}(\alpha') \cdot \mathbf{E}_{D,T,U,U'}[\chi_\alpha(D + T \wedge U) \cdot \chi_{\alpha'}(D + T \wedge U')] \\
&= \sum_{\alpha,\alpha'} \widehat{H_v}(\alpha) \cdot \widehat{H_v}(\alpha') \cdot \mathbf{E}_D[\chi_\alpha(D)\chi_{\alpha'}(D)] \cdot \mathbf{E}_{T,U,U'}[\chi_\alpha(T \wedge U) \cdot \chi_{\alpha'}(T \wedge U')] \\
&= \sum_\alpha \widehat{H_v}(\alpha)^2 \cdot \mathbf{E}_{T,U,U'}[\chi_\alpha(T \wedge U) \cdot \chi_\alpha(T \wedge U')] \quad + \sum_{\alpha \neq \alpha'} |\widehat{H_v}(\alpha)| \cdot |\widehat{H_v}(\alpha')| \cdot 0 \\
&\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (D \text{ is } 2k\text{-wise}) \\
&= \sum_\alpha \widehat{H_v}(\alpha)^2 \cdot \mathbf{E}_T[\mathbf{1}_{\{\alpha \cap T = \emptyset\}}] \\
&= 2^{-k} \cdot \sum_\alpha \widehat{H_v}(\alpha)^2. \qquad\qquad\qquad\qquad\qquad\qquad (T \text{ is } k\text{-wise independent}, |\alpha| = k)
\end{aligned}$$

◁

Finally, let us remark that we can also use δ-almost k-wise independent distributions T, D to construct $D + T \wedge U$. Doing an analysis similar as we have done for Claim 18, one can show that

$$|\mathbf{E}[P(U)] - \mathbf{E}[P(D + T \wedge U)]| \leq s \cdot \left(\sqrt{\gamma} + 2^{-k/2} + \sqrt{\gamma}\left(\sum_\alpha |\widehat{H}(\alpha)|\right)\right).$$

The argument is also similar to the one done in [8, Lemma 7.2]. We omit the detail here. Note that, if we can prove a good upper bound of $\sum_\alpha |\widehat{H}(\alpha)|$, we can hope to construct D, T using γ-almost k-wise independent distributions with larger γ. Recall the seed length to sample a γ-almost distribution is $O(\log(1/\gamma) + k + \log\log(n))$, which is smaller than the seed length to sample a perfect k-wise independent distribution by a $\log(n)$ factor for large γ (e.g., when $\gamma \approx 2^{-k}$).

4.2.1 PRG for Adaptive roBP

Given Lemma 17, we prove Theorem 7 now.

Proof of Theorem 7. The proof is nearly identical to that of Corollary 11.

Let $\{D^{(i)}\}_{i\in[\ell]}, \{T^{(i)}\}_{i\in[\ell]}$ be ℓ independent copies of $2k$-wise independent dsitributions defined in Lemma 17 with $k = \log\left(\frac{n}{\varepsilon}\right) + \log\log(\frac{n}{\varepsilon}) + 1$.

We construct pseudorandom distributions $G^{(0)}, G^{(1)}, \ldots, G^{(\ell)}$ with $\ell = \Theta(\log(n/\varepsilon))$. We let G_0 be the trivial PRG that outputs $1^n \in \{0,1\}^n$. Then we set

$$G^{(i+1)} = D^{(i)} + T^{(i)} \wedge G^{(i)}.$$

Define a branching program $B^{(i)}$ as $B^{(\ell)} = B$ and

$$B^{(i)}(x) = B^{(i+1)}(D^{(i)} + T^{(i)} \wedge x).$$

Note that $B^{(i)}$ is a random variable depending on $D^{(i)}$ and $T^{(i)}$. Since the restriction of an adaptive roBP is still a roBP. For any realization of $D^{(i)}$ and $T^{(i)}$, Lemma 17 says that,

$$\left|\mathbf{E}[B^{(i+1)}(U)] - \mathbf{E}[B^{(i)}(U)]\right| \leq \frac{\varepsilon/2}{\log(\frac{n}{\varepsilon})}.$$

From a standard Chernoff bound, with probability at least $1 - \varepsilon/2$, $T^{(1)} \wedge T^{(2)} \wedge \cdots \wedge T^{(\ell)} = 0000\ldots0$. Conditioning on this event, $B^{(0)}$ does not depend on its input, implying that $\left|\mathbf{E}[B^{(0)}(U)] - \mathbf{E}_{x\sim G^{(0)}}[B^{(0)}]\right| \leq \varepsilon/2$ since $B^{(0)}$.

On the other hand, by definition, we know $\mathbf{E}_{B^{(0)},x\sim G^{(0)}}[B^{(0)}(x)] = \mathbf{E}_{x\sim G^{(\ell)}}[B(x)]$. Hence a hybrid argument proves that

$$\begin{aligned}
|\mathbf{E}_{x\sim G^{(\ell)}}[B(x)] - \mathbf{E}[B(U)]| &= \left|\mathbf{E}_{x\sim G^{(0)}}[B^{(0)}(x)] - \mathbf{E}[B^{(0)}(U)]\right| + \left|\mathbf{E}[B^{(0)}(U)] - \mathbf{E}[B^{(\ell)}(U)]\right| \\
&\leq \varepsilon/2 + \sum_{i=1}^{\ell} \left|\mathbf{E}[B^{(i-1)}(U)] - \mathbf{E}[B^{(i)}(U)]\right| \\
&\leq \varepsilon,
\end{aligned}$$

completing the proof. ◀

A Fourier Growth of Constant-Width Adaptive roBP

In this appendix, we show that the Fourier growth of width-w adaptive roBP is upper bounded by that of width-$2w$ oblivious roBP. As a corollary, we can use almost k-wise independent primitives in the construction of Forbes-Kelley PRG, which saves the seed length from $O(\log^3(n/\varepsilon))$ to $\widetilde{O}(w\log^2(n/\varepsilon))$ when w is small.

A.1 Reducing Adaptive roBP to Oblivious roBP

We start by proving the following lemma.

▶ **Lemma 19.** *Suppose $B : \{0,1\}^n \to \{0,1\}$ is computed by a width-w adaptive roBP. Then there is a width-$2w$ oblivious roBP $B' : \{0,1\}^{n^2} \to \{0,1\}$ such that the following inequality holds for every $L \geq 1$,*

$$\sum_{\alpha\subseteq[n]:|\alpha|=L} |\widehat{B}(\alpha)| \leq \sum_{\alpha\subseteq[n^2]:|\alpha|=L} |\widehat{B'}(\alpha)|.$$

Proof. For an input $x \in \{0,1\}^{n^2}$ to B', we partition the bits into chunks of length n. Namely,

$$x = ((x_1^1,\ldots,x_1^n),(x_2^1,\ldots,x_2^n),\ldots,(x_n^1,\ldots,x_n^n)).$$

For each $i \in [n]$, we will think of $(x_j^i)_{j\in[n]}$ as n duplicate bits that equal to the i-th input bit to the original program B. Namely, consider a mapping $\sigma\colon \{0,1\}^n \to \{0,1\}^{n^2}$ as

$$\sigma(z) = ((z_1,z_2,\ldots,z_n),\ldots,(z_1,z_2,\ldots,z_n)).$$

Constructing the oblivious program. We construct a width-$2w$ oblivious roBP B' such that $B(x) = B'(\sigma(x))$. To illustrate, in the following, we use $x = (x_1, \ldots, x_n)$ to denote the input of B, and $z = (z_1^1, \ldots, z_n^n)$ to denote the input of B'. Note that if $z = \sigma(x)$, then $z_i^j = x_j$ for every i, j,

We describe the construction now. Note that B' involves $n^2 + 1$ layers and n^2 transitions. For each $i \in [n]$, We use the $((i-1)n+1)$-th to the (in)-th transitions of B' to implement the i-th transition of B.

Recall that the $(i-1)$-th (resp. i-th) layer of B contains states V_{i-1} (resp. V_i). Write $V_{i-1} = \{v_1, \ldots, v_w\}$ and $V_i = \{u_1, \ldots, u_w\}$. We construct $\overline{V}_{i-1} = \{v'_1, \ldots, v'_w, u'_1, \ldots, u'_w\}$. Identify $v'_1, \ldots, v'_w$ with $v_1, \ldots, v_w$, and $u'_1, \ldots, u'_w$ with $u_1, \ldots, u_w$. Recall that each vertex v_j reads one input bit $x_{\mathsf{pos}_{v_j}}$ from x.

We make $n+1$ copies of $\overline{V}_{i-1}$, denoted by $\overline{V}^0_{i-1}, \ldots, \overline{V}^n_{i-1}$. Next, we build a sub-program from $\overline{V}^0_{i-1}$ to $\overline{V}^n_{i-1}$, using inputs $z_i^1, \ldots, z_i^n$. For each $t \in [n]$, we add edges from $\overline{V}^{t-1}_{i-1}$ to $\overline{V}^t_{i-1}$. We let all states of $\overline{V}^{t-1}_{i-1}$ read the variable z_i^t (which is supposed to be x_t if $\sigma(x) = z$). For every v_j such that $\mathsf{pos}_{v_j} = t$, suppose v_j has two out edges to u_{j_0}, u_{j_1} with label 0 and 1. We add two edges from v'_j (in $\overline{V}^{t-1}_{i-1}$) to u'_{j_0} and $u'_{j,1}$ (in $\overline{V}^t_{i-1}$) with label 0 and 1. For every v_j where $\mathsf{pos}_{v_j} \neq t$ and every u_j, the state reads the input and simply ignores it. (operationally, this means we add two edges from the current state to the corresponding state in the next layer.)

Now we have n sub-programs: for each $i \in [n]$, we have a subprogram from $\overline{V}^0_{i-1}$ to $\overline{V}^n_{i-1}$. For each $i \in [n]$, observe that both the "u"-states of $\overline{V}^n_{i-1}$ and the "v"-states of $\overline{V}^0_i$ are identified with states in V_i. We naturally glue each pair of corresponding states together. We also glue "v"-states of $\overline{V}^n_{i-1}$ and "u"-states of $\overline{V}^0_i$ arbitrarily. This way, we construct a larger branching program of length n^2 (from $\overline{V}^0_1$ to $\overline{V}^n_n$) and width $2w$. It is straightforward to verify that $B(x) = B'(\sigma(x))$.

Calculating Fourier weights. Now we verify that B' satisfies the lemma statement. Consider the Fourier spectrum of B':

$$B'(z) = \sum_{\alpha \subseteq [n^2]} \widehat{B'}(\alpha)\chi_\alpha(z).$$

We claim that, for every $\alpha \subseteq [n^2]$ such that there exists $\{k_1 n + i, k_2 n + i\} \subseteq \alpha$ for some $k_1 \neq k_2$ and i, it must be the case that $|\widehat{B'}(\alpha)| = 0$. Indeed, we have

$$\widehat{B'}(\alpha) = \mathbf{E}_{z \sim U_{n^2}}[\chi_\alpha(z) \cdot B'(z)]. \tag{5}$$

We observe that

$$B'(z) = \sum_{\pi : \text{accepting computation path}} \mathbf{1}[B' \text{ on input } z \text{ follows } \pi].$$

Let $z^i_{k_1}, z^i_{k_2}$ be the two variables associated with indices $\{k_1 n + i, k_2 n + i\}$. By the promise that B is read-once, in any computation path π of B', it cannot be the case that both $z^i_{k_1}$ and $z^i_{k_2}$ are used (i.e., at least one of them is ignored in the path). It follows that each path contributes zero to (5). Consequently, $\widehat{B'}(\alpha) = 0$.

Next, we have

$$B(x) = B'(\sigma(x)) = \sum_{\alpha \subseteq [n^2]} \widehat{B'}(\alpha)\chi_\alpha(\sigma(x)).$$

As we have shown, $\widehat{B'}(\alpha)$ is non-zero only when α does not contain two variables $z^i_{k_1}, z^i_{k_2}$ in the same group k. For every such α, $\chi_\alpha(\sigma(x)) = \chi_{\Pi(\alpha)}(x)$ where Π denotes the projection of α onto $[n]$. Namely, $\Pi(\alpha)_i = 1$ if and only if $\alpha_{kn+i} = 1$ for some $k \in [n]$. It follows that $|\alpha| = |\Pi(\alpha)|$. Finally, applying the triangle inequality gives

$$\sum_{\beta \subseteq [n]:|\beta|=L} |\widehat{B}(\beta)| \leq \sum_{\alpha \subseteq [n^2]:|\alpha|=L} |\widehat{B'}(\alpha)|,$$

as desired. ◀

A.2 Fourier Growth and Pseudorandomness

Chattopadhyay, Hatami, Reingold and Tal [7] proved the following Fourier growth bound for width-w oblivious roBP.

▶ **Theorem 20** ([7]). *Suppose $B : \{0,1\}^n \to \{0,1\}$ is computed by a width-w oblivious roBP. Then, for every $k \geq 1$, it holds that*

$$\sum_{\alpha:|\alpha|=k} |\widehat{B}(\alpha)| \leq O(\log(nw))^{wk}.$$

As a direct corollary from Lemma 19 and Theorem 20, we obtain the following Fourier growth bound for width-w adaptive roBP.

▶ **Corollary 21.** *Suppose $B : \{0,1\}^n \to \{0,1\}$ is computed by a width-w adaptive roBP. Then, for every $k \geq 1$, it holds that*

$$\sum_{\alpha:|\alpha|=k} |\widehat{B}(\alpha)| \leq O(\log(nw))^{2wk}.$$

Similarly as done by Forbes and Kelley [8], one can use the Fourier growth bound to improve the seed length for small-width adaptive roBP, and obtain the following corollary.

▶ **Corollary 22** (Restating Theorem 8). *For every $n, w \geq 1$ and $\varepsilon > 0$, there is an explicit ε-PRG $G : \{0,1\}^s \to \{0,1\}^n$ fooling width-w adaptive roBPs with seed length $s = \widetilde{O}(w \log^2(n/\varepsilon))$.*

Approximate Nearest Neighbor for Polygonal Curves Under Fréchet Distance

Abstract

We propose κ-approximate nearest neighbor (ANN) data structures for n polygonal curves under the Fréchet distance in $\mathbb{R}^d$, where $\kappa \in \{1+\varepsilon, 3+\varepsilon\}$ and $d \geq 2$. We assume that every input curve has at most m vertices, every query curve has at most k vertices, $k \ll m$, and k is given for preprocessing. The query times are $\tilde{O}(k(mn)^{0.5+\varepsilon}/\varepsilon^d + k(d/\varepsilon)^{O(dk)})$ for $(1+\varepsilon)$-ANN and $\tilde{O}(k(mn)^{0.5+\varepsilon}/\varepsilon^d)$ for $(3+\varepsilon)$-ANN. The space and expected preprocessing time are $\tilde{O}(k(mnd^d/\varepsilon^d)^{O(k+1/\varepsilon^2)})$ in both cases. In two and three dimensions, we improve the query times to $O(1/\varepsilon)^{O(k)} \cdot \tilde{O}(k)$ for $(1+\varepsilon)$-ANN and $\tilde{O}(k)$ for $(3+\varepsilon)$-ANN. The space and expected preprocessing time improve to $O(mn/\varepsilon)^{O(k)} \cdot \tilde{O}(k)$ in both cases. For ease of presentation, we treat factors in our bounds that depend purely on d as $O(1)$. The hidden polylog factors in the big-$\tilde{O}$ notation have powers dependent on d.

1 Introduction

Given a set of trajectories, the *nearest neighbor* problem is to efficiently report the one most similar to a query trajectory. Trajectories are often represented as polygonal curves, and the nearest neighbor problem is encountered frequently in applications [19, 20, 21].

Various similarity metrics have been proposed for polygonal curves. We are interested in the *Fréchet distance* [3] which has attracted much attention in recent years. It is defined as follows. A parameterization of a curve τ is a function $\rho : [0,1] \to \mathbb{R}^d$ such that, as t increases from 0 to 1, the point $\rho(t)$ moves monotonically from the beginning of τ to its end. We may have $\rho(t_1) = \rho(t_2)$ for two distinct values t_1 and t_2. Two parameterizations ρ and ϱ for curves τ and σ, respectively, induce a *matching* $\mathcal{M}$: for all $t \in [0,1]$, $\mathcal{M}$ matches $\rho(t)$ with $\varrho(t)$. A point can be matched with multiple partners. The distance between τ and σ under $\mathcal{M}$ is $d_{\mathcal{M}}(\tau,\sigma) = \max_{t\in[0,1]} d(\rho(t), \varrho(t))$, where $d(\cdot,\cdot)$ denotes the Euclidean distance. The Fréchet distance is $d_F(\tau,\sigma) = \min_{\mathcal{M}} d_{\mathcal{M}}(\tau,\sigma)$. We call a minimizing matching a *Fréchet matching*.

Let $T = \{\tau_1, \ldots, \tau_n\}$ be a set of n polygonal curves with at most m vertices each. Given any value $\kappa \geq 1$, the *κ-approximate nearest neighbor (ANN) problem* is to construct a data structure so that for any query curve σ, we can quickly report a curve $\tau_l \in T$ with $d_F(\sigma,\tau_l) \leq \kappa \cdot \min_{\tau_i \in T} d_F(\sigma,\tau_i)$. We assume that every query curve has at most k vertices, and k is given for preprocessing. In the literature, if $k = m$, it is called the *symmetric* version; if $k < m$, it is called the *asymmetric version*. If the query curve is sketched by the user, it

is likely that $k \ll m$ and this is the scenario for which we design our data structures. We define the (κ, δ)-*ANN problem* as follows: for any query curve, we report "no" or a curve $\tau_l \in T$ with $d_F(\sigma, \tau_l) \leq \kappa\delta$; if we report "no", it must be the case that $\min_{\tau_i \in T} d_F(\sigma, \tau_i) > \delta$.

There have been many results on the ANN problem under the *discrete* Fréchet distance $\tilde{d}_F$, which restricts the definition of d_F to parameterizations ρ and ϱ that match each vertex of τ with at least one vertex of σ, and vice versa. As a result, $d_F(\tau, \sigma) \leq \tilde{d}_F(\tau, \sigma)$. It is possible that $d_F(\tau, \sigma) \ll \tilde{d}_F(\tau, \sigma)$; for example, σ is a long horizontal line segment, and τ is a parallel copy near σ with an extra vertex in the middle. The advantage of $\tilde{d}_F$ is that it can be computed using a simple dynamic programming algorithm [11].

Indyk and Motwani [17] and Har-Peled [14] proved that a solution for the (κ, δ)-ANN problem for points in a metric space gives a solution for the $\kappa(1 + O(\varepsilon))$-ANN problem. The result has been simplified in the journal version [15]. The method is general enough that it works for polygonal curves under d_F and $\tilde{d}_F$. Theorem 1 in Section 2 states the deterministic result in our context; the reduction increases the space and query time by polylogarithmic factors. If a probabilistic (κ, δ)-ANN solution with failure probability f is used, the bounds in Theorem 1 also hold, and the ANN solution has an $O(f \log n)$ failure probability.

Indyk [16] proposed the first (κ, δ)-ANN solution under $\tilde{d}_F$, where $\kappa = O(\log m + \log\log n)$, for the case that $k = m$ and the vertices come from a discrete point set X. It uses $O\big(|X|^{\sqrt{m}}(m^{\sqrt{m}}n)^2\big)$ space and answers a query in $O\big(m^{O(1)} \log n\big)$ time.[1] Driemel and Silverstri [10] developed probabilistic (κ, δ)-ANN solutions under $\tilde{d}_F$ with a failure probability $1/n$; they achieve the following combinations of (κ, query time, space) for the case of $k = m$: $\big(4d^{3/2}m, O(m), O(n \log n + mn)\big)$, $\big(4d^{3/2}, O(2^{4dm}m \log n), O(2^{4md}n \log n + mn)\big)$, and $\big(4d^{3/2}m/t, O(2^{2t}m^t \log n), O(2^{2t}m^{t-1}n \log n + mn)\big)$ for any integer $t \geq 1$. The approximation ratio has been reduced to $1 + \varepsilon$ by two research groups later. Filtser et. al. [13] proposed two deterministic $(1+\varepsilon, \delta)$-ANN data structures under $\tilde{d}_F$; one answers a query in $O(kd)$ time and uses $n \cdot O(\frac{1}{\varepsilon})^{kd}$ space and $O(mn(d \log m + O(\frac{1}{\varepsilon})^{kd}))$ expected preprocessing time; the other answers a query in $O(kd \log \frac{dkn}{\varepsilon})$ time and uses $n \cdot O(\frac{1}{\varepsilon})^{kd}$ space and $O(mn \log \frac{n}{\varepsilon} \cdot (d \log m + O(\frac{1}{\varepsilon})^{kd}))$ worst-case preprocessing time. Emiris and Psarros [12] obtained probabilistic $(1+\varepsilon)$-ANN and $(1 + \varepsilon, \delta)$-ANN data structures under $\tilde{d}_F$ with failure probabilities $1/2$ for the case of $k = m$. The $(1+\varepsilon)$-ANN data structure answers a query in $\tilde{O}(d2^{4m}m^{O(1/\varepsilon)})$ time and uses $\tilde{O}(dm^2n) \cdot (2 + d/\log m)^{O(dm^{O(1/\varepsilon)} \log(1/\varepsilon))}$ space and preprocessing time. The $(1 + \varepsilon, \delta)$-ANN data structure answers a query in $O(d2^{4m} \log n)$ time and uses $O(dn) + (mn)^{O(m/\varepsilon^2)}$ space and preprocessing time. The failure probabilities can be reduced to $1/n$ with an increase in the query time, space, and preprocessing time by an $O(\log n)$ factor.

Most known results under d_F are for $\mathbb{R}$. For curves in $\mathbb{R}$ (time series), Driemel and Psarros [9] developed the first (κ, δ)-ANN data structures under d_F with the following combinations of (κ, query time, space): $\big(5+\varepsilon, O(k), O(mn)+n\cdot O(\frac{1}{\varepsilon})^k\big)$, $\big(2+\varepsilon, O(2^k k), O(mn)+n\cdot O(\frac{m}{k\varepsilon})^k\big)$, and $\big(24k + 1, O(k \log n), O(n \log n + mn)\big)$. The last one is probabilistic, and the failure probability is $1/\text{poly}(n)$. Later, Bringman et al. [5] obtained improved solutions with the following combinations of (κ, query time, space): $\big(1 + \varepsilon, O(2^k k), n \cdot O(\frac{m}{k\varepsilon})^k\big)$, $\big(2 + \varepsilon, O(k), n \cdot O(\frac{m}{k\varepsilon})^k\big)$, $\big(2 + \varepsilon, O(2^k k), O(mn) + n \cdot O(\frac{1}{\varepsilon})^k\big)$, $\big(2 + \varepsilon, O(\frac{1}{\varepsilon})^{k+2}, O(mn)\big)$, and $\big(3 + \varepsilon, O(k), O(mn) + n \cdot O(\frac{1}{\varepsilon})^k\big)$. They also obtained lower bounds that are conditioned on the Orthogonal Vectors Hypothesis: for all $\varepsilon, \varepsilon' \in (0, 1)$, it is impossible to achieve the combination $\big(2 - \varepsilon, O(n^{1-\varepsilon'}), \text{poly}(n)\big)$ in $\mathbb{R}$ when $1 \ll k \ll \log n$ and $m = kn^{\Theta(1/k)}$, or $\big(3 - \varepsilon, O(n^{1-\varepsilon'}), \text{poly}(n)\big)$ in $\mathbb{R}$ when $m = k = \Theta(\log n)$, or $\big(3 - \varepsilon, O(n^{1-\varepsilon'}), \text{poly}(n)\big)$ in $\mathbb{R}^2$ when $1 \ll k \ll \log n$ and $m = kn^{\Theta(1/k)}$. Mirzanezhad [18] described a $(1 + \varepsilon, \delta)$-ANN data structure for $\mathbb{R}^d$ that answer a query in $O(kd)$ time and uses $O(n \cdot \max\{\sqrt{d}/\varepsilon, \sqrt{d}D/\varepsilon^2\}^{dk})$

[1] A tradeoff is also presented in [16].

space, where D is the diameter of the set of input curves. If k is not given, the approximation ratio and space increase to $5+\varepsilon$ and $n \cdot O(\frac{1}{\varepsilon})^{dm}$, respectively. There is no bound on D in the space complexity of the first solution. We summarize all these previous results in Table 1 for easier comparison.

Table 1 Comparison of our data structures to the previous results.

	$O(dn) + (mn)^{O(m/\varepsilon^2)}$	$O\left(d2^{4m} \log n\right)$	$(1+\varepsilon,\delta)$-ANN[c] [12]

[a] A randomized data structure with a failure probability of $1/\text{poly}(n)$.
[b] The query time is achieved by implementing the dictionary with a hash table. The query time is $O(kd \log \frac{dkn}{\varepsilon})$ when implementing the dictionary with a trie.
[c] A randomized data structure with a failure probability of $\frac{1}{2}$.

We develop (κ,δ)-ANN data structures under d_F in $\mathbb{R}^d$ for $\kappa \in \{1+\varepsilon, 3+\varepsilon\}$ and $d \geq 2$. We assume that every query curve has at most k vertices, $k \ll m$, and k is given for preprocessing. To simplify the bounds, we assume that $k \geq 3$ throughout this paper. There are three design goals. First, the query times are sublinear in mn. Second, the space complexities depend only on the input parameters. Third, the space complexities are neither proportional to $\min\{m^{\Omega(d)}, n^{\Omega(d)}\}$ nor exponential in $\min\{m,n\}$. It would be desirable to remove all exponential dependencies on d, but we are not there yet.

We achieve a query time of $\tilde{O}(k(mn)^{0.5+\varepsilon}/\varepsilon^d + k(d/\varepsilon)^{O(dk)})$ for $(1+\varepsilon,\delta)$-ANN. We remove the exponential dependence on k for $(3+\varepsilon,\delta)$-ANN and obtain an $\tilde{O}(k(mn)^{0.5+\varepsilon}/\varepsilon^d)$ query time. The space and expected preprocessing time are $\tilde{O}(k(mnd^d/\varepsilon^d)^{O(k+1/\varepsilon^2)})$ in both cases. For ease of presentation, we treat any factor in our bounds that depends only on d as $O(1)$. The hidden polylog factors in the big-$\tilde{O}$ notation have powers dependent on d. In two and three dimensions, we improve the query times to $O(1/\varepsilon)^{O(k)} \cdot \tilde{O}(k)$ for $(1+\varepsilon,\delta)$-ANN and $\tilde{O}(k)$ for $(3+\varepsilon,\delta)$-ANN. The space and expected preprocessing time improve to $O(mn/\varepsilon)^{O(k)} \cdot \tilde{O}(k)$ in both cases. Using the reduction in [15] (Theorem 1 in Section 2), we obtain $(1+\varepsilon)$-ANN and $(3+\varepsilon)$-ANN data structures by increasing the query time and space by an $O(\log n)$ and an $O(\frac{1}{\varepsilon}\log^2 n)$ factors, respectively. More precise bounds are stated in Theorems 9 and 11.

Our $(1+\varepsilon,\delta)$-ANN result is based on two new ideas. First, we develop a novel encoding of query curves that are based on local grids in the input vertex neighborhoods. Second, we draw a connection to an approximate segment shooting problem which we solve efficiently. We present these ideas in Sections 2 and 4. Our $(3+\varepsilon)$-ANN result is obtained by simplifying the encoding. We present this result in Section 3.

We work in the word RAM model. We use $(v_{i,1}, \ldots, v_{i,m})$ to denote the sequence of vertices of τ_i from beginning to end – τ_i is oriented from $v_{i,1}$ to $v_{i,m}$. We use $\tau_{i,a}$ to denote the edge $v_{i,a}v_{i,a+1}$. For any two points $x, y \in \tau_i$, we say that $x \leq_{\tau_i} y$ if x does not appear behind y along τ_i, and $\tau_i[x, y]$ denotes the subcurve between x and y. Given two subsets $X, Y \subseteq \tau_i$, $X \leq_{\tau_i} Y$ if and only if for every point $x \in X$ and every point $y \in Y$, $x \leq_{\tau_i} y$. A ball centered at the origin with radius r is denoted by B_r. Given two subsets $X, Y \subset \mathbb{R}^d$, $d(X, Y) = \min_{x \in X, y \in Y} d(x, y)$; their *Minkowski sum* is $X \oplus Y = \{x + y : x \in X, y \in Y\}$; if $X = \{p\}$, we write $p \oplus Y$ for simplicity. For any $x, y \in \mathbb{R}^d$, xy denotes the *oriented segment from x to y*, and $\mathrm{aff}(xy)$ is the *oriented support line of xy* that shares the orientation of xy.

2 $(1 + O(\varepsilon), \delta)$-ANN

Har-Peled et al. [15, Theorem 2.10] proved a reduction from the $(1 + \varepsilon)$-ANN problem to the $(1 + \varepsilon, \delta)$-ANN problem. Although the result is described for points in a metric space with a probabilistic data structure for the $(1 + \varepsilon, \delta)$-ANN problem, the method is general enough to work for polygonal curves under d_F or $\tilde{d}_F$ in $\mathbb{R}^d$ and any deterministic solution for the $(1 + \varepsilon, \delta)$-ANN problem. We rephrase their result in our context below.

▶ **Theorem 1** ([15]). *Let T be a set of n polygonal curves in $\mathbb{R}^d$. If there is a data structure for the (κ, δ)-ANN problem for T under d_F or $\tilde{d}_F$ that has space complexity S, query time Q, deletion time D, and preprocessing time P, then there is a $\kappa(1 + O(\varepsilon))$-ANN data structure for T under d_F or $\tilde{d}_F$ that has space complexity $O(\frac{1}{\varepsilon} S \log^2 n)$, query time $O(Q \log n)$, and expected preprocessing time $O\big(\frac{1}{\varepsilon \log^2 n} P + (Q + D) n \log n\big)$.*

By Theorem 1, we can focus on the $(1 + \varepsilon, \delta)$-ANN problem. Without loss of generality, we assume that each curve in T has exactly m vertices, and every query curve has exactly k vertices. If necessary, extra vertices can be added in an arbitrary manner to enforce this assumption without affecting the Fréchet distance.

The high level idea of our preprocessing is to identify all query curves that are within a Fréchet distance $(1 + O(\varepsilon))\delta$ from each $\tau_i \in T$, group the curves that share similar structural characteristics, assign each group a unique key value, and store these key values in a trie $\mathcal{D}$. It is possible for a query curve to belong to multiple groups. Each key value is associated with the subset of curves in T that induce that key value. Correspondingly, given a query curve σ, we generate all possible key values for σ and search $\mathcal{D}$ with them. If some curve in T is retrieved, it is the desired answer; otherwise, we report "no".

There are two challenges to overcome. First, it is impossible to examine all possible query curves. We can only check some space discretization in order to obtain a finite running time. To control the discretization error, it is easy to cover the input curves by a grid with an appropriate cell width; however, the grid size and hence the data structure size would then depend on some non-combinatorial parameters. We propose *coarse encodings* of query curves so that there are $O(\sqrt{d}/\varepsilon)^{4d(k-1)}(mn)^{4(k-1)}$ of them. A query curve may have $O(\sqrt{d}/\varepsilon)^{2d(k-2)}$ coarse encodings. The second challenge is to efficiently generate all possible coarse encodings of a query curve at query time. We reduce the coarse encoding generation to an approximate segment shooting problem. This step turns out to be the bottleneck in four and higher dimensions as we aim to avoid any factor of the form $m^{\Omega(d)}$ or $n^{\Omega(d)}$ in the space complexity. It is the reason for the $(mn)^{0.5+\varepsilon}$ term in the query time. In two and three dimensions, the approximate segment shooting problem can be solved more efficiently.

In the rest of this section, we present the coarse encoding and a $(1 + O(\varepsilon), \delta)$-ANN data structure, using an approximate segment shooting oracle. The approximate segment shooting problem can be solved by the results in [8] in two and three dimensions. We solve the approximate segment shooting problem in four and higher dimensions in Section 4.

2.1 Coarse encodings of query curves

Imagine an infinite grid in $\mathbb{R}^d$ of cell width $\varepsilon\delta/\sqrt{d}$. For any subset $R \subset \mathbb{R}^d$, we use $G(R)$ to denote the set of grid cells that intersect R. Let $\mathcal{G}_1 = \bigcup_{i\in[n],a\in[m]} G(v_{i,a} \oplus B_\delta)$. Let $\mathcal{G}_2 = \bigcup_{i\in[n],a\in[m]} G(v_{i,a} \oplus B_{(2+12\varepsilon)\delta})$. Both $\mathcal{G}_1$ and $\mathcal{G}_2$ have $O(mn/\varepsilon^d)$ size.

The coarse encoding of a curve $\sigma = (w_1, w_2, \ldots, w_k)$ is a 3-tuple $\mathcal{F} = (\mathcal{A}, \mathcal{B}, \mathcal{C})$. The component $\mathcal{C}$ is sequence of pairs of grid cells $((c_{j,1}, c_{j,2}))_{j\in[k-1]}$ such that $(c_{j,1}, c_{j,2}) \in (\mathcal{G}_1 \times \mathcal{G}_1) \cup \{\text{null}\}$. Both $\mathcal{A}$ and $\mathcal{B}$ are arrays of length $k-1$, and every element of $\mathcal{A}$ and $\mathcal{B}$ belongs to $\mathcal{G}_2 \cup \{\text{null}\}$. We first provide the intuition behind the design of $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ before describing the constraints that realize the intuition.

Imagine that a curve $\tau_i \in T$ is a $(1 + O(\varepsilon))$-ANN of σ. The data structure needs to cater for the preprocessing, during which the query curve σ is not available; it also needs to cater for the query procedure, during which we do not want to directly consult the input curves in T in order to avoid a linear dependence in mn.

In preprocessing, we use pairs of grid cells as surrogates of the possible query curve edges. The advantage is that we can enumerate all possible pairs of grid cells and hence cater for all possible query curve edges. Specifically, for $j \in [k-1]$, if $(c_{j,1}, c_{j,2}) \neq$ null, it is the surrogate of w_jw_{j+1}, so w_jw_{j+1} should pass near $c_{j,1}$ and $c_{j,2}$. Each non-null $(c_{j,1}, c_{j,2})$ corresponds to a contiguous subsequence $v_{i,a}, \ldots, v_{i,b}$ of vertices of τ_i that are matched to points in w_jw_{j+1} in a Fréchet matching. Of course, we do not know the Fréchet matching, so we will need to enumerate and handle all possibilities. Also, since w_jw_{j+1} is unknown in preprocessing, $v_{i,a}, \ldots, v_{i,b}$ can only be matched to a segment joining a vertex x_j of $c_{j,1}$ to a vertex y_j of $c_{j,2}$ so that $d_F(x'_jy'_j, \tau_i[v_{i,a}, v_{i,b}]) \leq (1 + O(\varepsilon))\delta$ for some subsegment $x'_jy'_j \subseteq x_jy_j$. This property will be enforced in the data structure construction later.

At query time, given $\sigma = (w_1, \ldots, w_k)$, we will make approximate segment shooting queries to determine a sequence of cell pairs $((c_{j,1}, c_{j,2}))_{j\in[k-1]}$. We do not always use $(c_{j,1}, c_{j,2})$ as a surrogate for the edge w_jw_{j+1} though. As mentioned in the previous paragraph, a non-null $(c_{j,1}, c_{j,2})$ denotes the matching of a contiguous subsequence of input curve vertices to w_jw_{j+1}; however, we must also allow the matching of a contiguous subsequence of vertices of σ to a single input edge. Therefore, after determining $((c_{j,1}, c_{j,2}))_{j\in[k-1]}$, we still have the choice of using $(c_{j,1}, c_{j,2})$ as is or substituting it by the null value. For a technical reason, $(c_{1,1}, c_{1,2})$ and $(c_{k-1,1}, c_{k-1,2})$ are always kept non-null, so we have 2^{k-3} possible sequences of pairs of cells. Take one of these sequences. If $(c_{r,1}, c_{r,2})$ and $(c_{s,1}, c_{s,2})$ are two non-null pairs such that $(c_{j,1}, c_{j,2}) =$ null for $j \in [r+1, s-1]$, it means that no vertex of τ_i is matched to w_jw_{j+1} for $j \in [r+1, s-1]$. As a result, the vertices $w_{r+1}, \ldots, w_s$ of σ are matched to the edge $v_{i,b}v_{i,b+1}$ of τ_i, where $v_{i,b}$ is the last vertex of τ_i matched to w_rw_{r+1} in the current enumeration. We use the pair of cells $\mathcal{A}[r]$ and $\mathcal{B}[s]$ as the surrogate of the edge $v_{i,b}v_{i,b+1}$. So we require $\mathcal{A}[r]$ and $\mathcal{B}[s]$ to be near $c_{r,2}$ and $c_{s,1}$, respectively, because $(c_{r,1}, c_{r,2})$ is the surrogate of w_rw_{r+1}, and $(c_{s,1}, c_{s,2})$ is the surrogate of w_sw_{s+1}. We have to try all possible locations of $\mathcal{A}[r]$ and $\mathcal{B}[s]$ in the vicinity of $c_{r,2}$ and $c_{s,1}$. $\mathcal{A}[r]$ and $\mathcal{B}[s]$ can be the surrogate for edges of multiple curves in T, which allows us to compare σ with multiple input curves simultaneously at query time. The constraint to be enforced is that $w_{r+1}, \ldots, w_s$ can be matched to a segment joining a vertex x_r of $\mathcal{A}[r]$ and a vertex x_s of $\mathcal{B}[s]$ so that $d_F(x'_rx'_s, \sigma[w_{r+1}, w_s]) \leq (1 + O(\varepsilon))\delta$ for some subsegment $x'_rx'_s \subseteq x_rx_s$. Figure 1 shows a illustration for the intuition above.

We present the constraints for $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ that realize the intuition above. When $(c_{j,1}, c_{j,2}) \neq$ null, a natural choice of $c_{j,1}$ is the first grid cell in $\mathcal{G}_1$ that we hit when walking from w_j to w_{j+1}, i.e., segment shooting. In $\mathbb{R}^d$ where $d \in \{2, 3\}$, there are ray shooting data structures for boxes [8]. In higher dimensions, ray shooting results are known for a single convex

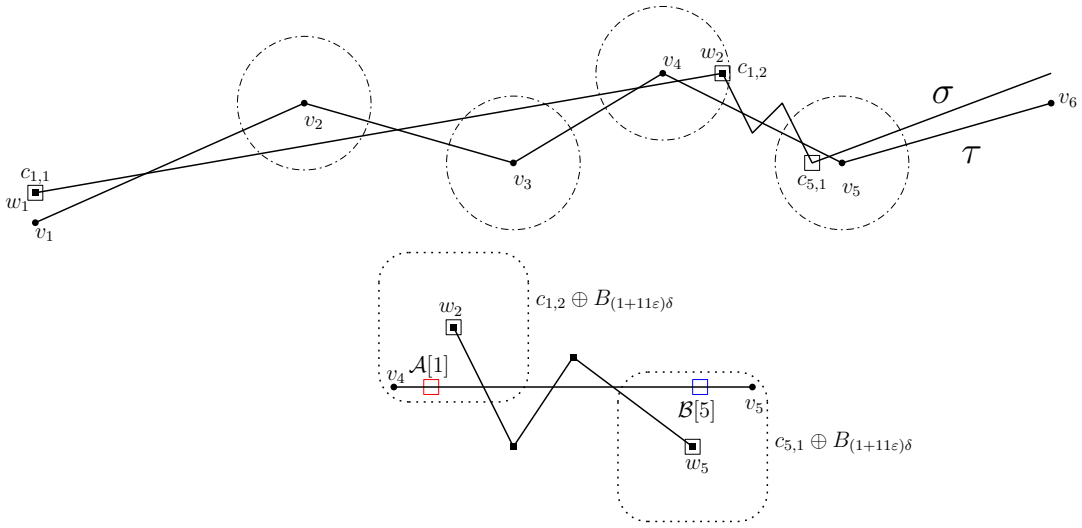

Figure 1 The underlying intuition for deriving the coarse encoding of σ. We use τ instead of τ_i for ease of notation. Assume that $d_F(\tau, \sigma) \leq \delta$ and the vertices v_1, v_2, v_3, v_4 are matched to the segment w_1w_2 by the Fréchet matching. w_1w_2 must intersect some balls centered at τ's vertices, which means that w_1w_2 intersects $\mathcal{G}_1$. Let $c_{1,1}$ and $c_{1,2}$ be the first and the last cells in $\mathcal{G}_1$ that intersect w_1w_2 along the direction of w_1w_2. $(c_{1,1}, c_{1,2})$ can serve as a surrogate of the edge w_1w_2 in a sense that we can verify whether v_1, v_2, v_3, v_4 can be matched to w_1w_2 properly by checking whether they can be matched to a segment that joins vertices of $c_{1,1}$ and $c_{1,2}$ properly. This idea can be generalized to all edges of σ with vertices of τ matched to them. The subcurve $\sigma[w_2, w_5]$ is matched to an edge v_4v_5 of τ. We introduce $\mathcal{A}[1] \subset G(c_{1,2} \oplus B_{(1+11\varepsilon)\delta})$ and $\mathcal{B}[5] \subset G(c_{5,1} \oplus B_{(1+11\varepsilon)\delta})$. $(\mathcal{A}[1], \mathcal{B}[5])$ can serve as a surrogate of v_4v_5. $(\mathcal{A}[1], \mathcal{B}[5])$ can encode $\sigma[w_2, w_5]$ sufficiently because for every segment x_1x_5 that joins a vertex x_1 of $\mathcal{A}[1]$ and a vertex x_5 of $\mathcal{B}[5]$, there exists a subsegment $x_1'x_5' \subset x_1x_5$ such that $d_F(x_1'x_5', \sigma[w_2, w_5]) \leq (1 + O(\varepsilon))\delta$.

polytope and an arrangement of hyperplanes [1]; even in such cases, the query time is substantially sublinear only if the space complexity is at least the input size raised to a power of $\Omega(d)$. It would be $(mn)^{\Omega(d)}$ in our case. We define a λ-segment query problem below that approximates the ray shooting problem, and we will present an efficient solution for $\lambda = 11\varepsilon\delta$ in Section 4 that avoids an $(mn)^{\Omega(d)}$ term in the space complexity. As mentioned before, the ray shooting result in [8] suffices in two and three dimensions.

λ-segment query. A set O of objects in $\mathbb{R}^d$ is preprocessed into a data structure so that for any oriented query segment pq, the *λ-segment query with pq on O* returns one of the following answers:

- If pq intersects an object in O, let x be the first intersection point with an object in O as we walk from p to q. In this case, the query returns an object $o \in O$ such that px intersects $o \oplus B_\lambda$. Figure 2 shows an illustration.
- Otherwise, the query returns null or an object $o \in O$ such that $d(o, pq) \leq \lambda$.

We are now ready to state the three constraints on $(\mathcal{A}, \mathcal{B}, \mathcal{C})$.

- **Constraint 1:**

(a) Both $(c_{1,1}, c_{1,2})$ and $(c_{k-1,1}, c_{k-1,2})$ belong to $\mathcal{G}_1 \times \mathcal{G}_1$.

(b) For $j \in [k-1]$, if $(c_{j,1}, c_{j,2}) \neq$ null, then:

(i) $c_{j,1}$ and $c_{j,2}$ are the grid cells returned by the $(11\varepsilon\delta)$-segment queries with w_jw_{j+1} and $w_{j+1}w_j$ on $\mathcal{G}_1$, respectively;

(ii) the minimum point in $w_jw_{j+1} \cap (c_{j,1} \oplus B_{11\varepsilon\delta})$ lies in front of the maximum point in $w_jw_{j+1} \cap (c_{j,2} \oplus B_{11\varepsilon\delta})$ with respect to $\leq_{w_jw_{j+1}}$.

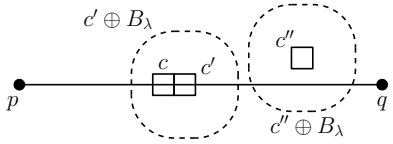

Figure 2 The λ-segment query with pq on the boxes $\{c, c', c''\}$ can return c or c' but not c''.

- **Constraint 2:**
  - **(a)** $\mathcal{B}[1]$ and $\mathcal{A}[k-1]$ belong to $\mathcal{G}_2$.
  - **(b)** $w_1 \in \mathcal{B}[1]$ and $w_k \in \mathcal{A}[k-1]$.
- **Constraint 3:**
  - **(a)** For $j \in [2, k-2]$, if $(c_{j,1}, c_{j,2}) = \text{null}$, then $\mathcal{A}[j]$ and $\mathcal{B}[j]$ are null.
  - **(b)** For $j \in [k-1]$, if $(c_{j,1}, c_{j,2}) \neq \text{null}$, then $\mathcal{A}[j]$ and $\mathcal{B}[j]$ belong to $\mathcal{G}_2$, $d(c_{j,1}, \mathcal{B}[j]) \leq (1+11\varepsilon)\delta$, and $d(c_{j,2}, \mathcal{A}[j]) \leq (1+11\varepsilon)\delta$.
  - **(c)** Let $\mathcal{J}$ be the set of $(r, s) \in [k-1] \times [k-1]$ such that $r < s$, $(c_{r,1}, c_{r,2}) \neq \text{null}$, $(c_{s,1}, c_{s,2}) \neq \text{null}$, and $(c_{j,1}, c_{j,2}) = \text{null}$ for $j \in [r+1, s-1]$. For every $(r, s) \in \mathcal{J}$, let x_r and x_s be the smallest vertices of $\mathcal{A}[r]$ and $\mathcal{B}[s]$ according to the lexicographical order of their coordinates, there exist $x'_r, x'_s \in x_r x_s$ such that $x'_r \leq_{x_r x_s} x'_s$ and $d_F(x'_r x'_s, \sigma[w_{r+1}, w_s]) \leq (1+\varepsilon)\delta$.

We remark that if $w_j w_{j+1}$ intersects the interior of the union of cells in $\mathcal{G}_1$, constraint 1(b)(ii) is satisfied automatically for $(c_{j,1}, c_{j,2})$ given constraint 1(b)(i). When $w_j w_{j+1}$ does not intersect the interior of the union of cells in $\mathcal{G}_1$, it is possible that the $(11\varepsilon\delta)$-segment queries return two cells that violate constraint 1(b)(ii). In this case, the input vertices are too far from $w_j w_{j+1}$ to be matched to any point in $w_j w_{j+1}$ within a distance δ, so we can set $(c_{j,1}, c_{j,2})$ to be null.

The next result shows that any query curve σ near a curve $\tau_i \in T$ has a coarse encoding with some additional properties. These properties will be useful in the analysis. Let $\mathcal{M}$ denote a matching between σ and some $\tau_i \in T$. For any subcurve $\sigma' \subseteq \sigma$, we use $\mathcal{M}(\sigma')$ to denote the subcurve of τ_i matched to σ' by $\mathcal{M}$.

▶ **Lemma 2.** *Let $\sigma = (w_1, \ldots, w_k)$ be a curve of k vertices. Let $\mathcal{M}$ be a matching between σ and $\tau_i \in T$ such that $d_{\mathcal{M}}(\tau_i, \sigma) \leq \delta$. Let $\tilde{\pi}_j = \{v_{i,a} : a \in [m-1], v_{i,a} \in \mathcal{M}(w_j w_{j+1}) \setminus \mathcal{M}(w_j)\}$ for all $j \in [k-1]$. Define $\pi_j = \tilde{\pi}_j$ for all $j \in [k-2]$, $\pi_{k-1} = \{v_{i,m}\} \cup \tilde{\pi}_{k-1}$, and $\pi_0 = \{v_{i,1} \ldots, v_{i,m}\} \setminus \bigcup_{j=1}^{k-1} \pi_j$. There is a coarse encoding $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ for σ that satisfies the following properties.*

- **(i)** *For $j \in [2, k-1]$, $\pi_j = \emptyset$ if and only if $(c_{j,1}, c_{j,2}) = \text{null}$.*
- **(ii)** *For all $(r, s) \in \mathcal{J}$, if $r = 1$ and $\pi_1 = \emptyset$, let $b_1 = 1$; otherwise, let $b_r = \max\{b : v_{i,b} \in \pi_r\}$. For all $(r, s) \in \mathcal{J}$, there exist a point $z \in \mathcal{A}[r] \cap \tau_{i,b_r}$ and another point $z' \in \mathcal{B}[s] \cap \tau_{i,b_r}$ such that $z \leq_{\tau_{i,b_r}} z'$.*

Proof. We define the component $\mathcal{C}$ as follows. Given that $v_{i,1} \in \mathcal{M}(w_1)$, $w_1 w_2$ intersects the interior of the union of cells in $\mathcal{G}_1$, so the $(11\varepsilon\delta)$-segment query with $w_1 w_2$ on $\mathcal{G}_1$ must return some cell; we define it to be $c_{1,1}$. Similarly, the $(11\varepsilon\delta)$-segment query with $w_2 w_1$ on $\mathcal{G}_1$ must return some cell; we define it to be $c_{1,2}$. The pair $(c_{k-1,1}, c_{k-1,2})$ are also defined in a similar way as $v_{i,m} \in \mathcal{M}(w_k)$. Consider any $j \in [2, k-1]$. If $v_{i,a} \in \pi_j$ for some $a \in [m]$, then $v_{i,a} \in \mathcal{M}(w_j w_{j+1})$, which implies that $w_j w_{j+1}$ intersects $v_{i,a} \oplus B_\delta$ and hence the interior of the union of cells in $\mathcal{G}_1$. Thus, $(c_{j,1}, c_{j,2})$ can be defined using the $(11\varepsilon\delta)$-segment queries with $w_j w_{j+1}$ and $w_{j+1} w_j$ as before. On the other hand, if $\pi_j = \emptyset$, we define $(c_{j,1}, c_{j,2})$ to be null. Constraint 1 and property (i) in the lemma are thus satisfied.

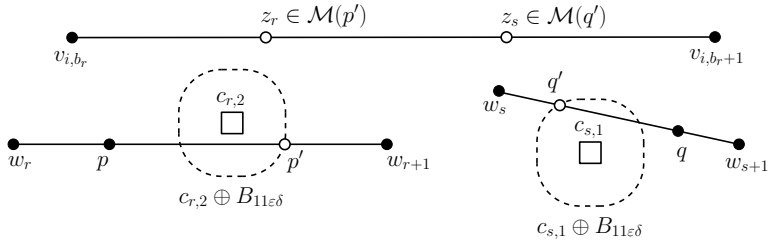

Figure 3 Illustration of p, p', q', q, z_r, and z_s.

Next, we define $\mathcal{A}$ and $\mathcal{B}$ to satisfy constraints 2 and 3.

As $v_{i,1} \in \mathcal{M}(w_1)$ and $v_{i,m} \in \mathcal{M}(w_k)$, both $d(w_1, v_{i,1})$ and $d(w_k, v_{i,m})$ are at most δ. So w_1 lies in a cell in $G(v_{i,1} \oplus B_\delta) \subset G(v_{i,1} \oplus B_{(2+12\varepsilon)\delta}) \subset \mathcal{G}_2$; we make this cell $\mathcal{B}[1]$. Similarly, we define $\mathcal{A}[k-1]$ to be the cell in $\mathcal{G}_2$ that contains w_k. Constraint 2 is thus enforced.

For $j \in [2, k-2]$, if $(c_{j,1}, c_{j,2}) = \text{null}$, let $\mathcal{A}[j]$ and $\mathcal{B}[j]$ be null, satisfying constraint 3(a). $\mathcal{B}[1]$ and $\mathcal{A}[k-1]$ have already been defined, and they belong to $\mathcal{G}_2$. Since w_1 lies in a cell in $G(v_{i,1} \oplus B_\delta) \subset \mathcal{G}_1$, we have $w_1 \in c_{1,1} \oplus B_{11\varepsilon\delta}$ by the $(11\varepsilon\delta)$-segment query. Then, $d(c_{1,1}, \mathcal{B}[1]) \le 11\varepsilon\delta$ as $w_1 \in \mathcal{B}[1]$. Similarly, $d(c_{k-1,2}, \mathcal{A}[k-1]) \le 11\varepsilon\delta$. So $\mathcal{B}[1]$ and $\mathcal{A}[k-1]$ satisfy constraint 3(b). It remains to discuss $\mathcal{A}[j]$ for $j \in [1, k-2]$ and $\mathcal{B}[j]$ for $j \in [2, k-1]$.

Consider an arbitrary $j_* \in [k-1]$ such that $(c_{j_*,1}, c_{j_*,2}) \neq \text{null}$. Recall that $\mathcal{J}$ is the set of $(r, s) \in [k-1] \times [k-1]$ such that $r < s$, $(c_{r,1}, c_{r,2}) \neq \text{null}$, $(c_{s,1}, c_{s,2}) \neq \text{null}$, and $(c_{j,1}, c_{j,2}) = \text{null}$ for $j \in [r+1, s-1]$. Thus, if $j_* \le k-2$, it must exist as the first value in exactly one element of $\mathcal{J}$, and if $j_* \ge 2$, it must also exist as the second value in exactly another element of $\mathcal{J}$. As a result, it suffices to define $\mathcal{A}[r]$ and $\mathcal{B}[s]$ for every $(r, s) \in \mathcal{J}$ and verify that constraints 3(b) and 3(c) are satisfied.

Take any $(r, s) \in \mathcal{J}$. If $\pi_r \neq \emptyset$, it is legal to define $b_r = \max\{b : v_{i,b} \in \pi_r\}$. If $\pi_r = \emptyset$, then $r = 1$ because for any $r > 1$, $\pi_r \neq \text{null}$ by (i) as $(c_{r,1}, c_{r,2}) \neq \text{null}$ by the definition of $\mathcal{J}$. In the case that $r = 1$ and $\pi_1 = \emptyset$, b_1 is defined to be 1. Therefore, b_r is well defined for all $(r, s) \in \mathcal{J}$. The definition of b_r implies that $b_r = \max\{b : v_{i,b} \in \mathcal{M}(w_r w_{r+1})\}$. Since $(c_{s,1}, c_{s,2}) \neq \text{null}$ and $(c_{j,1}, c_{j,2}) = \text{null}$ for $j \in [r+1, s-1]$, by (i), $\pi_s \neq \emptyset$ and $\pi_j = \emptyset$ for $j \in [r+1, s-1]$. It follows that $v_{i,b_r+1} \in \pi_s$ which is a subset of $\mathcal{M}(w_s w_{s+1})$. Pick any point $p \in w_r w_{r+1}$ and any point $q \in w_s w_{s+1}$ such that $v_{i,b_r} \in \mathcal{M}(p)$ and $v_{i,b_r+1} \in \mathcal{M}(q)$.

We claim that $p w_{r+1} \cap (c_{r,2} \oplus B_{11\varepsilon\delta})$ and $w_s q \cap (c_{s,1} \oplus B_{11\varepsilon\delta})$ are non-empty. Since $c_{r,2}$ is the cell in $\mathcal{G}_1$ returned by the $(11\varepsilon\delta)$-segment query with $w_{r+1} w_r$, for any intersection point x between $w_{r+1} w_r$ and any cell in $\mathcal{G}_1$, we have $x w_{r+1} \cap (c_{r,2} \oplus B_{11\varepsilon\delta}) \neq \emptyset$ by definition. We have $p \in w_r w_{r+1} \cap (v_{i,b_r} \oplus B_\delta)$ by our choice of p; it means that p is an intersection point between $w_r w_{r+1}$ and a cell in $G(v_{i,b_r} \oplus B_\delta) \subset \mathcal{G}_1$. We can thus substitute p for x and conclude that $p w_{r+1} \cap (c_{r,2} \oplus B_{11\varepsilon\delta}) \neq \emptyset$. Similarly, we get $w_s q \cap (c_{s,1} \oplus B_{11\varepsilon\delta}) \neq \emptyset$.

By our claim, when we walk from w_{r+1} to p, we hit $c_{r,2} \oplus B_{11\varepsilon\delta}$ at some point p', and when we walk from w_s to q, we hit $c_{s,1} \oplus B_{11\varepsilon\delta}$ at some point q'. Pick two points $z_r \in \mathcal{M}(p')$ and $z_s \in \mathcal{M}(q')$. By definition, $c_{r,2} \in G(v_{i_r,a_r} \oplus B_\delta)$ for some $\tau_{i_r} \in T$ and some index $a_r \in [m]$. The cell width of $c_{r,2}$ is $\varepsilon\delta/\sqrt{d}$, so $c_{r,2} \subset v_{i_r,a_r} \oplus B_{(1+\varepsilon)\delta}$. By triangle inequality, $p' \in v_{i_r,a_r} \oplus B_{(1+12\varepsilon)\delta}$ and hence $z_r \in v_{i_r,a_r} \oplus B_{(2+12\varepsilon)\delta}$, which implies that z_r is contained in a cell in $G(v_{i_r,a_r} \oplus B_{(2+12\varepsilon)\delta}) \subset \mathcal{G}_2$. By a similar reasoning, we can also deduce that z_s is contained in a cell in $\mathcal{G}_2$. We define $\mathcal{A}[r]$ and $\mathcal{B}[s]$ to be the cells in $\mathcal{G}_2$ that contain z_r and z_s, respectively. Figure 3 shows an illustration.

Since $d(c_{r,2}, z_r) \le d(c_{r,2}, p') + d(p', z_r) \le (1 + 11\varepsilon)\delta$, we get $d(c_{r,2}, \mathcal{A}[r]) \le (1 + 11\varepsilon)\delta$. Similarly, $d(c_{s,1}, \mathcal{B}[s]) \le (1 + 11\varepsilon)\delta$. This takes care of constraint 3(b).

As $v_{i,b_r} \in \mathcal{M}(p)$ and $p \leq_{w_r w_{r+1}} p'$, we have $v_{i,b_r} \leq_{\tau_i} \mathcal{M}(p')$. Similarly, we have $\mathcal{M}(q') \leq_{\tau_i} v_{i,b_{r+1}}$. Therefore, $v_{i,b_r} \leq_{\tau_i} \mathcal{M}(p') \leq_{\tau_i} \mathcal{M}(q') \leq_{\tau_i} v_{i,b_{r+1}}$. As $z_r \in \mathcal{M}(p')$ and $z_s \in \mathcal{M}(q')$, z_r and z_s satisfy property (ii) of the lemma. The distance between z_r and any vertex x_r of $\mathcal{A}[r]$ is at most $\varepsilon\delta$. So is the distance between z_s and any vertex x_s of $\mathcal{B}[s]$. Thus, we can use the linear interpolation $\mathcal{I}$ between $x_r x_s$ and $z_r z_s$ as a matching to get $d_{\mathcal{I}}(x_r x_s, z_r z_s) \leq \varepsilon\delta$. Combining $\mathcal{M}$ and $\mathcal{I}$ shows that there is a matching between $\sigma[p', q']$ and $x_r x_s$ within a distance of $(1+\varepsilon)\delta$. Since $\sigma[w_{r+1}, w_s] \subseteq \sigma[p', q']$, we have thus verified constraint 3(c). ◀

2.2 Data structure organization and construction

We construct $\mathcal{G}_1$ and $\mathcal{G}_2$ in $O(mn/\varepsilon^d)$ time and space. We need a point location data structure for $\mathcal{G}_2$ which is organized as a multi-level tree as follows. The top-level tree has leaves corresponding to the intervals of the cells on the first coordinate axis. Each leaf is associated with the cells that project to the interval of that leaf, and these cells are stored in a second-level tree with leaves corresponding to the intervals of these cells on the second coordinate axis. Continuing in this manner yields $d = O(1)$ levels, using $O(|\mathcal{G}_2|) = O(mn/\varepsilon^d)$ space and $O\big((mn/\varepsilon^d)\log\frac{mn}{\varepsilon}\big)$ preprocessing time. A point location takes $O(\log\frac{mn}{\varepsilon})$ time.

The $(1+O(\varepsilon), \delta)$-ANN data structure is a trie $\mathcal{D}$. Each key to be stored in $\mathcal{D}$ is a *candidate* coarse encoding, which is a 3-tuple $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ just like a coarse encoding. For a candidate coarse encoding, constraints 1(a), 2(a), 3(a), and 3(b) must be satisfied, but constraints 1(b), 2(b), and 3(c) are ignored. This difference is necessary because constraints 1(b), 2(b), and 3(c) require the query curve, which is not available in preprocessing. For each candidate coarse encoding E, let T_E be the subset of input curves that are within a Fréchet distance of $(1+O(\varepsilon))\delta$ from any query curve that has E as a coarse encoding, we will discuss shortly how to obtain the curves in T_E.

Each key E in $\mathcal{D}$ has $O(k)$ size because E stores $O(k)$ cells in $\mathcal{G}_1$ and $\mathcal{G}_2$. As a trie, $\mathcal{D}$ is a rooted tree with as many levels as the length of the key E. Searching in D boils down to visiting the appropriate child of an internal node of $\mathcal{D}$. Each component of the key E is an element of $\mathcal{G}_2 \cup \{\text{null}\}$ or $(\mathcal{G}_1 \times \mathcal{G}_1) \cup \{\text{null}\}$; there are $O(m^2n^2/\varepsilon^{2d})$ possibilities. We keep a dictionary at each internal node of $\mathcal{D}$ for finding the appropriate child to visit in $O(\log\frac{mn}{\varepsilon})$ time. Hence, the total search time of $\mathcal{D}$ is $O(k\log\frac{mn}{\varepsilon})$.

To bound the size of $\mathcal{D}$, observe that each key E at a leaf of $\mathcal{D}$ induces $O(k)$ entries in the dictionaries at the ancestors of that leaf. There are $O(\sqrt{d}/\varepsilon)^{4d(k-1)}(mn)^{4(k-1)}$ candidate coarse encodings. So the total space taken by the dictionaries at the internal nodes is $O(\sqrt{d}/\varepsilon)^{4d(k-1)}(mn)^{4(k-1)}k$. We will show that if a query curve has E as a coarse encoding, any curve in T_E is within a Fréchet distance of $(1+O(\varepsilon))\delta$ from that query curve. Therefore, we only need to store one of the curves in T_E at the leaf for E, and it suffices to store the index of this curve. Therefore, the total space complexity of $\mathcal{D}$ is $O(\sqrt{d}/\varepsilon)^{4d(k-1)}(mn)^{4(k-1)}k$.

The construction of $\mathcal{D}$ proceeds as follows. We initialize $\mathcal{D}$ to be empty. We enumerate all possible candidate coarse encodings based on constraints 1(a), 2(a), 3(a), and 3(b). Take a possible candidate coarse encoding E. The set T_E is initialized to be empty. We go through every input curve τ_i to determine whether to include τ_i in T_E. If $T_E \neq \emptyset$ in the end, we insert E together with one curve in T_E into $\mathcal{D}$. In the following, we discuss the checking of whether to include τ_i in T_E.

Let E be $(\mathcal{A}, \mathcal{B}, \mathcal{C})$. We generate all possible *partitions* of $\{v_{i,1}, \ldots, v_{i,m}\}$ that satisfy the following properties.

Partition: a sequence of k *disjoint* subsets $(\pi_0, \pi_1, \ldots, \pi_{k-1})$ such that $\bigcup_{j=0}^{k-1} \pi_j = \{v_{i,1}, \ldots, v_{i,m}\}$, $v_{i,1} \in \pi_0$, $v_{i,m} \in \pi_{k-1}$, π_j may be empty for some $j \in [k-2]$, and for any $v_{i,a} \in \pi_j$ and any $v_{i,b} \in \pi_l$, if $j < l$, then $a < b$.

There are fewer than m^{k-1} partitions. Given a partition $(\pi_0, \ldots, \pi_{k-1})$, the vertices in π_0 are to be matched with $v_{i,1}$; for $j \in [k-1]$, the vertices in π_j are to be matched with points in $w_j w_{j+1} \setminus \{w_j\}$, where $w_j w_{j+1}$ is the j-th edge of the query curve; $v_{i,m}$ and possibly other vertices of τ_i are matched with w_k. The reference to $w_j w_{j+1}$ is conceptual; we do not need to know the query curve in preprocessing.

We describe four tests for each partition below. As soon as we come across a partition that passes all four tests, we insert τ_i into T_E. If a partition fails any test, we move on to the next partition. If no partition can pass all four tests in the end, we do not include τ_i in T_E.

The first test is that for $j \in [2, k-1]$, $\pi_j = \emptyset$ if and only if $(c_{j,1}, c_{j,2}) = \text{null}$. This test takes $O(k)$ time. We exclude π_1 from this test because $(c_{1,1}, c_{1,2}) \neq \text{null}$ by constraint 1(a), whereas π_1 may be empty or not depending on the partition enumerated.

In the second test, for $j \in [k-1]$, if $\pi_j \neq \emptyset$, let $a_j, b_j \in [m]$ be the smallest and largest indices such that $v_{i,a_j}, v_{i,b_j} \in \pi_j$, the intuition is that $v_{i,a_j}, \ldots, v_{i,b_j}$ can be matched to the surrogate $(c_{j,1}, c_{j,2})$ of $w_j w_{j+1}$ within a distance of $(1 + O(\varepsilon))\delta$. The second test checks this property as follows. Observe that $(c_{j,1}, c_{j,2}) \neq \text{null}$: $(c_{1,1}, c_{1,2}) \neq \text{null}$ by constraint 1(a), and for $j \in [2, k-1]$, $(c_{j,1}, c_{j,2}) \neq \text{null}$ by the first test. Pick the smallest vertices x_j of $c_{j,1}$ and y_j of $c_{j,2}$ according to the lexicographical order of their coordinates. If $x_j y_j \cap (v_{i,a_j} \oplus B_{(1+12\varepsilon)\delta})$ or $x_j y_j \cap (v_{i,b_j} \oplus B_{(1+12\varepsilon)\delta})$ is empty, the test fails. Otherwise, compute the minimum point x'_j in $x_j y_j \cap (v_{i,a_j} \oplus B_{(1+12\varepsilon)\delta})$ and the maximum point y'_j in $x_j y_j \cap (v_{i,b_j} \oplus B_{(1+12\varepsilon)\delta})$ with respect to $\leq_{x_j y_j}$. If it is not the case that $x'_j \leq_{x_j y_j} y'_j$, the test fails. Suppose that $x'_j \leq_{x_j y_j} y'_j$. Compute $d_F(x'_j y'_j, \tau_i[v_{i,a_j}, v_{i,b_j}])$ and check whether it is $(1 + 12\varepsilon)\delta$ or less. If all of the above checks succeed for all $j \in [k-1]$, the second test succeeds; otherwise, the test fails. The test takes $O(m \log m)$ time, which is dominated by the computation of $d_F(x'_j y'_j, \tau_i[v_{i,a_j}, v_{i,b_j}])$ over all $j \in [k-1]$.

The third test is that $\mathcal{B}[1] \in G(v_{i,1} \oplus B_\delta)$ and $\mathcal{A}[k-1] \in G(v_{i,m} \oplus B_\delta)$, which boils down to checking whether $d(v_{i,1}, \mathcal{B}[1])$ and $d(v_{i,m}, \mathcal{A}[k-1])$ are at most δ.

The fourth test involves $\mathcal{J}$, the set of $(r, s) \in [k-1] \times [k-1]$ such that $r < s$, $(c_{r,1}, c_{r,2}) \neq \text{null}$, $(c_{s,1}, c_{s,2}) \neq \text{null}$, and $(c_{j,1}, c_{j,2}) = \text{null}$ for $j \in [r+1, s-1]$. Note that $|\mathcal{J}| \leq k-1$ and it can be constructed in $O(k)$ time. For every $(r, s) \in \mathcal{J}$, if $r = 1$ and $\pi_1 = \emptyset$, let $b_1 = 1$; otherwise, let $b_r = \max\{b : v_{i,b} \in \pi_r\}$. It follows that $b_r + 1 = \min\{a : v_{i,a} \in \pi_s\}$. We check if it is the case that $\tau_{i,b_r} \cap \mathcal{A}[r] \neq \emptyset$, $\tau_{i,b_r} \cap \mathcal{B}[s] \neq \emptyset$, and we hit $\mathcal{A}[r]$ no later than $\mathcal{B}[s]$ when we walk from v_{i,b_r} to v_{i,b_r+1}. (Recall the intuition that the pair $\mathcal{A}[r]$ and $\mathcal{B}[s]$ serve as the surrogate of the edge $\tau_{i,b_r} = v_{i,b_r} v_{i,b_r+1}$.) If check fails for any $(r, s) \in \mathcal{J}$, the test fails. Otherwise, the test succeeds. This test runs in $O(k)$ time.

The following result summarizes the construction of $\mathcal{D}$ and four properties of each candidate coarse encoding in $\mathcal{D}$.

▶ **Lemma 3.** *The trie $\mathcal{D}$ has $O(\sqrt{d}/\varepsilon)^{4d(k-1)}(mn)^{4(k-1)}k$ size and can be constructed in $O(\sqrt{d}/\varepsilon)^{4d(k-1)}(mn)^{4(k-1)}(k \log \frac{mn}{\varepsilon} + m^k \log m)$ time. We can search $\mathcal{D}$ with a coarse encoding in $O(k \log \frac{mn}{\varepsilon})$ time. For each candidate coarse encoding $E = (\mathcal{A}, \mathcal{B}, \mathcal{C})$, a curve $\tau_i \in T$ belongs to T_E if and only if there exists a partition $(\pi_0, \ldots, \pi_{k-1})$ of the vertices of τ_i that satisfy the following four properties. For $j \in [k-1]$, if $j = 1$ and $\pi_1 = \emptyset$, let $b_1 = 1$; otherwise, if $\pi_j \neq \emptyset$, let $a_j = \min\{a : v_{i,a} \in \pi_j\}$ and let $b_j = \max\{b : v_{i,b} \in \pi_j\}$.*

- **(i)** *For $j \in [2, k-1]$, $\pi_j = \emptyset$ if and only if $(c_{j,1}, c_{j,2}) = \text{null}$.*
- **(ii)** *For $j \in [k-1]$, if $\pi_j \neq \emptyset$, let x_j and y_j be the smallest vertices of $c_{j,1}$ and $c_{j,2}$ according to the lexicographical order of their coordinates, there exist $x''_j, y''_j \in x_j y_j$ such that $x''_j \leq_{x_j y_j} y''_j$ and $d_F(x''_j y''_j, \tau_i[v_{i,a_j}, v_{i,b_j}]) \leq (1 + 12\varepsilon)\delta$.*
- **(iii)** *$\mathcal{B}[1] \in G(v_{i,1} \oplus B_\delta)$ and $\mathcal{A}[k-1] \in G(v_{i,m} \oplus B_\delta)$.*
- **(iv)** *For every $(r, s) \in \mathcal{J}$, $\tau_{i,b_r} \cap \mathcal{A}[r] \neq \emptyset$, $\tau_{i,b_r} \cap \mathcal{B}[s] \neq \emptyset$, and we hit $\mathcal{A}[r]$ no later than $\mathcal{B}[s]$ when we walk from v_{i,b_r} to v_{i,b_r+1}.*

2.3 Querying

At query time, we are given a curve $\sigma = (w_1, ..., w_k)$. We enumerate all coarse encodings of σ; for each coarse encoding E enumerated, we search the trie $\mathcal{D}$ for E; if E is found, we return the curve in T_E stored with E as the answer of the query; if no coarse encoding of σ can be found in $\mathcal{D}$, we return "no".

Each search in $\mathcal{D}$ takes $O(k \log \frac{mn}{\varepsilon})$ time as stated in Lemma 3. The enumeration of the coarse encodings of σ require a solution for the $(11\varepsilon\delta)$-segment queries on $\mathcal{G}_1$ as stated in constraint 1(b)(i) in Section 2.1. We will discuss an efficient solution later.

For $j \in [k-1]$, we make two $(11\varepsilon\delta)$-segment queries with w_jw_{j+1} and $w_{j+1}w_j$ on $\mathcal{G}_1$ to obtain $u_{j,1}$ and $u_{j,2}$, respectively. If any of the two queries returns null, define $(u_{j,1}, u_{j,2})$ to be null. If $(u_{j,1}, u_{j,2}) \neq$ null and the minimum point in $w_jw_{j+1} \cap (u_{j,1} \oplus B_{11\varepsilon\delta})$ does not lie in front of the maximum point in $w_jw_{j+1} \cap (u_{j,2} \oplus B_{11\varepsilon\delta})$ with respect to $\leq_{w_jw_{j+1}}$, then constraint 1(b)(ii) is not satisfied. It must be the case that w_jw_{j+1} does not intersect the interior of the union of cells in $\mathcal{G}_1$, and the $(11\varepsilon\delta)$-segment queries just happen to return two cells that violate constraint 1(b)(ii). In this case, the input vertices are too far from w_jw_{j+1} to be matched to any point in w_jw_{j+1} within a distance δ, so we reset $(u_{j,1}, u_{j,2})$ to be null.

After defining $(u_{j,1}, u_{j,2})$ for $j \in [k-1]$, we generate the coarse encodings of σ as follows. The pairs $(c_{1,1}, c_{1,2})$ and $(c_{k-1,1}, c_{k-1,2})$ are defined to be $(u_{1,1}, u_{1,2})$ and $(u_{k-1,1}, u_{k-1,2})$, respectively. For $j \in [2, k-2]$, we enumerate all possible $\mathcal{C}$ by setting $(c_{j,1}, c_{j,2})$ to be $(u_{j,1}, u_{j,2})$ or null. This gives a total of 2^{k-3} possible $\mathcal{C}$'s. We query the point location data structure for $\mathcal{G}_2$ to find the cells $\mathcal{B}[1]$ and $\mathcal{A}[k-1]$ that contain w_1 and w_k, respectively. Then, for each $\mathcal{C}$ enumerated, we enumerate $\mathcal{A}[j]$ for $j \in [1, k-2]$ and $\mathcal{B}[j]$ for $j \in [2, k-1]$ according to constraints 3(a) and 3(b) in Section 2.1. This enumeration produces $O(\sqrt{d}/\varepsilon)^{2d(k-2)}$ tuples of $(\mathcal{A}, \mathcal{B}, \mathcal{C})$. For each $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ enumerated, we check whether it satisfies constraint 3(c), which can be done in $O(k \log k)$ time as implied by the following result.

▶ **Lemma 4.** *Take any $(r, s) \in \mathcal{J}$. Let x_r and x_s be the smallest vertices of $\mathcal{A}[r]$ and $\mathcal{B}[s]$ by the lexicographical order of their coordinates. We can check in $O((s-r)\log(s-r))$ time whether there are $x'_r, x'_s \in x_rx_s$ such that $x'_r \leq_{x_rx_s} x'_s$ and $d_F(x'_rx'_s, \sigma[w_{r+1}, w_s]) \leq (1+\varepsilon)\delta$.*

▶ **Lemma 5.** *The query time is $O(kQ_{\text{seg}}) + O(\sqrt{d}/\varepsilon)^{2d(k-2)} k \log \frac{mn}{\varepsilon}$, where Q_{seg} is the time to answer an $(11\varepsilon\delta)$-segment query.*

2.4 Approximation guarantee

First, we show that if σ is within a Fréchet distance δ from some input curve, there exists a coarse encoding E of σ such that $T_E \neq \emptyset$. Hence, E and a curve in T_E are stored in $\mathcal{D}$.

▶ **Lemma 6.** *If $d_F(\tau_i, \sigma) \leq \delta$, then $\tau_i \in T_E$ for some coarse encoding E of σ.*

Proof. Let $\mathcal{M}$ be a Fréchet matching between τ_i and σ. Let E be the coarse encoding specified for σ in Lemma 2. For any subcurve $\sigma' \subseteq \sigma$, we use $\mathcal{M}(\sigma')$ to denote the subcurve of τ_i matched to σ' by $\mathcal{M}$. For $j \in [k-1]$, let $\tilde{\pi}_j = \{v_{i,a} : a \in [m-1], v_{i,a} \in \mathcal{M}(w_jw_{j+1}) \setminus \mathcal{M}(w_j)\}$. Define $\pi_j = \tilde{\pi}_j$ for $j \in [k-2]$, $\pi_{k-1} = \{v_{i,m}\} \cup \tilde{\pi}_{k-1}$, and $\pi_0 = \{v_{i,1}, \ldots, v_{i,m}\} \setminus \bigcup_{j=1}^{k-1} \pi_j$. We obtain a partition $(\pi_0, ..., \pi_{k-1})$ of the vertices of τ_i.

We prove that E, τ_i, and $(\pi_0, ..., \pi_{k-1})$ satisfy Lemma 3(i)–(iv) which put τ_i in T_E. Lemma 3(i) follows directly from Lemma 2(i),

Take any $j \in [k-1]$ such that $\pi_j \neq \emptyset$. Let π_j be $\{v_{i,a}, v_{i,a+1}, \ldots, v_{i,b}\}$. By the definition of π_j, every vertex in π_j belongs to $\mathcal{M}(w_jw_{j+1})$, so $\tau_i[v_{i,a}, v_{i,b}] \subset \mathcal{M}(w_jw_{j+1})$. Then, there must exist two points $p, q \in w_jw_{j+1}$ such that $p \leq_{w_jw_{j+1}} q$ and $d_F(pq, \tau_i[v_{i,a}, v_{i,b}]) \leq \delta$. If $j = 1$, we

have $(c_{1,1}, c_{1,2}) \neq$ null by constraint 1(a); if $j \in [2, k-1]$, by Lemma 2(i), $(c_{j,1}, c_{j,2}) \neq$ null as $\pi_j \neq$ null. Therefore, $c_{j,1}$ and $c_{j,2}$ are cells in $\mathcal{G}_1$ returned by the $(11\varepsilon\delta)$-segment queries with $w_j w_{j+1}$ and $w_{j+1} w_j$, respectively. We have shown that $d_F(pq, \tau_i[v_{i,a}, v_{i,b}]) \leq \delta$; therefore, p is contained in a cell in $G(v_{i,a} \oplus B_\delta) \subset \mathcal{G}_1$. As $c_{j,1}$ is the cell returned by the $(11\varepsilon\delta)$-segment query with $w_j w_{j+1}$, there must be a point $z_p \in w_j w_{j+1} \cap (c_{j,1} \oplus B_{11\varepsilon\delta})$ such that $z_p \leq_{w_j w_{j+1}} p$. In a similar way, we can conclude that there must be a point $z_q \in w_j w_{j+1} \cap (c_{j,2} \oplus B_{11\varepsilon\delta})$ such that $q \leq_{w_j w_{j+1}} z_q$. That is, $z_p \leq_{w_j w_{j+1}} p \leq_{w_j w_{j+1}} q \leq_{w_j w_{j+1}} z_q$. Let x_j and y_j be the smallest vertices of $c_{j,1}$ and $c_{j,2}$ according to the lexicographical order of their coordinates. Both $d(z_p, x_j)$ and $d(z_q, y_j)$ are at most $12\varepsilon\delta$. A linear interpolation from $z_p z_q$ to $x_j y_j$ maps p and q to two points x''_j and y''_j on $x_j y_j$, respectively, such that $x''_j \leq_{x_j y_j} y''_j$. Also, the linear interpolation adds a distance $12\varepsilon\delta$ or less, which gives $d_F(x''_j y''_j, \tau_i[v_{i,a}, v_{i,b}]) \leq d_F(x''_j y''_j, pq) + d_F(pq, \tau_i[v_{i,a}, v_{i,b}]) \leq (1 + 12\varepsilon)\delta$. Hence, Lemma 3(ii) is satisfied.

The grid cells $\mathcal{B}[1]$ and $\mathcal{A}[k-1]$ are defined to contain w_1 and w_k, respectively. Also, $v_{i,1} \in \mathcal{M}(w_1)$ and $v_{i,m} \in \mathcal{M}(w_k)$. Hence, $\mathcal{B}[1] \in G(v_{i,1} \oplus B_\delta)$ and $\mathcal{A}[k-1] \in G(v_{i,m} \oplus B_\delta)$, satisfying Lemma 3(iii).

For any pair $(r, s) \in \mathcal{J}$, by Lemma 2(ii), there exist two points $z \in \mathcal{A}[r] \cap \tau_{i,b_r}$ and $z' \in \mathcal{B}[s] \cap \tau_{i,b_r}$ such that $z \leq_{\tau_{i,b_r}} z'$. Since $\mathcal{A}[r]$ and $\mathcal{B}[s]$ are interior-disjoint unless they are equal, we must hit $\mathcal{A}[r]$ no later than $\mathcal{B}[s]$ when we walk from v_{i,b_r} to v_{i,b_r+1}, satisfying Lemma 3(iv). ◀

We show that if E is a coarse encoding of σ, each curve in T_E is close to σ.

▶ **Lemma 7.** *Let E be a coarse encoding of σ. For every $\tau_i \in T_E$, $d_F(\tau_i, \sigma) \leq (1 + 24\varepsilon)\delta$.*

Proof. (Sketch) Suppose that $T_E \neq \emptyset$ as the lemma statement is vacuous otherwise. Take any $\tau_i \in T_E$. We construct a matching $\mathcal{M}$ between τ_i and σ such that $d_{\mathcal{M}}(\tau_i, \sigma) \leq (1+24\varepsilon)\delta$. Since $T_E \neq \emptyset$, there exists a partition $(\pi_0, \ldots, \pi_{k-1})$ of the vertices of τ_i that satisfy Lemma 3(i)–(iv). Using these properties, we can match the vertices of τ_i to points on σ and then the vertices of σ to points on τ_i. Afterwards, σ and τ_i divided into line segments by their vertices and images of their matching partners. We use linear interpolations to match the corresponding line segments. More details can be found in the appendix. ◀

In two and three dimensions, the ray shooting data structure for boxes in [8] can be used as the $(11\varepsilon\delta)$-segment query data structure. It has an $O(\log |\mathcal{G}_1|) = O(\log \frac{mn}{\varepsilon})$ query time and an $O(|\mathcal{G}_1|^{2+\mu}) = O((mn)^{2+\mu}/\varepsilon^{d(2+\mu)})$ space and preprocessing time for any fixed $\mu \in (0, 1)$. If the query segment does not intersect any cell in $\mathcal{G}_1$, we return null. In four and higher dimensions, we will prove the following result in Section 4.

▶ **Lemma 8.** *We can construct a data structure in $O(\sqrt{d}/\varepsilon)^{O(d/\varepsilon^2)} \cdot \tilde{O}((mn)^{O(1/\varepsilon^2)})$ space and preprocessing time such that given any oriented edge e of the query curve σ, the data structure either discovers that $\min_{\tau_i \in T} d_F(\sigma, \tau_i) > \delta$, or reports a correct answer for the $(11\varepsilon\delta)$-segment query with e on $\mathcal{G}_1$. The query time is $\tilde{O}((mn)^{0.5+\varepsilon}/\varepsilon^d)$.*

Combining the results in this section with the ray shooting result in [8], Lemma 8, and Theorem 1 gives $(1+\varepsilon)$-ANN data structures. Theorem 1 uses the deletion cost of a $(1+\varepsilon, \delta)$-ANN data structure. We perform each deletion by reconstructing the data structure from scratch because we do not have a more efficient solution.

▶ **Theorem 9.** *For any $\varepsilon \in (0, 0.5)$, there is a $(1 + O(\varepsilon))$-ANN data structure for T under the Fréchet distance with the following performance guarantees:*

- $d \in \{2,3\}$:
  query time $= O\big(\frac{1}{\varepsilon}\big)^{2d(k-2)} k \log \frac{mn}{\varepsilon} \log n$,
  space $= O\big(\frac{1}{\varepsilon}\big)^{4d(k-1)+1} (mn)^{4(k-1)} k \log^2 n$,
  expected preprocessing time $= O\big(\frac{1}{\varepsilon}\big)^{4d(k-1)} (mn)^{4(k-1)} \big(k \log \frac{mn}{\varepsilon} + m^k \log m\big) n \log n$.
- $d \geq 4$:
  query time $= \tilde{O}\big(\frac{1}{\varepsilon^d} k (mn)^{0.5+\varepsilon}\big) + O\big(\frac{\sqrt{d}}{\varepsilon}\big)^{2d(k-2)} k \log \frac{mn}{\varepsilon} \log n$,
  space $= O\big(\frac{\sqrt{d}}{\varepsilon}\big)^{4d(k-1)} (mn)^{4(k-1)} k \cdot \frac{1}{\varepsilon} \log^2 n + O\big(\frac{\sqrt{d}}{\varepsilon}\big)^{O(d/\varepsilon^2)} \cdot \tilde{O}((mn)^{O(1/\varepsilon^2)})$,
  expected preprocessing time $= O\big(\frac{\sqrt{d}}{\varepsilon}\big)^{4d(k-1)} (mn)^{4(k-1)} \big(k \log \frac{mn}{\varepsilon} + m^k \log m\big) n \log n +$
  $O\big(\frac{\sqrt{d}}{\varepsilon}\big)^{O(d/\varepsilon^2)} \cdot \tilde{O}((mn)^{O(1/\varepsilon^2)})$.

3 $(3 + O(\varepsilon), \delta)$-ANN

Given a query curve $\sigma = (w_1, w_2, \ldots, w_k)$, for $j \in [k-1]$, we solve the $(11\varepsilon\delta)$-segment queries with $w_j w_{j+1}$ and $w_{j+1} w_j$ on $\mathcal{G}_1$ as before. Let $((c_{j,1}, c_{j,2}))_{j \in [k-1]}$ denote the results of the queries. Recall that each $(c_{j,1}, c_{j,2})$ belongs to $(\mathcal{G}_1 \times \mathcal{G}_1) \cup \{\text{null}\}$.

Suppose that there are $k_0 \leq k-1$ non-null pairs in $((c_{j,1}, c_{j,2}))_{j \in [k-1]}$. Extract these non-null pairs to form the sequence $((c_{j_r,1}, c_{j_r,2}))_{r \in [k_0]}$. Note that $j_1 = 1$ and $j_{k_0} = k-1$ by constraint 1(a). We construct a polygonal curve σ_0 by connecting the centers of $c_{j_r,1}$ and $c_{j_r,2}$ for $r \in [k_0]$ and the centers of $c_{j_r,2}$ and $c_{j_{r+1},1}$ for $r \in [k_0 - 1]$. The polygonal curve σ_0 acts as a surrogate of σ. It has at most $2k-2$ vertices. We will use σ_0 as the key to search a trie at query time to obtain an answer for a $(3 + O(\varepsilon), \delta)$-ANN query. As a result, no enumeration is needed which avoids the exponential dependence of the query time on k.

In preprocessing, we enumerate all sequences of $2l$ cells in $\mathcal{G}_1$ for $l \in [2, k-1]$. For each sequence, we construct the polygonal curve σ' that connects the centers of the cells in the sequence, and we find the nearest input curve τ_i to σ'. If $d_F(\sigma', \tau_i) \leq (1 + 12\varepsilon)\delta$, we store (σ', i) in a trie $\mathcal{D}$. There are $O(\sqrt{d}/\varepsilon)^{2d(k-1)} (mn)^{2(k-1)}$ entries in $\mathcal{D}$. We organize the trie $\mathcal{D}$ in the same way as described in Section 2.2. The space required by $\mathcal{D}$ is $O(\sqrt{d}/\varepsilon)^{2d(k-1)} (mn)^{2(k-1)} k$. The search time of $\mathcal{D}$ is $O(k \log \frac{mn}{\varepsilon})$. The preprocessing time is $O(\sqrt{d}/\varepsilon)^{2d(k-1)} (mn)^{2(k-1)} (k \log \frac{mn}{\varepsilon} + kmn \log(km)) = O(\sqrt{d}/\varepsilon)^{2d(k-1)} (mn)^{2k-1} k \log \frac{mn}{\varepsilon}$ due to the computation of the nearest input curve for each sequence enumerated.

At query time, we construct σ_0 from σ in $O(kQ_{\text{seg}})$ time, where Q_{seg} is the time to answer a $(11\varepsilon\delta)$-segment query. We compute $d_F(\sigma, \sigma_0)$ in $O(k^2 \log k)$ time. If $d_F(\sigma, \sigma_0) > (2 + 12\varepsilon)\delta$, we report "no". Otherwise, we search $\mathcal{D}$ with σ_0 in $O(k \log \frac{mn}{\varepsilon})$ time. If the search fails, we report "no". Otherwise, the search returns (σ_0, i) for some $i \in [n]$.

▶ **Lemma 10.** *If $d_F(\sigma, \sigma_0) \leq (2 + 12\varepsilon)\delta$ and the search in $\mathcal{D}$ with σ_0 returns (σ_0, i), then $d_F(\sigma, \tau_i) \leq (3 + 24\varepsilon)\delta$. Otherwise, $\min_{\tau_i \in T} d_F(\sigma, \tau_i) > \delta$.*

Combining the results in this section with the ray shooting results in two and three dimensions [8], Lemma 8, and Theorem 1, we obtain the following theorem.

▶ **Theorem 11.** *For any $\varepsilon \in (0, 0.5)$, there is a $(3 + O(\varepsilon))$-ANN data structure for T under the Fréchet distance with the following performance guarantees:*

- $d \in \{2,3\}$:
  query time $= O(k \log \frac{mn}{\varepsilon} \log n)$,
  space $= O\big(\frac{1}{\varepsilon}\big)^{2d(k-1)+1} (mn)^{2(k-1)} k \log^2 n$,
  expected preprocessing time $= O\big(\frac{1}{\varepsilon}\big)^{2d(k-1)} (mn)^{2k-1} kn \log \frac{mn}{\varepsilon} \log n$.

- $d \geq 4$:
  query time $= \tilde{O}\big(\frac{1}{\varepsilon^d} k(mn)^{0.5+\varepsilon}\big)$,
  space $= O\big(\frac{\sqrt{d}}{\varepsilon}\big)^{2d(k-1)}(mn)^{2(k-1)}k \cdot \frac{1}{\varepsilon}\log^2 n + O\big(\frac{\sqrt{d}}{\varepsilon}\big)^{O(d/\varepsilon^2)} \cdot \tilde{O}((mn)^{O(1/\varepsilon^2)})$,
  expected preprocessing time $= O\big(\frac{\sqrt{d}}{\varepsilon}\big)^{2d(k-1)}(mn)^{2k-1}kn \log \frac{mn}{\varepsilon} \log n +$
  $O\big(\frac{\sqrt{d}}{\varepsilon}\big)^{O(d/\varepsilon^2)} \cdot \tilde{O}((mn)^{O(1/\varepsilon^2)})$.

4 ($11\varepsilon\delta$)-segment queries and proof of Lemma 8

We describe the $(11\varepsilon\delta)$-segment query data structure in Lemma 8. We first present the main ideas before giving the details. Let $w_j w_{j+1}$ be a query segment, which is unknown at preprocessing. There are three building blocks.

First, the intuition is to capture the support lines of all possible query segments using pairs of cells in $\mathcal{G}_1$. It would be ideal to retrieve a pair of cells intersected by $\text{aff}(w_j w_{j+1})$, but this seems to be as difficult as the ray shooting problem. For a technical reason, we need to use more grid cells in a larger neighborhood of the input vertices than in $\mathcal{G}_1$, so define $\mathcal{G}_3 = \bigcup_{i\in[n],a\in[m]} G(v_{i,a} \oplus B_{(1+6\varepsilon)\delta})$.

We find a grid vertex x of $\mathcal{G}_1$ that is a $(1+\varepsilon)$-approximate nearest grid vertex to $\text{aff}(w_j w_{j+1})$. We will show that if $d(x, \text{aff}(w_j w_{j+1})) > (1+\varepsilon)\varepsilon\delta$, the answer to the $(11\varepsilon\delta)$-segment query is null; otherwise, we can find a cell $\gamma \in \mathcal{G}_3$ near x that intersects $\text{aff}(w_j w_{j+1})$. We can use any other cell $c \in \mathcal{G}_1$ to form a pair with γ that acts as a surrogate for the support lines of query segments that pass near c and γ.

Second, given $w_j w_{j+1}$ at query time, among all possible choices of c, we need to find the right one(s) efficiently so that (c, γ) is a surrogate for $\text{aff}(w_j w_{j+1})$. We explain the ideas using the case that w_{j+1} lies between w_j and $\text{aff}(w_j w_{j+1}) \cap \gamma$. Note that w_j may not be near any cell in $\mathcal{G}_1$. In order that $\min_{\tau_i \in T} d(\sigma, \tau_i) \leq \delta$, w_j must be within a distance δ from some input edge $\tau_{i,a}$. We find a maximal packing of $\text{aff}(\tau_{i,a}) \oplus B_{O(\delta)}$ using lines that are parallel to $\tau_{i,a}$ and are at distance $\Theta(\varepsilon\delta)$ or more apart. There are $O(\varepsilon^{1-d})$ lines in the packing, and every point in $\text{aff}(\tau_{i,a}) \oplus B_\delta$ is within a distance $O(\varepsilon\delta)$ from some line in the packing. The projection of w_j to the approximately nearest line approximates the location of w_j. Hence, we should seek to divide the lines in the packing into appropriate segments so that, given w_j and its approximately nearest line in the packing, we can efficiently find the segment that contains the projection of w_j and retrieve some precomputed information for that segment.

Third, let ℓ be a line in the packing mentioned above, for each possible cell $c \in \mathcal{G}_1$, we use the geometric construct $F(c, \gamma) = \{x \in \mathbb{R}^d : \exists\ y \in \gamma \text{ s.t. } xy \cap c \neq \emptyset\}$ defined in [6] which can be computed in $O(1)$ time. The projection of $(\ell \oplus B_{2\varepsilon\delta}) \cap F(c, \gamma)$ in ℓ is the set of points on ℓ such that if the projection of w_j is in it, then (c, γ) is a surrogate for $\text{aff}(w_j w_{j+1})$. As a result, the endpoints of the projections of $(\ell \oplus B_{2\varepsilon\delta}) \cap F(c, \gamma)$ over all possible choices of c divide ℓ into segments that we desire. Each segment may stand for several choices of c's. For each segment, we store the cell c' close to that segment because the ideal choice is the cell that we hit first as we walk from w_j to w_{j+1}.

As described above, we use two approximate nearest neighbor data structures that involve lines. The first one is due to Andoni et al. [4] which stores a set of points P such that given a query line, the $(1+\varepsilon)$-approximate nearest point to the query line can be returned in $\tilde{O}(d^3|P|^{0.5+\varepsilon})$ time. It uses $\tilde{O}\big(d^2|P|^{O(1/\varepsilon^2)}\big)$ space and preprocessing time. The second result is due to Agarwal et al. [2] which stores a set L of lines such that given a query point, the 2-approximate nearest line to the query point can be returned in $\tilde{O}(1)$ time. It uses $\tilde{O}(|L|^2)$ space and expected preprocessing time.

4.1 Data structure organization

We restrict ε to be chosen from $(0, 0.5)$. We construct the data structure of Andoni et al. [4] for the grid vertices of $\mathcal{G}_1$ so that for any query line, the $(1+\varepsilon)$-approximate nearest grid vertex can be returned in $\tilde{O}((mn)^{0.5+\varepsilon}/\varepsilon^d)$ time. We denote this data structure by D_{anp}. It takes $O(\sqrt{d}/\varepsilon)^{O(d/\varepsilon^2)} \cdot \tilde{O}((mn)^{O(1/\varepsilon^2)})$ space and preprocessing time.

For each input edge $\tau_{i,a}$, define a set of lines $L_{i,a}$ as follows. Let H be the hyperplane through $v_{i,a}$ orthogonal to $\text{aff}(\tau_{i,a})$. Take a $(d-1)$-dimensional grid in H with $v_{i,a}$ as a grid vertex and cell width $\varepsilon\delta/\sqrt{d-1}$. The set $L_{i,a}$ includes every line that is orthogonal to H and passes through a vertex of this grid in H at distance within $(1+2\varepsilon)\delta$ from $v_{i,a}$. The set $L_{i,a}$ has $O(\varepsilon^{1-d})$ size, and it can be constructed in $O(\varepsilon^{1-d})$ time. Moreover, every point in the cylinder $\text{aff}(\tau_{i,a}) \oplus B_\delta$ is within a distance $\varepsilon\delta$ from some line in $L_{i,a}$.

Define $\mathcal{L} = \bigcup_{i\in[n],a\in[m-1]} L_{i,a}$. The size of $\mathcal{L}$ is $O(mn/\varepsilon^{d-1})$, and $\mathcal{L}$ can be constructed in $O(mn/\varepsilon^{d-1})$ time. We construct the data structure of Agarwal et al. [2] for $\mathcal{L}$ so that for any query point, a 2-approximate nearest line in $\mathcal{L}$ can be returned in $\tilde{O}(1)$ time. We denote this data structure by D_{anl}. It uses $\tilde{O}((mn)^2/\varepsilon^{2d-2})$ space and expected preprocessing time.

Recall that $\mathcal{G}_3 = \bigcup_{i\in[n],a\in[m]} G(v_{i,a} \oplus B_{(1+6\varepsilon)\delta})$.

For every $\gamma \in \mathcal{G}_3$ and every $c \in \mathcal{G}_1$, we construct $F(c,\gamma) = \{x \in \mathbb{R}^d : \exists\, y \in \gamma \text{ s.t. } xy \cap c \neq \emptyset\}$, which is empty or an unbounded convex polytope of $O(1)$ size that can be constructed in $O(1)$ time as a Minkowski sum [6]. The total time needed is $O((mn)^2/\varepsilon^{2d})$.

For every $\gamma \in \mathcal{G}_3$, every $c \in \mathcal{G}_1$, and every line $\ell \in \mathcal{L}$, compute the intersection $(\ell \oplus B_{2\varepsilon\delta}) \cap F(c,\gamma)$ and project it orthogonally to a segment in ℓ. Take any line $\ell \in \mathcal{L}$. The resulting segment endpoints in ℓ divide ℓ into *canonical segments*. There are $O((mn)^2/\varepsilon^{2d})$ canonical segments in ℓ. For every cell $\gamma \in \mathcal{G}_3$ and every canonical segment $\xi \subseteq \ell$, compute the set $C_{\gamma,\xi}$ of every cell $c \in \mathcal{G}_1$ such that ξ is contained in the projection of $(\ell \oplus B_{2\varepsilon\delta}) \cap F(c,\gamma)$ onto ℓ. Fix an arbitrary point in ξ and denote it by p_ξ. Each $C_{\gamma,\xi}$ has $O(mn/\varepsilon^d)$ size. The total time needed over all cells in $\mathcal{G}_3$ and all canonical segments in all lines in $\mathcal{L}$ is $\tilde{O}((mn)^5/\varepsilon^{5d-1})$.

Let p_γ be the center of the cell γ. Define $c_{\gamma,\xi}$ to be the cell in $C_{\gamma,\xi}$ such that $p_\xi p_\gamma \cap (c_{\gamma,\xi} \oplus B_{5\varepsilon\delta})$ is nearest to p_ξ among $\{p_\xi p_\gamma \cap (c \oplus B_{5\varepsilon\delta}) : c \in C_{\gamma,\xi}\}$. The total time to compute $c_{\gamma,\xi}$ over all cells in $\mathcal{G}_3$ and all canonical segments in all lines in $\mathcal{L}$ is $O((mn)^5/\varepsilon^{5d-1})$.

Finally, for every line $\ell \in \mathcal{L}$, we store the canonical segments in ℓ in an interval tree T_ℓ [7]. It uses linear space and preprocessing time. For any query point in ℓ, one can search T_ℓ in $O(\log \frac{mn}{\varepsilon})$ time to find the canonical segment in ℓ that contains the query point. For each canonical segment ξ stored in T_ℓ, we keep a dictionary T_ξ that stores the set $\{(\gamma, c_{\gamma,\xi}) : \gamma \in \mathcal{G}_3\}$ with γ as the key. For any cell $\gamma \in \mathcal{G}_3$, we can search T_ξ in $O(\log \frac{mn}{\varepsilon})$ time to report $c_{\gamma,\xi}$. These interval trees and dictionaries have a total size of $O((mn)^4/\varepsilon^{4d-1})$, and they can be constructed in $\tilde{O}((mn)^4/\varepsilon^{4d-1})$ time.

The data structures D_{anp}, D_{anl}, T_ℓ for $\ell \in \mathcal{L}$, and T_ξ for all canonical segments ξ's are what we need to support the $(11\varepsilon\delta)$-segment queries on $\mathcal{G}_1$.

▶ **Lemma 12.** *We can construct D_{anp}, D_{anl}, T_ℓ for $\ell \in \mathcal{L}$, and T_ξ for every $\ell \in \mathcal{L}$ and every canonical segment $\xi \subset \ell$ in $O(\sqrt{d}/\varepsilon)^{O(d/\varepsilon^2)} \cdot \tilde{O}((mn)^{O(1/\varepsilon^2)})$ space and preprocessing time.*

In the definition of $c_{\gamma,\xi}$, one may ask what if $p_\xi p_\gamma$ does not intersect $c \oplus B_{5\varepsilon\delta}$ for some $c \in C_{\gamma,\xi}$. We prove that this cannot happen. We also establish some other properties.

▶ **Lemma 13.** *Let γ be a cell in $\mathcal{G}_3$. Let ξ be a canonical segment. Let L_ξ be the cylinder with ξ as the axis and radius $2\varepsilon\delta$.*

(i) *For every cell $c \in \mathcal{G}_1$, if $c \cap xy \neq \emptyset$ for some points $x \in L_\xi$ and $y \in \gamma$, then $c \in C_{\gamma,\xi}$.*

(ii) *For every point $x \in L_\xi$, every point $y \in \gamma$ and every cell $c \in C_{\gamma,\xi}$, $xy \cap (c \oplus B_{5\varepsilon\delta}) \neq \emptyset$.*

(iii) *Let λ be any value greater than or equal to $11\varepsilon\delta$. When we walk from a point $x \in L_\xi$ to a point $y \in \gamma$, we cannot hit any $c \in C_{\gamma,\xi}$ earlier than $c_{\gamma,\xi} \oplus B_\lambda$ irrespective of the choices of x and y.*

4.2 Answering a query

Given an oriented segment w_jw_{j+1} of the query curve σ, we answer the $(11\varepsilon\delta)$-segment query with w_jw_{j+1} on $\mathcal{G}_1$ by the following steps.

- Step 1: We query D_{anp} with $\text{aff}(w_jw_{j+1})$ to report a grid vertex x of $\mathcal{G}_1$. This takes $\tilde{O}((mn)^{0.5+\varepsilon}/\varepsilon^d)$ time.

- Step 2: We check the distance $d(x, \text{aff}(w_jw_{j+1}))$. If $d(x, \text{aff}(w_jw_{j+1})) > (1+\varepsilon)\varepsilon\delta$, then $\text{aff}(w_jw_{j+1})$ is at distance more than $\varepsilon\delta$ from the closest grid vertex of $\mathcal{G}_1$, which implies that $\text{aff}(w_jw_{j+1})$ does not intersect any cell in $\mathcal{G}_1$. In this case, we report null.
  We also check the distances $d(w_j, \mathcal{L})$ and $d(w_{j+1}, \mathcal{L})$. We query D_{anl} with w_j in $\tilde{O}(1)$ time to find a line $\ell_j \in \mathcal{L}$. If $d(w_j, \ell_j) > 2\varepsilon\delta$, then $d(w_j, \mathcal{L}) > \varepsilon\delta$, which implies that w_j is at distance farther than δ from $\text{aff}(\tau_{i,a})$ for any $\tau_i \in T$ and any $a \in [m-1]$. As a result, $d_F(\sigma, \tau_i) > \delta$ for all $\tau_i \in T$, so we report "no" for the (κ, δ)-ANN query. Analogously, we query D_{anl} with w_{j+1} in $\tilde{O}(1)$ time to find a line $\ell_{j+1} \in \mathcal{L}$. If $d(w_{j+1}, \ell_{j+1}) > 2\varepsilon\delta$, we report "no" for the (κ, δ)-ANN query.

- Step 3: Suppose that $d(x, \text{aff}(w_jw_{j+1})) \leq (1+\varepsilon)\varepsilon\delta$, $d(w_j, \ell_j) \leq 2\varepsilon\delta$, and $d(w_{j+1}, \ell_{j+1}) \leq 2\varepsilon\delta$. Then, we check the cells in $G(x \oplus B_{2\varepsilon\delta})$ in $O(\varepsilon^{-d})$ time to find one that intersects $\text{aff}(w_jw_{j+1})$. Let γ be this cell. We do not know if γ belongs to $\mathcal{G}_1$ or not. Nevertheless, since x is a grid vertex of $\mathcal{G}_1$, γ is within a distance $(1+3\varepsilon)\delta$ from some input curve vertex. Therefore, γ must be a cell in $\mathcal{G}_3$. There are three cases depending on the relative positions of w_j and γ.

  - Step 3(a): $w_j \in \gamma \cap \text{aff}(w_jw_{j+1})$. We claim that $\mathcal{G}_1 \cap G(w_j \oplus B_{7\varepsilon\delta})$ is non-empty, and we report an arbitrary cell in it as the answer for the $(11\varepsilon\delta)$-segment query. This step takes $O(\varepsilon^{-d})$ time.
  - Step 3(b): w_j precedes $\gamma \cap \text{aff}(w_jw_{j+1})$ along $\text{aff}(w_jw_{j+1})$ oriented from w_j to w_{j+1}. We query T_{ℓ_j} to find the canonical segment $\xi \subset \ell_j$ that contains the projection of w_j in ℓ_j. Then, we query T_ξ with γ to return $c_{\gamma,\xi}$ as the answer for the $(11\varepsilon\delta)$-segment query. The time needed is $O(\log \frac{mn}{\varepsilon})$.
  - Step 3(c): $\gamma \cap \text{aff}(w_jw_{j+1})$ precedes w_j along $\text{aff}(w_jw_{j+1})$ oriented from w_j to w_{j+1}. We query $T_{\ell_{j+1}}$ to find the canonical segment $\xi \subset \ell_{j+1}$ that contains the projection of w_{j+1} in ℓ_{j+1}. Then, we query T_ξ with γ to obtain $c_{\gamma,\xi}$. We claim that $G(c_{\gamma,\xi} \oplus B_{5\varepsilon\delta}) \subset \mathcal{G}_3$ and some cell in $G(c_{\gamma,\xi} \oplus B_{5\varepsilon\delta})$ intersects w_jw_{j+1}. Pick one such cell $\hat{\gamma}$ in $O(\varepsilon^{-d})$ time. Either step 3(a) or 3(b) is applicable with γ replaced by $\hat{\gamma}$. Whichever case is applicable, we jump to that case with γ replaced by $\hat{\gamma}$ to return an answer for the $(11\varepsilon\delta)$-segment query. The time needed is $\tilde{O}(\varepsilon^{-d})$.

▶ **Lemma 14.** *It takes $\tilde{O}((mn)^{0.5+\varepsilon}/\varepsilon^d)$ time to answer a $(11\varepsilon\delta)$-segment query.*

Lemmas 12 and 14 gives the performance of the $(11\varepsilon\delta)$-segment query data structure in Lemma 8. The proof of the query output correctness in Lemma 8 can be found in the full version.

5 Conclusion

We present $(1+\varepsilon)$-ANN and $(3+\varepsilon)$-ANN data structures that achieve sublinear query times without having space complexities that are proportion to $\min\{m^{\Omega(d)}, n^{\Omega(d)}\}$ or exponential in $\min\{m, n\}$. The query times are $\tilde{O}(k(mn)^{0.5+\varepsilon}/\varepsilon^{O(d)} + k(d/\varepsilon)^{O(dk)})$ for $(1+\varepsilon)$-ANN and $\tilde{O}(k(mn)^{0.5+\varepsilon}/\varepsilon^{O(d)})$ for $(3+\varepsilon)$-ANN. In two and three dimensions, the query times can be improved to $\tilde{O}(k/\varepsilon^{O(k)})$ for $(1+\varepsilon)$-ANN and $\tilde{O}(k)$ for $(3+\varepsilon)$-ANN. It is an open problem is to lower the exponential dependence on d and k.

Abstract

This work continues the study of linear error correcting codes against adversarial insertion deletion errors (insdel errors). Previously, the work of Cheng, Guruswami, Haeupler, and Li [6] showed the existence of asymptotically good linear insdel codes that can correct arbitrarily close to 1 fraction of errors over some constant size alphabet, or achieve rate arbitrarily close to 1/2 even over the binary alphabet. As shown in [6], these bounds are also the best possible. However, known explicit constructions in [6], and subsequent improved constructions by Con, Shpilka, and Tamo [9] all fall short of meeting these bounds. Over any constant size alphabet, they can only achieve rate $< 1/8$ or correct $< 1/4$ fraction of errors; over the binary alphabet, they can only achieve rate $< 1/1216$ or correct $< 1/54$ fraction of errors. Apparently, previous techniques face inherent barriers to achieve rate better than 1/4 or correct more than 1/2 fraction of errors.

In this work we give new constructions of such codes that meet these bounds, namely, asymptotically good linear insdel codes that can correct arbitrarily close to 1 fraction of errors over some constant size alphabet, and binary asymptotically good linear insdel codes that can achieve rate arbitrarily close to 1/2. All our constructions are efficiently encodable and decodable. Our constructions are based on a novel approach of code concatenation, which embeds the index information implicitly into codewords. This significantly differs from previous techniques and may be of independent interest. Finally, we also prove the existence of linear concatenated insdel codes with parameters that match random linear codes, and propose a conjecture about linear insdel codes.

1 Introduction

Error correcting codes are fundamental objects in computer science and information theory. Starting from the seminal work of Shannon and Hamming, the study of error correcting codes has led to a deep understanding of how to ensure reliable communications in various noisy channels. Furthermore, error correcting codes have found rich applications in other seemingly unrelated areas such as complexity theory, learning theory, pseudorandomness and many more. Traditionally, the errors studied are either erasures (where a transmitted symbol is replaced by a '?') or symbol modifications (where a transmitted symbol is replaced by a different symbol), and they can be either random or adversarial. Through decades of effort, we now have an almost complete understanding of codes for such errors, and constructions with efficient encoding and decoding algorithms that match or are close to various known bounds.

An important and more general type of errors, known as *synchronization errors*, however, is much less understood. These errors include insertion and deletions (so we also call them insdel errors for short), which can cause the positions of received symbols to shift. On the other hand, they occur frequently in real world applications, including disk access, integrated circuits, communication networks and so on. They are also closely related to applications in computational biology and DNA-based storage systems [3, 25]. Although the study of codes for such errors started around the same time as Shannon's works, progress has historically been slow due to the apparent difficulty of handling the loss of index information with such errors. For example, many basic questions, such as the capacity of the binary deletion channel with deletion probability p is still wide open, and the first explicit construction that has a constant rate and can correct a constant fraction of adversarial errors is not known until 1999 [21].

From now on, we will focus exclusively on adversarial insdel errors. Over the past several years, with the development of new techniques such as *synchronization strings* [17], there has been a wave of new constructions of codes for these errors [17, 16, 22, 8, 4, 15, 19, 14, 5, 7, 18, 12, 20, 24, 14]. Some of them achieve excellent parameters, e.g., codes that approach the singleton bound over a large constant alphabet [17], codes with almost optimal redundancy over the binary alphabet [8, 15], list-decodable codes over large alphabets that can correct more errors than the length of the codeword [18], and list-decodable codes over any alphabet of positive rate for the information-theoretically largest possible combination of insertions and deletions [12, 20, 24, 14]. However, none of the above constructions gives a *linear* code, and the existence of asymptotically good linear codes for insdel errors over a constant size alphabet is not known until the work of Cheng, Guruswami, Haeupler, and Li [6].

The motivation of studying linear codes comes from several aspects. First, they have compact representations using either generator matrices or parity check matrices, which directly give efficient encoding and testing algorithms with running time $O(n^2)$. Second, such codes have simple structures, so they are often easier to analyze and allow one to use powerful techniques from linear algebra. Finally, linear codes have had great success in codes for erasures and symbol modifications, achieving some of the most well known constructions with (near) optimal parameters. Thus, one could ask if the same is true for insdel codes.

As is standard in the literature of error correcting codes, the two most important parameters of a linear insdel code are δ, the fraction of insdel errors the code can correct; and R, the rate of the code, defined as the message length divided by the codeword length. In [6], the authors established several bounds regarding the tradeoff between these two parameters for linear insdel codes. First, they showed that any linear code correcting δ fraction of insdel errors must have rate at most $\frac{1}{2}(1-\delta)$, regardless of the alphabet size. This is known as the *half-singleton bound* and generalizes a previous result in [1], which shows that any linear code

that can correct even a single deletion must have a rate of at most 1/2. This bound shows a severe limitation of linear codes for insdel errors, as general codes can correct δ fraction of errors with R approaching $1-\delta$. Taking into consideration the alphabet size q, this bound can be improved to $\frac{1}{2}(1-\frac{q}{q-1}\delta)+o(1)$, which is known as the *half-Plotkin bound*. On the other hand, the authors also showed that over the field F_q, for any $\delta>0$ there exists a linear code family that can correct δ fraction of insdel errors, with rate $(1-\delta)/2-\mathsf{H}(\delta)/\log_2 q$, where H is the binary entropy function. In particular, this implies the existence of binary linear codes with rate $1/2-\varepsilon$ capable of correcting $\Omega(\varepsilon\log^{-1}\frac{1}{\varepsilon})$ fraction of insdel errors for any $\varepsilon>0$; and linear insdel codes over F_q of rate $\frac{1}{2}(1-\delta)-\varepsilon$ capable of correcting any δ-fraction of insdel errors, for a large enough $q=2^{\Theta(\varepsilon^{-1})}$, which approaches the half-singleton bound. Hence, the rate can approach 1/2 even over the binary alphabet, and the fraction of errors corrected can approach 1 over a constant size alphabet, both of which are the best possible.

Going further, [6] also constructed explicit asymptotically good linear insdel codes. However, the fraction of errors the code can correct and the rate of the code are both quite small. [6] did not specify these constants, but a rough estimate shows that the code has $\delta<1/400$ and $R<2^{-80}$. Thus a natural question left in their work is to improve these parameters.

Recently, a subsequent work by Con, Shpilka, and Tamo [9] made progress in this direction. For a field F_q with $q=\mathsf{poly}(1/\varepsilon)$, they constructed explicit linear insdel codes that can correct δ fraction of errors with rate $R=(1-4\delta)/8-\varepsilon$. For the field F_2 their explicit linear code can correct δ fraction of errors with rate $R=(1-54\delta)/1216$. Hence, for a constant size alphabet their construction can achieve $\delta<1/4$ with a positive R, or $R<1/8$ with a positive δ. For the binary alphabet, their construction can achieve $\delta<1/54$ with a positive R, or $R<1/1216$ with a positive δ. One caveat is that their codes over the binary alphabet can only decode efficiently from deletions (although they can also decode from insertions inefficiently), while their codes over the large alphabet can decode efficiently from both deletions and insertions. In another work by the same authors [10], they also showed the existence of Reed-Solomon codes over a field of size $n^{O(k)}$ that have message length k, codeword length n, and can correct $n-2k+1$ insdel errors. This achieves the half-singleton bound. They complemented the existential result by providing a deterministic construction over a field of size $n^{k^{O(k)}}$, which runs in polynomial time for $k=O(\log n/\log\log n)$. Nevertheless, in this paper we only focus on the case of a constant alphabet size.

In summary, all known explicit constructions over constant size alphabets fall short of getting rate close to 1/2, or getting the fraction of errors correctable close to 1. In fact, previous techniques seem to face inherent barriers to achieve rate better than 1/4 or correct more than 1/2 fraction of errors, which we will talk about in more details when we give an overview of our techniques.

1.1 Our Results

In this paper we further improve the fraction of errors δ and the rate R that can be achieved by linear insdel codes with efficient encoding and decoding algorithms. In the case of high noise, we give explicit constructions of insdel codes with positive rate that can correct δ fraction of errors with δ arbitrarily close to 1, over a constant size alphabet. In the case of high rate, we give explicit constructions of insdel codes that can achieve rate arbitrarily close to 1/2 and correct a positive constant fraction of errors, over the binary alphabet.[1]

[1] It's also easy to generalize our constructions to larger alphabet size, but for clarity we omit the details in this version.

Specifically, we have the following theorems.

▶ **Theorem 1** (High noise). *For any constant $\varepsilon > 0$ there exists an efficient construction of linear insdel codes over an alphabet of size* $\mathsf{poly}(1/\varepsilon)$*, with rate $\Omega(\varepsilon^2)$ that can correct $1-\varepsilon$ fraction of insdel errors (possibly inefficiently).*

With efficient decoding, the rate becomes slightly worse.

▶ **Theorem 2** (High noise). *For any constant $\varepsilon > 0$, there is a family of linear codes with rate $\Omega(\varepsilon^4)$ and alphabet size* $\mathsf{poly}(1/\varepsilon)$*, that can be encoded in polynomial time and decoded from up to $1-\varepsilon$ fraction of insdel errors in polynomial time.*

▶ **Theorem 3** (High rate). *For any constant $\varepsilon > 0$, there is a family of binary linear codes with rate $1/2-\varepsilon$, that can be encoded in polynomial time and decoded from $\Omega(\varepsilon^3 \log^{-1} \frac{1}{\varepsilon})$ fraction of insdel errors in polynomial time.*

Our constructions are based on code concatenation. We complement our explicit constructions by showing that there exist linear concatenated codes that match the parameters of random linear codes. These constructions can be considered in a sense "semi-explicit" since the outer code is explicit, and we only need to find explicit inner codes.

▶ **Theorem 4.** *For any field F_{q_0} and any constant $\delta > 0$, there exists a family of linear concatenated code over F_{q_0} where the outer code is a Reed-Solomon code, such that the code has rate $\frac{1}{2}(1-\delta) - \mathsf{H}(\delta)/\log q_0 - o(1)$ and can correct δ fraction of insdel errors, where $\mathsf{H}()$ is the binary entropy function.*

We emphasize that the inner codes here may be different for different positions. So if one wants to use brute force to search for a sequence of proper inner codes, then this may take time at least $2^{n \log^2 n}$ where n is the length of the outer codewords.

This theorem implies the following corollaries.

▶ **Corollary 5.** *For any constant $\delta > 0$, there exists a family of binary linear concatenated code where the outer code is a Reed-Solomon code, such that the code has rate $\frac{1}{2}(1-\delta)$ and can correct $\Omega(\delta \log^{-1} \frac{1}{\delta})$ fraction of insdel errors.*

▶ **Corollary 6.** *For any constants $\delta, \varepsilon > 0$ there exists a family of linear concatenated code over an alphabet of size $q = 2^{\Theta(\varepsilon^{-1})}$ where the outer code is a Reed-Solomon code, such that the code has rate $\frac{1}{2}(1-\delta) - \epsilon$ and can correct δ fraction of insdel errors.*

Finally, we study the question of whether binary linear insdel codes can achieve δ arbitrarily close to $1/2$ with a positive rate R. Notice that even for general binary codes, it is well known that the maximum fraction of deletions that any non-trivial binary code of size $\geqslant 3$ can correct is below $1/2$ since any 3 different n-bit binary strings must contain two strings with the same majority bit, and thus their longest common subsequence is at least $n/2$. For binary linear codes this can also be seen from the half-Plokin bound. A recent work by Guruswami, He, and Li [13] in fact already provided a negative answer to this question even for general binary codes. In particular, they showed that there exists an absolute constant $\alpha > 0$ such that any binary code $\mathbb{C} \subseteq \{0,1\}^n$ with $|\mathbb{C}| \geqslant 2^{\mathsf{polylog} n}$ must have two strings whose longest common subsequence has length at least $(1/2+\alpha)n$. Thus $\mathbb{C}$ cannot correct more than $1/2-\alpha$ fraction of insdel errors. Since linear codes are more restricted, one may expect that a stronger result can be proved for binary linear codes. Specifically, we have the following conjecture:

▶ **Conjecture 7.** *There exists an absolute constant $\alpha > 0$ such that any linear subspace $\mathbb{C} \subseteq \mathsf{F}_2^n$ with dimension $\geqslant 3$ must have two strings (vectors) whose longest common subsequence has length at least $(1/2 + \alpha)n$.*

However, we are not able to prove this conjecture. Instead, we can prove a weaker result.

▶ **Theorem 8.** *There exists an absolute constant $\alpha > 0$ such that any linear subspace $\mathbb{C} \subseteq \mathsf{F}_2^n$ with dimension $\geqslant 3$ must have two strings (vectors) whose longest common subsequence has length at least $(\frac{1}{2} + \frac{\alpha}{\log n})n$.*

1.2 Overview of the Techniques

There have been only two previous works on explicit constructions of asymptotically good linear insdel codes over fields of constant size, i.e., [6] and [9]. The apparent difficulty of constructing such codes comes from the following aspects: First, many of the previous constructions of (non-linear) insdel codes are based on adding index information to the codewords, either in the form of direct encoding of indices, or more sophisticated objects such as synchronization strings. Since all of these result in fixed strings, adding such information in any naive way will lead to non-linear codes. Indeed, both [6] and [9] have to find alternative ways to "embed" synchronization strings into a linear code. Specifically, [6] uses what is called a *synchronization sequence*, which is a sequence of 0's added in between each pair of adjacent symbols in a codeword. This preserves the linearity if the original code is linear. [9], on the other hand, embeds the synchronization string by combining a codeword symbol x and a synchronization string symbol a into a pair $(x, a \cdot x)$, where $\cdot$ is the multiplication over the corresponding field F_q. This also preserves the linearity over F_q, but now the symbols from the synchronization strings are mixed with symbols from the codeword, and it is not easy to tell them apart. Note that for decoding, one needs to first use the synchronization string to recover the positions of the codeword symbols. To solve this problem, [9] also needs to add buffers of 0's between adjacent pairs, where the length of a buffer is at least as long as the pair $(x, a \cdot x)$.

It can be seen that the added 0's in the above two approaches form an inherent barrier to achieving high rate or high fraction of correctable errors. In [6], a constant number of 0's are added in between each pair of adjacent symbols in a codeword, which already decreases the rate and the possible decoding radius to a small constant. In [9], the operation of converting a codeword symbol x and a synchronization string symbol a into a pair $(x, a \cdot x)$ already decreases the rate of the code to below $1/2$, while adding 0's as buffers decreases the rate even more to below $1/4$. Similarly, add 0's as buffers also decreases the possible decoding radius to below $1/2$. For binary codes, [9] needs to use another layer of code concatenation, which further decreases the rate and decoding radius.

The key idea in all our constructions is to eliminate the use of 0's as buffers or synchronization sequences. Instead, we embed synchronization information directly into the codewords. To achieve this, we also use code concatenation, where for the outer code we choose a suitable Reed-Solomon code. On the other hand, the key difference between our constructions and standard concatenated codes is that we choose a *different* inner code for *every position* of the outer code. This way, we can make sure that the inner codewords corresponding to outer codeword symbols at different positions are far enough from each other, and thus we can roughly tell them apart by just looking at the received codeword. By using linear inner codes for all positions, this preserves the linearity of the code, and at the same time eliminates the use of 0's. On a high level, this is why our constructions can achieve either high rate (arbitrarily close to $1/2$) or high fraction of correctable errors (arbitrarily close to 1). We now discuss our techniques in more details for the two cases.

Constructions for high error. Note that to correct $1-\varepsilon$ fraction of insdel errors, a linear code must have alphbet size at least $1/\varepsilon$ by the half-Plotkin bound. Here we use an alphabet of size $\mathsf{poly}(1/\varepsilon)$. With an appropriately chosen parameter $\gamma = \Omega(\varepsilon)$, after picking an outer Reed-Solomon code with codeword length n, rate γ and relative distance $1-\gamma$, our strategy is to design n different inner codes $\mathbb{C}^1_{\mathsf{in}}, \cdots, \mathbb{C}^n_{\mathsf{in}}$. The goal is to ensure that codewords in different inner codes have large edit distance, or equivalently, the length of their longest common subsequence (LCS for short) is at most $\gamma n'$ where $n' = O(\log n)$ is the block length of the inner code. However, since all these codes are linear, 0 is a codeword of each inner code, and two 0's (even from different inner codes) are guaranteed to have 0 edit distance. We design the inner codes to ensure this is the only bad case.

More specifically, we ensure that for any two inner codewords x, y, unless they are both 0 or they correspond to the same message in one inner code $\mathbb{C}^i_{\mathsf{in}}$, their edit distance is large. We show that if we pick n random linear codes for $\mathbb{C}^1_{\mathsf{in}}, \cdots, \mathbb{C}^n_{\mathsf{in}}$, then this property holds with high probability. Furthermore, we can derandomize this by using a small biased sample space to generate the n generator matrices of $\mathbb{C}^1_{\mathsf{in}}, \cdots, \mathbb{C}^n_{\mathsf{in}}$. Roughly, this is because the property we want is *local* – it only looks at any two inner codewords x, y. By using a small biased sample space, we can show that (roughly) under the above conditions, any non-trivial parity of the bits (we treat a symbol in the alphabet of size $\mathsf{poly}(1/\varepsilon)$ as a binary string of length $O(\log(1/\varepsilon))$) of (x, y) has a small bias. Hence a standard XOR lemma implies the joint distribution of (x, y) is close to uniform. Since $n' = O(\log n)$, we only need to look at $\mathsf{poly}(n)$ such pairs of (x, y). Thus it suffices to choose the error in the small biased sample space to be $1/\mathsf{poly}(n)$. This gives us a sample space of size $\mathsf{poly}(n)$ and we can exhaustively search for a good construction. This gives us n different inner codes with rate $\Omega(\gamma)$.

Using these inner codes, it is now relatively straightforward to argue about the parameters of the concatenated code. The rate is $\Omega(\gamma^2) = \Omega(\varepsilon^2)$. To argue about the distance, we consider the LCS between any two different codewords C_1, C_2, and divide it sequentially into blocks according to the inner codewords of C_1. Each block now covers a substring of C_2. Intuitively, by the property of our inner codes, each block contains only a small number of matches compared to the total size of this block in C_1 and the substring covered in C_2, unless it is a 0 inner codeword in C_1 and is matched to another 0 inner codeword in C_2, or it is a match between the same inner codeword in a single inner code $\mathbb{C}^i_{\mathsf{in}}$. However our outer code guarantees that the latter cannot happen too many times (i.e., at most $O(\gamma n)$ times). Therefore the LCS has length at most $O(\gamma n n')$. By choosing γ appropriately, the code can correct $1-\varepsilon$ fraction of insdel errors.

We present a simple polynomial time decoding algorithm. Given any received string y, we consider the partition of y into n substrings $y_1, \cdots, y_n$ such that $y = y_1 \circ y_2 \circ \cdots \circ y_n$, where each y_i can be the empty string. For each y_i, we find the closest codeword $x_i \in \mathbb{C}^i_{\mathsf{in}}$ in edit distance and record their edit distance Δ_i. We then minimize $\Delta = \sum_{i\in[n]} \Delta_i$, by using a simple dynamic programming. We show that as long as there are not too many errors, by using the optimal partition returned from the dynamic programming, one can correctly recover a small fraction of the outer codewords. Intuitively, this is because if the partition results in too many errors in the recovered outer codewords, then again by the property of our inner codes, the quantity Δ will be very large, unless there are a lot of errors. We then use a list decoding algorithm for the Reed-Solomon code to get a list of candidate codewords, and search the list to find the correct codeword, which is the one closest to y in edit distance. For technical reasons, this decreases the rate of the code to $\Omega(\varepsilon^4)$.

Constructions with high rate. Now we explain our construction with high rate and polynomial time encoding and decoding. We first exhibit a warm-up construction achieving rate $1/3 - \gamma$. Then we improve the rate to $1/2 - \gamma$, while the construction will be significantly more involved due to additional issues arising in the analysis.

Inheriting the structure of the general construction, our first construction is as the following. The outer code is a Reed-Solomon code with block length n, alphabet size n, relative distance δ and rate $(1 - \delta)$, where $\delta = \gamma/2$. To achieve a high rate, we will design the inner codes to have a large rate, ideally close to $1/2$. At the same time, we also need to ensure that the code can correct a positive constant fraction of errors, thus we want to make sure that the LCS between any two different codewords is not too large.

As before, we will design the inner codes such that ideally, codewords from different inner codes are far away from each other (or equivalently, have small LCS). However, there are additional issues in the analysis of the LCS. First, the 0 codewords from different inner codes are always the same. This is inevitable since we are dealing with linear codes. Second, in a matching between two different codewords C_1, C_2, some inner codeword of C_1 may be matched to a substring of the concatenation of two adjacent inner codewords of C_2. Thus it is not enough to just ensure that codewords from different inner codes are far away from each other. We note that this issue also occurs in our constructions for high noise. However, there we designed the inner codes to have small rate but large distance, so the LCS between different inner codewords is quite small. When some inner codeword of C_1 is matched to a substring of the concatenation of two adjacent codewords of C_2, the size of the matching in this part at most doubles the size of the LCS between two different inner codewords, and is affordable in that case. Here however, since we are trying to achieve a high rate, the distance between two different inner codewords becomes quite small, and the LCS becomes relatively large (e.g., larger than $1/2$ fraction). Hence, we cannot afford to double this size.

On a high level, we resolve the second issue by strengthening our local property of inner codes, while our analysis will show that the first issue can also be resolved as a consequence. We begin by discussing the local property we need to achieve rate $1/3 - \gamma$. The distinct binary inner codes $\mathbb{C}^1_{\mathsf{in}}, \mathbb{C}^2_{\mathsf{in}}, \ldots, \mathbb{C}^n_{\mathsf{in}}$ are constructed to have block length n', message length $k' = (1/3 - \gamma/2)n'$, with the following property: for every $i, j \in [n]$, for every codeword w in $\mathbb{C}^i_{\mathsf{in}}$, for every two codewords u, v from two adjacent inner codes $\mathbb{C}^j_{\mathsf{in}}, \mathbb{C}^{j+1}_{\mathsf{in}}$, unless $w = u$ or $w = v$, the distance between w and any substring of $u \circ v$ is at least $d' = \Omega(n')$. We first explain why this property implies a good decoding radius and then explain how to construct these inner codes.

We show the decoding radius by directly providing the following decoding algorithm. On an input y which is a corrupted version of a codeword z, the algorithm first finds a string $\tilde{z} \in \{0,1\}^{nn'}$ which has a maximum block matching with y. A block matching is defined to be a set of matches where each match, denoted as $(i, [\alpha, \beta])$, consists of a non-zero inner codeword $u \in \mathbb{C}^i_{\mathsf{in}}$ and a substring $y_{[\alpha,\beta]}$, such that their edit distance is at most $d'/2$. Furthermore, the matching is monotone in the sense that the substrings of y involved in the matching do not overlap and the matches cannot cross. We call u a candidate string for the i-th block. We give a simple dynamic programming algorithm to find a maximum block matching together with a corresponding sequence of candidates. To construct $\tilde{z}$, we first fill these candidates to their corresponding blocks and then set all the other blocks to be 0.

Now we show that as long as there are at most $\rho nn'$ errors for some small constant $\rho > 0$, $\tilde{z}$ agrees with z in most of the blocks (inner codewords). To show this, divide z into blocks $z^1 \circ z^2 \circ \cdots \circ z^n$ such that each z^i corresponds to an inner codeword. Similarly, divide y into blocks $y^1 \circ y^2 \circ \cdots \circ y^n$ such that each y^i is the corrupted version of z^i. Notice that there can

be at most $\frac{\rho n n'}{d'/2} = (c\gamma)n$ blocks with at least $d'/2$ errors, for some constant $c = c(\rho)$. So the maximum block matching has size at least $\hat{n} - c\gamma n$ where $\hat{n}$ is the number of non-zero blocks in z. Now consider a maximum block matching and the sequence of candidates returned by the algorithm. We show that there are at most $c\gamma n$ candidates that are not equal to the corresponding blocks of z, by using the local property. As we fill all the other blocks to be 0, this also implies there are at most $c\gamma n$ zero-blocks being incorrectly recovered. Hence the algorithm correctly recovers $1 - O(c\gamma)$ fraction of blocks in z. By taking c (and thus also ρ) to be a small enough constant, one can use the list-decoding algorithm of Reed-Solomon codes to recover z.

Next, we explain how to construct the inner codes. We start by considering a random construction, that is, all the inner codes are independent random linear codes. We show the local property holds with high probability. Consider arbitrary codewords $w \in \mathbb{C}_{\mathsf{in}}^i \backslash \{0\}, u \in \mathbb{C}_{\mathsf{in}}^j, v \in \mathbb{C}_{\mathsf{in}}^{j+1}$ for some $i, j \in [n]$, where $w \neq u$ and $w \neq v$. Here the inequality means the two codewords are either from different inner codes or they correspond to different messages in one inner code. Suppose there is a substring w' of $u \circ v$, which has distance $< d'$ to w. So the LCS between w and w' should be $\ell \geqslant \frac{|w|+|w'|-d'}{2}$. Notice that $\ell \leqslant |w| \leqslant n'$. Consider any monotone alignment between w and w'. Because $w \neq u, w \neq v$ and the inner codes are all independent and generated randomly, by a similar argument as in [6], the event that the alignment is indeed a matching of bits happens with probability at most $2^{-\ell}$. We then apply a union bound over all possible alignments of size ℓ and all possible codewords w, u, v. A key observation is that the number of all possible codewords w, u, v is $2^{3k'}$ since we have three different codewords here. However, we have $\ell \leqslant n'$. Therefore for the union bound to work, we have to set $k' < n'/3$. This is the reason that we can only achieve rate close to $1/3$ with this construction.

Next, we derandomize the construction by replacing the uniform randomness used with an ε-biased distribution. Here, as before, we crucially use the fact that our property for the inner codes is local: the only place where we use randomness is when we bound the probability that an alignment is a valid matching, and it only involves three codewords. Since $n' = O(\log n)$, by using a standard XOR Lemma and taking $\varepsilon = 1/\mathsf{poly}(n)$, we can argue that when restricted to any three codewords, the ε-biased distribution is $1/\mathsf{poly}(n)$ close to the uniform distribution in statistical distance. This is enough for the union bound since there are at most $\mathsf{poly}(n)$ such triples w, u, v.

Since we only need $O(\log n)$ random bits to generate the above ε-biased distribution, one can exhaustively search for a good construction that satisfies our local property. This also takes polynomial time since one only needs to check every triple of inner codewords.

In our improved construction, we add new ideas to bypass the rate $1/3$ barrier in the above construction, by giving a new local property of the inner codes. Recall that the reason we need to choose $k' < n'/3$ in the above construction is that the alignment we consider in the local property consists of matches that involve three different codewords, which results in a $2^{3k'}$ term in the union bound, but the alignment has size at most n'. In the new local property, we generalize this by considering alignments that involve $2s + 1$ different codewords for some integer s. In a simplified version, consider any two different codewords C_1, C_2 of the concatenated codes and an LCS between them, we analyze any s consecutive inner codewords in C_1, and how they can be matched to a substring in C_2. Note that the s consecutive inner codewords cannot be matched to a substring with length much larger than sn', or there are already many unmatched bits in C_2. So we can imagine a new local property like the following: let w be the concatenation of any s adjacent inner codewords, and u be the concatenation of any $s + 1$ adjacent inner codewords. As long as the codewords in w and

u are sufficiently different, the distance between w and any substring of u is at least $\Omega(n')$. The idea is that an alignment between w and u can have size up to sn', while the union bound gives a $2^{(2s+1)k'}$ term. Thus we can potentially achieve $k' < \frac{s}{2s+1}n'$, and if s is large enough, the rate is close to $1/2$. Note that the warm-up construction i corresponds to the case of $s = 1$.

However, it is not straightforward to make this idea work. The main issue is that unlike the simple case of $s = 1$, when we consider s consecutive inner codewords for $s > 1$, there can be multiple 0 codewords in them, which can potentially be matched to the 0 codewords in u. Furthermore, there can be inner codewords in w and u that correspond to the same message in a single inner code. These issues will increase the probability that the alignment is a valid matching and can cause the union bound to fail. To fix this, we require the "unique" blocks in w to be dense. Specifically, we define a unique block of w (or u) to be a non-zero inner codeword such that either no block of u (or w) is in the same inner code with it, or any block of u (or w) in the same inner code with it corresponds to a different message. Now we define the following new local property:

For every w which is a sequence of $t = O(\frac{\log \frac{1}{\gamma}}{\gamma^2})$ consecutive inner codewords, every u which is a sequence of $t + 1$ consecutive inner codewords, and every w' which is a substring of u, the distance between w and w' is at least $d' = \Omega(\gamma n')$, as long as the number of unique blocks in w or u is at least $s = \Omega(\gamma t)$. By the distance property of the outer code, for any two different concatenated codewords, in at least one of them, the fraction of such t consecutive inner codewords with at least s unique blocks is a constant.

Using this new property, we can design a similar decoding algorithm as that of the first construction, and with a similar analysis, achieve decoding radius $\Omega(\gamma^3 n/\log \frac{1}{\gamma})$.

We defer these details to the technical part and mainly explain here how to construct the inner codes with the new property and why this indeed gives a rate of $1/2 - \gamma$.

Similar to before, we start with a construction where all inner codes are independent random linear codes, and later derandomize it with an ε-biased space. As long as the parameters s, t are constants, it is easy to see that the derandomization step still works. Therefore, now we only focus on the random construction and argue that the new local property holds with high probability. For this, we use a delicate combinatorial and probabilistic argument.

Suppose the property is not satisfied with some concatenated codewords C_1, C_2. Then there exists a w' such that the edit distance between w, w' is less than d', which implies the LCS between w and w' is $\ell > (|w| + |w'| - d')/2$. Consider an arbitrary monotone alignment M between w and w' of size ℓ. We have two cases. The first case is that there is a pair of indices (i, j) in M such that $|i - j| \geqslant d'$. This implies that there cannot be any pair of indices (i', j') in M such that $i' = j'$, for otherwise there are already at least d' bits in C_1 or C_2 that are not matched. Let $\hat{t}$ be the larger number of non-zero blocks in w and w'. Note that $\hat{t} \geqslant s$. Since all inner codes are independent and random, and every pair of indices (i, j) in M has $i \neq j$, the probability that M is a matching is at most $2^{-((\hat{t}-1)n'-O(d'))}$ (w' can have length as small as $(t + 1)n - n - d'$). Now if we apply the union bound, the main term is actually the total number of possible tuples of the non-zero inner codewords. Since there are at most $2\hat{t}$ non zero blocks in w and u, this number is at most $2^{2\hat{t}k'}$. Thus as long as s is a large enough integer, the rate of the code can approach $1/2$.

The second case is that every pair of indices (i, j) in M has $|i - j| < d'$. In this case, we focus on the unique blocks. Let s' be the larger number of unique blocks in w and u, and for simplicity assume u has more unique blocks. We delete all matches where the endpoint in u is not in a unique block, or the endpoint in w falls out of the block at the same position as the block in u which contains the endpoint in u. Thus we attain a trimmed alignment

M'. Under the assumed condition in this case, we don't lose too many matches. Indeed the number of matches left is at least $\ell' = s'(n' - d') - n' - d'$. We now upper bound the probability that there exists such an M' which is a valid matching. Since this event is implied by the original event, this also provides an upper bound of the original event.

The probability that any M' is a valid matching is $2^{\ell'}$, by our definition of unique blocks. Now in the union bound, the main term turns out to be the total number of possible tuples of the inner codewords corresponding to the s' unique blocks in u and the other s' blocks at the same positions in w, which is roughly $2^{(2s')k'}$. Notice that $s' \geqslant s$. Thus in this case, as long as s is large enough, the rate of the code can also approach $1/2$.

The existence of linear concatenated codes matching random linear codes. This part is similar in spirit to Thommesen's work [23], which shows the existence of binary linear concatenated codes with Reed-Solomon outer codes that asymptotically meet the Gilbert-Varshamov bound. In particular, we also take a Reed-Solomon code as the outer code, and use an independent random linear inner code for every symbol of the outer codeword. Interestingly, here we take the outer code to be a $[n, k = (1-\gamma)n/2, d = (1+\gamma)n/2]_q$ Reed-Solomon code with $q = \Theta(n)$, i.e., the rate of the outer code is less than $1/2$. On the other hand, we take all inner codes to have rate 1. Using a careful probabilistic counting argument together with an estimate of the number of Reed-Solomon codewords with a specific weight (as done in [23]), we can prove the existence of linear concatenated insdel codes with parameters as in Theorem 4.

The choice of the parameters of the outer code is different from our explicit constructions, suggesting that maybe different constructions based on these parameters can lead to better explicit linear insdel codes.

Organization of the paper. Our general construction is exhibited in Section 3. The high error construction and its analysis are given in Section 4. We put the technical details of the rest of our results in the full version.

2 Preliminaries

Notation. Let Σ be an alphabet. For a string $x \in \Sigma^*$,

1. $|x|$ denotes the length of the string.
2. $x[i, j]$ denotes the substring of x from position i to position j (both endpoints included).
3. $x[i]$ denotes the i-th symbol of x.
4. $x \circ x'$ denotes the concatenation of x and some other string $x' \in \Sigma^*$.
5. For a string s which is a concatenation of shorter strings $s_1, s_2, \ldots, s_t$, the i-th block of s refers to s_i.

▶ **Definition 9** (Edit distance and Longest Common Subsequence). *For any two strings $x, y \in \Sigma^n$, the edit distance $\Delta_E(x, y)$ is the minimum number of edit operations (insertions and deletions) required to transform x into y.*[2] *A longest common subsequence of x and y is a longest pair of subsequences of x and y that are equal as strings. We use $\mathsf{LCS}(x, y)$ to denote the length of a longest common subsequence between x and y.*

[2] The standard definition of edit distance also allows substitution, but for simplicity we only consider insertions and deletions here, as a substitution can be replaced by a deletion followed by an insertion.

Note that $\Delta_E(x,y) = |x| + |y| - 2 \cdot \mathsf{LCS}(x,y)$. We use $\Delta_H(x,y)$ to denote the Hamming distance between two strings x and y.

▶ **Definition 10.** *An (n,m,d)-code C is an error-correcting code (for Hamming errors) with codeword length n, message length m, such that the Hamming distance between every pair of codewords in C is at least d.*

▶ **Definition 11.** *Fix an alphabet Σ, an error-correcting code $C \subseteq \Sigma^n$ for edit errors with message length m and codeword length n consists of an encoding function $Enc : \Sigma^m \to \Sigma^n$ and a decoding function $Dec : \Sigma^* \to \Sigma^m$. The code can correct k edit errors if for every y, s. t. $\Delta_E(y, Enc(x)) \leqslant k$, we have $Dec(y) = x$. The rate of the code is defined as $\frac{m}{n}$.*

We say C is a linear code if the alphabet Σ is a finite field F_q and the encoding function $\mathrm{Enc} : \mathsf{F}_q^m \to \mathsf{F}_q^n$ is a F_q-linear map.

We use the following list decoding algorithm for Reed-Solomon codes due to Guruswami and Sudan [11].

▶ **Theorem 12.** *Given a family of Reed-Solomon codes of message rate γ, an error rate of $\varepsilon = 1 - \sqrt{\gamma}$ can be list-decoded in polynomial time.*

We use U_n to denote the uniform distribution on $\{0,1\}^n$.

▶ **Definition 13.** *An ε-biased distribution X over $\{0,1\}^n$ is such that for any $S \subseteq [n]$, $|\Pr[\bigoplus_{i \in S} X_i = 1] - 1/2| \leqslant \varepsilon$. A function $g : \{0,1\}^s \to \{0,1\}^n$ is an ε-biased generator if $g(U_s)$ is an ε-biased distribution.*

The following ε-biased generator is used.

▶ **Theorem 14** ([2])**.** *For every $n \in \mathbb{N}$, every $\varepsilon \in (0,1)$, there exists an explicit ε-biased generator $\{0,1\}^s \to \{0,1\}^n$ with $s = O(\log n + \log(1/\varepsilon))$.*

We also need the following XOR lemma.

▶ **Lemma 15** (XOR Lemma)**.** *The statistical distance between an ε-biased distribution and a uniform distribution, both over $\{0,1\}^n$, is at most $\varepsilon\sqrt{2^n}$.*

3 General Construction of Our Codes

All our codes follow the general strategy of code concatenation, which we describe below.

The outer code $\mathbb{C}_{\mathsf{out}}$ with encoding function : $\mathsf{Enc}_{out} : \Sigma_{\mathrm{out}}^k \to \Sigma_{\mathrm{out}}^n$ is an $[n,k,d]$ Reed Solomon Code for Hamming errors. We then use n different inner codes $\mathbb{C}_{\mathsf{in}}^1, \ldots, \mathbb{C}_{\mathsf{in}}^n$, such that for any $i \in [n]$, $\mathbb{C}_{\mathsf{in}}^i$ is a linear code $\mathsf{Enc}_{in}^i : \Sigma_{\mathrm{out}} \to \Sigma_{\mathrm{in}}^{n'}$, where n' is the block length of the inner code. In this paper Σ_{in} always has constant size and we let $n' = \Theta(\log n)$. For different applications, we will need the inner codes to have slightly different properties.

Our final code $\mathbb{C}$ works naturally by first encoding the message using the outer code, then encoding each symbol of the outer code using the inner codes. This gives a codeword over Σ_{in} with length $N = n \cdot n'$. If the outer code and all the inner codes are linear, the concatenated code is also linear.

4 Constructions For High Noise

In this section we give our linear codes that can correct $1 - \varepsilon$ fraction of insdel errors, for any constant $\varepsilon > 0$. Our codes can still achieve a constant rate.

The construction. Following our general construction, we take $\mathbb{C}_{\mathsf{out}}$ to be an $[n, k, d]_n$ Reed-Solomon code with $|\Sigma_{\text{out}}| = n$, $k = \gamma n$ and $d = (1-\gamma)n$ for some constant $\gamma > 0$ to be chosen later. We construct n different inner codes $\mathbb{C}^1_{\mathsf{in}}, \ldots, \mathbb{C}^n_{\mathsf{in}}$ with alphabet size $|\Sigma_{\text{in}}| = \mathsf{poly}(1/\gamma)$, message length $k' = \Theta(\log n)$, and codeword length $n' = \Theta(\log n)$, with the following property.

▶ **Property 1.** *For any two codewords $x \in \mathbb{C}^i_{in}, y \in \mathbb{C}^j_{in}$, if either of the following two conditions holds:*
1. *$i \neq j$, and $x \neq 0^{n'}$ or $y \neq 0^{n'}$.*
2. *$i = j$ and $x \neq y$.*

Then we have $\mathsf{LCS}(x, y) \leqslant \gamma n'$.

▶ **Lemma 16.** *There exists an efficient construction of n inner codes $\mathbb{C}^1_{in}, \ldots, \mathbb{C}^n_{in}$, where each $\mathbb{C}^i_{in}$ has alphabet size $|\Sigma_{in}| = \mathsf{poly}(1/\gamma)$ and rate $\Omega(\gamma)$.*

Proof. We first show that if we pick n independent random linear inner codes $\mathbb{C}^1_{\mathsf{in}}, \ldots, \mathbb{C}^n_{\mathsf{in}}$ over an alphabet size $|\Sigma_{\text{in}}| = \mathsf{poly}(1/\gamma)$, then they satisfy Property 1 with high probability. We then show how to derandomize the construction using a small biased sample space.

Fix a field F_q. For each $\mathbb{C}^i_{\mathsf{in}}$ we independently pick $\log n$ uniformly random vectors in $\mathsf{F}_q^{n'}$ with $n' = \Theta(\log n/\gamma)$ as the basis for $\mathbb{C}^i_{\mathsf{in}}$, or equivalently, the rows in the generating matrix of $\mathbb{C}^i_{\mathsf{in}}$. We bound the probability that there exist two codewords $x \in \mathbb{C}^i_{\mathsf{in}}, y \in \mathbb{C}^j_{\mathsf{in}}$ that satisfy the conditions of Lemma 16 but $\mathsf{LCS}(x, y) > \gamma n'$.

▷ Claim 17. Consider any fixed common subsequence between x and y of length t, where the corresponding indices in x are $\{s_1, \cdots, s_t\}$ and the corresponding indices in y are $\{r_1, \cdots, r_t\}$. Then

$$\Pr[\forall k \in [t], x_{s_k} = y_{r_k}] \leqslant q^{-t}.$$

To prove the claim we have two cases.

Case 1: $i \neq j$, and $x \neq 0^{n'}$ or $y \neq 0^{n'}$. This is the easy case. Since $i \neq j$, and all the entries in the generating matrices of $\mathbb{C}^i_{\mathsf{in}}$ and $\mathbb{C}^j_{\mathsf{in}}$ are chosen independently uniformly from F_q, we know that the events $x_{s_k} = y_{r_k}$ are all independent, even if $x = 0^{n'}$ or $y = 0^{n'}$. Furthermore, the probability of each such event is $1/q$. Hence the claim follows.

Case 2: $i = j$. In this case, the events $x_{s_k} = y_{r_k}$ are not necessarily all independent. However, the claim still follows from the following claim in [6], which deals exactly with this situation.

▷ Claim 18. [Claim 4.2 of [6]] Let G be a random generating matrix for a linear code over F_q. For any two different messages x^i, x^j and codewords $C^i = x^i G, C^j = x^j G$, consider any fixed common subsequence between C^i and C^j of length t, where the corresponding indices in C^i are $\{s_1, \cdots, s_t\}$ and the corresponding indices in C^j are $\{r_1, \cdots, r_t\}$. Then

$$\Pr[\forall k \in [t], C^i_{s_k} = C^j_{r_k}] \leqslant q^{-t}.$$

Now by a union bound, and noticing that the total number of possible cases where two strings of length n' have a common subsequence of length $\gamma n'$ is at most $\binom{n'}{\gamma n'}^2$, we have

$$\Pr[\text{Property 1 does not hold}] \leqslant n^2 q^{2\log n} \binom{n'}{\gamma n'}^2 q^{-\gamma n'} \leqslant \left(\frac{e}{\gamma}\right)^{2\gamma n'} n^2 q^{2\log n - \gamma n'}.$$

Therefore, one can set $q = (\frac{e}{\gamma})^3$ and $n' = \Theta(\log n/\gamma)$ so that the above probability is $q^{-\Omega(\log n)} = 1/\mathsf{poly}(n)$.

Next we show how to derandomize the above construction using a small biased space. Without loss of generality we assume the field we use is F_q with $q = 2^\ell$. Thus, by choosing an arbitrary basis $b_1, \cdots, b_\ell$ in F_q we can identify the field with the vector space F_2^ℓ, such that any $a \in \mathsf{F}_q$ can be expressed as $a = \sum_{i\in[\ell]} a_i b_i$, where $\forall i, a_i \in \mathsf{F}_2$. In this way, the generating matrix of each $\mathbb{C}_{\mathsf{in}}^i$ can be viewed as consisting of $\ell n' \log n = \Theta(\ell \log^2 n)$ bits.

We pick a τ-biased sample space with $n\ell n' \log n$ bits for some $\tau = 1/\mathsf{poly}(n)$ to be chosen later. Note that by Theorem 14 this can be generated by $O(\log n)$ uniform random bits.

Given ℓ bits $a_1, \cdots, a_\ell$ which defines the field element $a = \sum_{i\in[\ell]} a_i b_i$, and any $p \in \mathsf{F}_q$, consider the operation $p \cdot a$ and the corresponding coefficient in the basis b_1. It's not hard to see that this is a F_2-linear function (i.e., a parity) of $a_1, \cdots, a_\ell$. Call this parity $L_p(a_1, \cdots, a_\ell)$. We have the following claim.

▷ Claim 19. $L_p(a_1, \cdots, a_\ell) \equiv 0$ if and only if $p = 0$.

Proof of the claim. The "if" part is trivially true. For the other part, note that if $p \neq 0$ then $pb_1, \cdots, pb_\ell$ must also be linearly independent and thus form a basis of F_q. Therefore, some pb_i must have a non-zero coefficient in b_1 and thus $L_p(a_1, \cdots, a_\ell)$ has a term a_i in the parity, therefore it cannot be the 0 function. ◁

Note that there are altogether 2^ℓ different parity functions involving $a_1, \cdots, a_\ell$, and $q = 2^\ell$ elements in F_q. Thus the previous claim immediately implies the following claim.

▷ Claim 20. Any parity function involving $a_1, \cdots, a_\ell$ is equivalent to $L_p(a_1, \cdots, a_\ell)$ for some $p \in \mathsf{F}_q$.

Now consider the two codewords $x \in \mathbb{C}_{\mathsf{in}}^i, y \in \mathbb{C}_{\mathsf{in}}^j$. Let x_0 and y_0 be the corresponding messages for x and y respectively. We now have the following claim.

▷ Claim 21. Unless $i = j$ and $y_0 = p \cdot x_0$ or $x_0 = p \cdot y_0$ for some $p \in \mathsf{F}_q$, under the τ-biased sample space, the joint distribution of (x, y) is $q^{n'}\tau$-close to the uniform distribution over $\mathsf{F}_q^{2n'}$.

Proof of the claim. Let $x = (x_1, \cdots, x_{n'}) \in \mathsf{F}_q^{n'} = \mathsf{F}_2^{\ell n'}$ and $y = (y_1, \cdots, y_{n'}) \in \mathsf{F}_q^{n'} = \mathsf{F}_2^{\ell n'}$. Consider any non-trivial parity of the $2\ell n'$ bits, which by Claim 20 corresponds to the coefficient of b_1 under some function $\sum_{k\in[n']}(p_k^x x_k + p_k^y y_k)$, where $\forall k, p_k^x, p_k^y \in \mathsf{F}_q$, and they are not all 0.

If $i \neq j$, then $\sum_{k\in[n']} p_k^x x_k$ and $\sum_{k\in[n']} p_k^y y_k$ use different bits in the τ-biased sample space. Since x, y are not both $0^{n'}$, the resulted parity is a non-trivial parity of the bits in the sample space, which by definition has bias at most τ.

Otherwise we have $i = j$. Let G be the generating matrix for $\mathbb{C}_{\mathsf{in}}^i$, thus $x = x_0 G$ and $y = y_0 G$. For any $k \in [n']$, let G_k be the k'th column of G. We have

$$\sum_{k\in[n']}(p_k^x x_k + p_k^y y_k) = \sum_{k\in[n']}(p_k^x x_0 G_k + p_k^y y_0 G_k) = \sum_{k\in[n']}(p_k^x x_0 + p_k^y y_0) G_k.$$

Notice that each entry in each G_k is independently uniformly chosen from $\mathsf{F}_q = \mathsf{F}_2^\ell$. Thus by Claim 19 if the coefficient of the above sum in b_1 is the trivial parity 0, then we must have $\forall k \in [n'], p_k^x x_0 + p_k^y y_0 = 0$. This implies that either $y_0 = p \cdot x_0$ or $x_0 = p \cdot y_0$ for some $p \in \mathsf{F}_q$.

Otherwise, the parity is a non-trivial parity of the bits in the sample space, which by definition has bias at most τ. Now, by Lemma 15, the joint distribution of (x, y) is $q^{n'}\tau$-close to the uniform distribution over $\mathsf{F}_q^{2n'}$. ◁

Back to the proof of our lemma. If the conditions of the above claim hold, then the joint distribution of (x, y) is $q^{n'}\tau$-close to the uniform distribution. Hence, the probability that there exists any common subsequence of length $\gamma n'$ between x and y is at most $\binom{n'}{\gamma n'}^2 q^{-\gamma n'} + q^{n'}\tau$.

On the other hand, if the conditions of the above claim do not hold, then without loss of generality assume that $y_0 = p \cdot x_0$ for some $p \in \mathsf{F}_q$. Hence $p \neq 1$. In this case, notice that we also have $y = p \cdot x$, and thus the probability that there exists any common subsequence of length $\gamma n'$ between x and y is completely determined by the random variables in x. Note that any non-trivial parity of the bits in x is also a non-trivial parity of the bits of the τ-biased sample space, which has bias at most τ. By Lemma 15, the distribution of x is $q^{n'/2}\tau$-close to being uniform on $\mathsf{F}_q^{n'}$.

We have the following claim.

▷ Claim 22. Let x be a uniformly random vector in $\mathsf{F}_q^{n'}$, and $y = p \cdot x$. Then

$$\Pr[\exists \text{a common subsequence of length } t \text{ between } x \text{ and } y] \leqslant \binom{n'}{t}^2 q^{-t}.$$

Proof of the claim. Consider any fixed common subsequence of length t between x and y. Assume where the corresponding indices in x are $\{s_1, \cdots, s_t\}$ and the corresponding indices in y are $\{r_1, \cdots, r_t\}$, such that $s_1 < s_2 < \cdots < s_t$ and $r_1 < r_2 < \cdots < r_t$. For any $k \in [t]$, let $m_k = \max(s_k, r_k)$. Notice that $m_1 < m_2 < \cdots < m_t$. Define E_k to be the event $x_{s_k} = y_{r_k}$.

For each $k \in [t]$, if $s_k = r_k$, then

$$\Pr[E_k] = \Pr[x_{s_k} = p \cdot x_{s_k}] = \Pr[x_{s_k} = 0] = \frac{1}{q}.$$

Furthermore, since $s_k = r_k = m_k$ is larger than all $\{s_{k'}, r_{k'}, k' < k\}$, the event E_k is independent of all $\{E_{k'}, k' < k\}$. Thus

$$\Pr[E_k | \{E_{k'}, k' < k\}] = \frac{1}{q}.$$

Otherwise, $s_k \neq r_k$ and without loss of generality assume $s_k > r_k$. This means $s_k = m_k$ and is larger than all $\{s_{k'}, r_{k'}, k' < k\}$. We can now first fix all $\{x_{s_{k'}}, y_{r_{k'}}, k' < k\}$ and y_{r_k}, and conditioned on this fixing x_{s_k} is still uniform over F_q. Thus

$$\Pr[E_k] = \Pr[x_{s_k} = p \cdot x_{r_k}] = \frac{1}{q}.$$

Note that any such fixing also fixes the outcomes of all $\{E_{k'}, k' < k\}$. Hence we also have

$$\Pr[E_k | \{E_{k'}, k' < k\}] = \frac{1}{q}.$$

Therefore, the above equation holds in all cases, and for all k. This gives

$$\Pr[\bigcap_{k \in [t]} E_k] \leqslant q^{-t},$$

and the claim follows from a union bound. ◁

Since x is $q^{n'/2}\tau$-close to being uniform on $\mathsf{F}_q^{n'}$, the probability that there exists any common subsequence of length $\gamma n'$ between x and y is at most $\binom{n'}{\gamma n'}^2 q^{-\gamma n'} + q^{n'/2}\tau$ in this case.

To summarize, using the τ-biased sample space we always have that the probability that there exists any common subsequence of length $\gamma n'$ between x and y is at most $\binom{n'}{\gamma n'}^2 q^{-\gamma n'} + q^{n'}\tau$. By another union bound, we have

$$\begin{aligned}\Pr[\text{Property 1 does not hold}] &\leqslant n^2 q^{2\log n}\left(\binom{n'}{\gamma n'}^2 q^{-\gamma n'} + q^{n'}\tau\right)\\ &\leqslant \left(\frac{e}{\gamma}\right)^{2\gamma n'} n^2 q^{2\log n - \gamma n'} + n^2 q^{n'+2\log n}\tau.\end{aligned}$$

Therefore, one can still set $q = (\frac{e}{\gamma})^3$, $n' = \Theta(\log n/\gamma)$, and $\tau = q^{-\Omega(\log n/\gamma)} = 1/\mathsf{poly}(n)$ so that the above probability is $q^{-\Omega(\log n)} = 1/\mathsf{poly}(n)$.

Once we know this, we can exhaustively search the τ-biased sample space and find a sample point which gives us a construction that satisfies Property 1. Since we only have $\mathsf{poly}(n)$ sample points and checking each sample point takes polynomial time, altogether this takes polynomial time. ◀

Note that our concatenated code $\mathbb{C}$ now has rate $\Omega(\gamma^2)$. Further, Property 1 implies the following property:

▶ **Property 2.**
1. *$\forall i \neq j$, we have $\mathbb{C}_{in}^i \bigcap \mathbb{C}_{in}^j = \{0^{n'}\}$.*
2. *For any $i, j \in [n]$ and any two codewords $x \in \mathbb{C}_{in}^i, y \in \mathbb{C}_{in}^j$, if $x \neq y$ then $\mathsf{LCS}(x, y) \leqslant \gamma n'$.*

Let z be any substring of a codeword from the concatenated code $\mathbb{C}$, and assume z is a substring of $z_j \circ z_{j+1} \circ \cdots \circ z_{j+\ell}$, where $\forall t$, z_{j+t} is a codeword in $\mathbb{C}_{\mathsf{in}}^{j+t}$. We say the codewords $\{z_{j+t}, t = 0, \cdots, \ell\}$ contribute to the string z.

We now show that Property 1 and Property 2 give us the following lemma.

▶ **Lemma 23.** *Let x be a codeword from the code $\mathbb{C}_{in}^i$. Let z be any substring of a codeword from the concatenated code $\mathbb{C}$, and $\{z_{j+t}, t = 0, \cdots, \ell\}$ are the inner codewords contributing to z. If $\forall t$, $z_{j+t} \neq x$, then we have $\mathsf{LCS}(x, z) < 2\gamma(|x| + |z|)$.*

Proof. By Property 2, the longest common subsequence between x and any z_{j+t} has length at most $\gamma n'$. If $\ell = 1$, then we have

$$\mathsf{LCS}(x, z) \leqslant \gamma n' < 2\gamma(|x| + |z|).$$

Otherwise we have $\ell \geqslant 2$. Notice that $|z| > (\ell - 2)n'$. Thus we have

$$\mathsf{LCS}(x, z) \leqslant \ell\gamma n' \leqslant 2\gamma(\ell - 1)n' < 2\gamma(|x| + |z|).$$ ◀

We can now prove the following lemma.

▶ **Lemma 24.** *For any two different codewords $C_1, C_2 \in \mathbb{C}$, we have $\Delta_E(C_1, C_2) > 2(1-6\gamma)N$.*

Proof. We upper bound $\mathsf{LCS}(C_1, C_2)$ as follows. Consider a particular longest common subsequence and divide it sequentially according to the n inner codewords in C_1. Let the codewords in C_1 be $x_1, \cdots, x_n$ and the corresponding substrings in C_2 under the LCS be $z_1, \cdots, z_n$.

By Lemma 23, for any $i \in [n]$, we must have $\mathsf{LCS}(x_i, z_i) \leqslant 2\gamma(|x_i| + |z_i|)$, unless some inner codeword in z_i is equal to x_i. This could happen either because $x_i = 0^{n'}$ or because z_i contains part of x_i from exactly the i'th inner code. In the latter two cases, we call such an index i *bad*. Note that for a bad i we have $\mathsf{LCS}(x_i, z_i) \leqslant n'$, and there are at most γn such bad indices for either case, by our choice of the outer code. Let t be the number of bad indices, thus $t \leqslant 2\gamma n$. Therefore,

$$\begin{aligned}\mathsf{LCS}(x, z) &= \sum_{i \text{ is not bad}} \mathsf{LCS}(x_i, z_i) + \sum_{i \text{ is bad}} \mathsf{LCS}(x_i, z_i) \\ &\leqslant 2\gamma \sum_{i \text{ is not bad}} (|x_i| + |z_i|) + tn' \\ &< 2\gamma(2n'n) + 2\gamma nn' = 6\gamma N,\end{aligned}$$

where the last inequality follows from the fact that if the number of bad indices is larger than 0, then $\sum_{i \text{ is not bad}}(|x_i| + |z_i|) < 2n'n$. Therefore $\Delta_E(C_1, C_2) > 2N - 12\gamma N = 2(1 - 6\gamma)N$. ◀

Setting $\gamma = \varepsilon/6$, this gives the following theorem.

▶ **Theorem 25.** *For any constant $\varepsilon > 0$ there exists an efficient construction of linear insdel codes over an alphabet of size $\mathsf{poly}(1/\varepsilon)$, with rate $\Omega(\varepsilon^2)$ that can correct $1 - \varepsilon$ fraction of insdel errors (possibly inefficiently).*

Abstract

In a recent article, Alon, Hanneke, Holzman, and Moran (FOCS '21) introduced a unifying framework to study the learnability of classes of *partial* concepts. One of the central questions studied in their work is whether the learnability of a partial concept class is always inherited from the learnability of some "extension" of it to a total concept class.

They showed this is not the case for PAC learning but left the problem open for the stronger notion of online learnability.

We resolve this problem by constructing a class of partial concepts that is online learnable, but no extension of it to a class of total concepts is online learnable (or even PAC learnable).

1 Introduction

In many practical learning problems, the learning task is tractable because we are only required to predict the labels of the data points that satisfy specific properties. In the setting of binary classification problems, instead of learning a total concept $h : \mathcal{X} \to \{0, 1\}$, we are often content with learning a partial version of it $\widetilde{h} : \mathcal{X} \to \{0, 1, \star\}$, where $\widetilde{h}(x) = \star$ means that both 0 and 1 are acceptable predictions. This relaxation of allowing unspecified predictions renders a wider range of learning tasks tractable.

Consider, for example, predicting whether a person approves or disapproves of various political stances by observing their previous voting pattern. This person might not hold a strong opinion about particular political sentiments, and it might be impossible to predict their vote on those issues based on their previous history. However, the learning task might become possible if we allow both "approve" and "disapprove" as acceptable predictions in those cases where a firm conviction is lacking.

A well-studied example of this phenomenon is learning half-spaces with a large margin. In this problem, the domain is the set of points in a bounded region in an arbitrary Euclidean space, and the concepts are half-spaces that map each point to 1 or 0 depending on whether they belong to the half-space or not. It is well-known that when the dimension of the underlying Euclidean space is large, one needs many samples to learn a half-space. However, in the large margin setting, we are only required to correctly predict the label of a point if its distance from the defining hyperplane is bounded from below by some margin. Standard learning algorithms for this task, such as the classical Perceptron algorithm, due to Rosenblatt [9], show that this relaxation of the learning requirement makes the problem tractable even for high-dimensional Euclidean spaces. Motivated by such examples, Alon, Hanneke, Holzman, and Moran [1] initiated a systematic study of the learnability of partial concept classes $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$. They focused on the two frameworks of *probably approximately correct (PAC) learning* and *online learning*. We refer to [1] for the definition of PAC learnability of partial concept classes. We define online learnability in Definition 4.

PAC learning is an elegant theoretical framework characterized by the combinatorial parameter of the Vapnik–Chervonenkis (VC) dimension. The fundamental theorem of PAC learning states that a total binary concept class is PAC learnable if and only if its VC dimension is finite. Similarly, online learnability of total concept classes is characterized by a combinatorial parameter called the Littlestone dimension (LD). We formally define the VC dimension and the Littlestone dimension in Definitions 14 and 15 respectively. Alon, Hanneke, Holzman, and Moran [1] proved that these characterizations of PAC and online learnability extend to the setting of partial concept classes.

▶ **Theorem 1** ([1, Theorems 1 and 15]). *Let $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$ be a partial concept class.*

- *$\mathbb{H}$ is PAC learnable if and only if $\mathrm{VC}(\mathbb{H}) < \infty$.*
- *$\mathbb{H}$ is online learnable if and only if $\mathrm{LD}(\mathbb{H}) < \infty$.*

It follows from the definitions of VC and LD dimensions that for every partial concept class $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$, we have $\mathrm{VC}(\mathbb{H}) \leq \mathrm{LD}(\mathbb{H})$. In particular, online learnability always implies PAC learnability.

One of the central questions studied in [1] is whether the learnability of a partial concept class is always inherited from the learnability of some total concept class. To make this question precise, we need to define the notion of disambiguation of a partial concept class. While we defer the formal definitions to Section 2.2, one may understand a *strong disambiguation* of a partial class as simply an assignment of each $\star$ to either 1 or 0 for each partial concept in the class. When $\mathcal{X}$ is infinite, it is more natural to consider the weaker notion of *disambiguation* that we shall define in Definition 17. When $\mathcal{X}$ is finite, the notions of disambiguation and strong disambiguation coincide.

Consider the problem of learning the partial concept class $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$ in PAC learning or online learning. If the partial concept class $\mathbb{H}$ has a disambiguation $\overline{\mathbb{H}} \subseteq \{0,1\}^{\mathcal{X}}$ that is PAC learnable, then $\mathbb{H}$ is PAC learnable. This follows from $\mathrm{VC}(\mathbb{H}) \leq \mathrm{VC}(\overline{\mathbb{H}})$, or simply by running the PAC learning algorithm of $\overline{\mathbb{H}}$ on $\mathbb{H}$. Similarly, if a disambiguation $\overline{\mathbb{H}}$ of $\mathbb{H}$ is online learnable, then $\mathbb{H}$ is online learnable.

Is the learnability of every partial concept class inherited from the learnability of some disambiguation to a total concept class?

▶ **Question 2** (Informal [1]). *Does every learnable partial class have a learnable disambiguation?*

Equipped with the VC dimension characterization of Theorem 1, [1] proved that for PAC learning, the answer to Question 2 is *negative*.

▶ **Theorem 3** ([1, Theorem 11]). *For every $n \in \mathbb{N}$, there exists a partial concept class $\mathbb{H}_n \subseteq \{0,1,\star\}^{[n]}$ with $\mathrm{VC}(\mathbb{H}_n) = 1$ such that any disambiguation $\overline{\mathbb{H}}$ of $\mathbb{H}_n$ has $\mathrm{VC}(\overline{\mathbb{H}}) \geq (\log n)^{1-o(1)}$. Moreover, for $\mathcal{X} = \mathbb{N}$, there exists $\mathbb{H}_\infty \subseteq \{0,1,\star\}^{\mathcal{X}}$ with $\mathrm{VC}(\mathbb{H}_\infty) = 1$ such that $\mathrm{VC}(\overline{\mathbb{H}}) = \infty$ for every disambiguation $\overline{\mathbb{H}}$ of $\mathbb{H}_\infty$.*

While Theorem 3 gives a strong negative answer to Question 2 in the case of PAC learning, the question was left open for online learning. Roughly speaking, this question strengthens the bounded-VC assumption on $\mathbb{H}$ to bounded *Littlestone dimension* (LD), which pertains to *online learnability* of $\mathbb{H}$.

The authors in [1] also proposed a second open problem that replaces the bounded-VC dimension assumption by the assumption of *polynomial growth*. This assumption is weaker than bounded LD dimension but stronger than bounded VC dimension.

As we discuss below, our main result resolves these two open problems.

Online learnability

Online learning is performed in a sequence of consecutive rounds, where at round t, the learner is presented with an instance $x_t \in \mathcal{X}$ and is required to predict its label. After predicting the label, the correct label $y_t \in \{0,1\}$ is revealed to the learner. Note that even for partial concept classes, we require that the correct label is 0 or 1. The learner's goal is to make as few prediction mistakes as possible during this process. We assume that the true labels are always *realizable*, i.e. there is a partial concept $h \in \mathbb{H}$ with $h(x_i) = y_i$ for all $i = 1, \ldots, t$.

▶ **Definition 4** (Online Learnability). *A partial concept class $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$ is online learnable if there is a* mistake bound *$m := m(\mathbb{H}) \in \mathbb{N}$ such that for every $T \in \mathbb{N}$, there exists a learning algorithm that on every realizable sequence $(x_i, y_i)_{i=1,\ldots,T}$ makes at most m mistakes.*

Online learnability for total classes is equivalent to the bounded Littlestone dimension. In Theorem 1, Alon, Hanneke, Holzman, and Moran [1] showed that the same equivalence carries out in the setting of partial classes. They asked the following formulation of Question 2.

If a partial class is online learnable, is there a disambiguation of it that is online learnable?

More precisely, they pose the following question:

▶ **Problem 5** ([1]). *Let $\mathbb{H}$ be a partial class with $\mathrm{LD}(\mathbb{H}) < \infty$. Does there exist a disambiguation $\overline{\mathbb{H}}$ of $\mathbb{H}$ with $\mathrm{LD}(\overline{\mathbb{H}}) < \infty$? Is there one with $\mathrm{VC}(\overline{\mathbb{H}}) < \infty$?*

We give a negative answer to Problem 5:

▶ **Theorem 6** (Main Theorem). *For every $n \in \mathbb{N}$, there exists a partial concept class $\mathbb{H}_n \subseteq \{0,1,\star\}^{[n]}$ with $\mathrm{LD}(\mathbb{H}_n) \leq 2$ such that every disambiguation $\overline{\mathbb{H}}$ of $\mathbb{H}_n$ satisfies $\mathrm{LD}(\overline{\mathbb{H}}) \geq \mathrm{VC}(\overline{\mathbb{H}}) = \Omega(\log\log n)$. Consequently, for $\mathcal{X} = \mathbb{N}$, there exists $\mathbb{H}_\infty \subseteq \{0,1,\star\}^{\mathcal{X}}$ with $\mathrm{LD}(\mathbb{H}_\infty) \leq 2$ and $\mathrm{LD}(\overline{\mathbb{H}}) \geq \mathrm{VC}(\overline{\mathbb{H}}) = \infty$ for every disambiguation $\overline{\mathbb{H}}$ of $\mathbb{H}_\infty$.*

Polynomial growth

A general strategy to prove a super-constant lower bound on the VC dimension of a total concept class $\mathbb{H} \subseteq \{0,1\}^n$ is to show that the class is of super-polynomial size. This is the approach utilized in Theorem 3 and Theorem 6. For a total concept class $\mathbb{H} \subseteq \{0,1\}^n$ with VC dimension d, one has $2^d \leq |\mathbb{H}| \leq O(n^d)$: the lower bound is immediate from the definition of VC dimension, and the upper bound is the consequence of the celebrated Sauer-Shelah-Perles (SSP) lemma.

▶ **Theorem 7** (Sauer-Shelah-Perles lemma [10]). *Let* $\mathbb{H} \subseteq \{0,1\}^n$ *and* $\mathrm{VC}(\mathbb{H}) = d$. *Then*

$$|\mathbb{H}| \leq \binom{n}{\leq d} \coloneqq \sum_{i=0}^{d} \binom{n}{i} = O(n^d).$$

The direct analog of the SSP lemma is not true for partial concept classes: [1] proved that there exists $\mathbb{H} \subseteq \{0,1,\star\}^{[n]}$ with $\mathrm{VC}(\mathbb{H}) = 1$ such that every disambiguation $\overline{\mathbb{H}}$ has size $|\overline{\mathbb{H}}| \geq n^{\Omega(\log n)}$. This result, combined with the SSP lemma for total classes, immediately implies Theorem 3.

Interestingly, under the stronger assumption of the bounded Littlestone dimension, the polynomial growth behavior of the original SSP lemma remains valid.

▶ **Theorem 8** ([1]). *Every partial concept class* $\mathbb{H} \subseteq \{0,1,\star\}^{[n]}$ *with* $\mathrm{LD}(\mathbb{H}) \leq d$ *has a disambiguation* $\overline{\mathbb{H}}$ *with* $|\overline{\mathbb{H}}| \leq O(n^d)$.

We say that a partial concept class $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$ has *polynomial growth with parameter* $d \in \mathbb{N}$ if for every finite $\mathcal{X}' \subseteq \mathcal{X}$, there is a disambiguation $\overline{\mathbb{H}|_{\mathcal{X}'}}$ of $\mathbb{H}|_{\mathcal{X}'}$ of size at most $O(|\mathcal{X}'|^d)$. Note that by Theorem 8, every partial concept class with Littlestone dimension d has polynomial growth with parameter d.

Alon, Hanneke, Holzman, and Moran asked the following question:

▶ **Problem 9** ([1]). *Let* $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$ *be a partial concept class with polynomial growth. Does there exist a disambiguation* $\overline{\mathbb{H}}$ *of* $\mathbb{H}$ *such that* $\mathrm{VC}(\overline{\mathbb{H}}) < \infty$*?*

Note that Problem 9 cannot be resolved (in the negative) by a naive application of the SSP lemma to disambiguations of $\mathbb{H}$ or its restrictions. However, Theorem 6 combined with Theorem 8 refutes Problem 9 as well.

▶ **Theorem 10.** *For every* $n \in \mathbb{N}$, *there is* $\mathbb{H} \subseteq \{0,1,\star\}^{[n]}$ *with polynomial growth with parameter* 2 *such that every disambiguation* $\overline{\mathbb{H}}$ *of* $\mathbb{H}$ *has* $\mathrm{VC}(\overline{\mathbb{H}}) = \Omega(\log\log n)$.

Consequently, for $\mathcal{X} = \mathbb{N}$, *there exists* $\mathbb{H}_\infty \subseteq \{0,1,\star\}^{\mathcal{X}}$ *with polynomial growth with parameter* 2 *such that every disambiguation* $\overline{\mathbb{H}_\infty}$ *of* $\mathbb{H}_\infty$ *has* $\mathrm{VC}(\overline{\mathbb{H}_\infty}) = \infty$.

The Alon-Saks-Seymour Problem

The proof of Theorem 3 in [1] hinges on the breakthrough result of Göös [4] and its subsequent improvements [2] that led to almost optimal super-polynomial bounds on the "biclique partition number versus chromatic number" problem of Alon, Saks, and Seymour. The *biclique partition number* of a graph G, denoted by $\mathrm{bp}(G)$, is the smallest number of complete bipartite graphs (bicliques) that partition the edge set of G. Alon, Saks, and Seymour conjectured that the chromatic number of a graph with biclique partition number k is at most $k+1$. Huang and Sudakov refuted the Alon-Saks-Seymour conjecture in [6] by establishing a superlinear gap between the two parameters. Later in a breakthrough, Göös [4] proved a superpolynomial separation.

Our main result, Theorem 6, also builds on the aforementioned graph constructions. However, unlike previous works, our theorem demands a reasonable upper bound on the number of vertices. Since the constructions result from a complex sequence of reductions involving query complexity, communication complexity, and graph theory [3, 4, 5, 2], it is necessary to scrutinize them to ensure that the required parameters are met. We present a reorganized and partly simplified sequence of constructions in Section 3.3 that establishes the following theorem.

▶ **Theorem 11** (Small-size refutation of the Alon-Saks-Seymour conjecture). *There exists a graph G on $2^{\Theta(k^4 \log^3 k)}$ vertices that admits a biclique partition of size $2^{O(k \log^4 k)}$ but its chromatic number is at least $2^{\Omega(k^2)}$.*

Theorem 11 is essentially due to [2]. Our contribution to this theorem is obtaining an explicit and optimized bound on the size of G.

Standard Optimal Algorithm

Theorem 6 provides an example partial class with Littlestone dimension ≤ 2, such that the VC dimension of every disambiguation is $\Omega(\log \log n)$. Whether one can improve the $\Omega(\log \log n)$ lower bound is unclear. In particular, it is an interesting question whether every disambiguation of a partial class of Littlestone dimension at most 2 has VC dimension $O(\log \log n)$. One natural candidate approach for obtaining such an upper bound would be to utilize the Standard Optimal Algorithm (SOA).

SOA is an online learning algorithm devised by Littlestone [7] that can learn classes with bounded Littlestone dimensions. Alon, Hanneke, Holzman, and Moran, in their proof of Theorem 8, showed that applying SOA to a partial concept class $\mathbb{H}$ with Littlestone dimension d yields a disambiguation of size $|\overline{\mathbb{H}}| \leq O(n^d)$ and consequently VC dimension $O(d \log n)$. This shows that the lower bound of Theorem 6 on VC dimension of disambiguations cannot be improved beyond $O(\log n)$. It is hence natural to ask whether it is possible to obtain an improved upper bound on the VC dimension of the SOA-based disambiguation.

We answer this question in the negative by constructing a family of partial concept classes $\mathbb{H}$ of Littlestone dimension d where the disambiguation obtained by the SOA algorithm has VC dimension $\Omega(d \log(n/d))$.

▶ **Theorem 12.** *For every natural numbers $d \leq n$, there exists a partial concept class $\mathbb{H}_{n,d} \subseteq \{0,1,\star\}^{[n]}$ with $d \leq \mathrm{LD}(\mathbb{H}_{n,d}) \leq d+1$ such that the SOA disambiguation of $\mathbb{H}_{n,d}$ has* VC *dimension $\Omega(d \log(n/d))$.*

2 Preliminaries and Background

For a positive integer k, we denote $[k] \coloneqq \{1, \ldots, k\}$. We adopt the convention that $\{0,1\}^0$ or $\{0,1,\star\}^0$ contains the empty string only, which we denote by $()$.

We adopt the standard computer science asymptotic notations, such as Big-O, and use the asymptotic tilde notations to hide poly-logarithmic factors.

2.1 VC Dimension and Littlestone Dimension

Let $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$ be a partial concept class. When the domain $\mathcal{X}$ is finite, we sometimes view $\mathbb{H}$ as a partial matrix $\mathbf{M}_{\mathcal{X} \times \mathbb{H}}$, where each row corresponds to a point $x \in \mathcal{X}$ and each column corresponds to a concept $h \in \mathbb{H}$, and the entries are defined as $\mathbf{M}(x,h) = h(x)$.

Next, we define the VC dimension and the Littlestone dimension of partial classes, which generalize the definitions of these notions for total classes. As shown in [1], the VC and Littlestone dimensions for partial classes capture PAC and online learnability, respectively.

▶ **Definition 13** (Shattered set). *A finite* set *of points $C = \{x_1, \ldots, x_n\} \subseteq \mathcal{X}$ is* shattered *by a partial concept class $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$ if for every pattern $y \in \{0,1\}^n$, there exists $h \in \mathbb{H}$ with $h(x_i) = y_i$ for all $i \in [n]$.*

▶ **Definition 14** (VC dimension). *The* VC *dimension of a partial class* $\mathbb{H}$*, denoted by* $\mathrm{VC}(\mathbb{H})$*, is the maximum* d *such that there exists a size-*d *subset of* $\mathcal{X}$ *that is shattered by* $\mathbb{H}$*. If no such largest* d *exists, define* $\mathrm{VC}(\mathbb{H}) = \infty$*.*

Viewed as a matrix, the VC dimension of $\mathbb{H}$ is the maximum d such that the associated partial matrix $\mathbf{M}_{\mathcal{X}\times\mathbb{H}}$ contains a zero/one submatrix of dimensions $d \times 2^d$, where the columns enumerate all d-bit zero/one patterns.

The Littlestone dimension is defined through the shattering of decision trees instead of sets. Consider a full binary decision tree of height d where every non-leaf v is labelled with an element $x_v \in \mathcal{X}$. We identify every node of this tree by the string $v \in \bigcup_{k=0}^{d}\{0,1\}^k$ that corresponds to the path from the root to the node. That is, the root is the empty string, its children are the two elements in $\{0,1\}$, and more generally, the children of a node $\vec{v} \in \{0,1\}^k$ are the two strings $\vec{v}0$ and $\vec{v}1$ in $\{0,1\}^{k+1}$.

We say that such a tree is *shattered* by a partial concept class $\mathbb{H}$ if for every leaf $y \in \{0,1\}^d$, there exists $h \in \mathbb{H}$ such that $h(x_{y[<i]}) = y_i$ for each $i \in [d]$, where $y[< i]$ is the first $(i-1)$-th bits of y. In other words, applying the decision tree to h will result in the leaf y.

▶ **Definition 15** (Littlestone dimension). *The* Littlestone dimension *of a partial concept class* $\mathbb{H}$*, denoted by* $\mathrm{LD}(\mathbb{H})$*, is the maximum* d *such that there is an* $\mathcal{X}$*-labelled height-*d *full binary decision tree that is shattered by* $\mathbb{H}$*. If no such largest* d *exists, define* $\mathrm{LD}(\mathbb{H}) = \infty$*.*

The *dual* of a concept class $\mathbb{H}$ is the concept class with the roles of points and concepts exchanged. Concretely, the dual class of $\mathbb{H} \in \{0,1,\star\}^{\mathcal{X}}$, denoted by $\mathbb{H}^\top$, is the collection of functions $f_x : \mathbb{H} \to \{0,1,\star\}$ for every $x \in \mathcal{X}$, which is defined by $f_x(h) = h(x)$ for each $h \in \mathbb{H}$. When $\mathcal{X}$ is finite, taking the dual corresponds to transposing the matrix of the concept class. The VC-dimension of the dual-class is related to that of the primal class by the inequality

$$\mathrm{VC}(\mathbb{H}^\top) \le 2^{\mathrm{VC}(\mathbb{H})+1} - 1$$

(see [8]), which translates to a lower bound of the VC-dimension of the primal class.

2.2 Disambiguations

We start by formally defining *strong disambiguation* and *disambiguation*. As mentioned earlier, the two notions coincide when the domain $\mathcal{X}$ is finite.

▶ **Definition 16** (Strong Disambiguation). *A* strong disambiguation *of a partial concept class* $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$ *is a total concept class* $\overline{\mathbb{H}} \subseteq \{0,1\}^{\mathcal{X}}$ *such that for every* $h \in \mathbb{H}$*, there exists a* $\bar{h} \in \overline{\mathbb{H}}$ *that is consistent with* h *on the points* $h^{-1}(\{0,1\})$*.*

▶ **Definition 17** (Disambiguation). *A* disambiguation *of a partial concept class* $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$ *is a total concept class* $\overline{\mathbb{H}} \subseteq \{0,1\}^{\mathcal{X}}$ *such that for every* $h \in \mathbb{H}$ *and every finite* $S \subseteq h^{-1}(\{0,1\})$*, there exists* $\bar{h} \in \overline{\mathbb{H}}$ *that is consistent with* h *on* S*.*

A learning algorithm can often provide a disambiguation of a partial concept class by assigning the prediction of the algorithm to unspecified values. Relevant to our work is the disambiguation by the Standard Optimal Algorithm of Littlestone. It was observed in [1] that this algorithm can provide "efficient" disambiguations of partial classes with bounded Littlestone dimensions. We describe this disambiguation next.

Consider a partial concept class $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$ with a countable domain $\mathcal{X}$ and an ordering $x_1, x_2, \ldots$ of $\mathcal{X}$. Given $\vec{b} \in \{0,1,\star\}^k$, let $\mathbb{H}|_{\vec{b}}$ be the set of concepts h where $h(x_i) = b_i$ for every $i \in [k]$. For convenience, we identify $\mathbb{H}|_{()} = \mathbb{H}$. For the purpose of the algorithm, we adopt the convention $\mathrm{LD}(\emptyset) = -1$.

The SOA obtains a disambiguation iteratively and assigns a 0/1 value to each $\star$ in $\mathbb{H}$: for each $k \in \mathbb{N}$, consider $\mathbb{H}|_{\vec{b}}$ for every $\vec{b} \in \{0,1\}^{k-1}$. Pick $c \in \{0,1\}$ which maximizes $\mathrm{LD}(\mathbb{H}|_{\vec{b}c})$, breaking ties by favoring $c = 0$, and assign c to $h(x_k) = \star$ for every $h \in \mathbb{H}|_{\vec{b}\star}$.

We use the notation $\overline{\mathbb{H}}^{\mathrm{SOA}}$ for the SOA disambiguation of a partial concept class $\mathbb{H}$. As mentioned earlier, for a partial class with Littlestone dimension d, Theorem 8 gives an upper bound of $\binom{n}{\leq d} = O(n^d)$ on $\left|\overline{\mathbb{H}}^{\mathrm{SOA}}\right|$. The theorem follows from the mistake bound of SOA for online learning, which relies on the crucial property that at least one choice of $c \in \{0,1\}$ satisfies $\mathrm{LD}(\mathbb{H}|_{\vec{b}c}) \leq \mathrm{LD}(\mathbb{H}|_{\vec{b}}) - 1$ whenever $\mathbb{H}|_{\vec{b}} \neq \emptyset$.

3 Proofs

In this section, we present the proofs of Theorems 6, 10, 11, and 12.

3.1 Proofs of Theorems 6 and 10

As mentioned earlier, Theorem 10 is an immediate corollary of Theorem 6 and Theorem 8. We focus on proving Theorem 6.

Suppose $G = (V, E)$ is the graph supplied by Theorem 11 on $|V| = n = 2^{\Theta(k^4 \log^3 k)}$ vertices with a biclique partition of size $m = 2^{O(k \log^4 k)}$. We will use G to build a partial concept class $\mathbb{G} \subseteq \{0,1,\star\}^V$. This construction is simply the dual of the partial concept class of [1] in their proof of Theorem 6.

Let $\{B_1, \ldots, B_m\}$ be the size-m biclique partition of the edges of G. We fix an orientation $B_i = L_i \times R_i$ for each biclique. Define $\mathbb{G} \subseteq \{0,1,\star\}^V$ as follows. For each $i \in [m]$, associate a concept $h_i : V \to \{0,1,\star\}$ to the biclique B_i, defined by

$$h_i(v) = \begin{cases} 0 & \text{if } v \in L_i \\ 1 & \text{if } v \in R_i \\ \star & \text{otherwise} \end{cases}.$$

We first observe that the Littlestone dimension of this concept class is at most 2.

▷ Claim 18. $\mathrm{LD}(\mathbb{G}) \leq 2$.

Proof. We show that $\mathbb{G}$, viewed as a matrix, does not contain $\begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix}$ as a submatrix and then show that the existence of this submatrix is necessary for having a Littlestone dimension greater than 2.

If $\begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix}$ appears in $\mathbb{G}$ as a submatrix, then there exist $i \neq j$ and $u \neq v \in V(G)$ such that $h_i(v) = h_j(v) = 1$ and $h_i(u) = h_j(u) = 0$. However, this means that $v \in R_i \cap R_j$ and $u \in L_i \cap L_j$, which in turn implies that the edge $\{u, v\}$ is covered by both B_i and B_j, contradicting the assumption that each edge is covered exactly once.

On the other hand, for a class $\mathbb{H} \subseteq \{0,1,\star\}^{\mathcal{X}}$ with Littlestone dimension greater than 2, there exists a shattered $\mathcal{X}$-labelled height-3 full binary tree. In particular, there exists $h, h' \in \mathbb{H}$ and points $x_{()}, x_1, x_{10}$ such that

$$\begin{aligned} h(x_{()}) &= 1, \quad h(x_1) = 0, \quad h(x_{10}) = 0, \\ h'(x_{()}) &= 1, \quad h'(x_1) = 0, \quad h'(x_{10}) = 1. \end{aligned}$$

This means that the submatrix restricted to the columns $\{x_{()}, x_1\}$ and the rows $\{h, h'\}$ is $\begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix}$. We conclude that $\mathrm{LD}(\mathbb{G}) \leq 2$. ◁

Proof of Theorem 6. Consider the partial concept class $\mathbb{G} \subseteq \{0,1,\star\}^V$ above. By Claim 18, we have $\mathrm{LD}(\mathbb{G}) \leq 2$. We show that for every disambiguation $\overline{\mathbb{G}}$ of $\mathbb{G}$, we have $\mathrm{VC}(\overline{\mathbb{G}}) \geq \Omega(\log\log n)$. The argument here is similar to the proof of Theorem 3.

Consider a disambiguation $\overline{\mathbb{G}}$ of $\mathbb{G}$. Note that if two columns u and v are identical in $\overline{\mathbb{G}}$, then there is no edge between u and v, as otherwise, some h_i would have assigned 0 to one of u and v and 1 to the other. Therefore, if two columns u and v are identical, we can color the corresponding vertices with the same color. Consequently, the number of distinct columns in $\overline{\mathbb{G}}$ is at least the chromatic number $\chi(G) \geq 2^{\Omega(k^2)}$. By the SSP lemma (Theorem 7), if $\mathrm{VC}(\overline{\mathbb{G}}^\top) \leq d$, then $\overline{\mathbb{G}}$ must have at most $O(m^d)$ distinct columns. Therefore,

$$2^{\Omega(k^2)} \leq O(m^d).$$

Substituting $m = 2^{\tilde{O}(k)}$ shows that $d = \tilde{\Omega}(k)$. Finally,

$$\mathrm{VC}(\overline{\mathbb{G}}) \geq \Omega(\log \mathrm{VC}(\overline{\mathbb{G}}^\top)) \geq \Omega(\log k) \geq \Omega(\log\log n).$$

This completes the proof of the first part of Theorem 6.

For the second part, we adopt the same construction in the proof of [1, Theorem 11]. Let $\mathbb{H}_\infty$ be a union of disjoint copies of $\mathbb{H}_n$ over $n \in \mathbb{N}$, each supported on a domain $\mathcal{X}_n$ mutually disjoint from others and the partial concepts of $\mathbb{H}_n$ extend outside of its domain by $\star$. Since any disambiguation $\mathbb{H}$ of $\mathbb{H}_\infty$ simultaneously disambiguates all $\mathbb{H}_n$, the Sauer-Shelah-Perles lemma implies that $\mathrm{VC}(\mathbb{H})$ must be infinite. ◀

3.2 Disambiguations via the SOA algorithm (Theorem 12)

This section is dedicated to the proof of Theorem 12.

Proof of Theorem 12. We prove the statement by showing that for every $r, d \in \mathbb{N}$, there exists a partial concept class $\mathbb{H}_{r,d}$ on $[n]$, where $n = d(2^r + r)$, such that $d \leq \mathrm{LD}(\mathbb{H}_{r,d}) \leq d+1$ and the SOA disambiguation has VC dimension $\geq dr$ and at least 2^{dr} distinct rows. The other cases of n follow by trivially extending the domain.

For any $r, d \in \mathbb{N}$, define

$$\mathcal{F}_{r,d} = \{F \subseteq [d2^r] : |F| = d\}.$$

Note that $|\mathcal{F}_{r,d}| = \binom{d2^r}{d} \geq 2^{dr}$. We enumerate the sets in $\mathcal{F}_{r,d}$ as $F_1, \ldots, F_{\binom{d2^r}{d}}$ in the natural order.

Next, we define the partial concept class $\mathbb{H}_{r,d}$ on domain $[d(2^r + r)]$. The class consists of the partial concepts $h_{i,j}$ for $i \in [\binom{d2^r}{d}]$ and $j \in [dr]$ defined as follows:

$$h_{i,j}(x) = \begin{cases} 1 & \text{if } x \in F_i \\ 0 & \text{if } x \in [d2^r] \setminus F_i \\ \beta(i,j) & \text{if } x = d2^r + j \\ \star & \text{otherwise} \end{cases},$$

where $\beta(i,j)$ denotes j-th bit of the dr-bit binary representation of i if $i \in [2^{dr}]$, and $\beta(i,j) = \star$ otherwise.

We first prove that $d \leq \mathrm{LD}(\mathbb{H}_{r,d}) \leq d+1$. Note that there is a set of 2^d indices $I \subseteq [d2^r]$ which

$$\{F_i \cap [d] : i \in I\} = \mathcal{P}([d]),$$

therefore $[d]$ can be shattered by $\{h_{i,1} : i \in I\}$ and hence $\mathrm{LD}(\mathbb{H}_{r,d}) \geq \mathrm{VC}(\mathbb{H}_{r,d}) \geq d$. On the other hand, note that $|f^{-1}(1)| \leq d+1$ for any $f \in \mathbb{H}_{r,d}$, which implies that $\mathrm{LD}(\mathbb{H}_{r,d}) \leq d+1$.

Next, we consider the SOA disambiguation. We claim that $\{d2^r+1, \ldots, d(2^r+r)\}$ is shattered by $\{h_{i,1} : i \in [2^{dr}]\}$. There are no disambiguations for $x \in [d2^r]$. For $x > d2^r$, note that for any $\vec{b} \in \{0,1\}^{x-1}$, either $\mathbb{H}_{r,d}|_{\vec{b}} = \emptyset$ or

$$\mathbb{H}_{r,d}|_{\vec{b}} = \{h_{i,j} : j \in [dr]\},$$

where $i \in [d2^r]$ such that $F_i = \{k \in [d2^r] : b_k = 1\}$. We focus on the latter case and restrict to $i \in [2^{dr}]$. There is exactly one $c \in \{0,1\}$ such that $\mathbb{H}_{r,d}|_{\vec{b}c} \neq \emptyset$, namely $c = \beta(i, x - d2^r)$ and in this case $\mathbb{H}_{r,d}|_{\vec{b}c} = \{h_{i,c}\}$. This forces the algorithm to disambiguate every function f with $\vec{b} \in \{0,1\}^{x-1}$ by setting $f(x) = h_{i,c}(x) = \beta(i, x - d2^r)$. In this manner, every $h_{i,j}$ is eventually disambiguated into the same total function:

$$\overline{h_{i,j}}(x) = \begin{cases} 1 & \text{if } x \in F_i \\ 0 & \text{if } x \in [d2^r] \setminus F_i \\ \beta(i, x - d2^r) & \text{if } x > d2^r \end{cases}.$$

In particular, for every $i \in [2^{dr}]$, the bit string $(\overline{h_{i,1}}(d2^r+1), \ldots, \overline{h_{i,1}}(d2^r+dr))$ is the dr-bit binary representation of i. This provides a witness for which $\mathrm{VC}(\overline{\mathbb{H}_{r,d}}^{\mathrm{SOA}}) \geq dr$. ◀

As an illustration, we provide the matrix representation of $\mathbb{H}_{1,2}$ and some essential steps of the SOA disambiguation below in Figure 1.

$$\begin{pmatrix}
1 & 1 & 0 & 0 & 0 & \\
1 & 1 & 0 & 0 & & 0 \\
1 & 0 & 1 & 0 & 0 & \\
1 & 0 & 1 & 0 & & 1 \\
1 & 0 & 0 & 1 & 1 & \\
1 & 0 & 0 & 1 & & 0 \\
0 & 1 & 1 & 0 & 1 & \\
0 & 1 & 1 & 0 & & 1 \\
0 & 1 & 0 & 1 & & \\
0 & 1 & 0 & 1 & & \\
0 & 0 & 1 & 1 & & \\
0 & 0 & 1 & 1 & &
\end{pmatrix}$$

(a) Matrix representation of $\mathbb{H}_{1,2}$: all empty spaces are filled with stars.

$$\begin{pmatrix}
1 & 1 & 0 & 0 & 0 & 0 \\
1 & 1 & 0 & 0 & 0 & 0 \\
1 & 0 & 1 & 0 & 0 & 1 \\
1 & 0 & 1 & 0 & 0 & 1 \\
1 & 0 & 0 & 1 & 1 & 0 \\
1 & 0 & 0 & 1 & 1 & 0 \\
0 & 1 & 1 & 0 & 1 & 1 \\
0 & 1 & 1 & 0 & 1 & 1 \\
0 & 1 & 0 & 1 & & \\
0 & 1 & 0 & 1 & & \\
0 & 0 & 1 & 1 & & \\
0 & 0 & 1 & 1 & &
\end{pmatrix}$$

(b) The SOA disambiguation of $\mathbb{H}_{1,2}$: the shaded entries indicate where the shattering occurs.

Figure 1 $\mathbb{H}_{1,2}$ and its SOA disambiguation.

3.3 Small-size refutation of the Alon-Saks-Seymour conjecture (Theorem 11)

In this section, we present the construction of Theorem 11 in detail. The starting point is constructing a Boolean function due to [2] in query complexity. This Boolean function then goes through several reductions to be converted into a graph, as described below.

We first introduce some basic definitions related to the notion of *certificate complexity*. Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function. For $b \in \{0,1\}$ and an input $x \in f^{-1}(b)$, a partial input $\rho \in \{0,1,\star\}^n$ is called a b-certificate if x is consistent with ρ and for every

$x' \in \{0,1\}^n$ consistent with ρ, we have $f(x') = b$. The size of ρ is the number of non-$\star$ entries of ρ. Define $\mathrm{C}_b(f,x)$ as the smallest size of a b-certificate for x. The b-certificate complexity of f, denoted $\mathrm{C}_b(f)$, is the maximum of $\mathrm{C}_b(f,x)$ over all $x \in f^{-1}(b)$.

The *unambiguous* b-certificate complexity of f, denoted $\mathrm{UC}_b(f)$, is the smallest k such that

1. Every input $x \in f^{-1}(b)$ has a b-certificate ρ_x of size at most k;
2. For every $x \neq y$ in $f^{-1}(b)$, we have $\rho_x \neq \rho_y$.

The main result of [2] is the following separation between UC_1 and C_0.

▶ **Theorem 19** ([2, Theorem 1]). *There is a function* $f : \{0,1\}^{12n^4 \log^2 n} \to \{0,1\}$ *such that* $\mathrm{UC}_1(f) = O(n \log^3 n)$ *and* $\mathrm{C}_0(f) = \Omega(n^2)$.

The next step of the construction is to transform the function separating the certificate complexities UC_1 and C_0 into a communication problem. This is achieved by the "lifting" trick: given a function $f : \{0,1\}^n \to \{0,1\}$ and a "gadget" function $g : \{0,1\}^k \times \{0,1\}^k \to \{0,1\}$, we define $f \circ g^n : \{0,1\}^{nk} \times \{0,1\}^{nk} \to \{0,1\}$ as

$$f \circ g^n([x_1,\dots,x_n],[y_1,\dots,y_n]) = f(g(x_1,y_1),\dots,g(x_n,y_n)).$$

For a communication problem $f : \{0,1\}^m \times \{0,1\}^m \to \{0,1\}$ and $b \in \{0,1\}$, let $\mathrm{Cov}_b(f)$ denote the minimum number of b-monochromatic rectangles required to cover all the b-entries of f. We denote by $\mathrm{UCov}_b(f)$ the minimum number of b-monochromatic rectangles required to *partition* all the b-entries of f. The following theorem provides a connection between the communication complexity parameters and the certificate complexity parameters.

▶ **Theorem 20** ([5, Theorem 33]). *There exists a gadget* $g : \{0,1\}^k \times \{0,1\}^k \to \{0,1\}$ *with* $k = \Omega(\log n)$ *such that for every* $f : \{0,1\}^n \to \{0,1\}$*, we have*

$$\log \mathrm{Cov}_b(f \circ g^n) = \Omega(k\, \mathrm{C}_b(f)).$$

Note that for every $b \in \{0,1\}$, we have $\log \mathrm{UCov}_b(f \circ g^n) \leq 2k\, \mathrm{UC}_b(f)$. This combined with Theorem 20 allows one to "lift" the UC_1 vs C_0 separation of Theorem 19 into a UCov_1 vs Cov_0 separation.

▶ **Corollary 21.** *There exists a function* $f : \{0,1\}^{O(n^4 \log^3 n)} \times \{0,1\}^{O(n^4 \log^3 n)} \to \{0,1\}$ *such that*

$$\log \mathrm{Cov}_0(f) = \Omega(n^2) \qquad \textit{and} \qquad \log \mathrm{UCov}_1(f) = n \log^4 n.$$

Next, we show how to convert these communication parameters to graph parameters of the biclique partition number and chromatic number.

▶ **Lemma 22.** *Let* $h : \{0,1\}^t \times \{0,1\}^t \to \{0,1\}$ *be a Boolean function with* $\mathrm{Cov}_0(h) = c$ *and* $\mathrm{UCov}_1(h) = m$*. There exists a graph* $G = (V,E)$ *on at most* 2^{2t} *vertices with* $\mathrm{bp}(G) \leq m^2$ *and* $\chi(G) \geq \sqrt{c}$.

Proof. Define the graph G with $V \coloneqq h^{-1}(0)$ as follows. Two vertices $(x,y),(x',y') \in V$ are adjacent in G iff $h(x,y') = 1$ or $h(x',y) = 1$. By construction, if $\{(x_1,y_1),\dots,(x_\ell,y_\ell)\} \subseteq V$ is an independent set, then $\{x_1,\dots,x_\ell\} \times \{y_1,\dots,y_\ell\}$ is a 0-monochromatic rectangle for h. Thus every proper vertex coloring of G with $\chi(G)$ colors corresponds to a 0-cover of h with $\chi(G)$ many 0-monochromatic rectangles. Therefore, $\chi(G) \geq c$.

We next show that there exists a small set of bicliques such that every edge of E is covered at least once and at most twice by these bicliques. Let $h^{-1}(1) = \bigcup_{i=1}^{m}(A_i \times B_i)$ be a partition of $h^{-1}(1)$ into m many 1-monochromatic rectangles. Note that every 1-monochromatic rectangle $A_i \times B_i$ corresponds to a biclique $Q_i := S_i^- \times S_i^+$ in G, where

$$S_i^- := \{(x,y) \in V(G) : \ x \in A_i\} \text{ and } S_i^+ = \{(x,y) \in V(G) : \ y \in B_i\}.$$

Notice that each edge $\{(x,y),(x',y')\}$ of G is covered at least once by $Q_1, \ldots, Q_m$, and it is covered at most twice, the latter happening when $h(x,y') = h(x',y) = 1$.

We have thus constructed a graph G on at most 2^{2t} vertices such that $\chi(G) \geq c$, and there are at most m bicliques where every edge in G appears in at least one and at most two bicliques.

Define H_2 as the subgraph of G that consists of all the edges covered by exactly two bicliques among $Q_1, \ldots, Q_m$. For every $i, j \in [m]$, define $Q_{ij} = (S_i^- \cap S_j^+) \times (S_i^+ \cap S_j^-)$. Note that each Q_{ij} is a biclique of H_2, and moreover, each edge of H_2 appears in exactly one Q_{ij}. Hence, the biclique partition number of H_2 is at most m^2. Now, if $\chi(H_2) \geq \sqrt{c}$, we obtain H_2 as the desired graph. Suppose otherwise that $\chi(H_2) < \sqrt{c}$, and consider a proper vertex coloring of H_2 with $\sqrt{c}$ colors with color classes $V_1, \ldots, V_{\sqrt{c}}$. Since $\chi(G) \geq c$, there must exist i such that the induced subgraph of G on V_i, denoted by $G[V_i]$, satisfies $\chi(G[V_i]) \geq \sqrt{c}$. Since V_i is an independent set of H_2, thus the restrictions of bicliques $Q_1, \ldots, Q_m$ to V_i form a biclique partition of $G[V_i]$. ◀

Lemma 22 and Corollary 21 together imply Theorem 11.

▶ Remark 23. In addition to providing effective bounds on the size of the graph, Lemma 22 also simplifies the original chain of reductions utilized in prior work [2, 4, 3, 11] toward achieving a super-polynomial separation between the biclique partition and chromatic numbers. We will briefly describe the original proof below and highlight the differences.

(i) Similar to our proof of Theorem 11, the chain of reduction begins with the function f provided by Corollary 21, such that

$$\log \mathrm{Cov}_0(f) = \Omega(n^2) \qquad \text{and} \qquad \log \mathrm{UCov}_1(f) = n \log^4 n.$$

(ii) Yannakasis [11] (see also [4, Figure 1]) showed how to use f to construct a graph F on $\mathrm{UCov}_1(f) = 2^{O(n \log^4 n)}$ vertices such that every Clique-Stable set separator of F is of size at least $\mathrm{Cov}_0(f) = 2^{\Omega(n^2)}$. Here, a Clique-Stable set separator is a collection of cuts in F such that for every disjoint pair (C, I) of a clique C and a stable set I in F, there is a cut (A, B) in the collection with $C \subseteq A$ and $I \subseteq B$.

(iii) Bousquet et. al., [3, Lemma 23] show how to use F to construct a new graph G with the so-called oriented biclique packing number at most $2^{n \log^4 n}$ and chromatic number $\chi(G) \geq 2^{\Omega(n^2)}$.

(iv) The graph G is then turned into a separation between the biclique partition number and chromatic number in a different graph H via a final reduction in [3].

The above chain of reductions is not sufficient for our application because the graph G of Step (iii) has a vertex for each pair (C, I) of a clique C and a stable set I of F, and as a result, there are no effective upper-bounds on the number of vertices of G. Our proof of Theorem 11 bypasses Step (ii) and employs a more direct approach to construct a small-size graph G that has similar properties to the graph G of Step (iii).

4 Concluding remarks

A few natural questions remain unanswered. The first question is whether a similar example $\mathbb{H}$ for Theorem 6 with the stronger assumption $\mathrm{LD}(\mathbb{H}) = 1$ exists.

▶ **Problem 24.** *Let $\mathbb{H}$ be a partial class with $\mathrm{LD}(\mathbb{H}) = 1$. Does there exist a disambiguation of $\mathbb{H}$ by a total class $\overline{\mathbb{H}}$ such that $\mathrm{LD}(\overline{\mathbb{H}}) < \infty$? Is there one with $\mathrm{VC}(\overline{\mathbb{H}}) < \infty$?*

Theorem 10 shows that for partial classes, having polynomial growth is not a sufficient condition for PAC learnability. A natural candidate reinstatement of the theorem is to work with the more restrictive assumption of linear growth.

▶ **Problem 25.** *Let $\mathbb{H} \subseteq \{0, 1, \star\}^{\mathcal{X}}$ have polynomial growth with parameter 1. Does there exist a disambiguation $\overline{\mathbb{H}}$ of $\mathbb{H}$ with $\mathrm{VC}(\overline{\mathbb{H}}) < \infty$?*

Another question is whether one can improve the lower bound of $\Omega(\log \log n)$ in Theorem 6 to $\Omega(\log n)$.

▶ **Problem 26.** *Can the lower bound in Theorem 6 be improved to $\mathrm{VC}(\overline{\mathbb{H}}) \geq \Omega(\log n)$?*

Forbidding combinatorial patterns

A natural method to prove upper bounds on the VC dimension of a concept class is establishing that it does not contain a specific combinatorial pattern. For example, the construction for Theorem 3 in [1] utilized the fact that the concept class (viewed as a matrix) does not contain the combinatorial patterns $\begin{bmatrix} 1 & 1 \\ 0 & 0 \end{bmatrix}$ and $\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$, which are patterns that are in any concept class $\mathbb{H}$ with $\mathrm{VC}(\mathbb{H}) \geq 2$. Similarly, the dual construction in Theorem 6 forbids the pattern $\begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix}$, a compulsory pattern for any concept class $\mathbb{H}$ with $\mathrm{LD}(\mathbb{H}) \geq 3$.

▶ **Problem 27.** *Suppose $\mathbb{H} \subseteq \{0, 1, \star\}^{[n]}$ does not contain the pattern $\begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$. Does every disambiguation $\overline{\mathbb{H}}$ of $\mathbb{H}$ satisfy $\mathrm{VC}(\overline{\mathbb{H}}) = O(1)$?*

A General Framework for Learning-Augmented Online Allocation

Abstract

Online allocation is a broad class of problems where items arriving online have to be allocated to agents who have a fixed utility/cost for each assigned item so to maximize/minimize some objective. This framework captures a broad range of fundamental problems such as the Santa Claus problem (maximizing minimum utility), Nash welfare maximization (maximizing geometric mean of utilities), makespan minimization (minimizing maximum cost), minimization of ℓ_p-norms, and so on. We focus on divisible items (i.e., fractional allocations) in this paper. Even for divisible items, these problems are characterized by strong super-constant lower bounds in the classical worst-case online model.

In this paper, we study online allocations in the *learning-augmented* setting, i.e., where the algorithm has access to some additional (machine-learned) information about the problem instance. We introduce a *general* algorithmic framework for learning-augmented online allocation that produces nearly optimal solutions for this broad range of maximization and minimization objectives using only a single learned parameter for every agent. As corollaries of our general framework, we improve prior results of Lattanzi et al. (SODA 2020) and Li and Xian (ICML 2021) for learning-augmented makespan minimization, and obtain the first learning-augmented nearly-optimal algorithms for the other objectives such as Santa Claus, Nash welfare, ℓ_p-minimization, etc. We also give tight bounds on the resilience of our algorithms to errors in the learned parameters, and study the learnability of these parameters.

1 Introduction

Recent research has focused on obtaining learning-augmented algorithms for many online problems to overcome pessimistic lower bounds in competitive analysis. In this paper, we consider the *online allocation* framework in the learning-augmented setting. In this framework, a set of (divisible) items have to be allocated online among a set of agents, where each agent has a non-negative utility/cost for each item. This framework captures a broad range of classic problems depending on the objective one seeks to optimize. In load balancing (also called *makespan minimization*), the goal is to *minimize the maximum* (MinMax) cost of any agent. A more general goal is to minimize the ℓ_p-norm of the cost vector defined on the agents, for some $p \geq 1$. Both makespan minimization (which is ℓ_∞-minimization) and ℓ_p-minimization are classic problems in scheduling theory and have been extensively studied in competitive analysis. In a different vein, the online allocation framework also applies to

maximization problems, where the allocation of an item obtains some utility for the receiving agent. This includes the famous Santa Claus problem, where the goal is to *maximize the minimum* (MaxMin) utility of any agent, or the maximization of *Nash welfare* which is defined as the geometric mean of the agents' utilities. These maximization objectives have also been been extensively studied, particularly because of their connection to *fairness* in allocations.

Learning-Augmented Online Allocation. In this paper, we consider the online allocation framework in the *learning-augmented* setting. Typically, online allocation problems are characterized by strong super-constant lower bounds in competitive analysis, e.g., $\Omega(\log m)$ for load balancing [7], $\Omega(p)$ for ℓ_p-minimization [4] and $\Omega(m)$ for both Santa Claus (folklore) and Nash welfare [9]. A natural question, then, is whether some additional (machine-learned) information about the problem instance (we call these *learned parameters*) can help overcome these lower bounds and obtain a near-optimal solution. In this paper, we answer this question in the affirmative. In particular, we give a simple, unified framework for obtaining near-optimal (fractional) allocations *using a single learned parameter for every agent.* Our result holds for both maximization and minimization problems, and applies to all objective functions that satisfy two mild technical conditions that we define below. Indeed, the most interesting aspect of our techniques and results is this generality: prior work for online allocation problems, both in *competitive analysis* and *beyond worst-case algorithms*, has typically been specific to the objective at hand, and the techniques for maximization and minimization objectives bear no similarity. In contrast, our techniques surprisingly handles not only a broad range of objectives but applies both to maximization and minimization problems simultaneously. We hope that the generality of our methods will cast a new light on what is one of the most important classes of problems in combinatorial optimization.

Before proceeding further, we define the two technical conditions that the objective function of the online allocation problem needs to satisfy for our results to apply. Let $f : \mathbb{R}^m_{>0} \to \mathbb{R}_{>0}$ be the objective function defined on the vector of costs/utilities of the agents. Then, the conditions are:

- *Monotonicity:* f is said to be *monotone* if the following holds: for any $\ell, \ell' \in \mathbb{R}^m_{>0}$ such that $\ell_i \geq \ell'_i$ for all $i \in [m]$, we have $f(\ell) \geq f(\ell')$.
- *Homogeneity:* f is said to be *homogeneous* if the following holds: for any $\ell, \ell' \in \mathbb{R}^m_{>0}$ such that $\ell'_i = \alpha \cdot \ell_i$ for all $i \in [m]$, then we have $f(\ell') = \alpha \cdot f(\ell)$.

We say an objective function is *well-behaved* if it is both monotone and homogeneous. All online allocation objectives studied previously that we are aware of are well-behaved, including the examples given above.

1.1 Our Results

We now state our main result below:

▶ **Theorem 1** (Informal). *Fix any $\epsilon > 0$. For any online allocation problem with a well-behaved objective, there is an algorithm that achieves a competitive ratio of $1 - \epsilon$ for maximization problems or $1 + \epsilon$ for minimization problems using a single learned parameter for every agent.*

We remark that the role of ϵ in the above theorem is to ensure that the learned parameter vector is of bounded precision.

Comparison to Prior Work. Lattanzi et al. [17] were the first to consider online allocation in a learning-augmented setting. They considered a special case of the load balancing problem called restricted assignment, and showed the surprising result that a single (learned)

parameter for each agent is sufficient to bypass the lower bound and obtain a nearly optimal (fractional) allocation. This result was further generalized by Li and Xian [20] to the full generality of the load balancing problem, but instead of a single parameter, they now required two parameters for every agent. At a high level, their algorithm first uses one set of parameters to restrict the set of agents who can receive an item, and then solves the resulting restricted assignment problem using the second set of parameters. A a corollary of Theorem 1, we improve this result by obtaining a near-optimal solution using a single learned parameter for every agent. In both these papers, as well as in our paper, the (fractional) allocation uses *proportional allocation*. In the setting of online optimization, proportional allocations were used earlier by Agrawal et al. [1] for the (weighted) b-matching problem. As in our paper, they also gave an iterative algorithm for computing the parameters of the allocation. However, because the two problems are structurally very different (e.g., matching is a packing problem while our allocation problems are covering problems), the iterative algorithm in the Agrawal et al. paper is different from ours. To the best of our knowledge, our results for the other problems, namely Santa Claus, Nash welfare maximization, ℓ_p-norm minimization, and other objectives that can be defined in the online allocation framework are the first results in learning-augmented algorithms for these problems.

We now state our additional results.

Resilience to Prediction Error. A key desiderata of learning-augmented online algorithms is resilience to errors in the learned parameters. In other words, one desires that the competitive ratio of the algorithm should gracefully degrade when the learned parameters used in the algorithm deviate from their optimal values. For well-behaved objectives for both minimization and maximization problems, we give an error-resilient algorithm whose competitive ratio degrades gracefully with prediction error:

▶ **Theorem 2** (Informal). *For any online allocation problem with a well-behaved objective, there is an (learning-augmented) algorithm that achieves a competitive ratio of $O(\alpha)$ when the learned parameter input to the algorithm is within a multiplicative factor of α of the optimal learned parameter for every agent. This holds for both minimization and maximization objectives.*

The above theorem is asymptotically tight for the MaxMin objective. But, interestingly, for the MinMax objective we can do better:

▶ **Theorem 3** (Informal). *For the load balancing problem (*MinMax *objective), there is an (learning-augmented) algorithm that achieves a competitive ratio of $O(\log \alpha)$ when the learned parameter input to the algorithm is within a multiplicative factor of α of the optimal learned parameter for every agent. Moreover, the dependence $O(\log \alpha)$ in the above statement is asymptotically tight.*

An analogous statement was previously known only in the special case of restricted assignment [17].

▶ Remark 4. We use a multiplicative measure of error α similar to [17]. For both MinMax and MaxMin objectives, we may assume w.l.o.g. that $\alpha \leq m$. This is because by standard techniques, it is possible to achieve $O(\min(\alpha, m))$ and $O(\log \min(\alpha, m))$ competitiveness for the MaxMin and MinMax objectives respectively. We also show that our bounds are asymptotically tight as a function of α, in addition to matching existing lower bounds for the two problems as a function of m.

Learnability of Parameters. We also study the learnability of the parameters used in our algorithm. Following [20] and [18], we adopt the PAC framework. We assume that each item is drawn independently (but not necessarily identically) from a distribution, and show a bound on the sample complexity of approximately learning the parameter vector under this setting. For the MaxMin and MinMax objectives, we show the following:

▶ **Theorem 5** (Informal). *Fix any $\epsilon > 0$. For the online allocation problem with* MaxMin *or* MinMax *objectives, the sample complexity of learning a parameter vector that gives a $1-\epsilon$ (for* MaxMin*) or $1+\epsilon$ (for* MinMax*) approximation is $O(\frac{m}{\log m} \cdot \log \frac{m}{\epsilon})$.*

We note that a similar result was previously known for the MinMax objective (Li and Xian [20]). We also generalize this result to all well-behaved objectives subject to a technical condition of *superadditivity* for maximization or *subadditivity* for minimization. All the objectives described earlier in the introduction satisfy these conditions.

1.2 Our Techniques

Our learning-augmented online algorithms for both minimization and maximization objectives follow from a single, unified algorithmic framework that we develop in this paper. This is quite surprising because in the worst-case setting, the online algorithms for the different objectives do not share any similarity (indeed have different competitive ratios), particularly between maximization and minimization problems. First, let us first consider the MinMax and MaxMin objectives. To use common terminology across these problems, let us call the cost/utility of an item j to an agent i the *weight* of item j for agent i and denote it $p_{i,j}$. Our common algorithmic framework uses proportional allocation according to the learned parameters of the agents. Let w_i denote the parameter for agent i. Normally, proportional allocation would entail that we allocate a fraction $x_{i,j}$ of item j to agent i where $x_{i,j} = \frac{w_i p_{i,j}}{\sum_{i'} w_{i'} p_{i',j}}$. But, this is clearly not adequate, since it would produce the same allocation for both the MaxMin and MinMax objectives. Specifically, if $p_{i,j}$ is *large* for a pair i, j, then $x_{i,j}$ should be large for the MaxMin objective and small for the MinMax objective respectively. To implement this intuition, we exponentiate the weight $p_{i,j}$ by a fixed value α that depends on the objective (i.e., is different for MaxMin and MinMax) and then allocate using fractions $x_{i,j} = \frac{w_i p_{i,j}^{\alpha}}{\sum_{i'} w_{i'} p_{i',j}^{\alpha}}$. We call this an *exponentiated proportional* allocation (or EP-allocation in short), and call α the *exponentiation constant*.

Let us fix any value of α. It is clear that for both the MinMax and MaxMin objectives, an optimal allocation has *uniform* cumulative fractional weights (called *load*) across all agents. (Note that otherwise, an infinitesimal fraction of an item can be repeatedly moved from the most loaded to the least loaded agent to eventually improve the competitive ratio.) Following this intuition, we define a *canonical allocation* as one that sets learned parameters on the agents in a way that equalizes the loads on all agents. We show that the canonical allocation always exists and is *unique*. Indeed, this is true not only for all EP-allocation algorithms, but for a much broader class of proportional allocation schemes that we called *generalized proportional* allocations (or GP-allocations). In the latter class, we allow any transformation of the weights $p_{i,j}$ before applying proportional allocation. Thus, EP-allocations represent the subclass of GP-allocations where the transformation is exponentiation by the fixed value α. We also give a simple iterative (Sinkhorn-like) algorithm for computing the optimal learned parameters, and establish its convergence properties, for GP-allocations. GP-allocations give an even larger palette of proportional allocation schemes to choose from than EP-allocations, and we hope it will be useful in future work for problem settings that are not covered in this paper (e.g., non-linear utilities).

Finally, we need to set the value of α specifically for the MinMax and MaxMin objectives. Intuitively, it is clear that we need to set α to a large *positive* value for the MaxMin objective and a large *negative* value for the MinMax objective. Indeed, we show that in the limit of $\alpha \to \infty$ and $\alpha \to -\infty$, the canonical allocation defined above recovers optimal allocations for the MaxMin and MinMax objectives respectively. We also show a monotonicity property of the optimal objective (with the value of α) that can be used to set α to a finite value (function of ϵ) and obtain a $1-\epsilon$ (resp., $1+\epsilon$) approximation for the MaxMin (resp., MinMax) objective, for any $\epsilon > 0$.

Now that we have described the EP-allocation scheme for obtaining nearly optimal algorithms for the MinMax and MaxMin objectives, we generalize to all well-behaved objective functions. This is quite simple. The main advantage of the MinMax and MaxMin objectives that is not shared by other objectives is the property that the optimal solution has uniform load across all agents. Now, suppose for a maximization objective, the load of agent i in an optimal solution is s_i (we call this the *scaling parameter* for agent i). For now, suppose these values s_i are also provided offline as a second set of parameters. Then, we can first scale the weights $p_{i,j}$ using these parameters to obtain a new instance $q_{i,j} = \frac{p_{i,j}}{s_i}$. Clearly, the optimal solution for the original instance has uniform load across all agents for the transformed instance. Indeed, by the monotonicity of the maximization objective, this solution for the transformed instance is also optimal for the MaxMin objective. Using the above analysis for the MaxMin objective, we can now claim that there exist learned parameters w_i for $i \in [m]$ such that setting $x_{i,j} = \frac{w_i q_{i,j}^\alpha}{\sum_{i'} w_{i'} q_{i',j}^\alpha}$ gives an optimal solution to the original instance of the problem. Now, note that

$$x_{i,j} = \frac{w_i q_{i,j}^\alpha}{\sum_{i'} w_{i'} q_{i',j}^\alpha} = \frac{(w_i/s_i^\alpha) p_{i,j}^\alpha}{\sum_{i'} (w_{i'}/s_{i'}^\alpha) p_{i',j}^\alpha} = \frac{w_i' p_{i,j}^\alpha}{\sum_{i'} w_{i'}' p_{i',j}^\alpha} \text{ for } w_i' = w_i/s_i^\alpha.$$

It follows that by using learned parameters w_i' in an EP-allocation on the original instance, we can obtain an optimal solution for the original maximization objective. (The case for a minimization objective is identical to the above argument, with the MaxMin objective being replaced by the MinMax objective.) Finally, using the homogeneity of the objective function, we can also set α to a finite value (function of ϵ) and obtain a $1-\epsilon$ (resp., $1+\epsilon$) approximation for the maximization (resp., minimization) objective, for any $\epsilon > 0$.

1.3 Related Work

Learning-augmented online algorithms were pioneered by the work of Lykouris and Vassilvikskii [21] for the caching problem, and has become a very popular research area in the last few years. The basic idea of this framework is to augment an online algorithm with (machine-learned) predictions about the future, which helps overcome pessimistic worst case lower bounds in competitive analysis. Many online allocation problems have been considered in this framework in scheduling [27, 5, 6, 8, 15, 24], online matching [2, 13, 16], ad delivery [22, 19], etc. The reader is referred to the survey by Mitzenmacher and Vassilvitskii [25, 26] for further examples of online learning-augmented algorithms. The papers specifically related to our work are those of Lattanzi et al. [17] and Li and Xian [20] that we described above, and that of Lavastida et al. [18] that focuses on the learnability of the parameters for the same problem. As mentioned earlier, Agrawal et al. [1] used the proportional allocation framework earlier for the online (weighted) b-matching problem, and gave an iterative algorithm for computing the parameters of the allocation.

We now give a brief summary of online allocation in the worst-case model. For minimization problems, two classic objectives are makespan (i.e., ℓ_∞ norm) and ℓ_p norm minimization for $p > 1$. The former was studied in several works (e.g., [7, 3]), eventually

leading to an asymptotically tight bound of $\Theta(\log m)$. This was later generalized to arbitrary ℓ_p norms, and a tight bound of $\Theta(p)$ was obtained for this case [4, 12]. For maximization objectives, there are $\Omega(m)$ lower bounds for many natural objectives such as MaxMin (see, e.g., [14]) and Nash welfare [9]. Some recent work has focused on overcoming these lower bounds using additional information such as monopolist values for the agents [9, 10]. While this improves the competitive ratio to sub-linear in m, lower bounds continue to rule out near-optimal solutions (or even constant factor approximations) that we seek in this paper.

Organization. For most of the paper, we only consider the MinMax and MaxMin objectives. We establish the notation in Section 2 and give an overview of the results. Then, we prove these results by showing properties of GP-allocations in Section 3 and of EP-allocations in Section 4. Next, we give noise resilient algorithms in Section 5 and discuss learnability of the parameters in Section 6. Finally, in Section 7, we extend our results to all well-behaved objective functions via simple reductions to the MaxMin and MinMax objectives.

2 Preliminaries and Results

2.1 Problem Definition

We have n (divisible) items that arrive online and have to be (fractionally) allocated to m agents. The weight of item $j \in [n]$ for agent $i \in [m]$ is denoted $p_{i,j}$ and is revealed when item j arrives. We denote the *weight matrix*

$$P = \begin{bmatrix} p_{1,1} & \cdots & p_{1,n} \\ \vdots & \ddots & \vdots \\ p_{m,1} & \cdots & p_{m,n} \end{bmatrix} \text{ where all } p_{i,j} > 0 \text{ for all } i \in [m], j \in [n].^1$$

A feasible allocation is given by an *assignment matrix*

$$X = \begin{bmatrix} x_{1,1} & \cdots & x_{1,n} \\ \vdots & \ddots & \vdots \\ x_{m,1} & \cdots & x_{m,n} \end{bmatrix} \text{ where } x_{i,j} \in [0,1] \text{ for all } i \in [m], j \in [n] \text{ and } \sum_{i=1}^{m} x_{i,j} = 1 \text{ for all } j \in [n].$$

Note that every item has to be fully allocated among all the agents. We use $\mathcal{X}$ to denote the set of feasible solutions. The total weight of an agent i corresponding to an allocation X (we call this the *load* of i) is given by

$$\ell_i(P, X) = \sum_{j \in [n]} x_{i,j} \cdot p_{i,j},$$

and the vector of loads of all the agents is denoted $\boldsymbol{\ell}(P, X)$.

The load balancing problem is now defined as

$$\min_{X \in \mathcal{X}} \Big\{ T : \ell_i(P, X) \leq T \text{ for all } i \in [m] \Big\},$$

while the Santa Claus problem is defined as

$$\max_{X \in \mathcal{X}} \Big\{ T : \ell_i(P, X) \geq T \text{ for all } i \in [m] \Big\}.$$

2.2 Exponentiated and Generalized Proportional Allocations

Our algorithmic framework is simple: when allocating item j, we first exponentiate the weights $p_{i,j}$ to $p_{i,j}^{\alpha}$ for some fixed α (called the *exponentiation constant*) that only depends on the objective being optimized. Next, we perform proportional allocation weighted by the learned parameters w_i for agents $i \in [m]$:

$$x_{i,j} = \frac{p_{i,j}^{\alpha} \cdot w_i}{\sum_{i' \in [m]} p_{i',j}^{\alpha} \cdot w_{i'}}.$$

We call this an *exponentiated proportional* allocation or EP-allocation in short.

Our main theorem is the following:

▶ **Theorem 6.** *For the load balancing and Santa Claus problems, there are* EP*-allocations that achieve a competitive ratio of* $1+\epsilon$ *and* $1-\epsilon$ *respectively, for any* $\epsilon > 0$.

The Canonical Allocation. In order to define an EP-allocation and establish Theorem 6, we need to specify two things: the vector of learned parameters $\mathbf{w} \in \mathbb{R}^m_{>0}$ and the exponentiation constant α. First, we focus on the learned parameters. For any fixed α and a weight matrix P, we use learned parameters $\mathbf{w} \in \mathbb{R}^m_{>0}$ that result in *equal load* for every agent. We call this the *canonical allocation*. The corresponding learned parameters and the load of every agent are respectively called the *canonical parameters* (denoted $\mathbf{w}^*$) and the *canonical load* (denoted ℓ^*).

Apriori, it is not clear that a canonical allocation should even exist, and even if it does, that it is unique. Interestingly, we show this existence and uniqueness not just from EP-allocations but for the much broader class of proportional allocations where *any* function $f : \mathbb{R}_{>0} \to \mathbb{R}_{>0}$ (called the *transformation function*) can be used to transform the weights rather than just an exponential function. I.e.,

$$x_{i,j} = \frac{f(p_{i,j}) \cdot w_i}{\sum_{i' \in [m]} f(p_{i',j}) \cdot w_{i'}}.$$

We call this a *generalized proportional* allocation or GP-allocation in short.

We show the following theorem for GP-allocations:

▶ **Theorem 7.** *For any weight matrix* $P \in \mathbb{R}^{m \times n}_{>0}$ *and any transformation function* $f : \mathbb{R}_{>0} \to \mathbb{R}_{>0}$*, the canonical load for a* GP*-allocation exists and is unique. Moreover, it is attained by a unique (up to scaling) set of canonical parameters.*

We prove Theorem 7 algorithmically by giving a simple iterative (offline) algorithm that converges to the set of canonical parameters (see Algorithm 1). We will show later that the canonical allocations produced by appropriately setting the value of the exponentiation constant α are respectively optimal (fractional) solutions for the Santa Claus and the load balancing problems. Therefore, an interesting consequence of the iterative convergence of this algorithm to the canonical allocation is that it gives a simple alternative *offline* algorithm for computing an optimal fractional solution for these two problems. To the best of our knowledge, this was not explicitly known before our work.

An interesting direction for future research would be to explore other natural classes of transformation functions, other than the exponential functions considered in this paper. Since Theorem 7 holds for any transformation function, they also admit a canonical allocation,

and it is conceivable that such canonical allocations would optimize objective functions other than the MinMax and MaxMin functions considered here. For example, one natural open problem is following: are there a transformation functions whose canonical allocations correspond to maximizing Nash Social Welfare or minimizing p-norms of loads?

Monotonicity and Convergence of EP-allocations. Now that we have defined the learned parameters in Theorem 6 as the corresponding canonical parameters, we are left to define the values of the exponentiation constant α for the MaxMin and MinMax problems respectively. We show two key properties of canonical loads of EP-allocations. First, we show that the canonical load is monotone nondecreasing with the value of α. This immediately suggests that we should choose the largest possible value of α for the MaxMin problem since it is a maximization problem, and the smallest possible value of α for the MinMax problem since it is a minimization problem. Indeed, the second property that we show is that in the limit of $\alpha \to \infty$, the canonical load converges to the optimal objective for the Santa Claus problem (we denote this optimal value $\ell^{\mathbf{SNT}}$) and in the limit of $\alpha \to -\infty$, the canonical load converges to the optimal objective for the load balancing problem (we denote this optimal value $\ell^{\mathbf{MKS}}$).

For a fixed α, let $X(P, \alpha, \mathbf{w})$ denote the assignment matrix and $\boldsymbol{\ell}(P, \alpha, \mathbf{w})$ the load vector for a learned parameter vector $\mathbf{w}$. Let $\boldsymbol{\ell}^*(P, \alpha)$ denote the corresponding canonical load. We show the following properties of canonical EP-allocations:

▶ **Theorem 8.** *For any weight matrix $P \in \mathbb{R}^{m \times n}_{>0}$, the following properties hold for canonical* EP*-allocations:*

- *The monotonicity property: For $\alpha_1, \alpha_2 \in \mathbb{R}$ such that $\alpha_1 \geq \alpha_2$, we have $\ell^*(P, \alpha_1) \geq \ell^*(P, \alpha_2)$.*
- *The convergence property: $\lim_{\alpha \to \infty} \ell^*(P, \alpha) = \ell^{\boldsymbol{SNT}}(P)$ and $\lim_{\alpha \to -\infty} \ell^*(P, \alpha) = \ell^{\boldsymbol{MKS}}(P)$.*

Clearly, Theorem 8 implies Theorem 6 as a corollary when α is set sufficiently large for the Santa Claus problem and sufficiently small for the load balancing problem.

In the rest of the paper, we will prove Theorem 7 and Theorem 8.

3 Canonical Properties of Generalized Proportional Allocations

In this section, we prove Theorem 7. For notational convenience, we define a transformation matrix $G \in \mathbb{R}^{m \times n}_{>0}$ where $G(i, j) = f(p_{i,j})$ for the transformation function f. Using this notation, we denote by $x_{i,j}(G, \mathbf{w})$ the fractional allocation of item j to agent i, and by $\ell_i(P, G, \mathbf{w})$ the load of agent i (we use $\boldsymbol{\ell}(P, G, \mathbf{w})$ to denote the vector of agent loads) under the GP-allocation corresponding to the transformation matrix G and learned parameters $\mathbf{w}$.

We say two sets of learned parameters $\mathbf{w}, \mathbf{w}'$ are *equivalent* (denoted $\mathbf{w} \equiv \mathbf{w}'$) if there exists some constant $c > 0$ such that $w'_i = c \cdot w_i$ for every agent $i \in [m]$. The following is a simple observation from the GP-allocation scheme that two equivalent sets of learned parameters produce the same allocation:

▶ **Observation 9.** *For any $G \in \mathbb{R}^{m \times n}_{>0}$, if $\mathbf{w} \equiv \mathbf{w}' \in \mathbb{R}^m_{>0}$, then $x_{i,j}(G, \mathbf{w}) = x_{i,j}(G, \mathbf{w}')$ for all i, j.*

We also note that GP-allocations are monotone in the sense that if one agent's parameter decreases while the rest increase, then the allocation on this agent decreases as well.

▶ **Observation 10.** *Consider any $G \in \mathbb{R}^{m\times n}_{>0}$ and any nonzero vector $\boldsymbol{\epsilon} \in \mathbb{R}^m_{\geq 0}$ such that $-w_k < \epsilon_k \leq 0$ for some $k \in [m]$ and $\epsilon_i \geq 0$ for all $i \neq k$. Then, $x_{k,j}(G, \mathbf{w}') < x_{k,j}(G, \mathbf{w})$ for all $j \in [n]$, where $\mathbf{w}' = \mathbf{w} + \boldsymbol{\epsilon}$ and $\mathbf{w}' \neq \mathbf{w}$.*

Our first nontrivial property is that the load vector uniquely determines the learned parameters up to equivalence of the parameters.

▶ **Lemma 11.** *For any $P, G \in \mathbb{R}^{m\times n}_{>0}$, $\ell_i(P, G, \mathbf{w}) = \ell_i(P, G, \mathbf{w}')$ for all $i \in [m]$ if and only if $\mathbf{w} \equiv \mathbf{w}'$.*

Proof. In one direction, if $\mathbf{w} \equiv \mathbf{w}'$, the loads are identical because the allocations are identical (by Observation 9).

We now show the lemma in the opposite direction. Let $k = \arg\min_i \frac{w_i}{w'_i}$ and $c = \frac{w_k}{w'_k}$. Let us define $\hat{\mathbf{w}} = c \cdot \mathbf{w}'$. Then, $\hat{w}_k = w_k$, and $\hat{w}_{i'} = \left(\min_i \frac{w_i}{w'_i}\right) \cdot w'_{i'} \leq w_{i'}$ for all $i' \neq k$. Now, if $\mathbf{w}$ and $\mathbf{w}'$ are not equivalent, then there exists some $i' \in [m]$ such that $\hat{w}_{i'} < w_{i'}$. Therefore, by Observation 10, $x_{k,j}(G, \hat{\mathbf{w}}) > x_{k,j}(G, \mathbf{w})$ for all $j \in [n]$. But, by Observation 9, $x_{k,j}(G, \hat{\mathbf{w}}) = x_{k,j}(G, \mathbf{w}')$ for all $j \in [n]$. Thus, $x_{k,j}(G, \mathbf{w}') > x_{k,j}(G, \mathbf{w})$ for all $j \in [n]$, which contradicts $\ell_k(P, G, \mathbf{w}') = \ell_k(P, G, \mathbf{w})$. ◀

Similarly, we show that if the canonical load exists (i.e., a load vector where all loads are identical), it must be unique.

▶ **Lemma 12.** *For any $P, G \in \mathbb{R}^{m\times n}_{>0}$, if there exist $\mathbf{w}, \mathbf{w}' \in \mathbb{R}^m_{>0}$ such that $\ell_i(P, G, \mathbf{w}) = \ell$ and $\ell_i(P, G, \mathbf{w}') = \ell'$ for all $i \in [m]$, then $\ell = \ell'$.*

Proof. Assume for the purpose of contradiction that there exist $\mathbf{w}, \mathbf{w}' \in \mathbb{R}^m_{>0}$ such that for all $i \in [m]$, $\ell_i(P, G, \mathbf{w}) = \ell$ and $\ell_i(P, G, \mathbf{w}') = \ell'$ but $\ell > \ell'$. Let $k = \arg\min_i \frac{w_i}{w'_i}$ and $c = \frac{w_k}{w'_k}$, and let $\hat{\mathbf{w}} = c \cdot \mathbf{w}'$. We have

$$\ell' = \ell_k(P, G, \mathbf{w}') = \ell_k(P, G, \hat{\mathbf{w}}) \geq \ell_k(P, G, \mathbf{w}) = \ell, \text{which is a contradiction.}$$

Here, the second equality is by Observation 9, and the inequality is by Observation 10, since $\hat{w}_k = w_k$, and $\hat{w}_i \leq w_i$ for $i \in [m]$. ◀

3.1 Convergence of Algorithm 1

The rest of this section focuses on showing the existence of a canonical allocation for GP-allocations. We do so by showing convergence of the following simple iterative algorithm (Algorithm 1):

Note that Algorithm 1 ensures that if the loads of all agents are uniform at any stage, then the iterative process has converged and the algorithm terminates. So, it remains to show that for any $P, G \in \mathbb{R}^{m\times n}_{>0}$, this iterative process reaches a set of parameters $\mathbf{w}^* \in \mathbb{R}^m_{>0}$ such that $\ell_i(P, G, \mathbf{w}^*) = \ell_{i'}(P, G, \mathbf{w}^*)$ for all $i, i' \in [m]$.

Our proof has two parts. The first part shows that the maximum and minimum loads are (weakly) monotone over the course of the iterative process. For this, we focus on a single iteration. For a vector $\boldsymbol{\ell} \in \mathbb{R}^m_{>0}$, let $\ell_{\max} = \max_{i\in[m]} \ell_i$ and $\ell_{\min} = \min_{i\in[m]} \ell_i$ be the maximum and minimum coordinates of $\boldsymbol{\ell}$. We will show that if $\ell^{(r)}_{\max}$ and $\ell^{(r)}_{\min}$ are not equal at the beginning of an iteration, then $\ell^{(r)}_{\max}$ can only decrease (or stay unchanged) and $\ell^{(r)}_{\min}$ can only increase (or stay unchanged) in a single iteration.

▶ **Lemma 13.** *Consider any $P, G \in \mathbb{R}^{m\times n}_{>0}$, $\gamma > 0$. Let $\mathbf{w}, \mathbf{w}', \boldsymbol{\ell}, \boldsymbol{\ell}' \in \mathbb{R}^m_{>0}$ such that $\ell_i = \ell_i(P, G, \mathbf{w})$, $\ell'_i = \ell_i(P, G, \mathbf{w}')$ and $w'_i = \frac{w_i}{\ell_i} \cdot \gamma$ and let $\tilde{p}_i = \sum_j p_{i,j}$. Then, we have $\ell'_i \geq \ell_{\min} / \left(1 - \frac{\ell_i - \ell_{\min}}{\tilde{p}_i}\right)$ and $\ell'_i \leq \ell_{\max} / \left(1 + \frac{\ell_{\max} - \ell_i}{\tilde{p}_i}\right)$.*

Algorithm 1 The iterative algorithm showing the existence of a canonical allocation for GP-allocations.

- Initialize: $\mathbf{w}^{(0)} \leftarrow \mathbf{1}^m$

Iteration r:

- Compute $\boldsymbol{\ell}^{(r)}$ as $\ell_i^{(r)} \leftarrow \ell_i(P, G, \mathbf{w}^{(r)})$, for all $i \in [m]$, where $\ell_i(P, G, \mathbf{w}^{(r)})$ is the load of agent i under the GP-allocation with transformation matrix G and learned parameters $\mathbf{w}^{(r)}$.
- Set $\mathbf{w}^{(r+1)}$ as $w_i^{(r+1)} \leftarrow \frac{w_i^{(r)}}{\ell_i^{(r)}} \cdot \gamma^{(r)}$, for all $i \in [m]$.

  Here, $\gamma^{(r)} \in \mathbb{R}_{>0}$ is a scaling factor whose value does not affect the load (by Observation 9). But, by using, e.g., $\gamma^{(r)} = \ell_1^{(r)}$, we can ensure that the algorithm terminates with a single set of learned parameters instead of repeatedly finding equivalent sets of parameters after it has converged.

In the second part, we show that the ratio $\frac{\ell_{\max}^{(r)}}{\ell_{\min}^{(r)}}$ is strictly decreasing after a finite number of iterations. The proof of this stronger property requires the per-iteration weak monotonicity property that we establish in the first part of the proof. The proof is deferred to the full version of the paper.

▶ **Lemma 14.** *Let $P, G \in \mathbb{R}_{>0}^{m \times n}$ be given fixed matrices. Fix an iteration r in Algorithm 1 where $\ell_{\max}^{(r)} > \ell_{\min}^{(r)}$. Let $\ell_{\max}^{(r)} \geq (1+\epsilon) \cdot \ell_{\min}^{(r)}$ for some $\epsilon \in (0, 1]$. Then, in the next iteration, we have $\ell_{\min}^{(r+1)} \geq (1 + c \cdot \epsilon) \cdot \ell_{\min}^{(r)}$ for some constant $c > 0$ that only depends on P and G.*

Using Lemma 13 and Lemma 14, we complete the proof of Theorem 7.

Proof of Theorem 7. We are given fixed matrices $P, G \in \mathbb{R}_{>0}^{m \times n}$. Let $\ell_{\max}^{(r)}, \ell_{\min}^{(r)}$ denote the maximum and the minimum load respectively in iteration r of Algorithm 1. Let $c > 0$ be the constant (that depends only on P, G) in Lemma 14.

For a non-negative integer a, let r_a be defined recursively as follows:

$$r_a = r_{a-1} + \left\lceil \frac{\log(1 + 2^{-a+1})}{\log(1 + c \cdot 2^{-a})} \right\rceil + 1, \text{ where } r_0 = \left\lceil \frac{\log\left(\ell_{\max}^{(0)} / \ell_{\min}^{(0)}\right)}{\log(1+c)} \right\rceil + 1.$$

We will show for any a, in any iteration $r \geq r_a$, we have $\ell_{\max}^{(r)} / \ell_{\min}^{(r)} \leq 1 + 2^{-a}$. First, we prove it for $a = 0$. If there exists some $r \leq r_0$ such that $\ell_{\max}^{(r)} / \ell_{\min}^{(r)} \leq 2$, then this also holds for $r \geq r_0$ by Lemma 13. Otherwise, for all $r \leq r_0$ we have $\ell_{\max}^{(r)} / \ell_{\min}^{(r)} > 2$. Then, using Lemma 14 with $\epsilon = 1$, we get $\ell_{\min}^{(r+1)} \geq (1+c) \cdot \ell_{\min}^{(r)}$. Therefore, $\ell_{\min}^{(r_0)} \geq (1+c)^{r_0} \cdot \ell_{\min}^{(0)} > \ell_{\max}^{(0)}$ by our choice of r_0. This contradicts Lemma 13, thereby showing that $\ell_{\max}^{(r)} / \ell_{\min}^{(r)} \leq 2$ for any $r \geq r_0$.

Now, we show the inductive case. Assume the inductive hypothesis that $\ell_{\max}^{(r_{a-1})} / \ell_{\min}^{(r_{a-1})} \leq 1 + 2^{-(a-1)}$. We will prove that $\ell_{\max}^{(r_a)} / \ell_{\min}^{(r_a)} \leq 1 + 2^{-(a)}$. The proof is similar to the base case of $a = 0$. If there exists some $r \leq r_a$ such that $\ell_{\max}^{(r)} / \ell_{\min}^{(r)} \leq 1 + 2^{-a}$, then this inequality also holds for any $r \geq r_a$ by Lemma 13. Otherwise, for all $r \leq r_a$ we have $\ell_{\max}^{(r)} / \ell_{\min}^{(r)} > 1 + 2^{-a}$. Then, for all $r_{a-1} \leq r \leq r_a$, using Lemma 14 with $\epsilon = 2^{-a}$, we have $\ell_{\min}^{(r+1)} \geq (1 + c \cdot 2^{-a}) \cdot \ell_{\min}^{(r)}$. Therefore, $\ell_{\min}^{(r_a)} \geq (1 + c \cdot 2^{-a})^{r_a - r_{a-1}} \cdot \ell_{\min}^{(r_{a-1})}$. By our choice of r_a, this implies $\ell_{\min}^{(r_a)} > (1 + 2^{-(a-1)}) \cdot \ell_{\min}^{(r_{a-1})}$. By the induction hypothesis, this implies $\ell_{\min}^{(r_a)} > \ell_{\max}^{(r_{a-1})}$. But, this implies $\ell_{\max}^{(r_a)} > \ell_{\max}^{(r_{a-1})}$, which contradicts Lemma 13. Therefore,

$$\lim_{r \to \infty} \ell_{\max}^{(r)} / \ell_{\min}^{(r)} = 1,$$

and $\ell^*(P, G) = \lim_{r \to \infty} \ell_{\max}^{(r)}$. Moreover, by Lemma 12 this value is uniquely defined and attained by a unique (up to scaling) set of learned parameters. ◀

3.2 Weak Monotonicity of the Maximum and Minimum Loads in Algorithm 1: Proof of Lemma 13

For ease of description, we assume that G and $\mathbf{w}$ are normalized in the following sense:

$$\mathbf{w} = \mathbf{1}^m \text{ and } \sum_j g_{i,j} = 1.$$

This transformation is local to the current iteration, and only for the purpose of this proof. First, we explain why this change of notation is w.l.o.g. Suppose $\hat{G}, \hat{\mathbf{w}}$ represent the actual transformation matrix and learned parameters respectively. Now, we define G as follows:

$$g_{i,j} = \frac{\hat{g}_{i,j} \cdot \hat{w}_i}{\sum_{i' \in [m]} \hat{g}_{i',j} \cdot \hat{w}_{i'}},$$

and our new learned parameters is given by $\mathbf{1}^m$.

Note that the fractional allocation remains unchanged, i.e., $x_{i,j}(\hat{G}, \hat{w}) = x_{i,j}(G, \mathbf{1}^m) = g_{i,j}$, and therefore the loads are also unchanged: $\ell_i = \ell_i(P, \hat{G}, \hat{\mathbf{w}}) = \ell_i(P, G, \mathbf{1}^m) = \sum_{j \in [n]} g_{i,j} \cdot p_{i,j}$. Assume w.l.o.g. (by Observation 9) that $\gamma = \ell_1$, so $\hat{w}'_i = \frac{\hat{w}_i}{\ell_i} \cdot \ell_1$. In the normalized notation, the new parameters are $w'_i = \frac{\ell_1}{\ell_i}$. Again, the allocation is unchanged whether we use the original notation or the normalized one:

$$x_{i,j}(\hat{G}, \hat{\mathbf{w}}') = x_{i,j}(G, \mathbf{w}') = \frac{g_{i,j} \cdot w'_i}{\sum_{i' \in [m]} g_{i',j} \cdot w'_{i'}},$$

and we have, $\ell'_i = \ell_i(P, \hat{G}, \hat{\mathbf{w}}') = \ell_i(P, G, \mathbf{w}')$.

The case of Two Agents. For brevity, we will only consider the case of two agents here, i.e., $m = 2$. The reduction from general m to $m = 2$ is deferred to the full version of the paper.

We have

$$\ell_1 = \sum_j g_{1,j} \cdot p_{1,j} \qquad \text{and} \qquad \ell_2 = \sum_j g_{2,j} \cdot p_{2,j},$$

and the parameter for the second agent after the update is given by: $w'_2 = \frac{\ell_1}{\ell_2}$ (note that $w'_1 = 1$).

Accordingly, the loads after the update are given by:

$$\ell'_1 = \sum_j p_{1,j} \cdot \frac{g_{1,j}}{g_{1,j} + w'_2 \cdot g_{2,j}} \qquad \text{and} \qquad \ell'_2 = \sum_j p_{2,j} \cdot \frac{w'_2 \cdot g_{2,j}}{g_{1,j} + w'_2 \cdot g_{2,j}}.$$

Assume w.l.o.g that $\ell_1 < \ell_2$. First, note that, from monotonicity (Observation 10) we have:

$$\ell'_2 \leq \ell_2 = \ell_{\max} / \left(1 + \frac{\ell_{\max} - \ell_2}{\bar{p}_1}\right).$$

Next, we have to show that

$$\ell'_1 \leq \ell_{\max} / \left(1 + \frac{\ell_{\max} - \ell_1}{\bar{p}_1}\right) = \ell_2 / \left(1 + \frac{\ell_2 - \ell_1}{\bar{p}_1}\right). \tag{1}$$

The proof of the lower bound on ℓ'_1 is similar and is omitted for brevity.

We use the following standard inequality:

▶ **Fact 15** (Milne's Inequality [23]). *For any $a, b \in \mathbb{R}^n$, we have*

$$\sum_{j\in[n]} \frac{a_j \cdot b_j}{a_j + b_j} \quad \leq \quad \frac{\sum_{j\in[n]} a_j \cdot \sum_{j\in[n]} b_j}{\sum_{j\in[n]} (a_j + b_j)}.$$

In using this inequality, we set for any $j \in [n]$,

$$a_j = p_{1,j} \text{ and } b_j = p_{1,j} \cdot \left(\frac{f_j}{w'_2} - 1\right) \text{ where } f_j = g_{1,j} + w'_2 \cdot g_{2,j} = g_{1,j} + w'_2 \cdot (1 - g_{1,j}).$$

First, we calculate each term in Milne's inequality separately:

$$\sum_{j\in[n]} \frac{a_j \cdot b_j}{a_j + b_j} = \sum_{j\in[n]} p_{1,j} \cdot \frac{f_j - w'_2}{f_j} = \sum_{j\in[n]} p_{1,j} \cdot \frac{g_{1,j} + w'_2 \cdot g_{2,j} - w'_2}{f_j} = \sum_{j\in[n]} p_{1,j} \cdot \frac{g_{1,j} - w'_2 \cdot (1 - g_{2,j})}{f_j}$$

$$= \sum_{j\in[n]} p_{1,j} \cdot \frac{g_{1,j} - w'_2 \cdot g_{1,j}}{f_j} = \sum_{j\in[n]} p_{1,j} \cdot g_{1,j} \cdot \frac{1 - w'_2}{f_j} = \ell'_1 \cdot (1 - w'_2).$$

$$\sum_{j\in[n]} a_j = \tilde{p}_1.$$

$$\sum_{j\in[n]} b_j = \sum_{j\in[n]} p_{1,j} \cdot g_{1,j} \cdot \left(\frac{1}{w'_2} - 1\right) = \frac{\ell_1}{w'_2} - \ell_1 = \ell_2 - \ell_1 = \ell_2 \cdot (1 - w'_2).$$

Using Fact 15, we get

$$\ell'_1 \cdot (1 - w'_2) \leq \frac{\tilde{p}_1 \cdot \ell_2}{\ell_2 - \ell_1 + \tilde{p}_1} \cdot (1 - w'_2)$$

By our assumption that $\ell_1 < \ell_2$, and therefore $w'_2 < 1$. We now get Equation (1) by rearranging terms. This completes the proof for the lemma for the case of two agents. As mentioned previously, the reduction from general m to $m = 2$ is deferred to the full version of the paper.

4 Monotonicity and Convergence of Exponentiated Proportional Allocations

In this section, we prove the monotonicity and convergence of EP-allocations (Theorem 8).

First, we establish monotonicity of EP-allocations (first part of Theorem 8). We compare two EP-allocations with arbitrary learned parameters but different exponential constants. We show that with a larger exponent, at least one agent's load will be higher, regardless of the parameters used.

▶ **Lemma 16.** *Fix a weight matrix $P \in \mathbb{R}^{m\times n}_{>0}$. Let $\alpha, \alpha' \in \mathbb{R}$ such that $\alpha > \alpha'$. Now, for any two sets of learned parameters $\mathbf{w}_\alpha, \mathbf{w}_{\alpha'} \in \mathbb{R}^m_{>0}$, there exists an agent $k \in [m]$ such that*

$$\ell_k(P, \alpha, \mathbf{w}_\alpha) \geq \ell_k(P, \alpha', \mathbf{w}_{\alpha'}).$$

Proof. Let Δ denote the vector of differences of loads of the machines in the two allocations, namely $\Delta_i = \ell_i(P, \alpha, \mathbf{w}_\alpha) - \ell_i(P, \alpha', \mathbf{w}_{\alpha'})$. Our goal is to show that Δ has at least one nonnegative coordinate.

To show this, we define a vector in the positive orthant $\mathbf{c} \in \mathbb{R}^m_{>0}$ as follows:

$$c_i = \left(\frac{w_{\alpha,i}}{w_{\alpha',i}}\right)^{\frac{1}{\rho}}, \text{ where } \rho = \alpha - \alpha' > 0$$

and show that this vector $\mathbf{c}$ has a nonnegative inner product with the vector Δ. Note that this suffices since the inner product of a vector with all positive coordinates and one with all negative coordinates cannot be nonnegative. In other words, we want to show the following:

$$\sum_{i\in[m]} c_i \cdot (\ell_i(P,\alpha,w_\alpha) - \ell_i(P,\alpha',w_{\alpha'})) \geq 0. \tag{2}$$

Let us denote the fractional allocation of an item j in the two cases by $x_{i,j}$ and $x'_{i,j}$ respectively. Then, Equation (2) can be rewritten as

$$\sum_{i\in[m]} c_i \cdot \sum_{j\in[n]} p_{i,j} \cdot (x_{i,j} - x'_{i,j}) \geq 0.$$

Changing the order of the two summations, we rewrite further as

$$\sum_{j\in[n]} \left(\sum_{i\in[m]} c_i \cdot p_{i,j} \cdot (x_{i,j} - x'_{i,j}) \right) \geq 0.$$

We will prove this inequality separately for each item $j \in [n]$. Namely, we will show that

$$\sum_{i\in[m]} c_i \cdot p_{i,j} \cdot (x_{i,j} - x'_{i,j}) \geq 0, \text{ for every } j \in [n]. \tag{3}$$

Fix an item j. Since the item is fixed, we will drop j from the notation and define $\mathbf{u} \in \mathbb{R}^m$ as

$$u_i = p_i \cdot (x_i - x'_i).$$

So, we need to show that

$$\mathbf{c} \cdot \mathbf{u} \geq 0, \text{ i.e., } \sum_{i\in[m]} c_i \cdot u_i \geq 0. \tag{4}$$

We have

$$\begin{aligned}
\sum_i c_i \cdot u_i &= \sum_i c_i \cdot p_i \cdot \left(\frac{p_i^\alpha \cdot w_{\alpha,i}}{\sum_{i'} p_{i'}^\alpha \cdot w_{\alpha,i'}} - \frac{p_i^{\alpha'} \cdot w_{\alpha',i}}{\sum_{i'} p_{i'}^{\alpha'} \cdot w_{\alpha',i'}} \right) \\
&= \frac{1}{T} \cdot \sum_i c_i \cdot p_i \cdot \left(p_i^\alpha \cdot w_{\alpha,i} \cdot \left(\sum_{i'} p_{i'}^{\alpha'} \cdot w_{\alpha',i'} \right) - p_i^{\alpha'} \cdot w_{\alpha',i} \cdot \left(\sum_{i'} p_{i'}^{\alpha} \cdot w_{\alpha,i'} \right) \right) \\
&\text{where } T = \left(\sum_{i'} p_{i'}^{\alpha'} \cdot w_{\alpha',i'} \right) \cdot \left(\sum_{i'} p_{i'}^{\alpha} \cdot w_{\alpha,i'} \right).
\end{aligned}$$

Now, on the right hand side of the above equation, we replace α by $\alpha' + \rho$ and $w_{\alpha,i}$ by $w_{\alpha',i} \cdot c_i^\rho$ for every $i \in [m]$. This gives us:

$$\sum_i c_i \cdot u_i =$$
$$\frac{1}{T}\sum_i c_i \cdot p_i \left(p_i^{\alpha'} \cdot p_i^{\rho} \cdot w_{\alpha',i} \cdot c_i^{\rho} \left(\sum_{i'} p_{i'}^{\alpha'} \cdot w_{\alpha',i'} \right) - p_i^{\alpha'} \cdot w_{\alpha',i} \left(\sum_{i'} p_{i'}^{\alpha'} \cdot p_{i'}^{\rho} \cdot w_{\alpha',i'} \cdot c_{i'}^{\rho} \right) \right)$$
$$= \frac{1}{T}\sum_i b_i \left(a_i \cdot b_i^{\rho} \left(\sum_{i'} a_{i'} \right) - a_i \left(\sum_{i'} a_{i'} \cdot b_{i'}^{\rho} \right) \right),$$
where $a_i = w_{\alpha',i} \cdot p_i^{\alpha'}$ and $b_i = p_i \cdot c_i$.

Rearranging the summations on the two terms on the right hand side, we get

$$\sum_i c_i \cdot u_i = \frac{1}{T} \cdot \left(\sum_{i'} a_{i'} \right) \cdot \sum_i a_i \cdot b_i^{\rho+1} - \frac{1}{T} \cdot \left(\sum_{i'} a_{i'} \cdot b_{i'}^{\rho} \right) \cdot \sum_i a_i \cdot b_i$$

Now, let $z_i = a_i^{1/2}$, and $y_i = a_i^{1/2} \cdot b_i^{\rho/2+1/2}$, and $\theta = \frac{|\rho-1|}{\rho+1}$. Then, we have

$$\begin{aligned} T \cdot \sum_i c_i \cdot u_i &= \left(\sum_{i'} a_{i'} \right) \cdot \left(\sum_i a_i \cdot b_i^{\rho+1} \right) - \left(\sum_{i'} a_{i'} \cdot b_{i'}^{\rho} \right) \cdot \left(\sum_i a_i \cdot b_i \right) \\ &= \left(\sum_{i'} z_{i'}^2 \right) \cdot \left(\sum_i y_i^2 \right) - \left(\sum_{i'} z_{i'}^{1+\theta} \cdot y_{i'}^{1-\theta} \right) \cdot \left(\sum_i z_i^{1-\theta} \cdot y_i^{1+\theta} \right). \end{aligned}$$

In the last equation, the first term follows directly from $a_{i'} = z_{i'}^2$ and $a_i \cdot b_i^{\rho+1} = y_i^2$. The second term is more complicated. There are two cases. If $\rho \le 1$, then $a_{i'} \cdot b_{i'}^{\rho} = z_{i'}^{1+\theta} \cdot y_{i'}^{1-\theta}$ and $a_i \cdot b_i = z_i^{1-\theta} \cdot y_i^{1+\theta}$ but if $\rho > 1$, then the roles get reversed and we get $a_{i'} \cdot b_{i'}^{\rho} = z_{i'}^{1-\theta} \cdot y_{i'}^{1+\theta}$ and $a_i \cdot b_i = z_i^{1+\theta} \cdot y_i^{1-\theta}$.

Now, note that $T \ge 0$. So, to establish $\sum_i c_i \cdot u_i \ge 0$, it suffices to show that the right hard side of the equation is nonnegative. We do so by employing Callebaut's inequality which we state below:

▶ **Fact 17** (Callebaut's Inequality [11]). *For any $y, z \in \mathbb{R}^n$ and $\theta \le 1$, we have*

$$\left(\sum_{i'} z_{i'}^2 \right) \cdot \left(\sum_i y_i^2 \right) \ge \left(\sum_{i'} z_{i'}^{1+\theta} \cdot y_{i'}^{1-\theta} \right) \cdot \left(\sum_i z_i^{1-\theta} \cdot y_i^{1+\theta} \right)$$

Note that we can apply Callebaut's inequality because $\rho \ge 0$ implies that $\theta \le 1$. This completes the proof of the lemma. ◀

We now state a lemma asserting the convergence property of EP-allocations. The proof of the lemma, which is constructive in the sense that it gives an algorithm to determine α and $\mathbf{w}_\alpha$ or α' and $\mathbf{w}_{\alpha'}$, is deferred to the full version of the paper.

▶ **Lemma 18.** *Given any weight matrix $P \in \mathbb{R}_{>0}^{m \times n}$ and any constant $\epsilon > 0$,*

(a) *there exists an α (think of α as a sufficiently large negative number) and a corresponding set of parameters $\mathbf{w}_\alpha$ such that $\ell_i(P, \alpha, w_\alpha) \le (1+\epsilon) \cdot \ell^{\boldsymbol{MKS}}(P)$ for all $i \in [m]$.*

(b) *there exists an α' (think of α' as a sufficiently large positive number) and a corresponding set of parameters $\mathbf{w}_{\alpha'}$ such that $\ell_i(P, \alpha', w_{\alpha'}) \ge (1-\epsilon) \cdot \ell^{\boldsymbol{SNT}}(P)$ for all $i \in [m]$.*

We are now ready to complete the proof of Theorem 8.

Proof of Theorem 8. First by Lemma 11, there exists $\mathbf{w}^*_\alpha$ and $\mathbf{w}^*_{\alpha'}$, such that, for all $i \in [m]$, $\ell_i(P, \alpha, \mathbf{w}^*_\alpha) = \ell^*(P, \alpha)$ and $\ell_i(P, \alpha', \mathbf{w}^*_{\alpha'}) = \ell^*(P, \alpha')$. Now, if $\ell^*(P, \alpha) < \ell^*(P, \alpha')$, it would contradict Lemma 16. And combining Lemma 16 and Lemma 18, we completed the proof the second part of Theorem 8. ◀

5 Noise Resilience: Handling Predictions with Error

In this section, we show the noise resilience of our algorithms, namely that we can handle errors in the learned parameters. First, we will show that for both objectives (MaxMin and MinMax), an η-approximate set of learned parameters yields an online algorithm with a competitive ratio of at least/at most η. Second, for the MinMax objective, we show that it is possible to improve the competitive ratio further in the following sense: using a set of learned parameters with a multiplicative error of η with respect to the optimal parameters, we can obtain a $O(\log \eta)$-competitive algorithm. (This was previously shown by Lattanzi et al. [17] but only for the special case of restricted assignment.) We also rule out a similar guarantee for the MaxMin objective, i.e., we show that using η-approximate learned parameters, an algorithm cannot hope to obtain a competitive ratio better than η/c for some constant c. Finally, we show that noise-resilient bounds can be obtained not just for the MinMax and MaxMin objectives but also for any homogeneous monotone minimization or maximization objective function.

Formally, a weight vector $\mathbf{w}$ is η-approximate with respect to a weight vector to $\mathbf{w}^*$, if for any two agents $i, i' \in [m]$, $\frac{w_{i'}}{w_i} \leq \eta \cdot \frac{w^*_{i'}}{w^*_i}$. First, we show a basic noise resilience property that holds for both the MinMax and MaxMin objectives:

▶ **Lemma 19.** *Fix a weight matrix $P \in \mathbb{R}^{m \times n}_{>0}$ and a transformation matrix $G \in \mathbb{R}^{m \times n}_{>0}$. For any two parameter vectors $\mathbf{w}^*, \mathbf{w} \in \mathbb{R}^m_{>0}$, such that $\mathbf{w}$ is η-approximate to $\mathbf{w}^*$, we have that for any agent k:*

$$\frac{\ell_k(P, G, \mathbf{w}^*)}{\eta} \leq \ell_k(P, G, \mathbf{w}) \leq \eta \cdot \ell_k(P, G, \mathbf{w}^*).$$

Proof. Let $y_{i,j} = x_{i,j}(G, \mathbf{w}^*)$ and $z_{i,j} = x_{i,j}(G, \mathbf{w})$ be the respective fractional allocations under proportional allocation using the transformation matrix G. For an agent i, let $\tau_i = w_i / w^*_i$. Then for any two agents i, k, we have that $1/\eta \leq \tau_k/\tau_i \leq \eta$. We have, $\frac{y_{i,j}}{z_{i,j}} = \sum_{i' \in [m]} \frac{\tau_{i'}}{\tau_i} \cdot y_{i',j}$. Therefore,

$$\frac{y_{i,j}}{z_{i,j}} = \sum_{i' \in [m]} \frac{\tau_{i'}}{\tau_i} \cdot y_{i',j} \geq \sum_{i' \in [m]} \frac{1}{\eta} \cdot y_{i',j} = \frac{1}{\eta} \cdot \sum_{i' \in [m]} y_{i',j} = \frac{1}{\eta}, \text{ and}$$

$$\frac{y_{i,j}}{z_{i,j}} = \sum_{i' \in [m]} \frac{\tau_{i'}}{\tau_i} \cdot y_{i',j} \leq \sum_{i' \in [m]} \eta \cdot y_{i',j} = \eta \cdot \sum_{i' \in [m]} y_{i',j} = \eta.$$

Hence, $y_{i,j}/\eta \leq z_{i,j} \leq y_{i,j} \cdot \eta$. Finally, the lemma hold by summing over all items. ◀

The next theorem follows immediately by using a proportional allocation according to the parameter vector $\tilde{\mathbf{w}}$:

▶ **Theorem 20.** *Fix any $P, G \in \mathbb{R}^{m \times n}_{>0}$. Let $\mathbf{w}$ be a learned parameter vector that gives a solution of value γ for the* MaxMin *(resp.,* MinMax*) objective using proportional allocation. Let $\tilde{\mathbf{w}}$ be η-approximate to $\mathbf{w}$ for some $\eta > 1$. Then, there exists an online algorithm that given $\tilde{\mathbf{w}}$ generates a solution with value at least $\Omega(\gamma/\eta)$ (resp., at most $O(\eta\gamma)$).*

Algorithm 2 The online algorithm with predictions.

- Let $\hat{\mathbf{w}}$ a prediction vector and T is the offline optimal objective for the MinMax problem.
- Initialize: $\ell_i \leftarrow 0$ and $\tilde{w}_i \leftarrow \hat{w}_i$, for all $i \in [m]$

For each item j:

- Compute $x_{i,j} = \dfrac{f(p_{i,j}) \cdot \tilde{w}_i}{\sum_{i' \in [m]} f(p_{i',j}) \cdot \tilde{w}_{i'}}$
- $\ell_i \leftarrow \ell_i + p_{i.j} \cdot x_{i,j}$, for all $i \in [m]$
- If exists $i \in [m]$, s.t. $\ell_i > 2 \cdot T$
  Set $\ell_i \leftarrow 0$
  Update $\tilde{w}_i \leftarrow \tilde{w}_i/2$

In particular, if $\mathbf{w}$ is the *optimal* learned parameter vector in the above theorem and $\tilde{\mathbf{w}}$ is an η-approximation to it, then we obtain a competitive ratio of $\Omega(1/\eta)$.

The rest of this section focuses on the MinMax objective for which we can obtain an improved bound. In the next lemma, we establish an upper bound on the load, using Lemma 19 and monotonicity.

▶ **Lemma 21.** *Fix a weight matrix $P \in \mathbb{R}_{>0}^{m \times n}$ and a transformation matrix $G \in \mathbb{R}_{>0}^{m \times n}$. For any two parameter vectors $\mathbf{w}^*, \mathbf{w} \in \mathbb{R}_{>0}^m$ such that there exists an agent $k \in [m]$ for which $w_k^*/2 \leq w_k \leq w_k^*$ and for all other agents $i \neq k$, we have $w_i \geq w_i^*/2$, then the following holds: $\ell_k(P, G, \mathbf{w}) \leq 2 \cdot \ell_k(P, G, \mathbf{w}^*)$.*

Proof. Define $\mathbf{w}'$ where $w'_k = w_k^*$ (i.e., the maximum in its allowed range) and $w'_i = w_i^*/2$ for all $i \neq k$ (i.e., the minimum in their allowed ranges). Now, by monotonicity (Observation 10), we have $x_{k,j}(G, \mathbf{w}) \leq x_{k,j}(G, \mathbf{w}')$, and therefore, $\ell_k(P, G, \mathbf{w}) \leq \ell_k(P, G, \mathbf{w}')$. Note that for $\mathbf{w}'$, for any two agents i_1, i_2, $\frac{w_{i_1}}{w_{i_2}} \leq 2 \cdot \frac{w_{i_1}^*}{w_{i_2}^*}$. Therefore, by Lemma 19, we have $\ell_k(P, G, \mathbf{w}') \leq 2 \cdot \ell_k(P, G, \mathbf{w}^*)$. By combining the two inequalities, we have $\ell_k(P, G, \mathbf{w}) \leq \ell_k(P, G, \mathbf{w}') \leq 2 \cdot \ell_k(P, G, \mathbf{w}^*)$, as required. ◀

Let us denote the predicted learned parameter vector that is given offline to the MinMax algorithm by $\hat{\mathbf{w}}$. We also assume that the algorithm knows the optimal objective value T. By scaling, we assume w.l.o.g that $\tilde{\mathbf{w}}$ is coordinate-wise larger than the optimal learned parameter vector $\mathbf{w}$. The algorithm uses a learned parameter vector $\hat{\mathbf{w}}$ that is iteratively refined, starting with $\hat{\mathbf{w}} = \tilde{\mathbf{w}}$ (see Algorithm 2). In each iteration, the current parameter vector $\hat{\mathbf{w}}$ is used to determine the assignment using proportional allocation until an agent's load in the current phase exceeds $2T$. If this happens for any agent i, then the algorithm halves the value of $\hat{w}_i$, starts a new phase for agent i, and continues doing proportional allocation with the updated learned parameter vector $\hat{\mathbf{w}}$.

▶ **Theorem 22.** *Fix any $P, G \in \mathbb{R}_{>0}^{m \times n}$. Let $\mathbf{w}$ be a learned parameter vector that gives a fractional solution with maximum load T using proportional allocation. Let $\tilde{\mathbf{w}}$ be an η-approximate prediction for $\mathbf{w}$. Then there exists an online algorithm that given $\tilde{\mathbf{w}}$ generates a fractional assignment of items to agents with maximum load at most $O(T \log \eta)$.*

Proof. By the algorithm's definition, an agent's total load is at most $2T$ times the number of phases for the agent. We show that for any agent i, the parameter $\tilde{w}_i$ is always at least $w_i/2$. This immediately implies that the number of phases for machine i is $O(\log \eta)$, which in turn establishes the theorem.

Suppose, for contradiction, in some phase for agent k, we have $\tilde{w}_k < w_k/2$. Moreover, assume w.l.o.g. that agent k is the first agent for which this happens. Clearly, by the algorithm definition, there is a preceding phase for agent k when $\tilde{w}_k < w_k$. Note that, in this entire preceding phase, we have $w_k > \tilde{w}_k \geq w_k/2$, and for all $i \neq k$, $\tilde{w}_i \geq w_i/2$ (by our assumption that k is the first agent to have a violation). However, by Lemma 21, the load of agent k in the preceding phase would be at most $2T$. This contradicts the fact that the algorithm started a new phase for agent k when its load exceeded $2T$ in the preceding phase. ◀

6 Learnability of the Parameters

We consider the learning model introduced by [18], and show that under this model, the parameter vector $\mathbf{w}$ can be learned efficiently from sampled instances. Specifically, we consider the following model: the jth item (i.e., the values of $\mathbf{p}_j = (p_{i,j} : i \in [m])$ is independently sampled from a (discrete) distribution $\mathcal{D}_j$. In other words, the matrix P of utilities is sampled from $\mathcal{D} = \times_j \mathcal{D}_j$.

We set up the model for the MaxMin objective; the setup for the MinMax objective is very similar and is omitted for brevity. Let $T = \mathbb{E}_{P\sim\mathcal{D}}[\ell^{\mathbf{SNT}}(P)]$ be the expected value of the MaxMin objective in the optimal solution for an instance $\ell^{\mathbf{SNT}}(P)$ drawn from $\mathcal{D}$. Morally, we would like to say that we can obtain a vector $\mathbf{w}$ that gives a nearly optimal solution (in expectation) using proportional allocation (i.e., a MaxMin objective of $(1-\epsilon)\cdot T$ in expectation for some error parameter ϵ) using a bounded (as a function of ϵ) number of samples. Similar to [18], we need the following assumption:

Small Items Assumption. Conceptually, this assumption states that each individual item has a small utility compared to the overall utility of any agent in an optimal solution. Precisely, we need $p_{i,j} \leq \frac{T}{\zeta}$ for every $i \in [m], j \in [n]$ for some value $\zeta = \Theta\left(\frac{\log m}{\epsilon^2}\right)$.

Our main theorem in this section for the MaxMin and MinMax objectives are:

▶ **Theorem 23.** *Fix an $\epsilon > 0$ for which the small items assumption holds. Then, there is an (learning) algorithm that samples $O(\frac{m}{\log m} \cdot \log \frac{m}{\epsilon})$ independent instances from $\mathcal{D}$ and outputs (with high probability) a prediction vector $\mathbf{w}$ such that using $\mathbf{w}$ in the proportional allocation scheme gives a* MaxMin *objective of at least $(1 - \Omega(\epsilon)) \cdot T$ in expectation over instances $P \sim \mathcal{D}$.*

▶ **Theorem 24.** *Fix an $\epsilon > 0$ for which the small items assumption holds. Then, there is an (learning) algorithm that samples $O(\frac{m}{\log m} \cdot \log \frac{m}{\epsilon})$ independent instances from $\mathcal{D}$ and outputs (with high probability) a prediction vector $\mathbf{w}$ such that using $\mathbf{w}$ in the proportional allocation scheme gives a* MinMax *objective of at most $(1 + O(\epsilon))T$ in expectation over instances $P \sim \mathcal{D}$.*

Importantly, the description of the entries of $\mathbf{w}$ in Theorem 23 and Theorem 24 are bounded. Specifically, let us define $\mathbf{NET}(m, \epsilon) \subseteq \mathbb{R}^m_{>0}$ as follows: (a) for the MaxMin objective, $\mathbf{w} \in \mathbf{NET}(m, \epsilon)$ if there exist vectors $\mathbf{u}, \delta \in \mathbb{R}^m_{>0}$ such that $w_i = \frac{\delta_i}{u_i^\alpha}$ and $u_i, \delta_i \in \left\{\left(\frac{1}{1-\epsilon}\right)^r : r \in [K]\right\}$ for some $K = O(\frac{m}{\epsilon}\log\frac{m}{\epsilon})$, and (b) for the MinMax objective, $\mathbf{w} \in \mathbf{NET}'(m, \epsilon)$ if there exist vectors $\mathbf{u}, \delta \in \mathbb{R}^m_{>0}$ such that $w_i = \frac{\delta_i}{u_i^\alpha}$ and $u_i, \delta_i \in \{(1+\epsilon)^r : r \in [K]\}$ for some $K = O(\frac{m}{\epsilon}\log\frac{m}{\epsilon})$. The vectors $\mathbf{w}$ produced by the learning algorithm in Theorem 23 and Theorem 24 will satisfy $\mathbf{w} \in \mathbf{NET}(m, \epsilon)$ and $\mathbf{w} \in \mathbf{NET}'(m, \epsilon)$ in the respective cases.

Proof Idea for Theorem 23 and Theorem 24. Recall that in PAC theory, the number of samples needed to learn a function from a family of N functions is about $O(\log N)$. Indeed, restricting $\mathbf{w}$ to be in the class $\mathbf{NET}(m,\epsilon)$ or $\mathbf{NET}'(m,\epsilon)$ serves this role of limiting the hypothesis class to a finite, bounded set since $|\mathbf{NET}(m,\epsilon)| = |\mathbf{NET}'(m,\epsilon)| = K^{2m}$ where $K = O(\frac{m}{\epsilon}\log\frac{m}{\epsilon})$. Using standard PAC theory, this implies that using about $O(m\log K) = O(m\cdot\log\frac{m}{\epsilon})$ samples, we can learn the "best" vector in $\mathbf{NET}(m,\epsilon)$ or $\mathbf{NET}'(m,\epsilon)$ depending on whether we have the MaxMin or MinMax objective. Our main technical work is to show that this "best" vector produces an approximately optimal solution when used in proportional allocation. We state this lemma next:

▶ **Lemma 25.** *Fix any P. For the* MaxMin *objective, there exists a learned parameter vector $\mathbf{w} \in \boldsymbol{NET}(m,\epsilon)$ which when used in* EP*-allocation gives a $1-\Omega(\epsilon)$ approximation. For the* MaxMin *objective, there exists a learned parameter vector $\mathbf{w}' \in \boldsymbol{NET}'(m,\epsilon)$ which when used in* EP*-allocation gives a $1+O(\epsilon)$ approximation.*

The proofs of this lemma and the preceding theorems are deferred to the full version of the paper.

7 Generalization to Well-Behaved Objectives

We first generalize Theorem 6 to all well-behaved functions (Proofs for this section are deferred to the full version).

▶ **Theorem 26.** *Fix any instance of an online allocation problem with divisible items where the goal is to maximize or minimize a monotone homogeneous objective function. Then, there exists an online algorithm and a learned parameter vector in $\mathbb{R}^m_{>0}$ that achieves a competitive ratio of $1-\epsilon$ (for maximization) or $1+\epsilon$ (for minimization).*

Proof. Fix an objection function f and a matrix $P \in \mathbb{R}^{m\times n}_{>0}$. Let ℓ_i^f denote the load of agent i in an optimal solution for objective function f. Also, let $x_{i,j}$ denote the fraction of item j assigned to agent i in this optimal solution. Now, consider the matrix $\tilde{P}$, where $\tilde{p}_{i,j} = \frac{p_{i,j}}{\ell_i^f}$. By the monotonicity property of f, the optimal objective value for $\tilde{P}$ is 1. Therefore, by Theorem 8, there exist α and $\tilde{\mathbf{w}}$, such that using an EP-allocation, we get $\ell^*(\tilde{P},\alpha,\tilde{\mathbf{w}}) \geq 1-\epsilon$ for maximization and $\ell^*(\tilde{P},\alpha,\tilde{\mathbf{w}}) \leq 1+\epsilon$ for minimization. Let $x^*_{i,j}$ be the fraction of item j assigned to agent i in this approximate solution. By the definition of EP-allocation, $x^*_{i,j}$ is proportional to $\tilde{p}^\alpha_{i,j}\cdot\tilde{w}_i = \left(\frac{p_{i,j}}{\ell_i^f}\right)^\alpha \cdot \tilde{w}_i = p^\alpha_{i,j}\cdot\frac{\tilde{w}_i}{(\ell_i^f)^\alpha}$. Thus, if we define $\mathbf{w}$ such that $w_i = \frac{\tilde{w}_i}{(\ell_i^f)^\alpha}$, then the corresponding EP-allocation gives a $(1-\epsilon)$-approximate solution for maximization and $(1+\epsilon)$-approximate solution for minimization. ◀

7.1 Noise Resilience

Next, we consider noise resilience for well-behaved functions, i.e., we generalize Theorem 20 to all well-behaved objective functions. This follows immediately from Lemma 19 and the observation that if all loads are scaled by η, then the objective value for a well-behaved objective is also scaled by η. We state this generalized theorem below:

▶ **Theorem 27.** *Fix any $P, G \in \mathbb{R}^{m\times n}_{>0}$ and any monotone, homogeneous function f. Let $\mathbf{w}$ be a learned parameter vector that gives a solution of objective value γ using* EP*-allocation. Let $\tilde{\mathbf{w}}$ be η-approximate to $\mathbf{w}$ for some $\eta > 1$. Then, the* EP*-allocation for $\tilde{\mathbf{w}}$ gives a solution with value at least γ/η for maximization and at most $\eta\gamma$ for minimization.*

7.2 Learnability

Finally, we consider learnability of parameters for well-behaved functions, i.e., we generalize Theorem 23 and using an by assuming additional property of the objective function:

- For a maximization objective f, we need *superadditivity*: $f(\sum_r \ell_r) \geq \sum_r f(\ell_r)$.
- For a minimization objective f, we need *subadditivity*: $f(\sum_r \ell_r) \leq \sum_r f(\ell_r)$.

▶ **Theorem 28.** *Let f be a well-behaved function. If f is superadditive, the following theorem holds for maximization of f, while if f is subadditive, the following theorem holds for minimization of f. Let T be the expectation of the maximum value of f over instances sampled from $\mathcal{D}$. Fix an $\epsilon > 0$ for which the small items assumption holds. Then, there is an (learning) algorithm that samples $O(\frac{m}{\log m} \cdot \log \frac{m}{\epsilon})$ independent instances from $\mathcal{D}$ and outputs (with high probability) a prediction vector $\mathbf{w}$ such that using $\mathbf{w}$ in the* EP*-allocation gives a value of f that is at least $(1 - \Omega(\epsilon)) \cdot T$ for maximization and at most $(1 + O(\epsilon)) \cdot T$ for minimization, in expectation over instances $P \sim \mathcal{D}$.*

8 Conclusion and Future Directions

In this paper, we gave a unifying framework for designing near-optimal algorithm for fractional allocation problems for essentially all well-studied minimization and maximization objectives in the literature. The existence of this overarching framework is rather surprising because the corresponding worst-case problems exhibit a wide range of behavior in terms of the best competitive ratio achievable, as well as the techniques required to achieve those bounds. It would be interesting to gain further understanding of the optimal learned parameters introduced in this paper. One natural conjecture is that these are optimal dual variables for a suitably defined convex program (for instance, such convex programs are known for restricted assignment and b-matching [1]). Another interesting direction of future work would be to explore other polytopes beyond the simple assignment polytope considered in this paper, such as that corresponding to congestion minimization problems.

Sample-Based Distance-Approximation for Subsequence-Freeness

Omer Cohen Sidon
Tel Aviv University, Israel

Dana Ron
Tel Aviv University, Israel

Abstract

In this work, we study the problem of approximating the distance to subsequence-freeness in the sample-based distribution-free model. For a given subsequence (word) $w = w_1 \dots w_k$, a sequence (text) $T = t_1 \dots t_n$ is said to contain w if there exist indices $1 \leq i_1 < \dots < i_k \leq n$ such that $t_{i_j} = w_j$ for every $1 \leq j \leq k$. Otherwise, T is w-free. Ron and Rosin (ACM TOCT 2022) showed that the number of samples both necessary and sufficient for one-sided error testing of subsequence-freeness in the sample-based distribution-free model is $\Theta(k/\epsilon)$.

Denoting by $\Delta(T, w, p)$ the distance of T to w-freeness under a distribution $p : [n] \to [0, 1]$, we are interested in obtaining an estimate $\widehat{\Delta}$, such that $|\widehat{\Delta} - \Delta(T, w, p)| \leq \delta$ with probability at least $2/3$, for a given distance parameter δ. Our main result is an algorithm whose sample complexity is $\tilde{O}(k^2/\delta^2)$. We first present an algorithm that works when the underlying distribution p is uniform, and then show how it can be modified to work for any (unknown) distribution p. We also show that a quadratic dependence on $1/\delta$ is necessary.

1 Introduction

Distance approximation algorithms, as defined in [29], are sublinear algorithms that approximate (with constant success probability) the distance of objects from satisfying a prespecified property $\mathcal{P}$. Distance approximation (and the closely related notion of tolerant testing) is an extension of property testing [31, 20], where the goal is to distinguish between objects that satisfy a property $\mathcal{P}$ and those that are far from satisfying the property.[1] In this work we consider the property of subsequence-freeness. For a given subsequence (word) $w_1 \dots w_k$ over some alphabet Σ, a sequence (text) $T = t_1 \dots t_n$ over Σ is said to be w-free if there do not exist indices $1 \leq j_1 < \dots < j_k \leq n$ such that $t_{j_i} = w_i$ for every $i \in [k]$.[2]

In most previous works on property testing and distance approximation, the algorithm is allowed query access to the object, and distance to satisfying the property in question, $\mathcal{P}$, is defined as the minimum Hamming distance to an object that satisfies $\mathcal{P}$, normalized by

[1] Tolerant testing algorithms are required to distinguish between objects that are close to satisfying a property and those that are far from satisfying it.

[2] For an integer x, we use $[x]$ to denote the set of integers $\{1, \dots, x\}$

the size of the object. In this work we consider the more challenging, and sometimes more suitable, sample-based model in which the algorithm is only given a random sample from the object. In particular, when the object is a sequence $T = t_1 \dots t_n$, each element in the sample is a pair (j, t_j).

We study both the case in which the underlying distribution according to which each index j is selected (independently) is the uniform distribution over $[n]$, and the more general case in which the underlying distribution is some arbitrary unknown $p : [n] \to [0, 1]$. We refer to the former as the *uniform sample-based model*, and to the latter as the *distribution-free sample-based model*. The distance (to satisfying the property) is determined by the underlying distribution. Namely, it is the minimum total weight according to p of indices j such that t_j must be modified so as to make the sequence w-free. Hence, in the uniform sample-based model, the distance measure is simply the Hamming distance normalized by n.

The related problem of testing the property of subsequence-freeness in the distribution-free sample-based model was studied by Ron and Rosin [30]. They showed that the sample-complexity of one-sided error testing of subsequence-freeness in this model is $\Theta(k/\epsilon)$ (where ϵ is the given distance parameter). A natural question is whether we can design a sublinear algorithm, with small sample complexity, that actually approximates the distance of a text T to w-freeness. It is worth noting that, in general, tolerant testing (and hence distance-approximation) for a property may be much harder than testing the property [18, 3].

1.1 Our results

In what follows, when we say that a sample is selected uniformly from T, we mean that for each sample point (j, t_j), j is selected uniformly and independently from $[n]$. This generalizes to the case in which the underlying distribution is an arbitrary distribution p.

We start by designing a distance-approximation algorithm in the uniform sample-based model. Let $\Delta(T, w)$ denote the distance under the uniform distribution of T from being w-free (which equals the fraction of symbols in T that must be modified so as to obtain a w-free text), and let $\delta \in (0, 1)$ denote the error parameter given to the algorithm.

▶ **Theorem 1.** *There exists a sample-based distance-approximation algorithm for subsequence-freeness under the uniform distribution, that takes a sample of size* $\Theta\left(\frac{k^2}{\delta^2} \cdot \log\left(\frac{k}{\delta}\right)\right)$ *and outputs an estimate* $\widehat{\Delta}$ *such that* $|\widehat{\Delta} - \Delta(T, w)| \leq \delta$ *with probability at least* $2/3$.[3]

We then turn to extending this result to the distribution-free sample-based model. For a distribution $p : [n] \to [0, 1]$, we use $\Delta(T, w, p)$ to denote the distance of T from w-freeness under the distribution p (i.e., the minimum weight, according to p, of the symbols in T that must be modified so as to obtain a w-free text).

▶ **Theorem 2.** *There exists a sample-based distribution-free distance-approximation algorithm for subsequence-freeness, that takes a sample of size* $\Theta\left(\frac{k^2}{\delta^2} \cdot \log\left(\frac{k}{\delta}\right)\right)$ *from* T*, distributed according to an unknown distribution* p*, and outputs an estimate* $\widehat{\Delta}$ *such that* $|\widehat{\Delta} - \Delta(T, w, p)| \leq \delta$ *with probability at least* $\frac{2}{3}$.

Finally, we address the question of how tight is our upper bound. We show (using a fairly simple argument) that the quadratic dependence on $1/\delta$ is indeed necessary, even for the uniform distribution. To be precise, denoting by k_d the number of distinct symbols in w, we

[3] As usual, we can increase the success probability to $1 - \eta$, for any $\eta > 0$ at a multiplicative cost of $O(\log(1/\eta))$ in the sample complexity.

give a lower bound of $\Omega(1/(k_d\delta^2))$ under the uniform distribution (that holds for every w with k_d distinct symbols, sufficiently large n and sufficiently small δ – for a precise statement, see Theorem 27).

1.2 A high-level discussion of our algorithms

Our starting point is a structural characterization of the distance to w-freeness under the uniform distribution, which is proved in [30, Sec. 3.1].[4] In order to state their characterization, we introduce the notion of copies of w in T, and more specifically, role-disjoint copies.

A *copy* of $w = w_1 \dots w_k$ in $T = t_1 \dots t_n$ is a sequence of indices $(j_1, \dots, j_k)$ such that $1 \leq j_1 < \dots < j_k \leq n$ and $t_{j_1} \dots t_{j_k} = w$. It will be convenient to represent a copy as an array C of size k where $C[i] = j_i$. A set of copies $\{C_\ell\}$ is said to be *role-disjoint* if for every $i \in [k]$, the indices in $\{C_\ell[i]\}$ are distinct (though it is possible that $C_\ell[i] = C_{\ell'}[i']$ for $i \neq i'$ (and $\ell \neq \ell'$)). In the special case where the symbols of w are all different from each other, a set of copies is role disjoint simply if it consists of disjoint copies. Ron and Rosin prove [30, Theorem 3.4 + Claim 3.1] that $\Delta(T, w)$ equals the maximum number of role-disjoint copies of w in T, divided by n.

Note that the analysis of the sample complexity of one-sided error sample-based testing of subsequence-freeness translates to bounding the size of the sample that is sufficient and necessary for ensuring that the sample contains evidence that T is not w-free when $\Delta(T, w) > \epsilon$. Here evidence is in the form of a copy of w in the sample, so that the testing algorithm simply checks whether such a copy exists. On the other hand, the question of distance-approximation has a more algorithmic flavor, as it is not determined by the problem what must be done by the algorithm given a sample.

Focusing first on the uniform case, Ron and Rosin used their characterization (more precisely, the direction by which if $\Delta(T, w) > \epsilon$, then T contains more than ϵn role-disjoint copies of w), to prove that a sample of size $\Theta(k/\epsilon)$ contains at least one copy of w with probability at least $2/3$. In this work we go further by designing an algorithm that actually approximates the number of role-disjoint copies of w in T (and hence approximates $\Delta(T, w)$), given a uniformly selected sample from T. It is worth noting that the probability of obtaining a copy in the sample might be quite different for texts that have *exactly the same* number of role-disjoint copies of w (and hence the same distance to being w-free).[5]

In the next subsection we discuss the aforementioned algorithm (for the uniform case), and in the following one address the distribution-free case.

1.2.1 The uniform case

Let $R(T, w)$ denote the number of role-disjoint copies of w in T. In a nutshell, the algorithm works by computing estimates of the numbers of occurrences of symbols of w in a relatively small number of prefixes of T, and using them to derive an estimate of $R(T, w)$. The more precise description of the algorithm and its analysis are based on several combinatorial claims that we present and which we discuss shortly next.

Let $R_i^j(T, w)$ denote the number of role-disjoint copies of the length-i prefix of w, $w_1 \dots w_i$, in the length-j prefix of T, $t_1 \dots t_j$, and let $N_i^j(T, w)$ denote the number of occurrences of the symbol w_i in $t_1 \dots t_j$. In our first combinatorial claim, we show that for every $i \in [k]$

[4] Indeed, Ron and Rosin note that: "The characterization may be useful for proving further results regarding property testing of subsequence-freeness, as well as (sublinear) distance approximation."

[5] For example, consider $w = 1 \dots k$, $T_1 = (1 \dots k)^{n/k}$ and $T_2 = 1^{n/k} \dots k^{n/k}$.

and $j \in [n]$, the value of $R_i^j(T,w)$ can be expressed in terms of the values of $N_i^{j'}(T,w)$ for $j' \in [j]$ (in particular, $N_i^j(T,w)$) and the values of $R_{i-1}^{j'-1}(T,w)$ for $j' \in [j]$. In other words, we establish a recursive expression which implies that if we know what are $R_{i-1}^{j'-1}(T,w)$ and $N_i^{j'}(T,w)$ for every $j' \in [j]$, then we can compute $R_i^j(T,w)$ (and as an end result, compute $R(T,w) = R_k^n(T,w)$).

In our second combinatorial claim we show that if we only want an approximation of $R(T,w)$, then it suffices to define (also in a recursive manner) a measure that depends on the values of $N_i^j(T,w)$ for every $i \in [k]$ but only for a relatively small number of choices of j, which are evenly spaced. To be precise, each such j belongs to the set $J = \{r \cdot \gamma n\}_{r=1}^{1/\gamma}$ for $\gamma = \Theta(\delta/k)$. We prove that since each interval $[(r-1)\gamma n + 1, r\gamma n]$ is of size γn for this choice of γ, we can ensure that the aforementioned measure (which uses only $j \in J$) approximates $R(T,w)$ to within $O(\delta n)$.

We then prove that if we replace each $N_i^j(T,w)$ for these choices of j (and for every $i \in [k]$) by a sufficiently good estimate, then we incur a bounded error in the approximation of $R(T,w)$. Finally, such estimates are obtained using (uniform) sampling, with a sample of size $\tilde{O}(k^2/\delta^2)$.

1.2.2 The distribution-free case

In [30, Sec. 4] it is shown that, given a word w, a text T and a distribution p, it is possible to define a word $\widetilde{w}$ and a text $\widetilde{T}$ for which the following holds. First, $\Delta(T,w,p)$ is closely related to $\Delta(\widetilde{T},\widetilde{w})$. Second, the probability of observing a copy of w in a sample selected from T according to p is closely related to the probability of observing a copy of $\widetilde{w}$ in a sample selected uniformly from $\widetilde{T}$.

We use the first relation stated above (i.e., between $\Delta(T,w,p)$ and $\Delta(\widetilde{T},\widetilde{w})$). However, since we are interested in distance-approximation rather than one-sided error testing, the second relation stated above (between the probability of observing a copy of w in T and that of observing a copy of $\widetilde{w}$ in $\widetilde{T}$) is not sufficient for our needs, and we need to take a different (once again, more algorithmic) path, as we explain shortly next.

Ideally, we would have liked to sample uniformly from $\widetilde{T}$, and then run the algorithm discussed in the previous subsection using this sample (and $\widetilde{w}$). However, we only have sampling access to T according to the underlying distribution p, and we do not have direct sampling access to uniform samples from $\widetilde{T}$. Furthermore, since $\widetilde{T}$ is defined based on (the unknown) p, it is not clear how to determine the aforementioned subset of (evenly spaced) indices J.

For the sake of clarity, we continue the current exposition while making two assumptions. The first is that the distribution p is such that there exists a value β, such that p_j/β is an integer for every $j \in [n]$ (the value of β need not be known). The second is that in w there are no two consecutive symbols that are the same. Under these assumptions, $\widetilde{T} = t_1^{p_1/\beta} \dots t_n^{p_n/\beta}$, $\widetilde{w} = w$, and $\Delta(\widetilde{T},\widetilde{w}) = \Delta(T,w,p)$ (where t_j^x for an integer x is the subsequence that consists of x repetitions of t_j).

Our algorithm for the distribution-free case (working under the aforementioned assumptions), starts by taking a sample distributed according to p and using it to select a (relatively small) subset of indices in $[n]$. Denoting these indices by $b_0, b_1, \dots, b_\ell$, where $b_0 = 0 < b_1 < \dots < b_{\ell-1} < b_\ell = n$, we would have liked to ensure that the weight according to p of each interval $[b_{u-1}+1, b_u]$ is approximately the same (as is the case when considering the intervals defined by the subset J in the uniform case). To be precise, we would have liked each interval to have relatively small weight, while the total number of intervals is not

too large. However, since it is possible that for some single indices $j \in [n]$, the probability p_j is large, we also allow intervals with large weight, where these intervals consist of a single index (and there are few of them).

The algorithm next takes an additional sample, to approximate, for each $i \in [k]$ and $u \in [\ell]$, the weight, according to p, of the occurrences of the symbol w_i in the length-b_u prefix of T. Observe that prefixes of T correspond to prefixes of $\widetilde{T}$. Furthermore, the weight according to p of occurrences of symbols in such prefixes, translates to numbers of occurrences of symbols in the corresponding prefixes in $\widetilde{T}$, normalized by the length of $\widetilde{T}$. The algorithm then uses these approximations to obtain an estimate of $\Delta(\widetilde{T}, \widetilde{w})$.

We note that some pairs of consecutive prefixes in $\widetilde{T}$ might be far apart, as opposed to what we had in the algorithm for the uniform case described in Section 1.2.1. However, this is always due to single-index intervals in T (for j such that p_j is large). Each such interval corresponds to a consecutive subsequence in $\widetilde{T}$ with repetitions of the same symbol, and we show that no additional error is incurred because of such intervals.

1.3 Related results

As we have previously mentioned, the work most closely related to ours is that of Ron and Rosin on distribution-free sample-based testing of subsequence-freeness [30]. For other related results on property testing (e.g., testing other properties of sequences, sample-based testing of other types of properties and distribution-free testing (possibly with queries)), see the introduction of [30], and in particular Section 1.4. For another line of work, on sublinear approximation of the longest increasing subsequence, see [27] and references within. Here we shortly discuss related results on distance approximation / tolerant testing.

As already noted, distance approximation and tolerant testing were first formally defined in [29], and were shown to be significantly harder for some properties in [18, 3]. Almost all previous results are query-based, and where the distance measure is with respect to the uniform distribution. These include [21, 19, 1, 26, 16, 11, 23, 7, 25, 17, 28]. Kopparty and Saraf [24] present results for query-based tolerant testing of linearity under several families of distributions. Berman, Raskhodnikova and Yaroslavtsev [5] give tolerant (query based) L_p-testing algorithms for monotonicity. Berman, Murzbulatov and Raskhodnikova [4] give a sample-based distance-approximation algorithms for image properties that works under the uniform distribution.

Canonne et al. [12] study the property of k-monotonicity of Boolean functions over various posets. A Boolean function over a finite poset domain D is k-monotone if it alternates between the values 0 and 1 at most k times on any ascending chain in D. For the special case of $D = [n]$, the property of k-monotonicity is equivalent to being free of w of length $k+2$ where $w_1 \in \{0,1\}$ and $w_i = 1 - w_{i-1}$ for every $i \in [2, k+2]$. One of their results implies an upper bound of $\widetilde{O}\left(\frac{k}{\delta^3}\right)$ on the sample complexity of distance-approximation for k-monotonicity of functions $f : [n] \to \{0,1\}$ under the uniform distribution (and hence for w-freeness when w is a binary subsequence of a specific form). This result generalizes to k-monotonicity in higher dimensions (at an exponential cost in the dimension d).

Blum and Hu [9] study distance-approximation for k-interval (Boolean) functions over the line in the distribution-free active setting. In this setting, an algorithm gets an unlabeled sample and asks queries on a subset of sample points. Focusing on the sample complexity, they show that for any underlying distribution p on the line, a sample of size $\widetilde{O}\left(\frac{k}{\delta^2}\right)$ is sufficient for approximating the distance to being a k-interval function up to an additive error of δ. This implies a sample-based distribution-free distance-approximation algorithm with the same sample complexity for the special case of being free of the same pair of w's described in the previous paragraph, replacing $k+2$ by $k+1$.

Blais, Ferreira Pinto Jr. and Harms [8] introduce a variant of the VC-dimension and use it to prove lower and upper bounds on the sample complexity of distribution-free testing for a variety of properties. In particular, one of their results implies that the linear dependence on k in the result of [9] is essentially optimal.

Finally we mention that our procedure in the distribution-free case for constructing "almost-equal-weight" intervals by sampling is somewhat reminiscent of techniques used in other contexts of testing when dealing with non-uniform distributions [6, 22, 10].

1.4 Further research

The main open problem left by this work is closing the gap between the upper and lower bounds that we give, and in particular understanding the precise dependence on k, or possibly other parameters determined by w (such as k_d). One step in this direction can be found in the Master Thesis of the first author [13].

1.5 Organization

In Section 2 we present our algorithm for distance-approximation under the uniform distribution. Some of the main details of the distribution-free case appears in Section 3, and in Section 4 we prove our lower bound. All missing details and proofs can be found in the full version of this paper [14].

2 Distance approximation under the uniform distribution

In this section, we address the problem of distance approximation when the underlying distribution is the uniform distribution. As mentioned in the introduction, Ron and Rosin showed [30, Thm. 3.4] that $\Delta(T, w)$ (the distance of T from w-freeness under the uniform distribution), equals the number of role-disjoint copies of w in T, divided by $n = |T|$ (where role-disjoint copies are as defined in the introduction – see Section 1.2). We may use $T[j]$ to denote the j^{th} symbol of T (so that $T[j] = t_j$).

We start by introducing the following notations.

▶ **Definition 3.** *For every $i \in [k]$ and $j \in [n]$, let $N_i^j(T, w)$ denote the number of occurrences of the symbol w_i in the length j prefix of T, $T[1, j] = T[1] \dots T[j]$.*[6] *Let $R_i^j(T, w)$ denote the number of role-disjoint copies of the subsequence $w_1 \dots w_i$ in $T[1, j]$. When $i = k$ and $j = n$, we use the shorthand $R(T, w)$ for $R_k^n(T, w)$ (the total number of role-disjoint copies of w in T).*

Observe that $R_1^j(T, w)$ equals $N_1^j(T, w)$ for every $j \in [n]$.

Since, as noted above, $\Delta(T, w) = R(T, w)/n$, we would like to estimate $R(T, w)$. More precisely, given $\delta > 0$ we would like to obtain an estimate $\widehat{R}$, such that: $\left|\widehat{R} - R(T, w)\right| \leq \delta n$. To this end, we first establish two combinatorial claims. The first claim shows that the value of each $R_i^j(T, w)$ can be expressed in terms of the values of $N_i^{j'}(T, w)$ for $j' \in [j]$ (in particular, $N_i^j(T, w)$) and the values of $R_{i-1}^{j'-1}(T, w)$ for $j' \in [j]$. In other words, if we know what are $R_{i-1}^{j'-1}(T, w)$ and $N_i^{j'}(T, w)$ for every $j' \in [j]$, then we can compute $R_i^j(T, w)$.

▷ Claim 4. For every $i \in \{2, \dots, k\}$ and $j \in [n]$,

$$R_i^j(T, w) = N_i^j(T, w) - \max_{j' \in [j]} \left\{ N_i^{j'}(T, w) - R_{i-1}^{j'-1}(T, w) \right\} .$$

[6] Indeed, if $w_i = w_{i'}$ for $i \neq i'$, then $N_i^j(T, w) = N_{i'}^j(T, w)$ for every j.

Clearly, $R_i^j(T,w) \leq N_i^j(T,w)$ (for every $i \in \{2,\ldots,k\}$ and $j \in [n]$), since each role-disjoint copy of $w_1 \ldots w_i$ in $T[1,j]$ must end with a distinct occurrence of w_i in $T[1,j]$. Claim 4 states by exactly how much is $R_i^j(T,w)$ smaller than $N_i^j(T,w)$. Roughly speaking, the expression $\max_{j' \in [j]} \left\{ N_i^{j'}(T,w) - R_{i-1}^{j'-1}(T,w) \right\}$ accounts for the number of occurrences of w_i in $T[1,j]$ that cannot be used in role-disjoint copies of $w_1 \ldots w_i$ in $T[1,j]$.

Proof. For simplicity (in terms of notation), we prove the claim for the case that $i = k$ and $j = n$. The proof for general $i \in \{2,\ldots,k\}$ and $j \in [n]$ is essentially the same up to renaming of indices. Since T and w are fixed throughout the proof, we shall use the shorthand N_i^j for $N_i^j(T,w)$ and R_i^j for $R_i^j(T,w)$.

For the sake of the analysis, we start by describing a simple greedy procedure, that constructs $R = R_k^n$ role-disjoint copies of w in T. The correctness of this procedure follows from [30, Claim 3.5] and a simple inductive argument (details are provided in the full version of the paper [14]). Every copy C_m, for $m \in [R]$ is an array of size k whose values are monotonically increasing, where for every $i \in [k]$ we have that $C_m[i] \in [n]$, and $T[C_m[i]] = w_i$. Furthermore, for every $i \in [k]$ the indices $C_1[i], \ldots, C_R[i]$ are distinct. For every $m = 1,\ldots,R$ and $i = 1,\ldots,k$, the procedure scans T, starting from $T[C_m[i-1]+1]$ (where we define $C_m[0]$ to be 0) and ending at $T[n]$ until it finds the first index j such that $T[j] = w_i$ and $j \notin \{C_1[i], \ldots, C_{m-1}[i]\}$. It then sets $C_m[i] = j$. For $i > 1$ we say in such a case that the procedure *matches* j to the partial copy $C_m[1], \ldots, C_m[i-1]$.

For $i \in [k]$, define: $G_i = \{j \in [n] : T[j] = w_i\}$. Also define: $G_i^+ = \{j \in G_i : \exists m, C_m[i] = j\}$ and $G_i^- = \{j \in G_i : \nexists m, C_m[i] = j\}$ (recall that $C_m[i]$ is the i-th index in the m-th greedy copy).

It is easy to verify that $|G_i| = N_i^n$, $\left|G_i^+\right| = R_i^n$ and $|G_i| = \left|G_i^+\right| + \left|G_i^-\right|$. To complete the proof, we will show that $\left|G_i^-\right| = \max_{j \in [n]} \left\{ N_i^j - R_{i-1}^{j-1} \right\}$.

Let j^* be an index j that maximizes $\left\{ N_i^j - R_{i-1}^{j-1} \right\}$. In the interval $[j^*]$ we have $N_i^{j^*}$ occurrences of w_i, and in the interval $[j^*-1]$ we only have $R_{i-1}^{j^*-1}$ role-disjoint copies of $w_1 \ldots w_{i-1}$. This implies that in the interval $[j^*]$ there are at least $N_i^{j^*} - R_{i-1}^{j^*-1}$ occurrences of w_i that cannot be the i-th index of any greedy copy, and so we have

$$\left|G_i^-\right| \geq N_i^{j^*} - R_{i-1}^{j^*-1} = \max_{j \in [n]} \left\{ N_i^j - R_{i-1}^{j-1} \right\} . \tag{1}$$

On the other hand, denote by j^{**} the largest index in G_i^-. Since each index $j \in [j^{**}]$ such that $T[j] = w_i$ is either the i-th element of some copy or is not the i-th element of any copy, $N_i^{j^{**}} = R_i^{j^{**}-1} + \left|G_i^-\right|$. We claim that $R_i^{j^{**}-1} = R_{i-1}^{j^{**}-1}$. Otherwise, $R_i^{j^{**}-1} < R_{i-1}^{j^{**}-1}$, in which case the index j^{**} would have to be the the i-th element of a greedy copy. Hence,

$$\left|G_i^-\right| = N_i^{j^{**}} - R_{i-1}^{j^{**}-1} \leq \max_{j \in [n]} \left\{ N_i^j - R_{i-1}^{j-1} \right\} . \tag{2}$$

In conclusion,

$$\left|G_i^-\right| = \max_{j \in [n]} \left\{ N_i^j - R_{i-1}^{j-1} \right\} , \tag{3}$$

and the claim follows. ◀

In order to state our next combinatorial claim, we first introduce one more definition, which will play a central role in obtaining an estimate for $R(T,w)$.

▶ **Definition 5.** *For $\ell \leq n$, let $\mathcal{N}$ be a $k \times \ell$ matrix of non-negative numbers, where we shall use $\mathcal{N}_i^r$ to denote $\mathcal{N}[i][r]$. For every $r \in [\ell]$ let $M_1^r(\mathcal{N}) = \mathcal{N}_1^r$, and for every $i \in \{2, \ldots, k\}$, let*

$$M_i^r(\mathcal{N}) \stackrel{\text{def}}{=} \mathcal{N}_i^r - \max_{r' \leq r} \left\{ \mathcal{N}_i^{r'} - M_{i-1}^{r'}(\mathcal{N}) \right\} .$$

When $i = k$ and $r = \ell$ we use the shorthand $M(\mathcal{N})$ for $M_k^\ell(\mathcal{N})$.

In our second combinatorial claim we show that for an appropriate choice of a matrix $\mathcal{N}$, whose entries are a subset of all values in $\left\{ N_i^j(T,w) \right\}_{i \in [k]}^{j \in [n]}$, we can bound the difference between $M(\mathcal{N})$ and $R(T,w)$. We later use sampling to obtain an estimated version of $\mathcal{N}$.

▷ Claim 6. Let $J = \{j_0, j_1, \ldots, j_\ell\}$ be a set of indices satisfying $j_0 = 0 < j_1 < j_2 < \cdots < j_\ell = n$. Let $\mathcal{N} = \mathcal{N}(J,T,w)$ be the matrix whose entries are $\mathcal{N}_i^r = N_i^{j_r}(T,w)$, for every $i \in [k]$ and $r \in [\ell]$. Then we have

$$|M(\mathcal{N}) - R(T,w)| \leq (k-1) \cdot \max_{\tau \in [\ell]} \{ j_\tau - j_{\tau-1} \} .$$

Proof. Recall that $M(\mathcal{N}) = M_k^\ell(\mathcal{N})$ and $R(T,w) = R_k^{j_\ell}(T,w)$. We shall prove that for every $i \in [k]$ and for every $r \in [\ell]$, $\left| M_i^r(\mathcal{N}) - R_i^{j_r}(T,w) \right| \leq (i-1) \cdot \max_{\tau \in [r]} \{ j_\tau - j_{\tau-1} \}$. We prove this by induction on i.
For $i = 1$ and every $r \in [\ell]$,

$$\left| M_1^r(\mathcal{N}) - R_1^{j_r}(T,w) \right| = \left| N_1^{j_r}(T,w) - N_1^{j_r}(T,w) \right| = 0 \leq (1-1) \cdot \max_{\tau \in [1]} \{ j_\tau - j_{\tau-1} \} , \quad (4)$$

where the first equality follows from the setting of $\mathcal{N}$ and the definitions of $M_1^r(\mathcal{N})$ and $R_1^{j_r}(T,w)$.
For the induction step, we assume the claim holds for $i - 1 \geq 1$ (and every $r \in [\ell]$) and prove it for i. We have,

$$\begin{aligned}
& M_i^r(\mathcal{N}) - R_i^{j_r}(T,w) \\
&= N_i^{j_r}(T,w) - \max_{b \in [r]} \left\{ N_i^{j_b}(T,w) - M_{i-1}^b(\mathcal{N}) \right\} - R_i^{j_r}(T,w) && (5) \\
&= \max_{j \in [j_r]} \left\{ N_i^j(T,w) - R_{i-1}^{j-1}(T,w) \right\} - \max_{b \in [r]} \left\{ N_i^{j_b}(T,w) - M_{i-1}^b(\mathcal{N}) \right\} , && (6)
\end{aligned}$$

where Equation (5) follows from the setting of $\mathcal{N}$ and the definition of $M_i^r(\mathcal{N})$, and Equation (6) is implied by Claim 4. Denote by j^* an index $j \in [j_r]$ that maximizes the first max term and let b^* be the largest index such that $j_{b^*} \leq j^*$. We have:

$$\begin{aligned}
& \max_{j \in [j_r]} \left\{ N_i^j(T,w) - R_{i-1}^{j-1}(T,w) \right\} - \max_{b \in [r]} \left\{ N_i^{j_b}(T,w) - M_{i-1}^b(\mathcal{N}) \right\} \\
&\leq N_i^{j^*}(T,w) - R_{i-1}^{j^*-1}(T,w) - N_i^{j_{b^*}}(T,w) + M_{i-1}^{b^*}(\mathcal{N}) \\
&= N_i^{j^*}(T,w) + R_{i-1}^{j_{b^*}}(T,w) - R_{i-1}^{j_{b^*}}(T,w) - R_{i-1}^{j^*-1}(T,w) - N_i^{j_{b^*}}(T.w) + M_{i-1}^{b^*}(\mathcal{N}) \\
&\leq \left(M_{i-1}^{b^*}(\mathcal{N}) - R_{i-1}^{j_{b^*}}(T,w) \right) + \left(N_i^{j^*}(T,w) - N_i^{j_{b^*}}(T,w) \right) + \left(R_{i-1}^{j_{b^*}}(T,w) - R_{i-1}^{j^*-1}(T,w) \right) \\
&\leq (i-2) \max_{\tau \in [r]} \{ j_\tau - j_{\tau-1} \} + \left(j^* - j^{b^*} \right) + \left(j^{b^*} - (j^* - 1) \right) && (7) \\
&= (i-2) \max_{\tau \in [r]} \{ j_\tau - j_{\tau-1} \} + 1 \\
&\leq (i-2) \max_{\tau \in [r]} \{ j_\tau - j_{\tau-1} \} + \max_{\tau \in [r]} \{ j_\tau - j_{\tau-1} \} \\
&= (i-1) \max_{\tau \in [r]} \{ j_\tau - j_{\tau-1} \} , && (8)
\end{aligned}$$

where in Equation (7) we used the induction hypothesis. By combining Equations (6) and (8), we get that

$$M_i^r(\mathcal{N}) - R_i^{j_r}(T,w) \leq (i-1)\max_{\tau\in[r]}\{j_\tau - j_{\tau-1}\} \ . \tag{9}$$

Similarly to Equation (6),

$$R_i^{j_r}(T,w) - M_i^r(\mathcal{N}) = \max_{b\in[r]}\left\{N_i^{j_b}(T,w) - M_{i-1}^b(\mathcal{N})\right\} - \max_{j\in[j_r]}\left\{N_i^j(T,w) - R_{i-1}^{j-1}(T,w)\right\} \ . \tag{10}$$

Let b^{**} be the index $b\in[r]$ that maximizes the first max term. We have

$$\begin{aligned}
&\max_{b\in[r]}\left\{N_i^{j_b}(T,w) - M_{i-1}^b(\mathcal{N})\right\} - \max_{j\in[j_r]}\left\{N_i^j(T,w) - R_{i-1}^{j-1}(T,w)\right\} \\
&\quad\leq\ N_i^{j_{b^{**}}}(T,w) - M_{i-1}^{b^{**}}(\mathcal{N}) - N_i^{j_{b^{**}}}(T,w) + R_{i-1}^{j_{b^{**}}-1}(T,w) \\
&\quad\leq\ R_{i-1}^{j_{b^{**}}}(T,w) - M_{i-1}^{b^{**}}(\mathcal{N}) \ \leq\ \left|R_{i-1}^{j_{b^{**}}}(T,w) - M_{i-1}^{b^{**}}(\mathcal{N})\right| \\
&\quad\leq\ (i-2)\max_{\tau\in[r]}\{j_\tau - j_{\tau-1}\} \ \leq\ (i-1)\max_{\tau\in[r]}\{j_\tau - j_{\tau-1}\} \ .
\end{aligned} \tag{11}$$

Hence (combining Equations (10) and (11)),[7]

$$R_i^{j_r}(T,w) - M_i^r(\mathcal{N}) \leq (i-1)\max_{\tau\in[r]}\{j_\tau - j_{\tau-1}\} \ . \tag{12}$$

Together, Equations (9) and (12) give us that

$$\left|M_i^r(\mathcal{N}) - R_i^{j_r}(T,w)\right| \leq (i-1)\max_{\tau\in[r]}\{j_\tau - j_{\tau-1}\} \ , \tag{13}$$

and the proof is completed. ◁

In our next claim we bound the difference between $M(\widehat{\mathcal{N}}) - M(\widetilde{\mathcal{N}})$ for any two matrices (with dimensions $k\times\ell$), given a bound on the L_∞ distance between them. We later apply this claim with $\widetilde{\mathcal{N}} = \mathcal{N}$ for $\mathcal{N}$ as defined in Claim 6, and $\widehat{\mathcal{N}}$ being a matrix that contains estimates $\widehat{N}_i^r$ of $N_i^{j_r}(T,w)$ (respectively). We discuss how to obtain $\widehat{\mathcal{N}}$ in Claim 8.

▷ Claim 7. Let $\gamma\in(0,1)$, and let $\widehat{\mathcal{N}}$ and $\widetilde{\mathcal{N}}$ be two $k\times\ell$ matrices. If for every $i\in[t]$ and $r\in[\ell]$, $\left|\widehat{\mathcal{N}}_i^r - \widetilde{\mathcal{N}}_i^r\right| \leq \gamma n$, then $\left|M(\widehat{\mathcal{N}}) - M(\widetilde{\mathcal{N}})\right| \leq (2k-1)\gamma n$.

Proof. We shall prove that for every $t\in[k]$ and for every $r\in[\ell]$, $\left|M_t^r(\widehat{\mathcal{N}}) - M_t^r(\widetilde{\mathcal{N}})\right| \leq (2t-1)\gamma n$. We prove this by induction on t.
For $t=1$ and every $r\in[\ell]$, we have

$$\left|M_1^r(\widehat{\mathcal{N}}) - M_1^r(\widetilde{\mathcal{N}})\right| \ = \ \left|\widehat{\mathcal{N}}_1^r - \widetilde{\mathcal{N}}_1^r\right| \ \leq \ \gamma n \ . \tag{14}$$

Now assume the claim is true for $t-1\geq 1$ and for every $r\in[\ell]$, and we prove it for t. For any $r\in[\ell]$, by the definition of $M_t^r(\cdot)$,

$$\begin{aligned}
&\left|M_t^r(\widehat{\mathcal{N}}) - M_t^r(\widetilde{\mathcal{N}})\right| \\
&\quad=\ \left|\widehat{\mathcal{N}}_t^r - \max_{r''\in[r]}\left\{\widehat{\mathcal{N}}_t^{r''} - M_{t-1}^{r''}(\widehat{\mathcal{N}})\right\} - \widetilde{\mathcal{N}}_t^r + \max_{r'\in[r]}\left\{\widetilde{\mathcal{N}}_t^{r'} - M_{t-1}^{r'}(\widetilde{\mathcal{N}})\right\}\right| \\
&\quad\leq\ \gamma n + \left|\max_{r'\in[r]}\left\{\widetilde{\mathcal{N}}_t^{r'} - M_{t-1}^{r'}(\widetilde{\mathcal{N}})\right\} - \max_{r''\in[r]}\left\{\widehat{\mathcal{N}}_t^{r''} - M_{t-1}^{r''}(\widehat{\mathcal{N}})\right\}\right| \ ,
\end{aligned} \tag{15}$$

[7] It actually holds that $M_i^r(\mathcal{N}) \geq R_i^{j_r}(T,w)$, so that $R_i^{j_r}(T,w) - M_i^r(\mathcal{N}) \leq 0$, but for the sake of simplicity of the inductive argument, we prove the same upper bound on $R_i^{j_r}(T,w) - M_i^r(\mathcal{N})$ as on $M_i^r(\mathcal{N}) - R_i^{j_r}(T,w)$.

where in the last inequality we used the premise of the claim. Assume that the first max term in Equation (15) is at least as large as the second (the case that the second term is larger than the first is dealt with analogously), and let r^* be the index that maximizes the first max term. Then,

$$\begin{aligned}
&\left|\max_{r'\in[r]}\left\{\widetilde{\mathcal{N}}_t^{r'} - M_{t-1}^{r'}(\widetilde{\mathcal{N}})\right\} - \max_{r''\in[r]}\left\{\widehat{\mathcal{N}}_t^{r''} - M_{t-1}^{r''}(\widehat{\mathcal{N}})\right\}\right| \\
&\quad\leq \left|\left(\widetilde{\mathcal{N}}_t^{r^*} - \widehat{\mathcal{N}}_t^{r^*}\right) + \left(M_{t-1}^{r^*}(\widehat{\mathcal{N}}) - M_{t-1}^{r^*}(\widetilde{\mathcal{N}})\right)\right| \\
&\quad\leq \left|\widetilde{\mathcal{N}}_t^{r^*} - \widehat{\mathcal{N}}_t^{r^*}\right| + \left|M_{t-1}^{r^*}(\widehat{\mathcal{N}}) - M_{t-1}^{r^*}(\widetilde{\mathcal{N}})\right| \\
&\quad\leq \gamma n + (2t-3)\gamma n = (2t-2)\gamma n\ , \qquad (16)
\end{aligned}$$

where we used the premise of the claim once again, and the induction hypothesis. The claim follows by combining Equation (15) with Equation (16). ◁

The next claim states that we can obtain good estimates for all values in $\left\{N_i^{j_r}(T,w)\right\}_{i\in[k]}^{r\in[\ell]}$ (with a sufficiently large sample). Its (standard) proof is deferred to the full version of this paper [14].

▷ Claim 8. For any $\gamma \in (0,1)$ and $J = \{j_1, \ldots, j_\ell\}$ (such that $1 \leq j_1 < \cdots < j_\ell = n$), by taking a sample of size $\Theta\left(\frac{\log(k\cdot\ell)}{\gamma^2}\cdot\right)$ from T, we can obtain with probability at least $2/3$ estimates $\left\{\widehat{\mathcal{N}}_i^r\right\}_{i\in[k]}^{r\in[\ell]}$, such that

$$\left|\widehat{\mathcal{N}}_i^r - N_i^{j_r}(T,w)\right| \leq \gamma n\ , \qquad (17)$$

for every $i \in [k]$ and $r \in [\ell]$.

We can now restate and prove our main theorem for distance approximation under the uniform distribution.

▶ **Theorem 1**. *There exists a sample-based distance-approximation algorithm for subsequence-freeness under the uniform distribution, that takes a sample of size* $\Theta\left(\frac{k^2}{\delta^2}\cdot\log\left(\frac{k}{\delta}\right)\right)$ *and outputs an estimate* $\widehat{\Delta}$ *such that* $|\widehat{\Delta} - \Delta(T,w)| \leq \delta$ *with probability at least* $2/3$.[8]

While our focus is on the sample complexity of the algorithm, we note that its running time is linear in the size of the sample.

Proof. The algorithm sets $\gamma = \delta/(3k)$ and $J = \{\gamma n, 2\gamma n, \ldots, n\}$. It first applies Claim 8 with the above setting of γ to obtain the estimates $\left\{\widehat{\mathcal{N}}_i^r\right\}$ for every $i \in [k]$ and $r \in [\ell]$, which with probability at least $2/3$ are as stated in Equation (17). If we take $\widetilde{\mathcal{N}} = \mathcal{N}$ for $\mathcal{N}$ as defined in Claim 6, then the premise of Claim 7 holds. We can hence apply Claim 7, and combining with Claim 6 and the definition of J, we get that with probability at least $2/3$, for the matrix $\widehat{\mathcal{N}}$,

$$\left|M(\widehat{\mathcal{N}}) - R(T,w)\right| \leq (2k-1)\gamma n + (k-1)\gamma n = (3k-2)\gamma n \leq \delta n\ . \qquad (18)$$

The algorithm hence computes $M(\widehat{\mathcal{N}}) = M_k^\ell(\widehat{\mathcal{N}})$ in an iterative manner, based on Definition 5, and outputs $\widehat{\Delta} = M(\widehat{\mathcal{N}})/n$. Since $R(T,w)/n = \Delta(T,w)$, the theorem follows. ◀

[8] As usual, we can increase the success probability to $1-\eta$, for any $\eta > 0$ at a multiplicative cost of $O(\log(1/\eta))$ in the sample complexity.

3 Distribution-free distance approximation

As noted in the introduction, our algorithm for approximating the distance from subsequence-freeness under a general distribution p works by reducing the problem to approximating the distance from subsequence-freeness under the uniform distribution. However, we won't be able to use the algorithm presented in Section 2 as is. There are two main obstacles, explained shortly next. In the reduction, given a word w and access to samples from a text T, distributed according to p, we define a word $\widetilde{w}$ and a text $\widetilde{T}$ such that if we can obtain a good approximation of $\Delta(\widetilde{T}, \widetilde{w})$ then we get a good approximation of $\Delta(T, w, p)$. (Recall that $\Delta(T, w, p)$ denotes the distance of T from being w-free under the distribution p.) However, first, we don't actually have direct access to uniformly distributed samples from $\widetilde{T}$, and second, we cannot work with a set J of indices that induce equally sized intervals (of a bounded size), as we did in Section 2.

We address these challenges (as well as precisely define $\widetilde{T}$ and $\widetilde{w}$) in several stages. We start, in Sections 3.1 and 3.2, by using sampling according to p, in order to construct intervals in T that have certain properties (with sufficiently high probability). The role of these intervals will become clear as we proceed. Due to space constraints, several proofs are deferred to the full version of this paper [14].

3.1 Interval construction and classification

We begin this subsection by defining intervals in $[n]$ that are determined by p (which is unknown to the algorithm). We then construct intervals by sampling from p, where the latter intervals are in a sense approximations of the former (this will be formalized subsequently). Each constructed interval will be classified as either "heavy" or "light", depending on its (approximated) weight according to p. Ideally, we would have liked all intervals to be light, but not too light, so that their number won't be too large (as was the case when we worked under the uniform distribution and simply defined intervals of equal size). However, for a general distribution p we might have single indices $j \in [n]$ for which p_j is large, and hence we also need to allow heavy intervals (each consisting of a single index). We shall make use of the following two definitions.

▶ **Definition 9.** *For any two integers $j_1 \leq j_2$, let $[j_1, j_2]$ denote the interval $\{j_1, \ldots, j_2\}$. For every $j_1, j_2 \in [n]$, define $\mathrm{wt}_p([j_1, j_2]) \stackrel{\text{def}}{=} \sum_{j=j_1}^{j_2} p_j$ to be the weight of the interval $[j_1, j_2]$ according to p. We shall use the shorthand $\mathrm{wt}_p(j)$ for $\mathrm{wt}_p([j, j])$.*

▶ **Definition 10.** *Let S be a multiset of size s, with elements from $[n]$. For every $j \in [n]$, let $N_S(j)$ be the number of elements in S that equal j. For every $j_1, j_2 \in [n]$, define $\mathrm{wt}_S([j_1, j_2]) \stackrel{\text{def}}{=} \frac{1}{s} \sum_{j=j_1}^{j_2} N_S(j)$ to be the estimated weight of the interval $[j_1, j_2]$ according to S. We shall use the shorthand $\mathrm{wt}_S(j)$ for $\mathrm{wt}_S([j, j])$.*

In the next definition, and the remainder of this section, we shall use

$$z \;=\; c_z \frac{k}{\delta}\,, \tag{19}$$

where let $c_z = 100$.

We next define the aforementioned set of intervals, based on p. Roughly speaking, we try to make the intervals as equally weighted as possible, keeping in mind that some indices might have a large weight, so we assign each to an interval of its own.

▶ **Definition 11.** *Define a sequence of indices in the following iterative manner. Let* $h_0 = 0$ *and for* $\ell = 1, 2, \ldots,$ *as long as* $h_{\ell-1} < n$*, let* h_ℓ *be defined as follows. If* $\mathrm{wt}_p(h_{\ell-1}+1) > \frac{1}{8z}$*, then* $h_\ell = h_{\ell-1}+1$*. Otherwise, let* h_ℓ *be the maximum index* $h'_\ell \in [h_{\ell-1}+1, n]$ *such that* $\mathrm{wt}_p([h_{\ell-1}+1, h'_\ell]) \leq \frac{1}{4z}$ *and for every* $h''_\ell \in [h_{\ell-1}+1, h'_\ell]$, $\mathrm{wt}_p(h''_\ell) \leq \frac{1}{8z}$*. Let* L *be such that* $h_L = n$*.*

Based on the indices $\{h_\ell\}_{\ell=0}^{L}$ *defined above, for every* $\ell \in [L]$*, let* $H_\ell = [h_{\ell-1}+1, h_\ell]$ *and let* $\mathcal{H} = \{H_\ell\}_{\ell=1}^{L}$*. We partition* $\mathcal{H}$ *into three subsets as follows. Let* $\mathcal{H}_{sin}$ *be the subset of all* $H \in \mathcal{H}$ *such that* $|H| = 1$ *and* $\mathrm{wt}_p(H) > \frac{1}{8z}$*. Let* $\mathcal{H}_{med}$ *be the set of all* $H \in \mathcal{H}$ *such that* $|H| \neq 1$ *and* $\frac{1}{8z} \leq \mathrm{wt}_p(H) \leq \frac{1}{4z}$*. Let* $\mathcal{H}_{sml}$ *be the set of all* $H \in \mathcal{H}$ *such that* $\mathrm{wt}_p(H) < \frac{1}{8z}$*.*

Observe that since $\mathrm{wt}_p(T) = 1$, then $|\mathcal{H}_{sin} \cup \mathcal{H}_{med}| \leq 8z$. In addition, since between each $H', H'' \in \mathcal{H}_{sml}$ there has to be at least one $H \in \mathcal{H}_{sin}$, then we also have $|\mathcal{H}_{sml}| \leq 8z+1$.

By its definition, $\mathcal{H}$ is determined by p. We next construct a set of intervals $\mathcal{B}$ based on sampling according to p (in a similar, but not identical, fashion to Definition 11). Consider a sample S_1 of size s_1 selected according to p (with repetitions), where s_1 will be set subsequently.

▶ **Definition 12.** *Given a sample* S_1 *(multiset of elements in* $[n]$*) of size* s_1*, determine a sequence of indices in the following iterative manner. Let* $b_0 = 0$ *and for* $u = 1, 2, \ldots,$ *as long as* $b_{u-1} < n$*, let* b_u *be defined as follows. If* $\mathrm{wt}_{S_1}(b_{u-1}+1) > 1/z$*, then* $b_u = b_{u-1}+1$*. Otherwise, let* b_u *be the maximum index* $b'_u \in [b_{u-1}+1, n]$ *such that* $\mathrm{wt}_{S_1}([b_{u-1}+1, b'_u]) \leq \frac{1}{z}$*. Let* U *be such that* $b_U = n$*.*

Based on the indices $\{b_u\}_{u=0}^{U}$ *defined above, for every* $u \in [U]$*, let* $B_u = [b_{u-1}+1, b_u]$*, and let* $\mathcal{B} = \{B_u\}_{u=1}^{U}$*. For every* $u \in [U]$*, if* $\mathrm{wt}_{S_1}(B_u) > \frac{1}{z}$*, then we say that* B_u *is* heavy*, otherwise it is* light*.*

Observe that each heavy interval consists of a single element.

In order to relate between $\mathcal{H}$ and $\mathcal{B}$, we introduce the following event, based on the sample S_1.

▶ **Definition 13.** *Denote by* E_1 *the event where*

$$\forall H \in \mathcal{H}_{sin} \cup \mathcal{H}_{med}, \;\; \frac{1}{2}\mathrm{wt}_p(H) \leq \mathrm{wt}_{S_1}(H) \leq \frac{3}{2}\mathrm{wt}_p(H) \;, \tag{20}$$

$$\forall H \in \mathcal{H}_{sml}, \;\; \mathrm{wt}_{S_1}(H) \leq \frac{1}{2z} \;. \tag{21}$$

▷ Claim 14. If the size of the sample S_1 is $s_1 = 120z\log(240z)$, then $\Pr[E_1] \geq \frac{8}{10}$, where the probability is over the choice of S_1.

▷ Claim 15. Conditioned on the event E_1, for every $u \in [U]$ such that B_u is light, $\mathrm{wt}_p(B_u) < \frac{6}{z}$.

3.2 Estimation of symbol density and weight of intervals

In this subsection we estimate the weight, according to p, of every interval $[b_u]$ for $u \in U$, as well as its symbol density, focusing on symbols that occur in w. Note that $[b_u]$ is the union of the intervals $B_1, \ldots, B_u$. We first introduce some notations.

For any word w^*, text T^*, $i \in [|w^*|]$ and $j \in [|T^*|]$, let $I_i^j(T^*, w^*) = 1$ if $T^*[j] = w_i^*$ and 0 otherwise. We next set

$$\xi_i^u = \sum_{j \in [b_u]} I_i^j(T, w) p_j \;. \tag{22}$$

Consider a sample S_2 of size s_2 selected according to p (with repetitions), where s_2 will be set subsequently. For every $u \in [U]$ and $i \in [k]$, set

$$\breve{\xi}_i^u = \frac{1}{s_2} \sum_{j \in [b_u]} I_i^j(T, w) N_{S_2}(j) \ . \tag{23}$$

▶ **Definition 16.** *The event E_2 (based on S_2) is defined as follows. For every $i \in [k]$ and $u \in [U]$,*

$$\left| \breve{\xi}_i^u - \xi_i^u \right| \leq \frac{1}{z} \ , \tag{24}$$

and for every $u \in [U]$

$$|\mathrm{wt}_{S_2}([b_u]) - \mathrm{wt}_p([b_u])| \leq \frac{1}{z} \ . \tag{25}$$

▷ Claim 17. If the size of the sample S_2 is $s_2 = z^2 \log(40kU)$, then $\Pr[E_2] \geq \frac{9}{10}$, where the probability is over the choice of S_2.

3.3 Reducing from distribution-free to uniform

In this subsection we give the aforementioned reduction from the distribution-free case to the uniform case, using the intervals and estimators that were defined in the previous subsections. We start by providing three definitions, taken from [30], which will be used in the reduction. The first two definitions are for the notion of *splitting* (variants of this notion were also used in previous works, e.g., [15]).

▶ **Definition 18.** *For a text $T = t_1 \dots t_n$, a text $\widetilde{T}$ is said to be a splitting of T if $\widetilde{T} = t_1^{\alpha_1} \dots t_n^{\alpha_n}$ for some $\alpha_1 \dots \alpha_n \in \mathbb{N}^+$. We denote by ϕ the splitting map, which maps each (index of a) symbol of $\widetilde{T}$ to its origin in T. Formally, $\phi : [|\widetilde{T}|] \to [n]$ is defined as follows. For every $\ell \in [|\widetilde{T}|] = [\sum_{i=1}^{n} \alpha_i]$, let $\phi(\ell)$ be the unique $i \in [n]$ that satisfies $\sum_{r=1}^{i-1} \alpha_r < \ell < \sum_{r=1}^{i} \alpha_r$.*

Note that by this definition, ϕ is a non-decreasing surjective map, satisfying $\widetilde{T}[\ell] = T[\phi(\ell)]$ for every $\ell \in [|\widetilde{T}|]$. For a set $S \subseteq [|\widetilde{T}|]$ we let $\phi(S) = \{\phi(\ell) : \ell \in S\}$. With a slight abuse of notation, for any $i \in [n]$ we use $\phi^{-1}(i)$ to denote the set $\left\{\ell \in [|\widetilde{T}|] : \phi(\ell) = i\right\}$, and for a set $S \subseteq [n]$ we let $\phi^{-1}(S) = \left\{\ell \in [|\widetilde{T}|] : \phi(\ell) \in S\right\}$

▶ **Definition 19.** *Given text $T = t_1 \dots t_n$ and a corresponding probability distribution $p = (p_1, \dots, p_n)$, a splitting of (T, p) is a text $\widetilde{T}$ along with a corresponding probability distribution $\hat{p} = (\hat{p}_1, \dots, \hat{p}_{|\widetilde{T}|})$, such that $\widetilde{T}$ is a splitting of T and $\sum_{\ell \in \phi^{-1}(i)} \hat{p}_\ell = p_i$ for every $i \in [n]$.*

The third definition is of a set of words, where no two consecutive symbols are the same.

▶ **Definition 20.** *Let $\mathcal{W}_c = \{w : w_{j+1} \neq w_j, \forall j \in [k-1]\}$.*

3.3.1 A basis for reducing from distribution-free to uniform

Let $\widetilde{w}$ be a word of length $\widetilde{k}$ and $\widetilde{T}$ a text of length $\widetilde{n}$. In this subsection we establish a claim, which gives sufficient conditions on a (normalized version) of an estimation matrix $\widehat{\mathcal{N}}$, under which it can be used to obtain an estimate of $\Delta(\widetilde{T}, \widetilde{w})$ with a small additive error.

We first state a claim that is similar to Claim 6, with a small, but important difference, that takes into account intervals in $\widetilde{T}$ (determined by a set of indices J) that consist of repetitions of a single symbol. Recall that $M(\cdot)$ was defined in Definition 5, and that $R(\widetilde{T}, \widetilde{w})$ denotes the number of role-disjoint copies of $\widetilde{w}$ in $\widetilde{T}$.

▷ Claim 21. Let $J = \{j_0, j_1, \ldots, j_\ell\}$ be a set of indices satisfying $j_0 = 0 < j_1 < j_2 < \cdots < j_\ell = \widetilde{n}$. Let $\mathcal{N}$ be the matrix whose entries are $\mathcal{N}_i^r = N_i^{j_r}(\widetilde{T}, \widetilde{w})$ for every $i \in [\widetilde{k}]$ and $r \in [\ell]$. Let $J' = \{r \in [\ell] : \widetilde{T}[j_{r-1}+1] = \cdots = \widetilde{T}[j_r]\}$. Then

$$\left|M(\mathcal{N}) - R(\widetilde{T}, \widetilde{w})\right| \leq (\widetilde{k}-1) \cdot \max_{r \in [\ell] \setminus J'} \{(j_r - j_{r-1})\} \ .$$

The following observation can be easily proved by induction.

▶ **Observation 22.** *Let $\widehat{\mathcal{N}}$ be a matrix of size $\widetilde{k} \times \ell$. Then*

$$\frac{1}{\widetilde{n}} M(\widehat{\mathcal{N}}) = M\left(\frac{\widehat{\mathcal{N}}}{\widetilde{n}}\right) \ . \tag{26}$$

The next claim will serve as the basis for our reduction from the general, distribution-free case, to the uniform case.

▷ Claim 23. Let $\widehat{\mathcal{N}}$ be a $\widetilde{k} \times \ell$ matrix, $J = \{j_0, j_1, j_2, \ldots, j_\ell\}$ be a set of indices satisfying $j_0 = 0 < j_1 < j_2 < \cdots < j_\ell = \widetilde{n}$ and let c_1 and c_2 be constants. Suppose that the following conditions are satisfied.

1. For every $r \in [\ell]$, if $j_r - j_{r-1} > c_1 \cdot \frac{\delta\widetilde{n}}{\widetilde{k}}$, then $\widetilde{T}[j_{r-1}+1] = \cdots = \widetilde{T}[j_r]$.
2. For every $i \in [\widetilde{k}]$ and $r \in [\ell]$, $\left|\widehat{\mathcal{N}}_i^r - N_i^{j_r}(\widetilde{T}, \widetilde{w})\right| \leq c_2 \cdot \frac{\delta\widetilde{n}}{\widetilde{k}}$.

Then,

$$\left|M\left(\frac{\widehat{\mathcal{N}}}{\widetilde{n}}\right) - \Delta(\widetilde{T}, \widetilde{w})\right| \leq (c_1 + 2c_2)\delta \ .$$

3.3.2 Establishing the reduction for $w \in \mathcal{W}_c$ and quantized p

For the ease of readability, in this subsection we address the special case in which $w \in \mathcal{W}_c$ (recall Definition 20), and in the full version of this paper [14] we show how to deal with the general case.

For the case considered in this subsection, let $\widetilde{T} = t_1^{\alpha_1} \ldots t_n^{\alpha_n}$ where $\alpha_j = \frac{p_j}{\beta}$ for every $j \in [n]$, so that $|\widetilde{T}| = \frac{1}{\beta}$. Define $\widetilde{p}$ by $\widetilde{p}_j = \beta$ for every $j \in [|\widetilde{T}|]$, so that $\widetilde{p}$ is the uniform distribution. Since $p_j = \beta \cdot \alpha_j$, for every $j \in [n]$, we get that $(\widetilde{T}, \widetilde{p})$ is a splitting of (T, p) (recall Definition 19), and hence by [30, Clm. 4.4] (using the assumption that $w \in \mathcal{W}_c$),

$$\Delta(\widetilde{T}, w, \widetilde{p}) = \Delta(T, w, p) \ . \tag{27}$$

Denote $\widetilde{n} = |\widetilde{T}|$. We begin by defining a set of intervals of $[\widetilde{n}]$, where $\{b_0, \ldots, b_U\}$ and $\mathcal{B} = \{B_1, \ldots, B_U\}$ are as defined in Section 3.1, and ϕ is as in Definition 19.

▶ **Definition 24.** *Let $\widetilde{b}_0 = 0$, and for every $u \in [U]$, let $\widetilde{b}_u = \max\{h \in [\widetilde{n}] : \phi(h) = b_u\}$. For every $u \in [U]$ let $\widetilde{B}_u = [\widetilde{b}_{u-1}+1, \widetilde{b}_u]$, and define $\widetilde{\mathcal{B}} = \left\{\widetilde{B}_u\right\}_{u=1}^{U}$.*

We next introduce a notation for the weights, according to $\widetilde{p}$, of unions of these intervals. For every $i \in [k]$ and $u \in [U]$,

$$\widetilde{\xi}_i^u = \sum_{j \in [\widetilde{b}_u]} I_i^j(\widetilde{T}, w)\widetilde{p}_j \ . \tag{28}$$

Note that

$$\widetilde{\xi}_i^u = \frac{1}{\widetilde{n}} N_i^{b_u}(\widetilde{T}, w) \ . \tag{29}$$

▷ Claim 25. For every $i \in [k]$ and $u \in [U]$ $\widetilde{\xi}_i^u = \xi_i^u$, where ξ_i^u is as defined in Equation (22).

We can now state and prove the following lemma.

▶ **Lemma 26.** *Let w be a word of length k in $\mathcal{W}_c$, T a text of length n, and p a distribution over $[n]$ for which there exists $\beta \in (0,1)$ such that p_j/β is an integer for every $j \in [n]$. There exists an algorithm that, given a parameter $\delta \in (0,1)$, takes a sample of size $\Theta\left(\frac{k^2}{\delta^2} \cdot \log\left(\frac{k}{\delta}\right)\right)$ from T, distributed according to p, and outputs an estimate $\widehat{\Delta}$ such that $|\widehat{\Delta} - \Delta(T,w,p)| \leq \delta$ with probability at least $2/3$.*

As in the uniform case, the running time of the algorithm is linear in the size of the sample.

Proof. The algorithm first takes a sample S_1 of size $s_1 = 120z\log(240z)$ and constructs a set of intervals $\mathcal{B}$ as defined in Definition 12. Next the algorithm takes another sample, S_2, of size $s_2 = z^2\log(40kU)$ according to which it defines an estimation matrix $\widehat{\xi}$ of size $k \times U$ as follows. For every $i \in [k]$ and $u \in [U]$, it sets $\widehat{\xi}[i][u] = \breve{\xi}_i^u$, where $\breve{\xi}_i^u$ is as defined in Equation (23). Lastly the algorithm outputs $\widehat{\Delta} = M(\widehat{\xi})$, where M is as defined in Definition 5.

We would like to apply Claim 23 in order to show that $|\widehat{\Delta} - \Delta(\widetilde{T},w)| \leq \delta$ with probability of at least $\frac{2}{3}$. By the setting of s_1, applying Claim 14 gives us that with probability at least $\frac{8}{10}$, the event E_1, as defined in Definition 13, holds. By the setting of s_2, applying Claim 17 gives us that with probability at least $\frac{9}{10}$, the event E_2, as defined in Definition 16, holds. We henceforth condition on both events (where they hold together with probability at least $7/10$).

In order to apply Claim 23, we set $\widetilde{w} = w$, $J = \left\{\widetilde{b}_0, \widetilde{b}_1, \ldots, \widetilde{b}_U\right\}$ (recall Definition 24) and $\widehat{\mathcal{N}} = \widetilde{n}\widehat{\xi}$, for $\widehat{\xi}$ as defined above. Also, we set $c_1 = \frac{1}{2}$ and $c_2 = \frac{1}{4}$. We next show that both items in the premise of the claim are satisfied.

To show that Item 1 is satisfied, we first note that since $\widetilde{p}$ is uniform, then for every $u \in U$, $\mathrm{wt}_{\widetilde{p}}(b_u) = \frac{\widetilde{b}_u - \widetilde{b}_{u-1}}{\widetilde{n}}$. We use the consequence of Claim 15 (recall that we condition on E_1) by which for every u such that $\frac{\widetilde{b}_u - \widetilde{b}_{u-1}}{\widetilde{n}} \geq \frac{6}{z}$, B_u is heavy (since for every $u \in U$, $\mathrm{wt}_{\widetilde{p}}(\widetilde{B}_u) = \mathrm{wt}_p(B_u)$). By Definition 12 this implies that B_u contains only one index, and so $\widetilde{T}[\widetilde{b}_{u-1}+1] = \cdots = \widetilde{T}[\widetilde{b}_u]$. By the definition of z (Equation (19)) and the setting of c_1, the item is satisfied.

To show that Item 2 is satisfied, we use the definition of E_2 (Definition 16, Equation (24)) together with Claim 25, which give us $|\widehat{\xi}_i^u - \widetilde{\xi}_i^u| \leq \frac{1}{z}$ for every $i \in [k]$ and $u \in [U]$. By Equation (29), the definition of z and the setting of c_2, we get that the item is satisfied.

After applying Claim 23 we get that $|\widehat{\Delta} - \Delta(\widetilde{T},w)| \leq (c_1 + 2c_2)\delta$, which by the setting of c_1 and c_2 is at most δ. Since $\widetilde{p}$ is the uniform distribution, $\Delta(\widetilde{T},w) = \Delta(\widetilde{T},w,\widetilde{p})$ and since $\Delta(\widetilde{T},w,\widetilde{p}) = \Delta(T,w,p)$ (by Equation (27)), the lemma follows. ◀

In the full version of this paper [14] we address the general case where we do not necessarily have that $w \in \mathcal{W}_c$ or that there exists a value β such that for every $j \in [n]$, p_j/β is an integer.

4 A lower bound for distance approximation

In this section we give a lower bound for the number of samples required to perform distance-approximation from w-freeness of a text T. The lower bound holds when the underlying distribution is the uniform distribution.

▶ **Theorem 27.** *Let k_d be the number of distinct symbols in w. Any distance-approximation algorithm for w-freeness under the uniform distribution must take a sample of size $\Omega(\frac{1}{k_d\delta^2})$, conditioned on $\delta \leq \frac{1}{300k_d}$ and $n > \max\left\{\frac{8k}{\delta}, \frac{200}{k_d\delta^2}\right\}$.*

Note that if $\delta \geq 1/k_d$, then the algorithm can simply output 0. This is true since the number of role disjoint copies of w in T is at most the number of occurrences of the symbol in w that is least frequent in T. This number is upper bounded by $\frac{n}{k_d}$, and so the distance from w-freeness is at most $\frac{1}{k_d}$. In this case no sampling is needed, so only the trivial lower bound holds. The proof will deal with the case of $\delta \in (0, \frac{1}{300k_d}]$.

Proof. The proof is based on the difficulty of distinguishing between an unbiased coin and a coin with a small bias. Precise details follow.

Let $V = \{v_1, \ldots, v_{k_d}\}$ be the set of distinct symbols in w, and let 0 be a symbol that does not belong to V. We define two distributions over texts, $\mathcal{T}_1$ and $\mathcal{T}_2$ as follows. For each $\tau \in [\frac{n}{k_d}]$ and $\rho \in [0,1]$, let λ_ρ^τ be a random variable that equals 0 with probability ρ and equals v_1 with probability $1-\rho$. Let $\delta' = 3k_d\delta$ and consider the following two distributions over texts

$$\mathcal{T}_1 = \left[\lambda_{\frac{1}{2}}^1, v_2, v_3, \ldots, v_{k_d}, \lambda_{\frac{1}{2}}^2, v_2, v_3, \ldots, v_{k_d}, \ldots\ldots, \lambda_{\frac{1}{2}}^{n/k_d}, v_2, v_3, \ldots, v_{k_d}\right] , \tag{30}$$

$$\mathcal{T}_2 = \left[\lambda_{\frac{1}{2}+\delta'}^1, v_2, v_3, \ldots, v_{k_d}, \lambda_{\frac{1}{2}+\delta'}^2, v_2, v_3, \ldots, v_{k_d}, \ldots\ldots, \lambda_{\frac{1}{2}+\delta'}^{n/k_d}, v_2, v_3, \ldots, v_{k_d}\right] . \tag{31}$$

Namely, the supports of both distributions contain texts that consist of n/k_d blocks of size k_d each. For $i \in \{2, \ldots, k_d\}$, the i-th symbol in each block is v_i. The distributions differ only in the way the first symbol in each block is selected. In $\mathcal{T}_1$ it is 0 with probability $1/2$ and v_1 with probability $1/2$, while in $\mathcal{T}_2$ it is 0 with probability $1/2 + \delta' = 1/2 + 3\delta k_d$, and v_1 with probability $1/2 - \delta'$.

For $b \in \{1,2\}$, consider selecting a text T_b according to $\mathcal{T}_b$ (denoted by $T_b \sim \mathcal{T}_b$), and let O_b be the number of occurrences of v_1 in the text (so that O_b is a random variable). Observe that $\mathbb{E}[O_1] = \frac{n}{2k_d}$ and $\mathbb{E}[O_2] = \frac{n}{2k_d} - 3\delta n$. By applying the additive Chernoff bound (Theorem 28) and using the premise of the theorem regarding n,

$$\Pr_{T_1\sim\mathcal{T}_1}\left[O_1 < \mathbb{E}[O_1] - \delta n/8\right] \leq \exp(-2(k_d\delta/8)^2 \cdot n/k_d) \leq \frac{1}{100} , \tag{32}$$

and

$$\Pr_{T_2\sim\mathcal{T}_2}\left[O_2 < \mathbb{E}[O_2] + \delta n/8\right] \leq \exp(-2(k_d\delta/8)^2 \cdot n/k_d) \leq \frac{1}{100} . \tag{33}$$

For $b \in \{1,2\}$ let $R_b = R(T_b, w)$ (recall that $R(T_b, w)$ denotes the number of disjoint copies of w in T_b, and note that R_b is a random variable). Observe that $R_1 \geq O_1 - k + 1$, and $R_2 \leq O_2$.

Hence, by Equation (32), if we select T_1 according to $\mathcal{T}_1$ and use the premise that $n > \frac{8k}{\delta}$, then $R(T_1, w) \geq \frac{n}{2k_d} - \frac{1}{8}\delta n - k + 1 \geq \frac{n}{2k_d} - \frac{2}{8}\delta n$ with probability at least 99/100, and by Equation (33), if we select T_2 according to $\mathcal{T}_2$, then $R(T_2, w) \leq \frac{n}{2k_d} - 3\delta n + \frac{1}{8}\delta n = \frac{n}{2k_d} - \frac{23}{8}\delta n$ with probability at least 99/100.

Assume, contrary to the claim, that we have a sample-based distance-approximation algorithm for subsequence-freeness that takes a sample of size $Q(k_d, \delta) = 1/(ck_d\delta^2)$, for some sufficiently large constant c, and outputs an estimate of the distance to w-freeness that has additive error at most δ, with probability at least 2/3. Consider running the algorithm on either $T_1 \sim \mathcal{T}_1$ or $T_2 \sim \mathcal{T}_2$. Let L denote the number of times that the sample landed on an index of the form $j = \ell \cdot k_d + 1$ for an integer ℓ. By Markov's inequality, the probability that $L > 10 \cdot Q(k_d, \delta)/k_d = 10/(ck_d^2\delta^2)$ is at most 1/10.

By the above, if we run the algorithm on $T_1 \sim \mathcal{T}_1$, then with probability at least $2/3 - 1/100 - 1/10$ the algorithm outputs an estimate $\widehat{\Delta} \geq \frac{n}{2k_d} - \frac{10}{8}$ while $L \leq 10/(ck_d^2\delta^2)$. Similarly, if we run it on $T_2 \sim \mathcal{T}_2$, then with probability at least $2/3 - 1/100 - 1/10$ the algorithm outputs an estimate $\widehat{\Delta} \leq \frac{n}{2k_d} - \frac{15}{8}$ while $L \leq 10/(ck_d^2\delta^2)$. (In both cases the probability is taken over the selection of $T_b \sim \mathcal{T}_b$, the sample that the algorithm gets, and possibly additional internal randomness of the algorithm.) Based on the definitions of $\mathcal{T}_1$ and $\mathcal{T}_2$, this implies that it is possible to distinguish between an unbiased coin and a coin with bias $3k_d\delta$ with probability at least $2/3 - 1/100 - 1/10 > \frac{8}{15}$, using a sample of size $\frac{1}{c'k_d^2\delta^2}$ in contradiction to the result of Bar-Yosef [2, Thm. 8] (applied with $m = 2$, $\epsilon = 3k_d\delta$. Since we have $\delta < \frac{1}{300k_d}$, then $\epsilon < \frac{1}{96}$, as the cited theorem requires). ◀

Abstract

Interval scheduling is a basic problem in the theory of algorithms and a classical task in combinatorial optimization. We develop a set of techniques for partitioning and grouping jobs based on their starting and ending times, that enable us to view an instance of interval scheduling on *many* jobs as a union of multiple interval scheduling instances, each containing only *a few* jobs. Instantiating these techniques in dynamic and local settings of computation leads to several new results.

For $(1+\varepsilon)$-approximation of job scheduling of n jobs on a single machine, we develop a fully dynamic algorithm with $O(^{\log n}/_{\varepsilon})$ update and $O(\log n)$ query worst-case time. Further, we design a local computation algorithm that uses only $O(^{\log N}/_{\varepsilon})$ queries when all jobs are length at least 1 and have starting/ending times within $[0, N]$. Our techniques are also applicable in a setting where jobs have rewards/weights. For this case we design a fully dynamic *deterministic* algorithm whose worst-case update and query time are $\text{poly}(\log n, \frac{1}{\varepsilon})$. Equivalently, this is *the first* algorithm that maintains a $(1+\varepsilon)$-approximation of the maximum independent set of a collection of weighted intervals in $\text{poly}(\log n, \frac{1}{\varepsilon})$ time updates/queries. This is an exponential improvement in $1/\varepsilon$ over the running time of a randomized algorithm of Henzinger, Neumann, and Wiese [SoCG, 2020], while also removing all dependence on the values of the jobs' starting/ending times and rewards, as well as removing the need for any randomness.

We also extend our approaches for interval scheduling on a single machine to examine the setting with M machines.

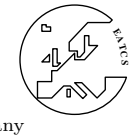
1 Introduction

Job scheduling is a fundamental task in optimization, with applications ranging from resource management in computing [21, 22] to operating transportation systems [14]. Given a collection of *machines* and a set of *jobs* (or tasks) to be processed, the goal of job scheduling is to assign those jobs to the machines while respecting certain constraints. Constraints set on



jobs may significantly vary. In some cases a job has to be scheduled, but the starting time of its processing is not pre-specified. In other scenarios a job can only be scheduled at a given time, but there is a flexibility on whether to process the job or not. Frequent objectives for this task can include either maximizing the number of scheduled jobs or minimizing needed time to process all the given jobs.

An important variant of job scheduling is the task of *interval scheduling*: here each job has a specified starting time and its length, but a job is not required to be scheduled. Given M machines, the goal is to schedule as many jobs as possible. More generally, each job is also assigned a *reward* or weight, which can be thought of as a payment received for processing the given job. If a job is not processed, the payment is zero, i.e., there is no penalty. We refer to this variant as *weighted interval scheduling*. This problem in a natural way captures real-life scenarios. For instance, consider an assignment of crew members to flights, where our goal is to assign (the minimum possible) crews to the specified flights. In the context of interval scheduling, flights can be seen as jobs and the crew members as machines [14, 17]. Interval scheduling also has applications in geometrical tasks – it can be seen as a task of finding a collection of non-overlapping geometric objects. In this context, its prominent applications are in VLSI design [13] and map labeling [1, 25].

The aforementioned scenarios are executed in different computational settings. For instance, some use-cases are dynamic in nature, e.g., a flight gets cancelled. Then, in certain cases we have to make online decisions, e.g., a customer must know immediately whether we are able to accept its request or not. While in some applications there might be so many requests that we would like to design extremely fast ways of deciding whether a given request/job can be scheduled or not, e.g., providing an immediate response to a user submitting a job for execution in a cloud. In this work, our aim is to develop methods for interval scheduling that can be turned into efficient algorithms across many computational settings:

Can we design unified techniques for approximating interval scheduling very fast?

In this paper we develop fast algorithms for the dynamic and local settings of computation. We also give a randomized black-box approach that reduces the task of interval scheduling on multiple machines to that of interval scheduling on a single machine by paying only $2 - 1/M$ in the approximation factor for unweighted jobs, where M is the number of machines, and e in approximation factor for weighted jobs. A common theme in our algorithms is partitioning jobs over dimensions (time and machines). It is well studied in the dynamic setting how to partition the time dimension to enable fast updates. It is also studied how to partition over the machines to enable strong approximation ratios for multiple-machine scheduling problems. We design new partitioning methods for the time dimension (starting and ending times of jobs), introduce a partitioning method over machines, and examine the relationship of partitioning over the time dimension and machines simultaneously in order to solve scheduling problems. We hope that, in addition to improving the best-known results, our work provides a new level of simplicity and cohesiveness for this style of approach.

1.1 Computation Models

In our work, we focus on the following two models of computation.

Dynamic setting. Our algorithms for the fully dynamic setting design data structures that maintain an approximately optimal solution to an instance of the interval scheduling problem while supporting insertions and deletions of jobs/intervals. The data structures also support queries of the maintained solution's total weight and whether or not a particular interval is used in the maintained solution.

Local computation algorithms (LCA). The LCA model was introduced by Rubinfeld et al. [20] and Alon et al. [2]. In this setting, for a given job J we would like to output whether J is scheduled or not, but we do not have a direct access to the entire list of input jobs. Rather, the LCA is given access to an oracle that returns answers to questions of the form: "*What is the input job with the earliest ending time among those jobs that start after time x?*" The goal of the LCA in this setting is to provide (yes/no) answers to user queries that ask "Is job i scheduled?" (and, if applicable, "On which machine?"), in such a manner that all answers should be consistent with the same valid solution, while using as few oracle-probes as possible.

1.2 Our Results

Our first result, given in Section 4, focuses on designing an efficient dynamic algorithm for unweighted interval scheduling on a single machine. Prior to our work, the state-of-the-art result for this unweighted interval scheduling problem was due to [4], who design an algorithm with $O(\log n/\varepsilon^2)$ update and query time. We provide an improvement in the dependence on ε.

▶ **Theorem 1** (Unweighted dynamic, single machine). *Let $\mathcal{J}$ be a set of n jobs. For any $\varepsilon > 0$, there exists a fully dynamic algorithm for $(1+\varepsilon)$-approximate unweighted interval scheduling for $\mathcal{J}$ on a single machine performing updates in $O\left(\frac{\log(n)}{\varepsilon}\right)$ and queries in $O(\log(n))$ worst-case time.*

Theorem 1 can be seen as a warm-up for our most challenging and technically involved result, which is an algorithm for the dynamic *weighted* interval scheduling problem on a single machine. We present our approach in detail in the full version. As a function of $1/\varepsilon$, our result constitutes an exponential improvement compared to the running times obtained in [12]. We also remove all use of randomness, remove all dependence on the job starting/ending times (previous work crucially used assumptions on the coordinates to bound the ratio of jobs' lengths by a parameter N), and remove all dependence on the value of the job rewards.

▶ **Theorem 2** (Weighted dynamic, single machine). *Let $\mathcal{J}$ be a set of n weighted jobs. For any $\varepsilon > 0$, there exists a fully dynamic algorithm for $(1+\varepsilon)$-approximate weighted interval scheduling for $\mathcal{J}$ on a single machine performing updates and queries in worst-case time $T \in \text{poly}(\log n, \frac{1}{\varepsilon})$. The exact complexity of T is given by*

$$O\left(\frac{\log^{12}(n)}{\varepsilon^7} + \frac{\log^{13}(n)}{\varepsilon^6}\right).$$

1.2.1 Implications in Other Settings

Local Computation Algorithms. We show that the ideas we developed to obtain Theorem 1 can also be efficiently implemented in the local setting, as we explain in detail in the full version and prove the following claim. This is the first non-trivial local computation algorithm for the interval scheduling problem.

▶ **Theorem 3** (Unweighted LCA, single machine). *Let $\mathcal{J}$ be a set of n jobs with length at least 1 and ending times upper-bounded by N. For any $\varepsilon > 0$, there exists a local computation algorithm for $(1+\varepsilon)$-approximate unweighted interval scheduling for $\mathcal{J}$ on a single machine using $O\left(\frac{\log N}{\varepsilon}\right)$ probes.*

Multiple machines. By building on techniques we introduced to prove Theorems 1 and 3, we show similar results in the full version in the case of interval scheduling on multiple machines at the expense of slower updates. To the best of our knowledge, these results initiate a study of dynamic and local interval scheduling in the general setting, i.e., in the setting of maximizing the total reward of jobs scheduled on multiple machines.

1.3 Related Work

The closest prior work to ours is that of Henzinger et al. [12] and of Bhore et al. [4]. [12] studies $(1+\varepsilon)$-approximate dynamic interval scheduling for one machine in both the weighted and unweighted setting. Unlike our main result in Theorem 2, they assume jobs have rewards within $[1, W]$, assume jobs have length at least 1, and assume all jobs start/end within times $[0, N]$. They obtain randomized algorithms with $O(\exp(1/\varepsilon)\log^2 n \cdot \log^2 N)$ update time for the unweighted and $O(\exp(1/\varepsilon)\log^2 n \cdot \log^5 N \cdot \log W)$ update time for the weighted case. They cast interval scheduling as the problem of finding a maximum independent set among a set of intervals lying on the x-axis. The authors extend this setting to multiple dimensions and design algorithms for approximating maximum independent set among a set of d-dimensional hypercubes, achieving a $(1+\varepsilon)2^d$-approximation in the unweighted and a $(4+\varepsilon)2^d$-approximation in the weighted regime.

The authors of [4] primarily focus on the unweighted case of approximating maximum independent set of a set of cubes. For the 1-dimensional case, which equals interval scheduling on one machine, they obtain $O(\log n/\varepsilon^2)$ update time, which is slower by a factor of $1/\varepsilon$ than our approach. They also show that their approach generalizes to the d-dimensional case, requiring $\operatorname{poly}\log n$ amortized update time and providing $O(4^d)$ approximation.

The problem of dynamically maintaining an exact solution to interval scheduling on one or multiple machines is studied by [11]. They attain a guarantee of $\tilde{O}(n^{1/3})$ update time for unweighted interval scheduling on $M = 1$ machine, and $\tilde{O}(n^{1-1/M})$ for $M \geq 2$. Moreover, they show an almost-linear time conditional hardness lower bound for dynamically maintaining an exact solution to the weighted interval scheduling problem on even just $M = 1$ machine. This further motivates work such as ours that dynamically maintains approximate solutions for weighted interval scheduling.

The authors of [9] consider dynamic interval scheduling on multiple machines in the setting in which all the jobs must be scheduled. The worst-case update time of their algorithm is $O(\log(n) + d)$, where d refers to the depth of what they call *idle intervals* (depth meaning the maximal number of intervals that contain a common point); they define an idle interval to be the period of time in a schedule between two consecutive jobs in a given machine. The same set of authors, in [10], study dynamic algorithms for the monotone case as well, in which no interval completely contains another one. For this setup they obtain an algorithm with $O(\log(n))$ update and query time.

In the standard model of computing (i.e. one processor, static), there exists an $O(n+m)$ running time algorithm for (exactly) solving the unweighted interval scheduling problem on a single machine with n jobs and integer coordinates bounded by m [8]. An algorithm with running time independent of m is described in [24], where it is shown how to solve this problem on M machines in $O(n\log(n))$ time. An algorithm is designed in [3] for weighted interval scheduling on M machines that runs in $O(n^2\log(n))$ time.

We refer a reader to [14] and references therein for additional applications of the interval scheduling problem.

Other related work. There has also been a significant interest in job scheduling problems in which our goal is to schedule *all* the given jobs across multiple machines, with the objective to minimize the total scheduling time. Several variants have been studied, including setups which allow preemptions, or setting where jobs have precedence constraints. We refer a reader to [15, 7, 19, 23, 5, 18, 16] and references therein for more details on these and additional variants of job scheduling. Beyond dynamic algorithms for approximating maximum independent sets of intervals or hypercubes, [6] show results for geometric objects such as disks, fat polygons, and higher-dimensional analogs. After we had published a preprint of this work, [6] proved a result that captures Theorem 1 with a more general class of fat objects.

2 Overview of Our Techniques

Our primary goal is to present unified techniques for approximating scheduling problems that can be turned into efficient algorithms for many settings. In this section, we discuss key insights of our techniques.

In the problems our work tackles, partitioning the problem instance into independent, manageable chunks is crucial. Doing so enables an LCA to determine information about a job of interest without computing an entire schedule, or enables a dynamic data structure to maintain a solution without restarting from scratch.

2.1 Unweighted Interval Scheduling – Partitioning Over Time (Section 4)

For simplicity of presentation, we begin by examining our method for partitioning over time for just the unweighted interval scheduling problem on one machine (i.e., $M = 1$). In particular, we first focus on doing so for the dynamic setting.

Recall that in this setting the primary motivation for partitioning over time, is to divide the problem into independent, manageable chunks that can be utilized by a data structure to quickly modify a solution while processing an update. In our work, we partition the time dimension by maintaining a set of *borders* that divide time into some number of contiguous regions. By doing so, we divide the problem into many *independent regions*, and we ignore jobs that intersect multiple regions; equivalently, we ignore jobs that contain a border. Our goal is then to dynamically maintain borders in a way such that we can quickly recompute the optimal solution completely within some region, and that the suboptimality introduced by these borders does not affect our solution much. In Section 4, we show that by maintaining borders where the optimal solution inside each region, i.e., a time-range between two borders, is of size $\Theta(\frac{1}{\varepsilon})$, we can maintain a $(1+\varepsilon)$-approximation of an optimal solution as long as we optimally compute the solution within each region.

Here, the underlying intuition is that because each region has a solution of size $\Omega(\frac{1}{\varepsilon})$, we can charge any suboptimality caused by a border against the selected jobs in an adjacent region. Likewise, because each region's solution has size $O(\frac{1}{\varepsilon})$, we are able to recompute the optimal solution within some region quickly using a balanced binary search tree. We dynamically maintain borders satisfying our desired properties by adding a new border when a region becomes too large, or merging with an adjacent region when a region becomes too small. As only $O(1)$ regions will require any modification when processing an update,

this method of partitioning time, while simple, enables us to improve the fastest known update/query time to $O(\log(n)/\varepsilon)$.[1] In Section 2.2 we build on these ideas to design an algorithm for the weighted interval scheduling problem.

2.2 Weighted Interval Scheduling

In our most technically involved result, we design the first deterministic $(1+\varepsilon)$ approximation algorithm for weighted interval scheduling that runs in $\text{poly}(\log n, \frac{1}{\varepsilon})$ time. In this section we give an outline of our techniques and discuss key insights. For full details we refer a reader to the full version.

2.2.1 Job data structure

Let $\mathcal{E}$ be the set of all the endpoints of given jobs, i.e., $\mathcal{E}$ contains s_i and f_i for each job $[s_i, f_i]$. We build a hierarchical data structure over $\mathcal{E}$ as follows. This structure is organized as a binary search tree T. Each node Q of T contains value $\text{KEY}(Q) \in \mathcal{E}$, with "1-1" mapping between $\mathcal{E}$ and the nodes of T. Each node Q is *responsible for a time range*. The root of T, that we denote by Q_{root}, is responsible for the entire time range $(-\infty, \infty)$. Each node Q has at most two children, that we denote by Q_L and Q_R. If Q is responsible for the time range $[X, Y]$, then Q_L is responsible for $[X, \text{KEY}(Q)]$, while Q_R is responsible for $[\text{KEY}(Q), Y]$.

Jobs are then assigned to nodes, where a job J is assigned to every node Q such that J is contained within the Q's responsible time range.

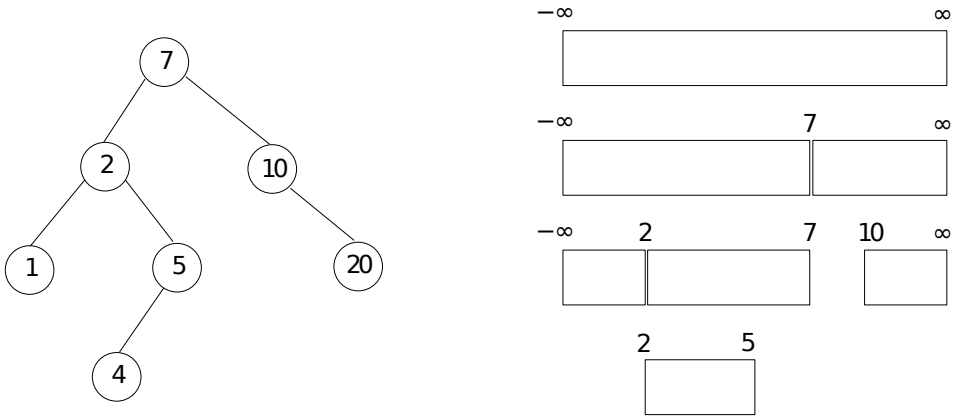


Figure 1 Visual example for hierarchical decomposition. Consider we are given jobs with the following ranges of $(1, 5), (2, 10), (7, 20), (4, 5)$. On the left is T, a balanced binary search tree over the set of all s_i and f_i. On the right is the hierarchical decomposition that corresponds to T. That is, in each row, the intervals on the right correspond to the $[l_Q, r_Q]$ for the nodes on the left. For instance, in the third row, $(-\infty, 2]$ corresponds to the node Q with $KEY(Q) = 1$.

[1] The main advantage of this techniques is that it leads to worst-case $O(\log(n)/\varepsilon)$ update time, as opposed to only an amortized one. We point out that it is not difficult to obtain such amortized guarantee in the following way: after each $\varepsilon \cdot OPT$ many updates, recompute the optimum solution from scratch. Given access to the balanced binary tree structure described above, this re-computation can be done in $O(OPT \cdot \log n)$ time.

2.2.2 Organizing computation

We now outline how the structure T is used in computation. As a reminder, our main goal is to compute a $(1+\varepsilon)$-approximate weighted interval scheduling. This task is performed by requesting Q_{root} to solve the problem for the range $(-\infty, \infty)$. However, instead of computing the answer for the entire range $(-\infty, \infty)$ directly, Q_{root} *partitions* the range $(-\infty, \infty)$ into:

- a number of ranges over which it is relatively easy to compute approximate solutions, such ones are called *sparse*, and
- the remaining ranges over which it is relatively hard to compute approximate solutions at the level of Q_{root}.

These hard-to-approximate ranges are deferred to the children of Q_{root}, and are hard to approximate because any near-optimal solution for the range contains many jobs. On the other hand, solutions in sparse ranges are of size $O(1/\varepsilon)$. As we discuss later, approximate optimal solutions within sparse ranges can be computed very efficiently; for details, see the paragraph *Approximate dynamic programming* below.

In general, a child Q_C of Q_{root} might receive *multiple* ranges from Q_{root} for which it is asked to find an approximately optimal solution. Q_C performs computation in the same manner as Q_{root} did – the cell Q_C partitions each range it receives into "easy" and "hard" to compute subranges. The first type of subranges is computed by Q_C, while the second type if deferred to the children of Q_C. The same as in Section 2.3, these "hard" ranges have large weight and allow for drawing a boundary and hence dividing a range into two or more *independent* ranges. We now discuss how the partitioning into ranges is undertaken.

2.2.3 Auxiliary data structure

To divide a range into "easy" and "hard" ranges at the level of a node Q, we design an auxiliary data structure, which relates to a rough approximation of the problem. This structure, called $Z(Q)$, maintains a set of points (we call these points *grid endpoints*) that partition Q into *slices of time*. We use slice to refer to a time range between two *consecutive* points of $Z(Q)$. Recall how for unweighted interval scheduling, we maintained a set of borders and ignored a job that crossed any border. In the weighted version, we will instead use $Z(Q)$ as a set of partitions from which we will use *some subset* to divide time. Our method of designing $Z(Q)$ reduces the task of finding a partitioning over time $Z(Q)$ within a cell for the $(1+\varepsilon)$-approximate weighted interval scheduling problem to finding multiple partitionings for the $(1+\varepsilon)$-approximate unweighted problem.

It is instructive to think of $Z(Q)$ in the following way. First, we view weighted interval scheduling as $O(\log n)$ independent instances of unweighted interval scheduling – instance i contains the jobs having weights in the interval $(w_{max}(Q)/2^{i+1}, w_{max}(Q)/2^i]$. Then, for each unweighted instance we compute borders as described in Section 2.1. $Z(Q)$ constitutes a subset of the union of those borders across all unweighted instances. We point out that the actual definition of $Z(Q)$ contains some additional points that are needed for technical reasons, but in this section we will adopt this simplified view. In particular, as we will see, $Z(Q)$ is designed such that the optimal solution within each slice has small total reward compared to the optimal solution over the entirety of Q. This enables us to partition the main problem into subproblems such that the suboptimality of discretizing the time towards slices, that we call *snapping*, is negligible.

However, a priori, it is not even clear that such structure $Z(Q)$ exists. So, one of the primary goals in our analysis is to show that there exists a near-optimal solution of a desirable structure that can be captured by $Z(Q)$. The main challenge here is to detect/localize sparse

and dense ranges efficiently and in a way that yields a fast dynamic algorithm. As an oversimplification, we define a solution as having *nearly-optimal sparse structure* if it can be generated with roughly the following process:

- Each cell Q receives a set of disjoint time ranges for which it is supposed to compute an approximately optimal solution using jobs assigned to Q or its descendants. Each received time range must have starting and ending time in $Z(Q)$.
- For each time range $\mathcal{R}$ that Q receives, the algorithm partitions $\mathcal{R}$ into disjoint time ranges of three types: sparse time ranges, time ranges to be sent to Q_L for processing, and time ranges to be sent to Q_R for processing. In particular, this means that subranges of $\mathcal{R}$ are deferred to the children of Q for processing.
- For every sparse time range, Q computes an optimal solution using at most $1/\varepsilon$ jobs.
- The union of the reward/solution of all sparse time ranges on all levels must be a $(1+\varepsilon)$-approximation of the globally optimal solution without any structural requirements.

Moreover, we develop a *charging method* that enables us to partition each cell with only $|Z(Q)| = \text{poly}(1/\varepsilon, \log(n))$ points and still have the property that it contains a $(1+\varepsilon)$-approximately optimal solution with nearly-optimal sparse structure. Then, we design an approximate dynamic programming approach to efficiently compute near-optimal solutions for sparse ranges. Combined, this enables a very efficient algorithm for weighted interval scheduling. On a high-level, $Z(Q)$ enables us to eventually decompose an entire solution into sparse regions.

2.2.4 The charging method

We now outline insights of our charging arguments that enable us to convert an optimal solution OPT into a near-optimal solution OPT' with nearly-optimal sparse structure while relaxing our partitioning to only need $|Z(Q)| = \text{poly}(1/\varepsilon, \log(N))$ points. For a visual aid, see Figure 2.

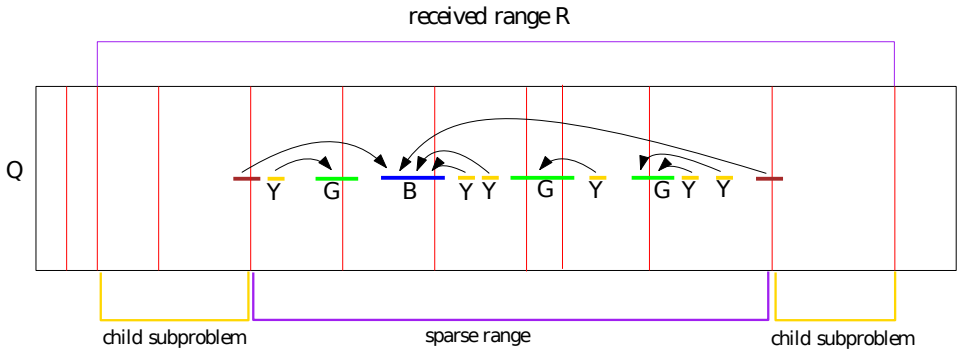

Figure 2 Visual example for charging argument.

As outlined in our overview of the nearly-optimal sparse structure, each cell Q receives a set of disjoint time ranges, with each time range having endpoints in $Z(Q)$, and must split them into three sets: sparse time ranges, time ranges for Q_L, and time ranges for Q_R. We will now modify OPT by deleting some jobs. This new solution will be denoted by OPT' and will have the following properties:

(1) OPT' exhibits nearly-optimal sparse structure; and

(2) OPT' is obtained from OPT by deleting jobs of total reward at most $O(\varepsilon \cdot w(OPT))$.

We outline an example of one such time range a cell Q may receive in Figure 2, annotated by "received range $\mathcal{R}$". We will color jobs in Figure 2 to illustrate aspects of our charging argument, but note that jobs do not actually have a color property beyond this illustration. Since our structure only allows a cell Q to use a job within its corresponding time range, any relatively valuable job that crosses between Q_L and Q_R must be used now by Q putting it in a sparse time range. One such valuable job in Figure 2 is in blue marked by "B". To have "B" belong to a sparse range, we must divide the time range $\mathcal{R}$ somewhere, as otherwise our solution in the received range will be dense. If we naively divide $\mathcal{R}$ at the partition of $Z(Q)$ to the left and right of the job "B", we might be forced to delete some valuable jobs; such jobs are pictured in green and marked by "G". Instead, we expand the division outwards in a more nuanced manner. Namely, we keep expanding outwards and looking at the job that contains the next partition point (if any). If the job's value exceeds a certain threshold, as those pictured as green and marked by "G" in Figure 2, we continue expanding. Otherwise, the job crossing a partition point is below a certain threshold, pictured as brown and not marked in Figure 2, and its deletion can be charged against the blue job. We delete such brown jobs and the corresponding partition points, i.e., the vertical red lines crossing those brown jobs, constitute the start and the end of the sparse range. By the end, we decided the starting and ending time of the sparse range, and what remains inside are blue job(s), green job(s), and yellow job(s) (also marked by "Y"). Note that yellow jobs must be completely within a partition slice of $Z(Q)$. Since we define $Z(Q)$ such that the optimal total reward within any grid slice is small, the yellow jobs have relatively small rewards compared to the total reward of green and blue jobs that we know must be large. Accordingly, we can delete the yellow jobs (to help make this time range's solution sparse) and charge their cost against a nearby green or blue job. In Figure 2, an arrow from one job to another represents a deleted job pointing towards the job who we charge its loss against. Finally, each sparse range contains only green job(s) and blue job(s). If there are more than $1/\varepsilon$ jobs in such a sparse range, we employ a simple sparsifying step detailed in the full proof.

It remains to handle the time ranges of the received range that were not put in sparse ranges. These will be time ranges that are sent to Q_L and Q_R. In Figure 2, these ranges are outlined in yellow and annotated by "child subproblem". However, the time ranges do not necessarily align with $Z(Q_L)$ or $Z(Q_R)$ as is required by nearly-optimal sparse structure. We need to adjust these ranges such that they align with $Z(Q_L)$ or $Z(Q_R)$ so we can send the ranges to the children. See Figure 3 for intuition on why we cannot just immediately "snap" these child subproblems to the partition points in $Z(Q_L)$ and $Z(Q_R)$. (We say that a range $\mathcal{R}$ is *snapped* inward (outward) within cell Q if $\mathcal{R}$ is shrunk (extended) on both sides to the closest points in $Z(Q)$. Inward snapping is illustrated in Figure 3.) Instead, we employ a similar charging argument to deal with snapping. As an analog to how we expanded outwards from the blue job for defining sparse ranges, we employ a charging argument where we contract inwards from the endpoints of the child subproblem. In summary, these charging arguments enabled us to show a solution of nearly-optimal sparse structure exists even when only partitioning each cell Q with $|Z(Q)| = \text{poly}(1/\varepsilon, \log(n))$ points.

2.2.5 Approximate dynamic programming

Now, we outline our key advance for more efficiently calculating the solution of nearly-optimal sparse structure. This structure allows us to partition time into ranges with sparse solutions. More formally, we are given a time range and we want to approximate an optimal solution within that range that uses at most $1/\varepsilon$ jobs. We outline an approximate dynamic programming approach that only requires polynomial time dependence on $1/\varepsilon$.

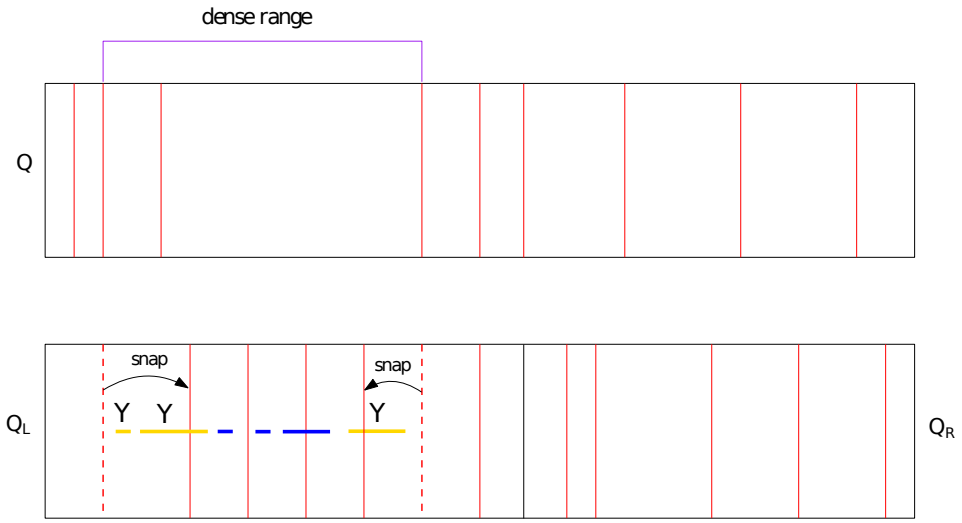

Figure 3 This example illustrates why the snapping we perform has to be done with care. The horizontal segments in this figure represent jobs. We show an initial dense range (outlined in purple) with endpoints in $Z(Q)$. With dashed vertical lines, we show where these endpoints are in Q_L. Importantly, they are not aligned with $Z(Q_L)$, i.e., the vertical dashed lines do not belong to $Z(Q_L)$. However, our structure *requires* that dense ranges align with $Z(Q_{child})$, so we must address this. If we were to naively snap the endpoints of the dense range inwards to the endpoints of $Z(Q_L)$, then we would need to delete some jobs (these deleted jobs are colored in yellow and marked by "Y"), while some other jobs would not be affected (like the remaining jobs in this example, those colored in blue). While this naive snapping may be fine in some cases, it will incur significant loss in cases in which the "Y" jobs have large weight. Notice that naively snapping outward to define a new region corresponding to the purple one is not a solution neither, as this could cause the dense time range to overlap with a previously selected sparse time range. Having overlapping ranges can cause us to choose intersecting jobs, and thus an invalid solution. Thus, we detail a more comprehensive manner of dealing with snapping.

The relatively well-known dynamic programming approach for computing weighted interval scheduling is to maintain a dynamic program where the state is a prefix range of time and the output is the maximum total reward that can be obtained in that prefix range of time. However, for our purposes, there are too many possibilities for prefix ranges of time to consider. Instead, we invert the dynamic programming approach, and have a state referencing some amount of reward, where the dynamic program returns the minimum length prefix range of time in which one can obtain a given reward. Unfortunately, there are also too many possible amounts of rewards. We observe that we do not actually need this exact state, but only an approximation. In particular, we show that one can round this state down to powers of $(1+\varepsilon^2)$ and hence significantly reduce the state-space. In the full version, we show how one can use this type of observation to quickly compute approximate dynamic programming for a near-optimal sparse solution inside any time range.

2.2.6 Comparison with Prior Work

The closest to our work is the one of [12]. In terms of improvements, we achieve the following: we remove the dependence on N and $w_{\max}$ in the running-time analysis; we obtain a deterministic approach; and, we design an algorithm with $\text{poly}(1/\varepsilon, \log n)$ update/query time, which is exponentially faster in $1/\varepsilon$ compared the prior work.

In this prior work, jobs are assumed to have length at least 1 and belong in the time-interval $[1, N]$. To remove the dependence on N and such assumptions, we designed a new way of bookkeeping jobs. Instead of using a complete binary tree on $[1, N]$ to organize jobs as done in the prior work, we employ binary balanced search tree on the endpoints of jobs. A complete binary tree on $[1, N]$ is oblivious to the density of jobs. On the other hand, and intuitively, our approach allows for "instance-based" bookkeeping: the jobs are in a natural way organized with respect to their density. Resorting to this approach incurs significant technical challenges. Namely, the structure of solution our tree maintains is hierarchically organized. However, each tree update, which requires node-rotations, breaks this structure which requires additional care in efficiently maintaining approximate solution after an update, as well as requiring an entirely different approach for maintaining a partitioning of time $Z(Q)$ within cells. Moreover, we show how to further leverage these ideas to obtain a deterministic approach.

In our work, we use borders to define the so-called sparse and dense ranges. This idea is inspired by the work of [12]. We emphasize, though, that one of our main contributions and arguably the most technically involved component is showing how to algorithmically employ those borders in running-time only polynomially dependent on $1/\varepsilon$, while [12] require exponential dependence on $1/\varepsilon$.

Our construction of auxiliary data structure $Z(Q)$ enables us to boost an $O(\log(n))$-approximate solution into a decomposition enabling a $(1+\varepsilon)$-approximate solution is inspired by the approach of [12]. They similarly develop $Z(Q)$ to boost an instead $O(1)$-approximation that fundamentally relies on the bounded coordinate assumptions of jobs being within $[1, N]$ and having length at least 1. Our different approach towards $Z(Q)$ enables simplification of some arguments as well as not relying on randomness, or on length or bounded coordinate assumptions. Further, we note that the dynamic programming approach for sparse regions that we develop is significantly faster than the enumerative approach used in the prior work, that eventually enables us to obtain a poly$(1/\varepsilon)$ dependence in the running time. The way we combine solutions over sparse regions is similar to the way it is done in the prior work.

2.3 Localizing the Time-Partitioning Method

We also show that this method of partitioning over time can be used to develop local algorithms for interval scheduling. Here, we desire to answer queries about whether a particular job is in our schedule. We hope to answer each of these queries consistently (i.e., they all agree with some approximately optimal schedule) and in less time than it would take to compute an entire schedule from scratch. Partitioning over time seems helpful for this setting, because this would enable us to focus on just the region of the job being queried. However, our previously mentioned method for maintaining borders does so in a sequential manner that we can no longer afford to do in this model of computation. Instead, we use a hierarchical approach to more easily compute the locations of borders that create regions with solutions not too big or too small.

For simplicity, we again focus on the unweighted setting with only one machine. In the standard greedy algorithm for computing unweighted interval scheduling on one machine, we repeatedly select the job *successor*(x): "*What is the interval with the earliest endpoint, of those that start after point* x*?*" (where x is the endpoint of the previously chosen job). As reading the entire problem instance would take longer than desired, an LCA requires some method of probing for information about the instance. Our LCA utilizes such successor probes to do so. For further motivation, see the full version. We outline a three-step approach towards designing an LCA that utilizes few probes:

Hierarchizing the greedy. Instead of just repeatedly using $successor(x)$ to compute the solution as the standard greedy does, we add hierarchical structure that adds no immediate value but serves as a helpful stepping stone. Consider a *binary search tree* (BST) like structure, where the root node corresponds to the entire time range $[0, N]$. Each node in the structure has a left-child and a right-child corresponding to the 1st and the 2nd half, respectively, of that node's range. Eventually, leaf nodes have no children and correspond to a time range of length one unit. At a high-level, we add hierarchical structure by considering jobs contained in some node's left-child, then considering jobs that go between the node's left-child and right-child, and then considering jobs contained in the node's right-child. This produces the same result as the standard greedy, but we do so with a hierarchical structure that will be easier to utilize.

Approximating the hierarchical greedy. Now, we modify the hierarchical greedy so that it is no longer exactly optimal but is instead an approximation. At first this will seem strictly worse, but it will yield an algorithm that is easier to localize. When processing each node, we will first check whether it is the case that both the left-child and the right-child have optimal solutions of size $> \frac{1}{\varepsilon}$. A key observation here is that checking whether a time range has an optimal solution of size $> \frac{1}{\varepsilon}$ can be done by making at most $1 + \frac{1}{\varepsilon}$ successor probes (i.e., one does not necessarily need to compute the entire optimal solution to check if it is larger than some relatively small threshold). If both the left-child and the right-child would have optimal solutions of size $> \frac{1}{\varepsilon}$, then we can afford to draw a border at the midpoint of our current node and solve the left-child and right-child independently. Jobs intersecting a border are *ignored*, and we charge the number of such ignored jobs, i.e., the number of drawn borders, to the size of solution in the corresponding left- and right-child. Ultimately, we show that the addition of these borders makes our algorithm $(1 + \varepsilon)$-approximate. Moreover, and importantly, these borders introduce *independence* between children with large solutions.

Localizing the approximate, hierarchical greedy. Finally, we localize the approximate, hierarchical greedy. To do so, we note that when some child of a node has a small optimal solution, then we can get all the information we need from that child in $O(\frac{1}{\varepsilon})$ probes. As such, if a node has a child with a small optimal solution, we can make the required probes from the small child and recurse to the large child. Otherwise, if both children have large solutions, we can draw a border at the midpoint of the current node and only need to recurse down the child which contains the job the LCA is being queried about.

With these insights, we have used our partitioning method over time for local algorithms to produce an LCA only requiring $O(\frac{\log(N)}{\varepsilon})$ successor probes.

3 Problem Setup

In the interval scheduling problem, we are given n jobs and M machines. With each job j are associated two numbers s_j and $l_j > 0$, referring to "start" and "length" respectively, meaning that the job j takes l_j time to be processed and its processing can only start at time s_j. While prior work such as [12] used assumptions such as $s_j \geq 0, l_j \geq 1$ and have an upper-bound N on $s_j + l_j$, we utilize such assumptions *only in our LCA results*. In addition, with each job j is associated weight/reward $w_j > 0$, that refers to the reward for processing the job j. The task of *interval scheduling* is to schedule jobs across machines while maximizing the total reward and respecting that each of the M machines can process at most one job at any point in time.

4 Dynamic Unweighted Interval Scheduling on a Single Machine

In this section we prove Theorem 1. As a reminder, Theorem 1 considers the case of interval scheduling in which $w_j = 1$ for each j and $M = 1$, i.e., the jobs have unit reward and there is only a single machine at our disposal. This case can also be seen as a task of finding a maximum independent set among intervals lying on the x-axis. The crux of our approach is in designing an algorithm that maintains the following invariant:

▶ **Invariant 1.** *The algorithm maintains a set of borders such that an optimal solution schedules between $1/\varepsilon$ and $2/\varepsilon$ intervals within each two consecutive borders.*

We will maintain this invariant unless the optimal solution has fewer than $1/\varepsilon$ intervals, in which case we are able to compute the solution from scratch in negligible time. We aim for our algorithm to maintain Invariant 1 while keeping track of the optimal solution between each pair of consecutive borders. The high level intuition for this is that if we do not maintain too many borders, then our solution must be very good (our solution decreases by size at most one every time we add a new border). Furthermore, if the optimal solution within borders is small, it is likely easier for us to maintain said solutions. We prove that this invariant enables a high-quality approximation:

▶ **Lemma 4.** *A solution that maintains an optimal solution within consecutive pairs of a set of borders, where the optimal solution within each pair of consecutive borders contains at least K intervals, maintains a $\frac{K+1}{K}$-approximation.*

Proof. For our analysis, suppose there are implicit borders at $-\infty$ and $+\infty$ so that all jobs are within the range of borders. Consider an optimal solution OPT. We will now design a K-approximate optimal solution OPT' as follows: given OPT, delete all intervals in OPT that overlap a drawn border. Fix an interval J appearing in OPT but not in OPT'. Assume that J intersects the i-th border. Recall that between the $(i-1)$-st and the i-th border there are at least K intervals in OPT'. Moreover, at most one interval from OPT intersects the i-th border. Hence, to show that OPT' is a $\frac{K+1}{K}$-approximation of OPT, we can charge the removal of J to the intervals appearing between the $(i-1)$-st and the i-th border in OPT'. ◀

Not only does Invariant 1 enable high-quality solutions, but it also assists us in quickly maintaining such a solution. We can maintain a data structure with $O(\frac{\log(n)}{\varepsilon})$ updates and $O(\log(n))$ queries that moves the borders to maintain the invariant and thus maintains an $(1+\varepsilon)$-approximation as implied by Lemma 4.

▶ **Theorem 1** (Unweighted dynamic, single machine)**.** *Let $\mathcal{J}$ be a set of n jobs. For any $\varepsilon > 0$, there exists a fully dynamic algorithm for $(1+\varepsilon)$-approximate unweighted interval scheduling for $\mathcal{J}$ on a single machine performing updates in $O\left(\frac{\log(n)}{\varepsilon}\right)$ and queries in $O(\log(n))$ worst-case time.*

Proof. Our goal now is to design an algorithm that maintains Invariant 1, which by Lemma 4 and for $K = 1/\varepsilon$ will result in a $(1+\varepsilon)$-approximation of Maximum-IS.

On a high-level, our algorithm will maintain a set of borders. When compiling a solution of intervals, the algorithm will not use any interval that contains any of the borders, but proceed by computing an optimal solution between each two consecutive borders. The union of those between-border solutions is the final solution. Moreover, we will maintain the invariant that the optimal solution for every contiguous region is of size within $[\frac{1}{\varepsilon}, \frac{2}{\varepsilon})$.

In the rest, we show how to implement these steps in the claimed running time.

Maintained data-structures. Our algorithm maintains a balanced binary search tree T_{all} of intervals sorted by their starting points. Each node of T_{all} will also maintain the end-point of the corresponding interval. It is well-known how to implement a balanced binary search tree with $O(\log n)$ worst-case running time per insertion, deletion and search query. Using such an implementation, the algorithm can in $O(\log n)$ time find the smallest ending-point in a prefix/suffix on the intervals sorted by their starting-points. That is, in $O(\log n)$ time we can find the interval that ends earliest, among those that start after a certain time.

In addition, the algorithm also maintains a balanced binary search tree T_{borders} of the borders currently drawn.

Also, we will maintain one more balanced binary search tree T_{sol} that will store the intervals that are in our current solution.

We will use that for any range with optimal solution of size S, we can make $O(S)$ queries to these data structures to obtain an optimal solution for the range in $O(S \cdot \log n)$ time.

Update after an insertion. Upon insertion of an interval J, we add J to T_{all}. We make a query to T_{borders} to check whether J overlaps a border. If it does, we need to do nothing; in this case, we ignore J even if it belongs to an optimal solution. If it does not, we recompute the optimal solution within the two borders adjacent to J. If after recomputing, the new solution between the two borders is too large, i.e, it has at least $\frac{2}{\varepsilon}$ intervals, then draw/add a border between the $\frac{1}{\varepsilon}$-th and the $(1+\frac{1}{\varepsilon})$-th of those intervals.

Update after a deletion. Upon deletion of an interval J, we delete J from T_{all}. If J was not in our solution, we do nothing else. Otherwise, we recompute the optimal solution within the borders adjacent to J and modify T_{sol} accordingly. Let those borders be the i-th and the $(i+1)$-st. If the new solution between borders i and $i+1$ now has size less than $1/\varepsilon$ (it would be size exactly $1/\varepsilon$), we delete an arbitrary one of the two borders (thus combining this region with an adjacent region). Then, we recompute the optimal solution within the (now larger) region J is in. If this results in a solution of size at least $2/\varepsilon$, we will need to split the newly created region by adding a border. Before splitting, the solution will have size upper-bounded by one more than the size of the solutions within the two regions before combining them as an interval may have overlapped the now deleted border (one region with size exactly $\frac{1}{\varepsilon}-1$ and the other upper-bounded by $\frac{2}{\varepsilon}-1$). Thus, the solution has size at in range $[2/\varepsilon, \frac{3}{\varepsilon})$. We can add a border between interval $1/\varepsilon$ and $1/\varepsilon+1$ of the optimal solution, and will have a region with exactly $1/\varepsilon$ intervals and another with $[1/\varepsilon, 2/\varepsilon)$ intervals, maintaining our invariant.

In all of these, the optimal solution for each region has size $O(1/\varepsilon)$, so recomputing takes $O(\log(n)/\varepsilon)$ time.

For queries, we will have maintained T_{sol} in our updates such that it contains exactly the intervals in our solution. So each query we just need to do a lookup to see if the interval is in T_{sol} in $O(\log n)$ time. ◀

This result improves the best-known time complexities [4, 12]. Unfortunately, it does not immediately generalize well to the weighted variant. In the full version, we show our more technically-challenging result for the weighted variant.

Abstract

We consider the distributed complexity of the (degree+1)-list coloring problem, in which each node u of degree $d(u)$ is assigned a palette of $d(u)+1$ colors, and the goal is to find a proper coloring using these color palettes. The (degree+1)-list coloring problem is a natural generalization of the classical $(\Delta+1)$-coloring and $(\Delta+1)$-list coloring problems, both being benchmark problems extensively studied in distributed and parallel computing.

In this paper we settle the complexity of the (degree+1)-list coloring problem in the Congested Clique model by showing that it can be solved deterministically in a constant number of rounds.

1 Introduction

Graph coloring problems are among the most extensively studied problems in the area of distributed graph algorithms. In the distributed graph coloring problem, we are given an undirected graph $G = (V, E)$ and the goal is to properly color the nodes of G such that no edge in E is monochromatic. In the distributed setting, the nodes of G correspond to devices that interact by exchanging messages throughout some underlying communication network such that the nodes communicate with each other in synchronous rounds by exchanging

messages over the edges in the network. Initially, the nodes do not know anything about G (except possibly for some global parameters, e.g., the number of nodes n or the maximum degree Δ). At the end of computation, each node $v \in V$ should output its color (from a given palette) in the computed coloring. The *time* or *round complexity* of a distributed algorithm is the total number of rounds until all nodes terminate.

If adjacent nodes in G can exchange arbitrarily large messages in each communication round (and hence the underlying communication network is equal to the input graph G), this distributed model is known as the LOCAL model [30], and if messages are restricted to $O(\log n)$ bits per edge (limited bandwidth) in each round, the model is known as the CONGEST model [38]. If we allow all-to-all communication (i.e., the underlying network is a complete graph and thus the communication is independent of the input graph G) using messages of size $O(\log n)$ bits then the model is known as the CongestedClique model [31].

The most fundamental graph coloring problem in distributed computing (studied in the seminal paper by Linial [30] that introduced the LOCAL model) is $(\Delta+1)$-*coloring*: assuming that the input graph G is of maximum degree Δ, the objective is to color nodes of G using $\Delta+1$ colors from $\{1, 2, \ldots, \Delta+1\}$. The $(\Delta+1)$-coloring problem can be easily solved by a sequential greedy algorithm, but the interaction between local and global aspects of graph coloring create some non-trivial problems in a distributed setting. The problem has been used as a benchmark to study distributed symmetry breaking in graphs, and it is at the very core of the area of distributed graph algorithms. $(\Delta+1)$-*list coloring* is a natural generalization of $(\Delta+1)$-coloring: each node has a an arbitrary palette of $\Delta+1$ colors, and the goal is to compute a legal coloring in which each node is assigned a color from its own palette. A further generalization is the *(degree+1)-list coloring (D1LC)* problem, which is the same as the $(\Delta+1)$-list coloring problem except that the size of each node v's palette is $d(v)+1$, which might be much smaller than $\Delta+1$. These three problems always have a legal coloring (easily found sequentially using a greedy approach), and the main challenge in the distributed setting is to find the required coloring in as few rounds as possible.

These three graph coloring problems have been studied extensively in distributed computing, though $(\Delta+1)$-coloring, as the simplest, has attracted most attention. However, one can also argue that (degree+1)-list coloring, as the most versatile, is more algorithmically fundamental than $(\Delta+1)$-coloring. For example, given a partial solution to a $(\Delta+1)$-coloring problem, the remaining coloring problem on the uncolored nodes is an instance of the (degree+1)-list coloring problem. The (degree+1)-list coloring problem is self-reducible: after computing a partial solution to a (degree+1)-list coloring problem, the remaining problem is still a (degree+1)-list coloring problem. It also naturally appears as a subproblem in more constrained coloring problems: for example, it has been used as a subroutine in distributed Δ-coloring algorithms (see, e.g., [19]), in efficient $(\Delta+1)$-coloring and edge-coloring algorithms (see, e.g., [28]), and in other graph coloring applications (see, e.g. [4]).

Following an increasing interest in the distributed computing community for (degree+1)-list coloring, it is natural to formulate a central challenge relating it to $(\Delta+1)$-coloring:

> *Can we solve the (degree+1)-list coloring problem in asymptotically the same round complexity as the simpler* $(\Delta+1)$*-coloring problem?*

This challenge has been elusive for many years and only in the last year the affirmative answer was given for randomized algorithms in LOCAL and CONGEST. First, in a recent breakthrough, Halldórsson, Kuhn, Nolin, and Tonoyan [24] gave a randomized $O(\log^3 \log n)$-

round distributed algorithm for (degree+1)-list coloring in the LOCAL model, matching the state-of-the-art complexity for the $(\Delta+1)$-coloring problem [10, 40]. This has been later extended to the CONGEST model by Halldórsson, Nolin, and Tonoyan [25], who designed a randomized algorithm for (degree+1)-list coloring that runs in $O(\log^5 \log n)$-round, matching the state-of-the-art complexity for the $(\Delta+1)$-coloring problem in CONGEST [23].

The main contribution of our paper is a complete resolution of this challenge in the CongestedClique model, and in fact, even for deterministic algorithms. We settle the complexity of the (degree+1)-list coloring problem in CongestedClique by showing that it can be solved deterministically in a constant number of rounds.

▶ **Theorem 1.** *There is a deterministic* CongestedClique *algorithm which finds a (degree+1)-list coloring of any graph in a constant number of rounds.*

1.1 Background and Related Works

Distributed graph coloring problems have been extensively studied in the last three decades, starting with a seminal paper by Linial [30] that introduced the LOCAL model and originated the area of local graph algorithms. Since the $(\Delta+1)$-coloring problem can be solved by a simple sequential greedy algorithm, but it is challenging to be solved efficiently in distributed (and parallel) setting, the $(\Delta+1)$-coloring problem became a benchmark problem for distributed computing and a significant amount of research has been devoted to the study of these problems in all main distributed models: LOCAL, CONGEST, and CongestedClique. The monograph [6] gives a comprehensive description of many of the earlier results.

It is long known from research on parallel algorithms that $(\Delta+1)$-coloring can be computed in $O(\log n)$ rounds by randomized algorithms in the LOCAL model [2, 32]. Linial [30] observed that for smaller values of Δ, one can do better: he showed that it is possible to deterministically color arbitrary graphs of maximum degree Δ with $O(\Delta^2)$ colors in $O(\log^* n)$ rounds; this can be easily extended to obtain a deterministic LOCAL algorithm for $(\Delta+1)$-coloring that runs in $O(\Delta^2+\log^* n)$ rounds, and thus in bounded degree graphs, a $(\Delta+1)$-coloring can be computed in $O(\log^* n)$ rounds. Improve results have since been found for general values of Δ: the current state-of-the-art for the $(\Delta+1)$-coloring problem in LOCAL is $O(\log^3 \log n)$ rounds for randomized algorithms [10, 40] and $O(\log^2 \Delta \cdot \log n)$ for deterministic algorithms [22]. Furthermore, the fastest algorithms mentioned above can be modified to work also for the more general $(\Delta+1)$-list coloring problem in the LOCAL model. (In fact, many of those algorithms critically rely on this problem as a subroutine.)

For the CONGEST model, the parallel algorithms mentioned above [2, 32] can be implemented in the CONGEST model to obtain randomized algorithms for both the $(\Delta+1)$-coloring and $(\Delta+1)$-list coloring problems that run in $O(\log n)$ rounds. Only recently this bound has been improved for all values of Δ: In a seminal paper, Halldórsson et al. [23] designed a randomized CONGEST algorithm that solves the $(\Delta+1)$-coloring and $(\Delta+1)$-list coloring problems in $O(\log^5 \log n)$ rounds. For deterministic computation, the best LOCAL algorithm [22] works directly in CONGEST, running in $O(\log^2 \Delta \cdot \log n)$ rounds.

As for the lower bounds, one of the first results in distributed computing was a lower bound in LOCAL of $\Omega(\log^* n)$ rounds for computing an $O(1)$-coloring of a graph of maximum degree $\Delta = 2$, shown by Linial [30] for deterministic algorithms, and by Naor [35] for randomized ones. Improved coloring lower bounds have not been forthcoming, and $\Omega(\log^* n)$ rounds is still the best known lower bound complexity for the $(\Delta+1)$-coloring problem in LOCAL and CONGEST.

This lower bound does not hold in the CongestedClique model, and in fact we can color faster. After years of gradual improvements, Parter [36] exploited the LOCAL shattering approach from [10] to give the first sublogarithmic-time randomized $(\Delta+1)$-coloring algorithm for CongestedClique, which runs in $O(\log\log\Delta\cdot\log^*\Delta)$ rounds. This bound was later improved by Parter and Su [37] to $O(\log^*\Delta)$ rounds. Finally, Chang et al. [9] settled the randomized complexity of $(\Delta+1)$-coloring (and also for $(\Delta+1)$-list coloring) and obtained a randomized CongestedClique algorithm that runs in a constant number of rounds. This result has been later simplified and extended into a deterministic constant-round CongestedClique algorithm by Czumaj et al. [15].

(degree+1)-list coloring (DILC). The D1LC problem in distributed setting has been studied both on its own, and also as a tool in designing distributed algorithms for other coloring problems, like $(\Delta+1)$-coloring, $(\Delta+1)$-list coloring, and Δ-coloring. The problem is more general than the $(\Delta+1)$-coloring and the $(\Delta+1)$-list coloring problems, and the difficulty of dealing with vertices having color palettes of significantly different sizes adds an additional challenge. As the result, until very recently the obtained complexity bounds have been significantly weaker than the bounds for the $(\Delta+1)$-coloring problem, see, e.g., [5, 20, 28]. This changed last year, when in a recent breakthrough Halldórsson et al. [24] gave a randomized $O(\log^3\log n)$-round distributed algorithm for D1LC in the LOCAL distributed model. Observe that this bound matches the state-of-the-art complexity for the (easier) $(\Delta+1)$-coloring problem [10]. This work has been later extended to the CONGEST model by Halldórsson et al. [25], who designed a randomized CONGEST algorithm for D1LC that runs in $O(\log^5\log n)$ rounds. Similarly as for the LOCAL model, this bound matches the state-of-the-art complexity for the $(\Delta+1)$-coloring problem in CONGEST [23].

Specifically for the CongestedClique model, the only earlier D1LC result we are aware of is by Bamberger et al. [5], who extended their own CONGEST algorithm for the problem to obtain a deterministic D1LC algorithm requiring $O(\log\Delta\log\log\Delta)$ rounds in CongestedClique. However, the randomized state-of-the-art D1LC bound in the CongestedClique model follows from the aforementioned $O(\log^5\log n)$-round CONGEST algorithm by Halldórsson et al. [25], which works directly in CongestedClique. This should be compared with the state-of-the-art $O(1)$-round CongestedClique algorithms for $(\Delta+1)$-coloring [9, 15].

Recent work in DILC on MPC. Various coloring problems have been also studied in a related model of parallel computation, the so-called *Massively Parallel Computation* (MPC) model. The MPC model, introduced by Karloff et al. [27], is now a standard theoretical model for parallel algorithms. The MPC model with $O(n)$ local space and n machines is essentially equivalent to the CongestedClique model (see, e.g., [7, 26]), and this implies that many MPC algorithms can be easily transferred to the CongestedClique model. (However, this relationship requires that the local space of MPC is $O(n)$ words, not more.)

Both the $(\Delta+1)$-coloring and $(\Delta+1)$-list coloring problems have been studied in MPC extensively (see, e.g., [5, 15] for linear local space MPC and [5, 9, 14] for sublinear local space MPC). We are aware only of a few works for the D1LC problem on MPC, see [5, 11, 24]. The work most relevant to our paper is the result of Halldórsson et al. [24]. They give a constant-round MPC algorithm assuming the local MPC space is *slightly superlinear*, i.e., $\Omega(n\log^4 n)$ [24, Corollary 2]. This result relies on the palette sparsification approach due to Alon and Assadi [1] (see also [3]) to the D1LC problem, which reduces the problem to a sparse instance of size $O(n\log^4 n)$; hence, on an MPC with $\Omega(n\log^4 n)$ local space one can put the entire graph on a single MPC machine and then solve the problem in a single

round. Given the similarity of CongestedClique and the MPC model with *linear local space*, one could hope that the use of "slightly superlinear" MPC local space in [24] can be overcome and the approach can allow the problem to be solved in linear local space, resulting in a CongestedClique algorithm with a similar performance. Unfortunately, we do not think this is the case. The palette sparsification approach of Alon and Assadi does not reduce the number of vertices in an input graph, and can only hope to reduce the maximum degree of the graph down to, at best, $\Theta(\log n)$. It has no effect on graphs that already have $\Delta = O(\log n)$, and these sparse graphs are still hard instances for D1LC, with no better known upper bound than on general graphs.

Further, we have recently seen a similar situation in $(\Delta + 1)$-coloring. The palette sparsification by Assadi et al. [3] trivially implies a constant-round MPC algorithm for $(\Delta + 1)$-coloring with local space $\Omega(n \log^2 n)$, but does not give a constant-round algorithm for $(\Delta + 1)$-coloring in CongestedClique. Only by using a fundamentally different approach were Chang et al. [9] and then (deterministically) Czumaj et al. [13] able to obtain constant-round $(\Delta+1)$-coloring algorithms in CongestedClique. Hence, despite having a constant-round algorithm for D1LC in MPC with local space $\Omega(n \log^4 n)$, possibly a different approach than palette sparsification is needed to achieve a similar performance for D1LC in CongestedClique.

Derandomization tools for distributed coloring algorithms. In our paper we rely on a recently developed general scheme for derandomization in the CongestedClique model (and used also extensively in the MPC model) by combining the methods of bounded independence with efficient computation of conditional expectations. This method was first applied by Censor-Hillel et al. [8], and has since been used in several other works for graph coloring problems, (see, e.g., [15, 36]), and for other problems in CongestedClique and MPC.

The underlying idea begins with the design of a randomized algorithm using random choices with only *limited independence*, e.g., $O(1)$-wise-independence. Then, each round of the randomized algorithm can be simulated by giving all nodes a shared random seed of $O(\log n)$ bits. Next, the nodes deterministically compute a seed which is at least as good as a random seed is in expectation. This is done by using an appropriate estimation of the local quality of a seed, which can be aggregated into a global measure of the quality of the seed. Combining this with the techniques of conditional expectation, pessimistic estimators, and bounded independence, this allows selection of the bits of the seed "batch-by-batch," where each batch consists of $O(\log n)$ bits. Once all bits of the seed are computed, we can used it to simulate the random choices of that round, as it would have been performed by a randomized algorithm. A more detailed explanation of this approach is given in Section 2.2.

1.2 Technical Overview

The core part of our constant-round deterministic CongestedClique D1LC algorithm (given as BucketColor, Algorithm 4) does *not* follow the route of recent D1LC algorithms for LOCAL and CONGEST due to Halldórsson et al. [24, 25]. Instead, it uses fundamentally different techniques, extending the approach developed recently in a simple deterministic $O(1)$-round CongestedClique algorithm for $(\Delta + 1)$-list coloring of Czumaj, Davies, and Parter [15]. Their $(\Delta + 1)$-list coloring algorithm works by partitioning nodes into Δ^{ε} *buckets*, for a small constant ε. (This partitioning is initially at random, but then it is derandomized using the method of conditional expectations). The available colors are also distributed among all buckets, except for one *"leftover" bucket*, which is left without colors and is set aside to be colored later. Then, each node's palette is restricted to only the colors assigned to its bucket (except those in the leftover bucket, whose palettes are not restricted). This ensures

that nodes in different buckets have entirely disjoint palettes, and therefore edges between different buckets can be removed from the graph, since they would never cause a coloring conflict. One important property is that nodes still have sufficient colors when their palettes are restricted in this way. This is achieved in [15] using two main arguments: firstly, the fact that colors are distributed among one fewer buckets than nodes provides enough "slack" to ensure that with reasonably high probability, a node would receive more colors than neighbors in its bucket. Secondly, the few nodes that do *not* satisfy this property induce a small graph (of size $O(n)$), and therefore can be collected onto a single network node and colored separately.

Using the approach from [15] sketched above, a $(\Delta + 1)$-list coloring instance can be reduced into multiple smaller $(\Delta + 1)$-list coloring instances (i.e., on fewer nodes and with a new, lower maximum degree) that are *independent* (since they had disjoint palettes), and so can be solved in parallel without risking coloring conflicts. The final part of the analysis of [15] was to show that, after recursively performing this bucketing process $O(1)$ times, these instances are of $O(n)$ size and therefore they could be collected to individual nodes and solved in a constant number of rounds in CongestedClique.

There are major barriers to extending this approach to (degree+1)-list coloring. Crucially, it required the number of buckets to be dependent on Δ, and all nodes' palette sizes to be at least Δ. Dividing nodes among too few buckets would cause the induced graphs to be too large, and the algorithm would not terminate in $O(1)$ rounds; using too few buckets would fail to provide nodes with sufficient colors in their bucket. In the D1LC problem, we no longer have a uniform bound on palette size, so it is unclear how to perform this bucketing.

Our first major conceptual change is that, rather than simply partitioning among a number (dependent on Δ) of equivalent buckets, we instead use a tree-structured hierarchy of buckets, with the $O(\log \log \Delta)$ levels in the hierarchy corresponding to doubly-exponentially increasing degree ranges (see Figure 1). Nodes with degree $d(v)$ will be mapped to a bucket in a level containing (very approximately) $d(v)^{0.7}$ buckets. Colors will be mapped to a top-level (leaf) bucket, but will also be assigned to every bucket on the leaf-root path in the bucket tree (see Figure 2). We can therefore discard all edges between different buckets that do not have an ancestor-descendant relationship, since these buckets will have disjoint palettes.

This change allows nodes to be bucketed correctly according to their own degree. However, it introduces several new difficulties:

- We no longer get a good bound on the number of lower-degree neighbors of a node v that may share colors with it. We can only hope to prove that v receives enough colors relative to its higher (or same)-degree neighbors.
- The technique of having a leftover bucket which is not assigned colors no longer works to provide slack (nor even makes sense - we would need a leftover bucket at every level, but, for example, level 0 only contains one bucket).

In order to cope with these challenges, firstly, we employ the observation that if we were to greedily color in non-increasing order of degree, we would require nodes to have a palette size of $d^+(v) + 1$ (where $d^+(v)$ is the number of v's neighbors of equal or higher degree), rather that $d(v) + 1$ (since $d^+(v)$ of v's neighbors will have been colored at the point v is considered). Therefore, we argue that we can still show that the graph is colorable even though our bucketing procedure may leave nodes with many more lower-degree neighbors than palette colors. (It is not necessarily clear how to find such a coloring in a parallel fashion, but in our analysis, we will be able to address this issue.)

This observation also helps us with the problem of generating slack without a leftover bucket. We show that, since lower-degree neighbors are now effectively providing slack,

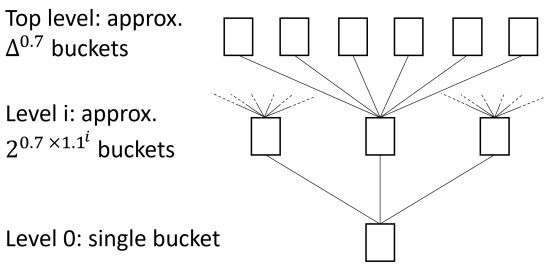

Figure 1 Bucket structure.

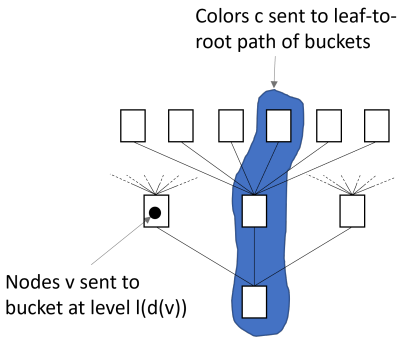

Figure 2 Partitioning nodes and colors.

only nodes with very few lower-degree neighbors may not receive enough colors (relative to higher-degree neighbors) in their bucket. It transpires that we can easily generate slack for these nodes prior to BucketColor via derandomizations of fairly standard procedures (ColorTrial, Algorithm 2, and Subsample, Algorithm 3). The randomized bases for all these procedures would inevitably result in some nodes failing to meet the necessary properties for the next stage. To overcome this, we derandomize all of these procedures, using the method of conditional expectations. As well as making the algorithm deterministic, this has the important property of ensuring that *failed* nodes form an $O(n)$-size induced graph, which can be easily dealt with later.

Having solved the problem of slack for the bucketing process (by showing that nodes have received palettes of size at least $d^+(v) + 1$ within their buckets), it remains to find a parallel analog to greedily coloring in non-increasing order of degree. Our approach here is to repeatedly move all nodes from their current bucket to a child of that bucket in the bucket tree (which further restricts their neighborhood and available palette). We show that, by correct choice of bucket and order of node consideration, we will always be able to find child buckets such that each node still has palette size at least $d^+(v) + 1$ according to the new bucket assignment. We also show that, after $O(1)$ iterations of this process, nodes only have one palette color in their bucket, and zero neighbors earlier in the coloring order. Then, all nodes can safely color themselves this palette color, and the coloring is complete.

The overall structure of the main algorithm Color (Algorithm 1) is more complicated, since Subsample produces a graph G' of leftover nodes that are deferred to be colored later. We recursively run Algorithm 1 on this graph G', and show that it is sufficiently smaller than the original input graph that after $O(1)$ recursive calls, the remaining graph has size $O(n)$ and can be collected and solved on a single node.

If we combine all these tools together then we will be able to obtain a randomized CongestedClique algorithm that finds a (degree+1)-list coloring of any graph in $O(1)$ rounds. Using the *method of conditional expectation* using *bounded-independence hash function* (see Section 2.2 and Appendix A), each randomized step of our algorithm can be derandomized.

2 Preliminaries

The main model considered in this paper is CongestedClique, as introduced by Lotker et al. [31]. It is a variant of CONGEST, in which nodes can send a message of size $O(\log n)$ to each neighboring node in the graph in each communication round: the difference is that CongestedClique allows all-to-all communication, and hence the underlying communication

network is a complete graph on the nodes V. In particular, this allows the communication to be performed between all pairs of nodes rather than being restricted to the edges of the input graph. CongestedClique has been introduced as a theoretical model to study overlay networks: an abstraction that separates the problems emerging from the topology of the communication network from the problems emerging from the structure of the problem at hand. It allows us to study a model in which each pair of nodes can communicate, and we do not consider any details of how this communication is executed by the underlying network.

The **degree+1 list coloring (D1LC) problem** is for a given graph $G = (V, E)$ on n nodes and given color palettes $\Psi(u)$ assigned to each node $u \in V$, such that $|\Psi(u)| \geq d(u)+1$, the objective to find a proper coloring of nodes in G such that each node as assigned to a color from its color palette (and, as in proper coloring, no edge in G is monochromatic). The input to the D1LC problem in CongestedClique is a graph G, where each node v of G has assigned a network node and this network node knows $\Psi(v)$ and all neighbors of v in G.

A useful property of the CongestedClique model is that thanks to the constant-round routing algorithm of Lenzen [29], information can be redistributed essentially arbitrarily in the communication network, so there is no need to associate the computational entities with nodes in the input graph G. (This is in stark contrast to the related LOCAL and CONGEST distributed models in which the link between computation and input graph locality is integral.) In particular, this allows us to collect graphs of size $O(n)$ on a single node in $O(1)$ rounds. Because of this "decoupling" of the computation from the input graph, where appropriate we will distinguish the nodes in their roles as computational entities ("network nodes") from the nodes in the input graph ("graph nodes").

2.1 Notation

For $k \in \mathbb{N}$ we let $[k] := \{1, \ldots, k\}$. We consider a graph $G = (V(G), E(G))$ with $V(G)$ as the node set and $E(G)$ as the edge set. The size of a graph G refers to the number of edges in G and is denoted by $|G|$. The set of neighbors of a node v is denoted by $N_G(v)$ and the degree of a node v is denoted by $d_G(v)$. The maximum degree of any node in G is denoted by Δ_G. For any node v, we partition its neighbors into two sets $N^+_G(v) := \{u \in N_G(v) : d_G(u) \geq d_G(v)\}$ and $N^-_G(v) := \{u \in N_G(v) : d_G(u) < d_G(v)\}$, and let $d^+_G(v) := |N^+_G(v)|$ and $d^-_G(v) := |N^-_G(v)|$. When G is clear from the context, we suppress G from the subscripts of the notation.

For the coloring problem, for a node v, $\Psi_G(v)$ denotes the list of colors in the color palette of v and $p_G(v) := |\Psi_G(v)|$. As we proceed in coloring the nodes of the input graph G the graph will be changing and the color palettes of the nodes may also change. We will ensure that at any moment, if G denotes the current graph then we have $p_G(v) \geq d_G(v) + 1$. We use $\mathcal{C}$ to denote the set of all colors present in the palette of any node (in a given moment).

For binary strings a and a' in $\{0,1\}^*$, $a \sqsubseteq a'$ denotes that a is a prefix of a', and $a \sqsubset a'$ denotes that it is a *strict* prefix of a'. Furthermore, $a' \sqsupseteq a$ iff $a \sqsubseteq a'$, and $a' \sqsupset a$ iff $a \sqsubset a'$.

Due to the space constraint, the missing proofs are deferred to the full version.

2.2 Derandomization in CongestedClique

The *method of conditional expectations* using *bounded-independence hash functions* is a nowadays classical technique for the derandomization of algorithms [17, 33, 34, 39]. Starting with the recent work of Censor-Hillel et al. [8], this approach has been found very powerful also in the setting of distributed and parallel algorithms, see e.g., [5, 12, 13, 14, 15, 16, 18, 21, 36].

This technique requires that we show that our randomized algorithm can be made to work in expectation using only bounded-independence. It is known that small families of bounded-independence hash functions exist, and that hash functions in these families can be specified by a short seed. It is also known that such a family must contain a hash function which beats the expectation due to the probabilistic method. Using these facts, we can perform an efficient search for a hash function which beats the expectation by iteratively setting a larger and larger prefix of the seed of the hash function.

We give a more detailed explanation of bounded-independence hash functions and the method of conditional expectations with its implementation in Appendix A.

3 The DILC Algorithm

The framework of our CongestedClique algorithm is Color(G, x) (Algorithm 1), which colors graph G relying on three main procedures: ColorTrial, Subsample, and BucketColor.

ColorTrial is a derandomized version of a simple and frequently used coloring procedure: all nodes nominate themselves with some constant probability, and nominated nodes then pick a color from their palette. If no neighbors choose this same color, the node is successful and takes this color permanently. For our algorithm, the goal of ColorTrial is to provide permanent slack for nodes whose neighbors mostly have higher degree than their own.

Subsample is a derandomized version of sampling: nodes v *defer* themselves to S (to be colored later) with probability $d(v)^{-0.1}$. The purpose of this is to provide temporary slack to nodes whose neighbors mostly have similar degrees to their own. We will then recursively run the whole algorithm on S, and we will show that after $O(1)$ recursive calls the remaining graph will be of size $O(n)$, which can be trivially colored in CongestedClique in $O(1)$ rounds.

BucketColor is our main coloring procedure, and is designed to color all nodes for which ColorTrial and Subsample have generated sufficient slack, as well as all nodes whose neighbors mostly have lower degree than their own.

All these three algorithms begin with a randomized procedure, and use the method of conditional expectations on a family of $O(1)$-wise independent hash functions to derandomize it. Note that *this derandomization is an essential part of the algorithm* even if one is only concerned with probabilistic success guarantees. This is because in low-degree graphs, we cannot obtain the necessary properties with high probability, and some nodes will fail. The method of conditional expectations ensures that these graphs of failed nodes are of $O(n)$ size (and hence can collected onto a single network node in $O(1)$ rounds to color sequentially).

Using ColorTrial, Subsample, and BucketColor, we can present our main algorithm Color(G, x) (Algorithm 1) to color graph G. The algorithm assumes that $\Delta_G \leq O(\sqrt{n})$ and it uses a parameter x, $0 \leq x \leq 0.9$, that quantifies the size of the remaining graph over recursive calls (the algorithm starts with $x = 0$ and recursively increases by 0.1 until $x = 1$). In Section 6 (Lemma 19), we extend the analysis to arbitrary graphs, allowing arbitrary Δ_G.

Step 1 in Color(G, x) uses the fact that if G is of size $O(n)$, then in CongestedClique, the entire graph can be collected onto a single network node in $O(1)$ rounds and the coloring can be done locally. In the same way, since L_0 consists of vertices of constant degree, we can color them in step 7 in $O(1)$ rounds. Similarly, we will argue that the graph F (of failed nodes in ColorTrial) is of size $O(n)$, and hence it can be colored in step 7 in $O(1)$ rounds. The central part of our analysis will be to show that after a constant number of recursive calls the algorithm terminates with a correct solution to D1LC of G.

To prove the correctness of our algorithm, we show the following properties of Color(G, x):

Algorithm 1 COLOR(G, x): $\Delta_G \leq O(\sqrt{n})$; $0 \leq x \leq 0.9$; C is a sufficiently large constant.

1 If $|G| = O(n)$, then collect G in a single network node and solve the problem locally.
2 Set $L_0 := \{v \in G : p_G(v) < C\}$ and $G_0 := G \setminus L_0$.
3 $G_1, F \leftarrow$ COLORTRIAL(G_0).
4 $G_2, G' \leftarrow$ SUBSAMPLE(G_1, x).
5 BUCKETCOLOR(G_2).
6 COLOR$(G', x + 0.1)$.
7 Collect and solve L_0 and then F at a single node.

1. COLORTRIAL, SUBSAMPLE, and BUCKETCOLOR run deterministically in $O(1)$ rounds.
2. The size of F is $O(n)$.
3. Each node in G_2 has sufficient slack to be colored by BUCKETCOLOR. For each node v of G_2, either $p_{G_2}(v) \geq d_{G_2}(v) + \frac{1}{4} d_{G_2}(v)^{0.9}$, or $|N^-_{G_2}(v)| \geq \frac{1}{3} d_{G_2}(v)$.
4. The size of the (remaining) graph reduces over recursive calls in the following sense:

$$\sum_{v \in G'} d_{G_1}(v)^{x+0.1} \leq Cn + 2 \sum_{v \in G_1} d_{G_1}(v)^x \ . \tag{1}$$

   Observe that when $x = 0.9$, expression (1) bounds the number of edges of G'. In particular, we show that the total size of the remaining graph is $O(n)$ after 10 recursive calls.

In Section 4, we describe the procedures COLORTRIAL and SUBSAMPLE. Also, we prove the desired properties of F, G_2, and G' in Section 4. In Section 5, we describe the procedure BUCKETCOLOR. Finally, we prove our main theorem (Theorem 1) in Section 6.

For simplicity of the presentation, in the pseudocode of our algorithms in the following sections, we will only present the randomized bases of each procedure. In each case, the full deterministic procedure comes from applying the method of conditional expectations to the randomized bases, with some specific cost function we will make clear in the analysis.

4 ColorTrial and Subsample

We describe procedure COLORTRIAL and SUBSAMPLE in Section 4.1 and Section 4.2, respectively, along with some of their crucial useful properties. In particular, we show that $|F| = O(n)$ in Lemma 9 of Section 4.1 and show that graph G' has the desired property in Lemma 11 of Section 4.2. Finally, we give a lemma capturing the desired property of graph G_2 (which is the input to BUCKETCOLOR).

4.1 ColorTrial

We first note that, because nodes with palette size less than C are removed immediately prior to COLORTRIAL(G_0) in COLOR(G, x), we may assume that all nodes v in G_0 have $p_{G_0}(v) \geq C$. The randomized procedure on which COLORTRIAL is based is Algorithm 2. COLORTRIAL has two major steps: nomination step (line 1) and coloring step (line 3). The coloring of a node can be deferred if it is a *failed* node either in nomination step and coloring step. Note that the notions of failed nodes are different in nomination step and coloring step, and we will define both the notions in the following part of this section.

We define some notions that will be useful to define failed nodes in both the nomination step and the coloring step of COLORTRIAL.

Algorithm 2 ColorTrial(G_0) – Randomized Basis.

1 Each node v in G_0 independently self-nominates with probability $\frac{1}{4}$.
2 Each node v decides if it is successful or failed in the nomination step.
3 For each self-nominated node v (that is successful in the nomination step):
- v chooses a random palette color $c(v) \in \Phi_{G_0}(v)$;
- v colors itself with color $c(v)$ if no neighbor u of v choose $c(u) = c(v)$;
- v decides if it is successful or failed in the coloring step.

Return
- G_1, the induced graph of remaining (non-failed) uncolored nodes, with updated palettes,
- F, the induced graph of failed nodes (either in nomination step or in the coloring step), with updated palettes.

▶ **Definition 2.** *$N^*(v) \subseteq N_{G_0}(v)$ is defined as the subset of neighbors u of v that have $d_{G_0}(u) \geq 3d_{G_0}(v)$. $\mathrm{Nom}_v \subseteq N_{G_0}(v)$ is defined as the subset of v's neighbors that self-nominate, and $\mathrm{Nom}_v^* := \mathrm{Nom}_v \cap N^*(v)$.*

Next, we define the notion of failed nodes in the nomination step.

▶ **Definition 3.** *A node v is* successful *during the nomination step of ColorTrial if both of the following hold (if either condition does not hold, node v* fails*):*
- $|\mathrm{Nom}_v| \leq \frac{1}{4}d_{G_0}(v) + p_{G_0}(v)^{0.7}$;
- $|\mathrm{Nom}_v^*| \geq \frac{1}{4}|N^*(v)| - p_{G_0}(v)^{0.7}$.

To derandomize ColorTrial, we replace each of the random choices of lines 1 and 3 (the nomination step and the coloring step respectively) with choices determined by a random hash function from a $O(1)$-wise independent family $[n^{O(1)}] \to [n^{O(1)}]$. We show that, under such a choice of hash function, the subgraph induced by the failed nodes in the nomination step is of size $O(n)$ in expectation (Lemma 4). We are then able to derandomize this selection using the method of conditional expectations to obtain Lemma 5.

▶ **Lemma 4.** *When nomination choices of ColorTrial are determined by a random hash function from a $O(1)$-wise independent hash family $[n^{O(1)}] \to [n^{O(1)}]$, any node v fails in the nomination step of ColorTrial with probability at most $1/p_{G_0}(v)$.*

▶ **Lemma 5.** *We can deterministically choose a hash function in $O(1)$ rounds, from a $O(1)$-wise independent family $[n^{O(1)}] \to [n^{O(1)}]$, to run the nomination step of ColorTrial such that the size of the subgraph induced by the failed nodes (in the nomination step) is $O(n)$.*

Besides the nomination step, a node can also fail in the coloring step of ColorTrial. Now we formally define what it means for a node to fail in the coloring step.

▶ **Definition 6.** *A node v is* successful *during the coloring step of ColorTrial if any of the following hold (if none hold, node v* fails*):*
- $p_{G_0}(v) \geq 1.1d_{G_0}(v)$;
- $|N^*(v)| < \frac{1}{3}d_{G_0}(v)$;
- *at least* $0.03d_{G_0}(v)$ *of v's neighbors failed in the nomination step;*
- *at least* $0.01p_{G_0}(v)$ *of v's neighbors successfully color themselves a color not in v's palette.*

Notice that the first three properties are already determined by the nomination step. Here, we need to handle the fourth property. Similar to our analysis for the nomination step, we are able to show that choosing a hash function uniformly at random from a $O(1)$-wise independent family to make decisions in the coloring step yields a subgraph of failed nodes of size $O(n)$ in expectation (Lemma 7). We can then derandomize this result using the method of conditional expectations, achieving Lemma 8.

▶ **Lemma 7.** *When color choices in the coloring step of* ColorTrial *are determined by a random hash function from a $O(1)$-wise independent hash family $[n^{O(1)}] \to [n^{O(1)}]$, any node v that did not fail in the nomination step fails in the coloring step of* ColorTrial *with probability at most $1/p_{G_0}(v)$.*

▶ **Lemma 8.** *We can deterministically choose a hash function in $O(1)$ rounds, from a $O(1)$-wise independent family $[n^{O(1)}] \to [n^{O(1)}]$, to run the coloring step of* ColorTrial *such that the size of the subgraph induced by the failed nodes (in the coloring step) is at most n.*

Note that Lemma 8 is the only lemma whose prove requires the assumption $\Delta_G = O(\sqrt{n})$.

Recall that F denotes the subgraph of G induced by the nodes that is either failed in the nomination step or in the coloring step of ColorTrial. The following lemma bounds $|F|$, and follows immediately from Lemma 5 and Lemma 8.

▶ **Lemma 9.** *We can deterministically choose hash functions in $O(1)$ rounds, from a $O(1)$-wise independent hash family $[n^{O(1)}] \to [n^{O(1)}]$, to run each step of* ColorTrial *such that the size of the subgraph induced by the failed nodes is at most $O(n)$, i.e., $|F| = O(n)$.*

4.2 Subsample

After executing ColorTrial(G_0), Color(G, x) executes procedure Subsample(G_1, x). The randomized procedure on which Subsample is based is Algorithm 3. To derandomize Subsample, we replace the random choice of line 1 (to generate a set S of vertices) with a choice determined by a hash function from a $O(1)$-wise independent family $[n^{O(1)}] \to [n^{O(1)}]$.

Algorithm 3 Subsample(G_1, x) – Randomized Basis.

1 Each node v in G_1 independently joins S with probability $d_{G_1}(v)^{-0.1}$
2 Each node v decides whether it succeeds or fails. Let F_1 be the set of failed nodes.
3 Let L denote the nodes with $p_{G_1}(v) < C$. Return:
- G_2, consisting of $G_1 \setminus (F_1 \cup S \cup L)$
- $G' = (S \cup F_1 \cup L)$

Note that while x is not used explicitly in Algorithm 3, it increases by 0.1 in each recursive call to Color, and this plays a significant role in the analysis (see Lemma 11). Our aim is to show that after 10 levels of recursion of Color$(G, 0)$, the remaining graph is of size $O(n)$.

We start by defining the notion of failed nodes in Subsample:

▶ **Definition 10.** *Let us define $N^{\approx}(v) \subseteq N_{G_1}(v)$ to be the subset of v's neighbors u with $\frac{1}{2}d_{G_1}(v) \leq d_{G_1}(u) \leq 6d_{G_1}(v)$. A node v is classed as* successful *during* Subsample *if either*
- *$p_{G_1}(v) \geq 1.1d_{G_1}(v)$; or*
- *$|N^{\approx}(v)| \leq \frac{1}{3}d_{G_1}(v)$; or*
- *at least $\frac{1}{4}p_{G_1}(v)^{0.9}$ of v's neighbors join S.*

v is classed as failed *if none of the above three conditions hold.*

In a similar way to the analysis in Section 4.1, we can express the analysis of SubSample in terms of bounded-independence hash functions and derandomize it, obtaining the following:

▶ **Lemma 11.** *Let x be such that $0 \leq x \leq 0.9$. We can deterministically choose a hash function in $O(1)$ rounds, from a $O(1)$-wise indepedenet hash family, to execute line 1 of SubSample to generate set S such that the following holds:*

$$\sum_{v \in G'} d_{G_1}(v)^{x+0.1} \leq Cn + 2 \sum_{v \in G_1} d_{G_1}(v)^x.$$

We end with a lemma which explains what properties the graph G_2 has. Recall that G_2 is the graph of successful nodes that results from running ColorTrial and SubSample on our input graph, and it is the input graph to our main coloring procedure BucketColor in Section 5. Here, we show that each node in G_2 has sufficient slack to be colored in $O(1)$ rounds by BucketColor.

▶ **Lemma 12.** *For any $v \in G_2$, either $p_{G_2}(v) \geq d_{G_2}(v) + \frac{1}{4} d_{G_2}(v)^{0.9}$, or $|N^-_{G_2}(v)| \geq \frac{1}{3} d_{G_2}(v)$.*

5 BucketColor

In this section, we describe our core coloring procedure BucketColor(G_2). Note that, each node in the input graph G_2 to BucketColor has sufficient slack as mentioned in Lemma 12. Throughout this section, the graph under consideration is always G_2, so we omit the subscript G_2 from $N_{G_2}(v), d(v), N^+_{G_2}(v), d^+_{G_2}(v), N^-_{G_2}(v), d^-_{G_2}(v), \Psi(v)$, $p(v)$ and Δ_G.

In Section 5.1, we first formalize the bucket structure of nodes (as discussed in Section 1.2), and then introduce some useful definitions. Then we describe algorithm BucketColor in Section 5.1. In Sections 5.2, we analyze the correctness of BucketColor.

5.1 Assigning nodes to buckets

We use two special functions in the description of our algorithm in this section: $l : V(G_2) \to \mathbb{N}_{\geq 0}$ and $b : \mathbb{N}_{\geq 0} \to \mathbb{N}_{\geq 0}$. l is defined as $l(v) := \max\{\lfloor \log_{1.1} \log_2 d(v) \rfloor, 0\}$ for node v, and b is defined as $b(i) := \lfloor 0.7 \cdot 1.1^i \rfloor$ for $i \in \mathbb{N}_{\geq 0}$. If $d(v)$ is at least a suitable constant, then $b(l(v)) = \Theta(\log d(v))$ and $b(l(v)) \leq 0.7 \log_2 d(v)$.

We consider a partition of the nodes of G_2 into $O(\log \log \Delta)$ levels, with the *level* of a node v equal to $l(v) = \max\{\lfloor \log_{1.1} \log_2 d(v) \rfloor, 0\}$. The nodes of a particular level will be further partitioned into buckets. The *level of a bucket x* is the level of a possible node that can be put into this bucket, and is denoted by $level(x)$. The buckets of *level i* (or *level-i* buckets) are identified by binary strings of length $b(i)$, where $i \in \mathbb{N}_{\geq 0}$, as well as their level. [1] So, there are $2^{b(i)}$ *level-i* buckets. To put a node v to a bucket, (in our algorithm) we generate a random binary string of length $b(l(v))$.

The set of buckets forms a hierarchical tree structure as described below. We say that a bucket a' is a *child* of a (and a is the *parent* of a') if $level(a') = level(a) + 1$ and $a \sqsubseteq a'$. We say that a' is a *descendant* of a (and a is an *ancestor* of a') if $level(a') \geq level(a)$ and

[1] Note that, at low levels, buckets in different levels can be identified by the same string, because the function $b(i) = \lfloor 0.7 \cdot 1.1^i \rfloor$ is not injective for $i \leq 24$. Therefore, for example, $b(0) = b(1) = 0$, and so levels 0 and 1 both in fact contain a single bucket specified by the empty string. We treat these as different buckets in order to conform to a standard rooted tree structure, and therefore must identify buckets by their level as well as their specifying string.

$a \sqsubseteq a'$ (note that by definition a is a descendant and ancestor of itself). The buckets form a rooted tree structure: the root is the single level 0 bucket, specified by the empty string; each bucket in level $i > 0$ has one parent in level $i-1$ and multiple children in level $i+1$.

We also put colors into the buckets. For any color c, we put c into a bucket of level $\lfloor \log_{1.1} \log_2 \Delta \rfloor$ by generating a random binary string of length $b(\lfloor \log_{1.1} \log_2 \Delta \rfloor + 20)$. Consider a bucket a and a color c which is put in a. We say c is assigned to bucket a' (and that bucket a' contains c) iff $a' \sqsubseteq a$. Note that a' is a leaf, since the string generated for c is of maximum length; note also that c is assigned to all buckets on the path from a to the root bucket.

Our algorithm uses a hash function to generate the binary strings (and hence the buckets) for the colors and nodes. Based on the partition of the nodes and colors into buckets, it is sufficient to color a set of reduced instances (one per bucket) of the original D1LC instance. The following definition formalizes the effective palettes and neighborhoods of a node under any function mapping nodes and colors to strings.

▶ **Definition 13.** *Let $h : (\mathcal{C} \cup V(G_2)) \to \{0,1\}^*$ be a function mapping colors and nodes to binary strings. For each node $v \in G_2$, define:*

- *the graph $G^+_{h(v)}$ to contain all edges $\{u, w\} \in G_2$ with $d(u) \leq d(w)$ for which $h(u) = h(v)$ and $h(w) \sqsupseteq h(v)$, and all nodes which are endpoints of such edges;*
- $\Psi_{h(v)}(v) = \{c \in \Psi(v) : h(c) \sqsupseteq h(v)\}$ *{$\Psi_{h(v)}(v)$ is the set of palette colors v has in $h(v)$};*
- $N^+_{h(v)}(v) := \{w \in N^+(v) : h(w) \sqsupseteq h(v)\}$ *{$d^+_{h(v)}(v)$ is the number of neighbors u that v has in descendants of $h(v)$ with $d(v) \leq d(u)$};*
- $p_{h(v)}(v) = \left|\Psi_{h(v)}(v)\right|$ *and* $d^+_{h(v)}(v) = \left|N^+_{h(v)}(v)\right|$.

Observe that there is a reduced instance for each bucket. Notice that each node u is present in only one reduced instance, i.e., in $G^+_{h(u)}$ (the reduced instance corresponding to the bucket where u is present); and each edge $\{u, w\}$ with $d_{G_2}(u) \leq d_{G_2}(w)$ is present in at most one reduced instance, i.e., possibly in $G^+_{h(u)}$ only when $h(u) \sqsubseteq h(w)$ (i.e., w is present in some descendent bucket of u). Consider a node u in the reduced instance G^+_x (i.e., $h(u) = x$). $N^+_x(u)$ and $d^+_x(u)$ denote the set of neighbors and the degree of u in G^+_x, respectively. Moreover, for coloring the reduced instance G^+_x, let $\Psi_x(u)$ and $p_x(u)$ denote the color palette and the size of the the color palette of u, respectively.

Observe that the reduced G^+_x instances are not independent, and they can be of size $\omega(n)$. Also, it may be the case that G^+_x may not be a valid D1LC instance. To handle the issue, we define the notion of *bad nodes* in Definition 14. Intuitively, bad nodes are those who do not behave as expected when mapped to their bucket (e.g. have too many neighbors or too few colors therein), and we will show that the subgraphs of buckets restricted to good nodes are of size $O(n)$ and can be colored in $O(1)$ rounds. If we choose our hash function uniformly at random from a $O(1)$-wise independent family of hash functions, the subgraph G_{bad} (induced by the bad nodes) has size $O(n)$ in expectation. We also show that it is possible to choose a of hash function deterministically in $O(1)$ rounds such that the size of G_{bad} is $O(n)$.

▶ **Definition 14.** *Given a hash function $h : (\mathcal{C} \cup V(G_2)) \to \{0,1\}^*$ mapping colors and nodes to binary strings, define a node v to be* bad *if any of the following occur:*

1. $d^+_{h(v)}(v) \geq d^+(v) 2^{-b(l(v))} + \frac{1}{8} d(v)^{0.9} 2^{-b(l(v))}$;
2. $p_{h(v)}(v) \leq p(v) 2^{-b(l(v))} - \frac{1}{8} d(v)^{0.9} 2^{-b(l(v))}$;
3. *any of v's level $l(v) + 20$ descendant buckets contain more than one of v's palette colors;*
4. *more than $2n2^{-b(l(v))}$ nodes v' have $h(v) = h(v')$.*

(1) and (2) ensure that each reduced instance (after removing the bad nodes) are valid D1LC instances; (3) ensure that the dependencies among the reduced instances are limited; and (4) when combined with (1) ensures that the subgraph induced by bad nodes is $O(n)$.

Now we are ready to discuss our algorithm BucketColor. The randomized procedure on which BucketColor is based is Algorithm 4. Note that only line 1 of Algorithm 4 is a randomized step, and it can be derandomized by replacing its random choices with choices determined by a hash function from a $O(1)$-wise independent family $[n^{O(1)}] \to [n^{O(1)}]$. The subgraph induced by the bad nodes, G_{bad}, is deferred to be colored later. Then in Lines 3 to 11, BucketColor colors the (good) nodes in $G_2 \setminus G_{bad}$ in $O(1)$ rounds deterministically.

Algorithm 4 BucketColor(G_2) – Randomized Basis.

1 Each node v uniformly randomly chooses a $b(l(v))$-bit binary string $h(v)$, and each color is uniformly randomly assigned a $b(\lfloor \log_{1.1} \log_2 \Delta \rfloor + 20)$-bit binary string $h(c)$.
2 Each node v decides whether it is bad or good. Let G_{bad} be the subgraph induced by the bad nodes.
3 **for** $O(1)$ *iterations* **do**
4 Each node $v \in G_2 \setminus G_{bad}$ restricts its palettes to colors c with $h(v) \sqsubseteq h(c)$, i.e., $\Psi_{h(v)}(v) = \{c \in \Psi(v) : h(c) \sqsupset h(v)\}$ is the current palette of v.
5 **for** *each* $i \in [\lfloor \log_{1.1} \log_2 \Delta \rfloor + 20]$ *and each string* $x \in \{0,1\}^{b(i)}$ **do**
6 collect the graph G_x^+ to a dedicated network node $node_x$.
7 **end**
8 **for** *each node* $v \in G_2 \setminus G_{bad}$ *in a bucket* $h(v)$*, in non-increasing order of degree, performed on* $node_{h(v)}$ **do**
9 $h(v) \leftarrow h^*$, where $h^* \sqsupseteq h(v)$ is a child bucket of $h(v)$ with $d^+_{h^*}(v) < p_{h^*}(v)$.
10 **end**
11 **end**
12 Color each node $v \in G_2 \setminus G_{bad}$ with the only palette color in its current bucket.
13 Update the palettes of G_{bad}, collect to a single node, and color sequentially.

Overview of coloring good nodes. To color the (good) nodes in $G_2 \setminus G_{bad}$, we proceed in non-increasing order of node degree and start with the hash function h chosen in Line 1 of BucketColor. Recall that $h(v)$ denotes the bucket in which node v is present. The algorithm goes over iterations and the bucket status of the nodes change over iterations.

In every iteration, for every node v, we restrict the color palettes of v to the colors present in the descendant bucket of (current) $h(v)$. Also, for every binary string x such that the bucket x has at least one node, we gather the graph having set of edges with one endpoint in bucket x and the other endpoint in some descendent bucket of x, i.e., G_x^+ (of size $O(n)$) at a network node in $O(1)$ rounds. Though all G_x^+'s are a valid D1LC instance in any iteration, G_x^+'s are not necessarily independent: there can be an edge between a node v in G_x^+ and a node w outside G_x^+ such that the current palettes of v intersects with the current palette of w. We can show that every node v satisfies $d^+_{h(v)}(v) < p_{h(v)}(v)$ in the first iteration – i.e., each node has enough colors in its bucket to be greedily colored in the non-increasing order of degree. That is, (in first iteration) each graph G_x^+ is a valid D1LC instance.

In each iteration, we move each node down to a child bucket h^* of its current bucket $h(v)$, in such a way that we maintain this colorability property (having more colors in the palette than the degree). This will imply that, when we find graphs G_x^+ in the next iteration, those are also valid D1LC instances. We will show that after $O(1)$ iterations, each node has

only 1 palette color in its bucket (and therefore zero higher-degree neighbors in descendant buckets, since $d^+_{h^*}(v) < p_{h^*}(v)$). At this point, nodes can safely color themselves the single palette color in their bucket. To decide on child buckets for the nodes in any iteration, it is essential that each G^+_x will always fit onto a single network node (which is in fact the case).

5.2 Correctness of BucketColor

To prove the correctness of BucketColor formally, we give Lemma 15 and Lemma 16, which jointly imply Lemma 17.

▶ **Lemma 15.** *All network nodes can simultaneously choose a hash function (in line 1 of BucketColor) such that the size of G_{bad} is $O(n)$.*

▶ **Lemma 16.** *After 20 iterations of the outer for-loop of BucketColor, all nodes in $G_2 \setminus G_{bad}$ can be colored without conflicts.*

▶ **Lemma 17.** *BucketColor successfully colors graph G_2 in $O(1)$ rounds.*

6 Proof of the main theorem

Now, we are ready to complete our analysis of a constant-round CongestedClique and prove Theorem 1. We begin with a theorem summarizing the properties of Color$(G, 0)$.

▶ **Theorem 18.** *Color$(G, 0)$ colors any* D1LC *instance G with $\Delta_G \leq O(\sqrt{n})$ in $O(1)$ rounds.*

Proof. From the description of Color$(G, 0)$ and its subroutines, it is evident that Color$(G, 0)$ colors a graph G successfully when $\Delta_G \leq O(\sqrt{n})$. It remains to analyze the total number of rounds spent by Color$(G, 0)$.

Note that the steps of Color$(G, 0)$, other than the call to subroutines ColorTrial, Subsample, BucketColor and recursive call, can be executed in $O(1)$ rounds. ColorTrial and Subsample can be executed in $O(1)$ rounds by Lemma 9 and Lemma 11, respectively. Also, $O(1)$ rounds are sufficient for BucketColor due to Lemma 17.

To analyze the round complexity of recursive calls in Color$(G, 0)$, let G^i denote the graph on which the i^{th}-level recursive call of Color, i.e., Color$(G^i, 0.1i)$ is made. Color$(G^i, 0.1i)$ does $O(1)$ rounds of operations and makes a recursive call Color$(G^{i+1}, 0.1(i+1))$.

We show by induction that $\sum_{v \in G_i} d_{G_i}(v)^{0.1i} \leq 3^i Cn$ for $i \leq 10$. This is true for $G^0 = G$, since $\sum_{v \in G} d_G(v)^0 = n$. For the inductive step, for $1 \leq i \leq 9$, by Lemma 11 using $x = 0.1i$,

$$\sum_{v \in G^{i+1}} d_{G^{i+1}}(v)^{0.1(i+1)} \leq \sum_{v \in G^{i+1}} d_{G^i}(v)^{0.1(i+1)} \leq Cn + 2\sum_{v \in G^i} d_{G^i}(v)^{0.1i} \leq Cn + 2 \cdot 3^i Cn \leq 3^{i+1} Cn \ .$$

So, $|E(G^{10})| \leq \sum_{v \in G^{10}} d_{G^{10}} \leq 3^{10} Cn = O(n)$. Therefore, after 10 recursive calls, the remaining uncolored graph can simply be collected to a single network node and solved. ◀

While Theorem 18 requires that $\Delta_G \leq O(\sqrt{n})$, we note that we can generalize this result to any maximum degree:

▶ **Lemma 19.** *In $O(1)$ rounds of* CongestedClique*, we can recursively partition an input* D1LC *instance into sub-instances, such that each sub-instance has maximum degree $O(\sqrt{n})$. The sub-instances can be grouped into $O(1)$ groups where each group can be colored in parallel.*

Proof. We use the LowSpacePartition procedure from [14], which reduces a coloring instance to $O(1)$ sequential instances of maximum degree n^ε for any constant $\varepsilon > 0$. The procedure is for $\Delta + 1$-coloring, but it extends immediately to D1LC, as discussed in Section 5 of [11]. Since we can simulate low-space MPC in CongestedClique, we can execute LowSpacePartition, setting ε appropriately to reduce the maximum degree of all instances to $O(\sqrt{n})$. By subsequent arguments in [14], $O(1)$ sequential sets of base cases are created. ◀

Now the proof of Theorem 1 follows immediately from Theorem 18 and Lemma 19. ◀

A Derandomization in CongestedClique

In this section we first give some useful lemmas regarding $O(1)$-wise independence and the existence of small families of $O(1)$-wise independent hash functions, and then we give a formal description of the method of conditional expectations and how it is implemented in the CongestedClique model.

A.1 Bounded Independence

Our algorithm will be finding a hash function of sufficient quality from a family of $O(1)$-independent hash functions. In the following, we recall the standard notions of *k-wise independent hash functions* and *k-wise independent random variables*. Then, we recall that we can construct small families of bounded-independence hash functions, and that each hash function in this family can be specified by a short seed.

▶ **Definition 20.** *Let $k \geq 2$ be an integer. A set $\{X_1, \ldots, X_n\}$ of n random variables taking values in S are said to be* k-wise independent *if for any $I \subset [n]$ with $|I| \leq k$ and any $x_i \in S$ for $i \in I$, we have*

$$\mathbf{Pr}\left[\bigwedge_{i\in[k]} X_i = x_i\right] = \prod_{i=1}^{k} \mathbf{Pr}\left[X_i = x_i\right] \quad .$$

▶ **Definition 21.** *A family of hash functions $\mathcal{H} : \{h : X \to Y\}$ is said to be k-wise independent if $\{h(x) : x \in X\}$ are k-wise independent when h is drawn uniformly at random from $\mathcal{H}$.*

We use the property that small families of $O(1)$-wise independent hash functions can be constructed, and each hash function in such a family can be specified with a small number of bits:

▶ Remark 22. For all positive integers c_1, c_2, there is a family of k-wise independent hash functions $\mathcal{H} = \{h : [n^{c_1}] \to [n^{c_2}]\}$ such that each function from $\mathcal{H}$ can be specified using $O(k \log n)$ bits.

A.2 The Method of Conditional Expectations

We now describe in more detail the method of conditional expectations and its implementation in CongestedClique. We briefly recall the setup to the problem: we have a randomized algorithm which "succeeds" if a "bad" outcome occurs for less than some number T of

nodes. This algorithm succeeds in expectation using bounded-independence randomness. We would like to derandomize this algorithm. In order to achieve this, given a family of $O(1)$-independent hash functions $\mathcal{H}$, we need to find a "good" hash function $h^* \in \mathcal{H}$ which solves our problem, when used to make decisions for nodes instead of randomness.

First, we define some cost function $f : \mathcal{H} \times V \to \{0, 1\}$ such that $f(h, v) = 1$ if the node v has a "bad" outcome when h is the selected hash function, and $f(h, v) = 0$ if the outcome is "good". We further define $F(h) = \sum_{v \in V} f(h, v)$ as the total cost of the hash function h: i.e., the number of bad nodes when h is the selected hash function. Finally, we use $\mathbb{E}_{h \in \mathcal{H}} x(h)$ to denote the expected value of some function $x(h)$ when h is drawn uniformly at random from $\mathcal{H}$.

To successfully derandomize our algorithm, we need to find a hash function $h^* \in \mathcal{H}$ such that $F(h^*) \leq T$. We need the following conditions to hold for our derandomization to work:

- $\mathbb{E}_{h \in \mathcal{H}}[F(h)] \leq T$ (i.e., the expected cost of a hash function selected uniformly at random from $\mathcal{H}$ is at most T); and
- Node v can locally (i.e., without communication) evaluate $f(h, v)$ for all $h \in \mathcal{H}$.

We can now use the method of conditional expectations to find a $h^* \in \mathcal{H}$ for which $F(h^*) \leq T$. We first recall that each hash function in our family of $O(1)$-wise independent hash functions $\mathcal{H}$ can be specified using $O(\log n)$ bits, by Remark 22. Next, let $\Pi = \{0, 1\}^{\log n}$ be the set of binary strings of length $\log n$, and for each $\pi \in \Pi$, let $\mathcal{H}_\pi$ denote the hash functions in $\mathcal{H}$ whose seeds begin with the prefix π.

Our goal is to find some seed-prefix $\pi \in \Pi$ for which $\mathbb{E}_{h \in \mathcal{H}_\pi}[F(h)] \leq T$: the existence of such a prefix is guaranteed by the probabilistic method. Since each node v can locally evaluate $f(h, v)$ for all $h \in \mathcal{H}$, nodes can also compute $\mathbb{E}_{h \in \mathcal{H}_\pi}[f(h, v)]$ for all $\pi \in \Pi$. Since $|\Pi| = n$, each node v can be made responsible for a prefix $\pi_v \in \Pi$. Node v can then collect the value of $\mathbb{E}_{h \in \mathcal{H}_{\pi_v}}[f(h, u)]$ for each $u \in V \setminus \{v\}$: since this requires all nodes sending and receiving $O(n)$ messages it can be done in $O(1)$ rounds using Lenzen's routing algorithm [29]. Now, by linearity of expectation:

$$\sum_{v \in V} \left(\mathbb{E}_{h \in \mathcal{H}_{\pi_v}} [f(h, v)] \right) = \mathbb{E}_{h \in \mathcal{H}_{\pi_v}} [F(h)] \quad .$$

Therefore v can compute the expected value of F for the sub-family of hash functions which are prefixed with π_v. Nodes can broadcast this expected value to all other nodes in $O(1)$ rounds, again using Lenzen's routing algorithm [29]. All nodes then know the expected value of F for all $(\log n)$-bit prefixes and can, without communication (breaking ties in a predetermined and arbitrary way), pick the prefix with the lowest expected value of F. Recall that this prefix is guaranteed to have an expected value of at most T by the probabilistic method.

We have now fixed the first $(\log n)$ bits of the prefix and obtained a smaller set $\mathcal{H}_1 \subset \mathcal{H}$ of hash functions. We can then perform the same procedure described above on $\mathcal{H}_1$ to set the next $(\log n)$ bits of the seed, obtaining a smaller set $\mathcal{H}_2 \subset \mathcal{H}_1 \subset \mathcal{H}$ of hash functions. After repeating this procedure $O(1)$ times we will have fixed the entire seed, since we fix $(\log n)$ bits each time and the seeds of hash functions in $\mathcal{H}$ were $O(\log n)$ bits in length.

Incremental Maximization via Continuization

Abstract

We consider the problem of finding an incremental solution to a cardinality-constrained maximization problem that not only captures the solution for a fixed cardinality, but also describes how to gradually grow the solution as the cardinality bound increases. The goal is to find an incremental solution that guarantees a good competitive ratio against the optimum solution for all cardinalities simultaneously. The central challenge is to characterize maximization problems where this is possible, and to determine the best-possible competitive ratio that can be attained. A lower bound of 2.18 and an upper bound of $\varphi + 1 \approx 2.618$ are known on the competitive ratio for monotone and accountable objectives [Bernstein et al., Math. Prog., 2022], which capture a wide range of maximization problems. We introduce a continuization technique and identify an optimal incremental algorithm that provides strong evidence that $\varphi + 1$ is the best-possible competitive ratio. Using this continuization, we obtain an improved lower bound of 2.246 by studying a particular recurrence relation whose characteristic polynomial has complex roots exactly beyond the lower bound. Based on the optimal continuous algorithm combined with a scaling approach, we also provide a 1.772-competitive randomized algorithm. We complement this by a randomized lower bound of 1.447 via Yao's principle.

1 Introduction

A classical optimization problem takes as input a single instance and outputs a single solution. While this paradigm can be appropriate in static situations, it fails to capture scenarios that are characterized by perpetual growth, such as growing infrastructure networks, expanding companies, or private households with a steady income. In these cases, a single static solution may be rendered useless unless it can be extended perpetually into larger, more expansive solutions that are adequate for the changed circumstances.

To capture scenarios like this more adequately, we adopt the *incremental optimization* framework formalized as follows. An instance of the IncMax problem is given by a countable set U of elements and a monotone objective function $f\colon 2^U \to \mathbb{R}_{\geq 0}$ that assigns each subset $X \subseteq U$ a value $f(X)$. A solution for an IncMax instance is an order $\sigma = (e_1, e_2, \dots)$ of the elements of U such that each prefix of σ yields a good solution with respect to the objective function f. Formally, for $k \in [n]$, let $\textsc{Opt}(k) = \max\{f(X) : |X| = k, X \subseteq U\}$ denote the optimal value of the problem of maximizing $f(X)$ under the cardinality-constraint $|X| = k$. A deterministic solution $\sigma = (e_1, e_2, \dots)$ is called α-competitive if $\textsc{Opt}(k)/f(\{e_1, \dots, e_k\}) \leq \alpha$ for all $k \in [n]$. A randomized solution is a probability distribution $\Sigma = (E_1, E_2, \dots)$ over deterministic solutions (where $E_1, E_2, \dots$ are random variables). It is called α-competitive if $\textsc{Opt}(k)/\mathbb{E}[f(\{E_1, \dots, E_k\})] \leq \alpha$ for all $k \in [n]$. In both cases, we call the infimum over all $\alpha \geq 1$, such that the solution is α-competitive, the *(randomized) competitive ratio* of the solution. A (randomized) algorithm is called α-competitive for some $\alpha \geq 1$ if, for every instance, it produces an α-competitive solution, and its *(randomized) competitive ratio* is the infimum over all such α. The *(randomized) competitive ratio* of a class of problems (or a problem instance) is the infimum over the competitive ratios of all (randomized) algorithms for it.

Clearly, in this general form, no meaningful results regarding the existence of competitive solutions are possible. For illustration consider the instance $U = \{a, b, c\}$ where for some $M \in \mathbb{N}$ we have

$$f(X) = \begin{cases} M, & \text{if } \{b, c\} \subseteq X, \\ |\{a\} \cap X|, & \text{otherwise} \end{cases} \qquad \text{for all } X \subseteq U.$$

Then, every solution needs to start with element a in order to be competitive for $k = 1$, but any such order cannot be better than M-competitive for $k = 2$. The underlying issue is that the optimal solution for $k = 2$ given by $\{b, c\}$ does not admit a competitive partial solution of cardinality $k = 1$. To circumvent this issue, Bernstein et al. [1] consider *accountable* functions, i.e., functions f, such that, for every $X \subseteq U$, there exists $e \in X$ with $f(X \setminus \{e\}) \geq f(X) - f(X)/|X|$. They further show that many natural incremental optimization problems are monotone and accountable such as the following.

Weighted matching: U is the set of edges of a weighted graph, and $f(X)$ is the maximum weight of a matching contained in X;

Set packing: U is a set of weighted subsets of a ground set, and $f(X)$ is the maximum weight of a set of mutually disjoint subsets of X;

Submodular function maximization: U is arbitrary, and f is monotone and submodular;

(Multi-dimensional) Knapsack: U is a set of items with (multi-dimensional) sizes and values, and $f(X)$ is the maximum value of a subset of items of X that fits into the knapsack.

Bernstein et al. [1] gave an algorithm to compute a $(1 + \varphi)$-competitive incremental solution and showed that the competitive ratio of the IncMax problem is at least 2.18. Throughout this work, we assume that the objective f is accountable.

Our results. As a first step, we reduce the general IncMax problem to the special case of IncMaxSep, where the elements of the instance can be partitioned into a (countable) set of uniform and modular subsets such that the overall objective is the maximum over the modular functions on the subsets. We then define the IncMaxCont problem as a continuization, where there exists one such subset with (fractional) elements of every size $c \in \mathbb{R}_{>0}$. The smooth structure of this problem better lends itself to analysis.

We consider the continuous algorithm GreedyScaling(c_1, ρ) that adds a sequence of these subsets, starting with the subset of size $c_1 > 0$ and proceeding along a sequence of subsets of largest possible sizes under the constraint that ρ-competitiveness is maintained for as long as possible. We first show that there always exists an optimal solution of this form.

▶ **Theorem 1.** *For every instance of* IncMaxCont*, there exists a starting value c_1 such that the algorithm* GreedyScaling(c_1, ρ^*) *achieves the best-possible competitive ratio $\rho^* \geq 1$.*

Our continuous embedding allows us to view every algorithm as an increasing sequence of sizes of subsets that are added one after the other. Using elementary calculus, we can show that, with the golden ratio $\varphi := \frac{1}{2}(1 + \sqrt{5}) \approx 1.618$, GreedyScaling$(c_1, \rho)$ achieves the known upper bound of $\varphi + 1$ for a range of starting values. Here, $d(c)$ refers to the density, i.e., value per size, of the subset of size c (see Sec. 2).

▶ **Theorem 2.** GreedyScaling$(c_1, \varphi + 1)$ *is $(\varphi + 1)$-competitive if and only if $d(c_1) \geq \frac{1}{\varphi+1}$.*

On the other hand, we are able to, for every starting value c_1, construct an instance of IncMaxCont where GreedyScaling(c_1, ρ) is not better than $(\varphi + 1)$-competitive for any $\rho > 1$. We emphasize that the optimum value of $\varphi + 1$ emerges naturally from the geometry of complex roots. Based on this evidence, we conjecture that $\varphi + 1$ is the best-possible competitive ratio.

Of course, proving a general lower bound requires to construct a single instance such that GreedyScaling is not better than $(\varphi + 1)$-competitive for *every* starting value. Careful chaining of our construction for a single starting value yields the following.

▶ **Proposition 3.** *For every countable set $S \subset \mathbb{R}_{>0}$ of starting values, there exists an instance of* IncMaxCont *such that* GreedyScaling(c_1, ρ) *is not ρ-competitive for any $c_1 \in S$ and any $\rho < \varphi + 1$.*

Crucially, while this gives a lower bound if we only allow rational starting values $c_1 \in \mathbb{Q}$, transferring the lower bound back to IncMax requires excluding all reals. Even though we are not able to achieve this, we can extrapolate our analysis in terms of complex calculus to any IncMaxCont algorithm. With this, we beat the currently best known lower bound of 2.18 in [1].

▶ **Theorem 4.** *The* IncMax *problem has a competitive ratio of at least* 2.246*.*

We can also apply our technique, specifically the reduction to separable problem instances and the structure of the GreedyScaling algorithm, to the analysis of randomized algorithms for IncMax. We employ a scaling approach based on the algorithms in [1], combined with a randomized selection of the starting value c_1 inspired by a randomized algorithm for the CowPath problem in [16]. The resulting algorithm has a randomized competitive ratio that beats our deterministic lower bound.

▶ **Theorem 5.** *IncMax admits a* 1.772*-competitive randomized algorithm.*

We complement this result with a lower bound via Yao's principle for separable instances of IncMax.

▶ **Theorem 6.** *Every randomized* IncMax *algorithm has competitive ratio at least* 1.447*.*

Related work. Our work is based on the incremental maximization framework introduced by Bernstein et al. [1]. We provide a new structural understanding that leads to a better lower bound and new randomized bounds.

A similar framework is considered for matchings by Hassin and Rubinstein [13]. Here, the objective f is the total weight of a set of edges and the solution is additionally required to be a matching. Hassin and Rubinstein [13] show that the competitive ratio in this setting is $\sqrt{2}$ and Matuschke, Skutella, and Soto [19] show that the randomized competitive ratio is $\ln(4) \approx 1.38$. The setting was later generalized to the intersection of matroids [7] and to independence systems with bounded exchangeability [15, 21]. Note that, while our results hold for a broader class of objective functions, we require monotonicity of the objective and cannot model the constraint that the solution must be a matching. We can, however, capture the matching problem by letting the objective f be the largest weight of a matching contained as a subset in the solution (i.e., not all parts of the solution need to be used). That being said, it is easy to verify that the lower bound of $\sqrt{2}$ on the competitiveness of any deterministic algorithm in the setting of [13] also applies in our case.

Hassin and Segev [14] studied the problem of finding a small subgraph that contains, for all k, a path (or tree) of cardinality at most k with weight at least α times the optimal solution and show that for this $\alpha|V|/(1-\alpha^2)$ edges suffice. There are further results on problems where the items have sizes and the cardinality-constraint is replaced by a knapsack constraint [4, 6, 17, 20]. Goemans and Unda [9] studied general incremental maximization problems with a sum-objective.

Incremental *minimization* problems further been studied for a variety of minimzation problems such as k-median [3, 22, 18], facility location [18, 23], and k-center [10, 18]. As noted by Lin et al. [18], the results for the minimum latency problem in [2, 8] implicitly yield results for the incremental k-MST problem. There are further results on incremental optimization problems where in each step the set of feasible solution increases [11, 12].

2 Separability of Incremental Maximization

As a first step to bound the competitive ratio of IncMax, we introduce a subclass of instances of a relatively simple structure, and show that it has the same competitive ratio as IncMax. Thus, we can restrict ourselves to this subclass in our search for bounds on the competitive ratio.

▶ **Definition 7.** *An instance of IncMax with objective $f\colon 2^U \to \mathbb{R}_{>0}$ is called* separable *if there exist a partition $U = R_1 \cup R_2 \cup \dots$ of U and values $d_i > 0$ such that*

$$f(X) = \max_{i \in \mathbb{N}} \{|X \cap R_i| \cdot d_i\} \quad \text{for all } X \subseteq U.$$

We refer to d_i as the density *of set R_i and to $v_i := |R_i| \cdot d_i$ as the* value *of set R_i. The restriction of IncMax to separable instances will be denoted by IncMaxSep.*

We start our analysis of IncMaxSep with the following immediate observation.

▶ **Lemma 8.** *Any instance of IncMaxSep can be transformed into one with the same or a worse competitive, that satisfies the following properties.*

1. *There is exactly one set of every cardinality, i.e., $|R_i| = i$.*
2. *Densities are decreasing, i.e., $1 \geq d_1 \geq d_2 \geq \dots$.*
3. *Values are increasing, i.e., $v_1 \leq v_2 \leq \dots$.*

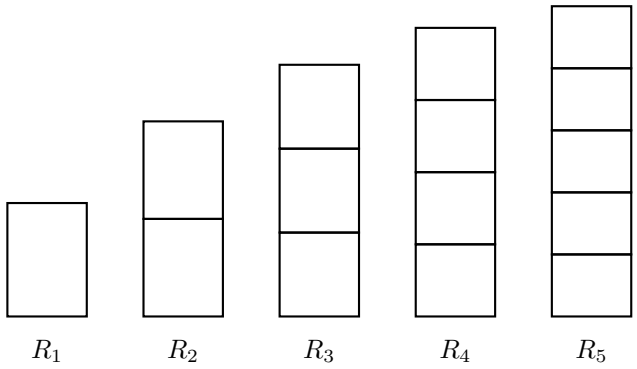

Figure 1 Illustration of an instance of IncMaxSep with $N = 5$ sets. Each set R_i consists of i elements. The height of the elements represents their value. As in Lemma 8, the values of the single elements becomes less the larger i is, while the value of the whole set R_i increases.

Proof. We will show that every instance that does not satisfy the assumptions can be transformed into one that does, without changing the optimum value for any size, and without changing the value of the best incremental solution. Thus the competitive ratio of the two instances coincide.

If there are two sets R_i, R_j with $|R_i| = |R_j|$, it only makes sense to consider the one with higher density, as every solution adding elements from the set of lower density can be improved by adding elements from the other set instead. If there is $i \in \mathbb{N}_{\geq 2}$ such that there is no set with i elements, we can add a new set with i elements to the instance. This new set will have value v_{i-1} . Then, every solution that adds elements from the newly introduced set can be improved by adding elements from set R_{i-1} instead. If there is no set R_1 with 1 element, we can introduce it with density d_2. Then, every solution that adds this one element can instead also add one element from R_2. Thus, the first assumption can be made.

The assumption that $1 \geq d_1$ is without loss of generality by rescaling the objective f. If there was $i \in \mathbb{N}$ with $d_i < d_{i+1}$, every solution to the problem instance that adds elements from the set R_i could be improved by adding elements from the set R_{i+1} instead. Since $|R_{i+1}| \geq |R_i|$, this is possible.

The third assumption can be made because, if there was $i \in \mathbb{N}$ with $v_i > v_{i+1}$, a solution that adds elements from R_{i+1} can be improved by adding elements from R_i instead. ◀

In the following, we assume that every instance satisfies the properties from Lemma 8.

▶ **Definition 9.** *We say that a solution for* IncMaxSep *is* represented *by a sequence of sizes* $(c_1, c_2, \dots)$ *if it first adds all elements from the set* R_{c_1}*, then all elements from the set* R_{c_2}*, and so on.*

A solution of IncMaxSep can only improve if it is altered in a way that it is represented by a sequence of sizes. Indeed, if not all elements of one set are added, the solution does not degrade if a smaller set is added instead because the density of the smaller set is at least as large as the density of the larger set. Moreover, adding all elements of one set consecutively is better because the value of the solution increases faster this way.

▶ **Lemma 10** ([1], Observation 2). *There is an algorithm achieving the best-possible competitive ratio for* IncMaxSep *such that the solution generated by this algorithm can be represented by a sequence* $(c_1, c_2, \dots)$*. We can assume that* $v_{c_i} < v_{c_{i+1}}$ *and thus, since the values* $(v_i)_{i \in \mathbb{N}}$ *are non-decreasing,* $c_i < c_{i+1}$ *for all* $i \in \mathbb{N}$*.*

From now on, we will only consider solutions of this form and denote a solution X by the sequence it is represented by, i.e., $X = (c_1, c_2, \dots)$. For a size $C \in \mathbb{N}$, we denote by $X(C)$ the first C elements added by X, i.e., $|X(C)| = C$ and, with $O_i := \arg\max\{f(S) \mid S \subseteq U, |S| = i\}$, we have $X\left(\sum_{i=1}^{k} c_i\right) = \bigcup_{i=1}^{k} O_{c_i}$.

▶ **Proposition 11.** *The competitive ratios of* IncMax *and* IncMaxSep *coincide.*[1]

Proof Sketch. As IncMaxSep is a subclass of IncMax, the competitive ratio of IncMaxSep is not larger than that of IncMax.

It remains to show that the competitive ratio of IncMax is smaller or equal to that of IncMaxSep. To see this, consider an instance of IncMax. We will construct an instance of IncMaxSep such that every ρ-competitive solution to this problem instance induces a ρ-competitive solution for the initial instance of IncMax.

To define the instance of IncMaxSep, let $R_1, R_2, \dots$ be disjoint sets with $|R_i| = i$ for all $i \in \mathbb{N}$. For $i \in \mathbb{N}$, let $d_i = \textsc{Opt}(i)/i$. By modularity of the value function within one set R_i, the value of the optimal solution of a given size in this instance is the same as that in the instance of IncMax.

For $\rho \geq 1$, let $(c_1, c_2, \dots)$ be a ρ-competitive solution for the separable instance. We consider the solution for the initial problem that starts by adding the optimal solution of size c_1, then adds the optimal solution of size c_2, and so on. Accountability guarantees that it is possible to add the elements within one optimal solution such that the value of the partially added solution grows at least proportionally with the size of the solution. Since the values of the optimal solutions of a given size in the two instances coincide, the value of the solution for the initial instance we defined above is always greater or equal to that of the solution $(c_1, c_2, \dots)$. Thus, the solution for the initial instance is also ρ-competitive, which implies that the competitive ratio of IncMax is smaller or equal to that of IncMaxSep. ◀

3 Continuization Results

In order to find lower bounds on the competitive ratio of IncMaxSep, we transform the problem into a continuous one.

▶ **Definition 12.** *In the* IncMaxCont *problem, we are given a* density function $d\colon \mathbb{R}_{\geq 0} \to (0, 1]$ *and a* value function $v(c) := cd(c)$. *As for the discrete problem, we denote an incremental solution X for* IncMaxCont *by a sequence of sizes $X = (c_1, c_2, \dots)$. For a given size $c \geq 0$, we denote the solution of this size by $X(c)$. With $n \in \mathbb{N}$ such that $\sum_{i=1}^{n-1} c_i < c \leq \sum_{i=1}^{n} c_i$, the value of $X(c)$ is defined as*

$$f(X(c)) := \max\left\{\max_{i \in \{1,\dots,n-1\}} v(c_i), \left(c - \sum_{i=1}^{n-1} c_i\right) d(d_n)\right\}.$$

An incremental solution X is ρ-competitive if $\rho \cdot f(X(c)) \geq v(c)$ for all $c > 0$. The competitive ratio of X is defined as $\inf\{\rho \geq 1 \mid X \text{ is } \rho\text{-competitive}\}$.

The interpretation of the functions d and v is that the instance is partitioned into sets, one for every positive size $c \in \mathbb{R}$, each consisting of c fractional units with a value of $d(c)$ per unit, for a total value of $v(c)$ for the set. The solution can be interpreted in the following way: It starts by adding the set of size c_1, then the set of size c_2, and so on. With $n \in \mathbb{N}$ such that

[1] A full proof of this and all other results can be found in [5].

$\sum_{i=1}^{n-1} c_i < c \leq \sum_{i=1}^{n} c_i$, the solution $X(c)$ has added all of the sets of sizes $c_1, \ldots, c_{n-1}$ and $c - \sum_{i=1}^{n-1} c_i$ units of the set of size c_n. Unlike the IncMaxSep problem, the IncMaxCont problem includes subsets of all real sizes instead of only integer sizes and, furthermore, allows fractional elements to be added to solutions instead of only an integral number of elements.

As for the discrete version of the problem, without loss of generality, we assume that the density function d is non-increasing and the value function v is non-decreasing. These assumptions imply that d is continuous: If this was not the case and d was not continuous for some size c', i.e., $\lim_{c \nearrow c'} d(c) > \lim_{c \searrow c'} d(c)$, then $\lim_{c \nearrow c'} v(c) > \lim_{c \searrow c'} v(c)$ by definition of v, i.e., v would not be increasing in c. So d is continuous, and, by definition of v, also v is continuous. Furthermore, without loss of generality, we assume that $d(0) = 1$.

For a fixed size $c \geq 0$, we define $p(c) = \max\{c' \geq 0 \mid v(c') \leq \rho v(c)\}$. This value gives the size up to which a solution with value $v(c)$ is ρ-competitive. Throughout our analysis, we assume that $p(c)$ is defined for every $c \geq 0$, i.e., that $\lim_{c \to \infty} v(c) = \infty$. Otherwise, any algorithm can terminate when the value of its solution is at least $\frac{1}{\rho} \sup_{c \in \mathbb{R}_{\geq 0}} v(c)$.

▶ **Proposition 13.** *The competitive ratio of IncMaxSep is greater or equal to that of IncMaxCont.*

Proof Sketch. Given a lower bound construction for the competitive ratio of IncMaxCont, one can discretize it with arbitrary resolution such that, with an arbitrarily small loss, it carries over to the IncMaxSep problem. ◀

This proposition implies that instead of devising a lower bound for the IncMaxSep problem, we can construct a lower bound for the IncMaxCont problem.

Note that it is not clear whether the competitive ratio of IncMaxSep and IncMaxCont coincide. This is due to the fact that a solution to the IncMaxCont problem may add fractional elements while a solution to the IncMaxSep problem may only add an integral number of items. There are even discrete instances where every continuization of the instance has a competitive ratio smaller than the initial instance.

▶ **Observation 14.** *There exists an instance of IncMaxSep that has a competitive ratio that is strictly larger than that of every instance of IncMaxCont that monotonically interpolates the IncMaxSep instance.*

Proof Sketch. We show that the instance of IncMaxSep with $N = 16$ sets and

$$\begin{aligned} d_1 &= 1, \\ d_3 = d_4 &= \frac{17}{40}, \\ d_{12} = d_{13} = d_{14} = d_{15} = d_{16} &= \frac{16473}{107200}. \end{aligned}$$

has a competitive ratio of at least 1.446, while every monotone interpolation of it has a competitive ratio of at most 1.425. ◀

Note that, even though this shows that there are instances where the continuous problem is easier than the discrete one, this does not rule out that the competitive ratios of IncMaxSep and IncMaxCont coincide. This is due to the fact that the instance in the proof is not a worst-case instance.

3.1 Optimal Continuous Online Algorithm

In this section, we present an algorithm to solve the IncMaxCont problem, and analyze it. To get an idea what the algorithm does, consider the following lemma. It gives a characterization of a solution $(c_1, c_2, \dots)$ being ρ-competitive, depending on $(c_1, c_2, \dots)$, v and d.

▶ **Lemma 15.** *A solution $(c_1, c_2, \dots)$ for an instance of the IncMaxCont problem is ρ-competitive if and only if $d(c_1) \geq \frac{1}{\rho}$ and, for all $i \in \mathbb{N}$, $d(c_{i+1}) \geq \frac{v(c_i)}{p(c_i) - \sum_{j=1}^{i} c_j}$.*

The intuition behind the fraction

$$\frac{v(c_i)}{p(c_i) - \sum_{j=1}^{i} c_j}$$

is the following: The value of the solution $(c_1, \dots, c_{i-1}, c_i)$ is $v(c_i)$ and this value is ρ-competitive up to size $p(c_i)$. The size required for this solution is $\sum_{j=1}^{i} c_j$. Thus, in order to stay competitive, the size added next, namely c_{i+1}, needs to be chosen such that $\big(p(c_i) - \sum_{j=1}^{i} c_j\big) d(c_{i+1}) \geq v(c_i)$, i.e., the density $d(c_{i+1})$ is large enough such that the value of the solution of size $p(c_i)$ is $\big(p(c_i) - \sum_{j=1}^{i} c_j\big) d(c_{i+1})$.

We use this fraction to define an algorithm for solving the IncMaxCont Problem. For the algorithm, we assume that v is strictly increasing and d is strictly decreasing to make the choice of our algorithm unique. Every instance of IncMaxCont can be transformed to satisfy this with an arbitrarily small loss by simpliy "tilting" constant parts of d and v by a small amount. The algorithm GreedyScaling(c_1, ρ) starts by adding the optimal solution of size $c_1 > 0$ and chooses the size c_{i+1} such that

$$d(c_{i+1}) = \frac{v(c_i)}{p(c_i) - \sum_{j=1}^{i} c_j}, \tag{1}$$

i.e., as large as possible while still satisfying the inequality in Lemma 15. An illustration of the algorithm can be found in Figure 2.

Using the definition of the algorithm in (1) and Lemma 15, we are able to prove the following.

▶ **Proposition 16.** *The algorithm GreedyScaling(c_1, ρ) is ρ-competitive if and only if it produces a solution $(c_1, c_2, \dots)$ with $c_i < c_{i+1}$ for all $i \in \mathbb{N}$ and $d(c_1) \geq \frac{1}{\rho}$.*

Proof Sketch. "⇐": If $c_i < c_{i+1}$ for all $i \in \mathbb{N}$ and $d(c_1) \geq 1/\rho$, we can simply apply Lemma 15 and obtain that the solution is ρ-competitive.

"⇒": If $d(c_1) < 1/\rho$, Lemma 15 yields that the solution is not ρ-competitive. If $c_{k+1} \leq c_k$ for some $k \in \mathbb{N}$, one can iteratively show that $c_{i+1} \leq c_i$ for all $i \in \{k, k+1, \dots\}$. This implies that the value of the solution $(c_1, c_2, \dots)$ is smaller or equal to $v(c_k)$ for all sizes. Yet, for large sizes $C \in \mathbb{N}$, we have $v(C) > \rho v(c_k)$ as $\lim_{c \to \infty} v(c) = \infty$. ◀

The algorithm GreedyScaling(c_1, ρ) only depends on the desired competitive ratio ρ and the starting value c_1. Given that some algorithm can achieve a competitive ratio of ρ, we can show that GreedyScaling(c_1^*, ρ) with the correct starting value $c_1^* > 0$ also gives a ρ-competitive solution.

▶ **Theorem 1.** *For every instance of IncMaxCont, there exists a starting value c_1 such that the algorithm GreedyScaling(c_1, ρ^*) achieves the best-possible competitive ratio $\rho^* \geq 1$.*

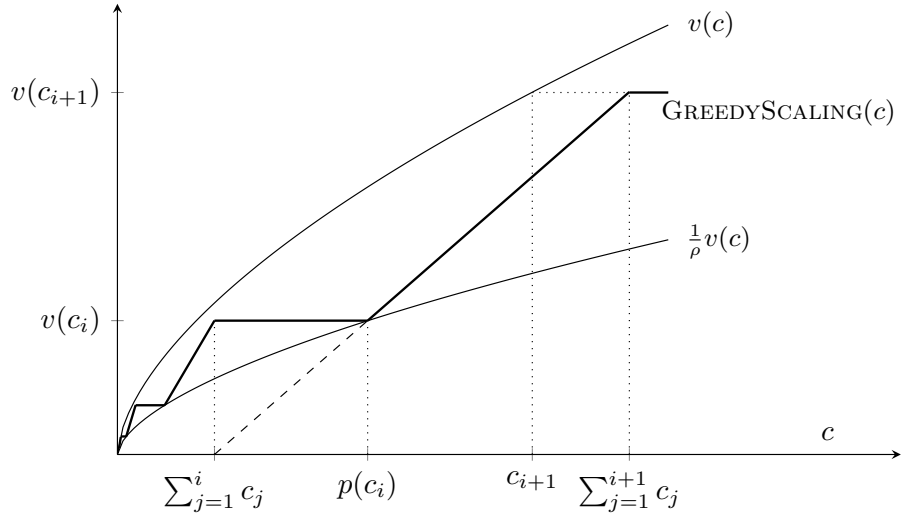

Figure 2 Illustration how GreedyScaling(c_1, ρ) works. Between size $\sum_{j=1}^{i} c_j$ and size $\sum_{j=1}^{i+1} c_j$, the algorithm adds the optimal solution of size c_{i+1}. This size is chosen in a way that the value of the partially added solution has value $v(c_i)$ exactly at size $p(c_i)$, i.e., when the previously added solution of size c_i loses ρ-competitiveness.

Proof sketch. The idea of the proof is to start with a ρ^*-competitive solution $(c_1, c_2, \dots)$ for the instance of IncMaxCont. For every $k \in \mathbb{N}$, we define a new ρ^*-competitive solution $(c_1^k, c_2^k, \dots)$ as follows. For $i \in \mathbb{N}$ with $\sum_{j=1}^{i} c_j \geq k$, we set $c_i^k = c_i$. For $i \in \mathbb{N}$ with $\sum_{j=1}^{i} c_j < k$, we choose $c_i^k \geq 0$ as small as possible without losing ρ^*-competitiveness. This new solution satisfies the inequality

$$d(c_{i+1}^k) \geq \frac{v(c_i^k)}{p(c_i^k) - \sum_{j=1}^{i} c_j^k}$$

from Lemma 15 with equality for $i \in \{1, \dots, k-1\}$. This implies, that we can calculate $c_2^k, \dots, c_k^k$ solely based on c_1^k, d, and v. For every $k \in \mathbb{N}$, we obtain such a solution $(c_1^k, c_2^k, \dots)$. For all $k \in \mathbb{N}$, we have $d(c_1^k) \geq 1/\rho^*$, which implies that all sizes in $\{c_1^1, c_1^2, \dots\}$ are from the finite interval $[0, d^{-1}(1/\rho^*)]$. By the Bolzano-Weierstrass theorem, this implies that the sequence $(c_1^1, c_1^2, \dots)$ contains a converging sub-sequence. If we choose the limit of this sub-sequence to be the starting value c_1^* of the algorithm GreedyScaling(c_1^*, ρ^*), we obtain a ρ^*-competitive algorithm. ◀

For a range of starting values c_1, we are able to show the upper bound on the competitive ratio of GreedyScaling$(c_1, \varphi + 1)$ in Theorem 2, where $\varphi = \frac{1}{2}(1 + \sqrt{5}) \approx 1.618$ is the golden ratio.

▶ **Theorem 2.** *GreedyScaling$(c_1, \varphi+1)$ is $(\varphi+1)$-competitive if and only if $d(c_1) \geq \frac{1}{\varphi+1}$.*

Proof Sketch. By Proposition 16, it suffices to show that, for the solution $(c_1, c_2, \dots)$ produced by GreedyScaling$(c_1, \varphi + 1)$, we have $c_{i+1} > c_i$ for every $c_1 > 0$ with $d(c_1) > \frac{1}{\varphi+1}$. We show iteratively that $c_{i+1} \geq (\varphi + 1)c_i$. In order to do this, we observe that

$$p(c_i) = \frac{(\varphi + 1)v(c_i)}{d(p(c_i))} \geq (\varphi + 1)c_i.$$

By a straighforward induction that uses the fact that $(\varphi+1)^{i-j}c_j \leq c_i$ for all $j \in \{1,\dots,i-1\}$ as well as the definition of GreedyScaling$(c_1, \varphi+1)$ we obtain that $d(c_{i+1}) < d(p(c_i))$. This implies $c_{i+1} > p(c_i) \geq (\varphi+1)c_i$. ◀

Since GreedyScaling(c_1,ρ) with the correct starting value c_1 is the best-possible algorithm for a fixed instance, we can give a lower bound of $\rho > 1$ for the IncMaxCont problem by finding an instance that is a lower bound for GreedyScaling(c_1,ρ) with all starting values $c_1 > 0$ that satisfy $d(c_1) \leq 1/\rho$. In the following, we show that, for every countable set of starting values, there is an instance where GreedyScaling(c_1,ρ) cannot have a competitive ratio of better than $\varphi+1$ for any of these starting values. In order to do this, we need the following lemma.

▶ **Lemma 17.** *For $\alpha,\beta,\rho,\epsilon \in \mathbb{R}_{\geq 0}$ with $\beta > 0$, consider the recursively defined sequence $(t_n)_{n\in\mathbb{N}}$ with*

$$t_0 = \beta, \qquad t_{n+1} = \frac{1}{\frac{\rho}{t_n(1-\epsilon)} - \left(\sum_{j=0}^{n} \frac{(\rho+\epsilon)^{j-n}}{t_j}\right) - \frac{\alpha}{(\rho+\epsilon)^n}} \quad \text{for all } n \in \mathbb{N}\cup\{0\}.$$

If $1 < \rho < \varphi+1$, then there exists $\epsilon' > 0$ such that, for all $\epsilon \in (0,\epsilon']$, there is $\ell \in \mathbb{N}$ with $t_\ell < 0$.

Proof sketch. We define an auxiliary sequence $(a_n)_{n\in\mathbb{N}}$ with $a_n = \frac{1}{t_n}$ for all $n \in \mathbb{N}\cup\{0\}$. This sequence becomes negative if and only if $(t_n)_{n\in\mathbb{N}\cup\{0\}}$ becomes negative. We show that $(a_n)_{n\in\mathbb{N}\cup\{0\}}$ is fully described by the homogeneous recurrence relation

$$a_{n+1} = a_n\left(\frac{1}{\rho+\epsilon} + \frac{\rho}{1-\epsilon} - 1\right) - a_{n-1}\frac{\rho}{(1-\epsilon)(\rho+\epsilon)}$$

for all $n \in \mathbb{N}$, together with the start values $a_0 = 1/\beta$ and

$$a_1 = \frac{1}{t_1} = \frac{\rho}{\beta(1-\epsilon)} - \frac{1}{\beta} - \alpha.$$

Its characteristic polynomial is

$$0 = x^2 - \left(\frac{1}{\rho+\epsilon} + \frac{\rho}{1-\epsilon} - 1\right)x + \frac{\rho}{(1-\epsilon)(\rho+\epsilon)}.$$

We show that the roots x and y of this polynomial are complex if $\rho < \varphi+1$ and $\epsilon > 0$ small enough. Thus, they are also distinct which implies that the sequence $(a_n)_{n\in\mathbb{N}\cup\{0\}}$ has the closed-form expression

$$a_n = \lambda x^n + \mu y^n$$

for all $n \in \mathbb{N}\cup\{0\}$ where $\lambda,\mu \in \mathbb{C}$ are chosen accordingly. The fact that the starting values a_0 and a_1 are real valued imply that λ and μ are complex conjugate. Thus, we obtain

$$a_n = 2\Re(\lambda x^n)$$

for all $n \in \mathbb{N}\cup\{0\}$, where $\Re(\lambda x^n)$ denotes the real part of λx^n. We analyze this equation by visualizing it on the complex plane (cf. Figure 3). Since x is not real valued, multiplying by x corresponds to a rotation by an angle that is not 0 and not π. Thus, for some $n \in \mathbb{N}\cup\{0\}$, $\Re(\lambda x^n)$ must become negative. ◀

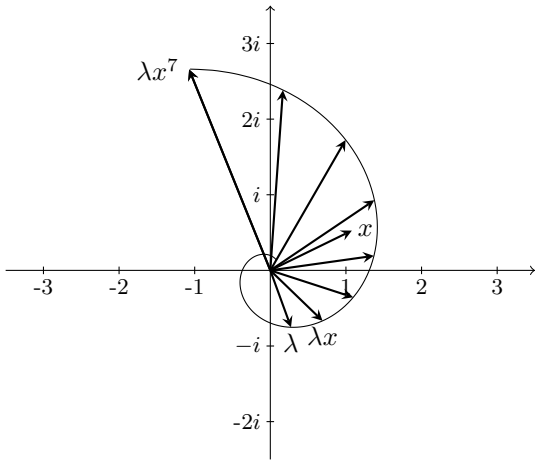

Figure 3 Multiplying λ repeatedly by $x \in (\mathbb{C} \setminus \mathbb{R})$ is equivalent to a rotation around the origin that, at some point, reaches the half-plane corresponding to negative real parts.

▶ **Proposition 3.** *For every countable set $S \subset \mathbb{R}_{>0}$ of starting values, there exists an instance of* IncMaxCont *such that* GreedyScaling(c_1, ρ) *is not ρ-competitive for any $c_1 \in S$ and any $\rho < \varphi + 1$.*

Proof Sketch. We give an overview how to construct an instance where the algorithm GreedyScaling(c_1, ρ) is not ρ-competitive for one fixed starting value $c_1 > 0$ and every $\rho \in [1, \varphi + 1)$. For the sake of simplicity, in this overview, we describe an instance where the density function d and the value function v are locally constant. In the final construction, we avoid this by slightly tilting constant parts of the function.

Let $\epsilon > 0$ be arbitrarily small. The beginning of the instance up to size c_1 can be chosen arbitrarily. We set $d(c) = d(c_1)$ for all $c \in [c_1, (\rho + \epsilon)c_1]$. By doing this, we ensure that the value obtained by adding the optimal solution of the first size c_1 is ρ-competitive for as few sizes as possible, i.e., until $p(c_1) = \rho c_1$. Then, $d(c_2) = \frac{v(c_1)}{\rho c_1 - c_1}$ can be calculated. We set $v(c) = v((\rho+\epsilon)c_1)$ for all $c \in [(\rho + \epsilon)c_1, \frac{v((\rho+\epsilon)c_1)}{d(c_2)}]$. This ensures that c_2 is as small as possible, namely $c_2 = \frac{v((\rho+\epsilon)c_1)}{d(c_2)}$. Now we repeat what we did for c_1, i.e., we define d to be constant so that the value $v(c_2)$ is ρ-competitive for as few sizes as possible. Then, we calculate $d(c_3)$ and define v to be constant so that c_3 is as small as possible. We continue doing this for all larger c_i with $i \geq 3$. It turns out that we have $d(c_i) = t_i$ where the sequence $(t_i)_{i \in \mathbb{N}}$ is defined as in Lemma 17. Thus, at some point, the density GreedyScaling(c_1, ρ) calculates the next capacity to be negative, which is not possible, i.e., the algorithm is not ρ-competitive.

We have seen how to construct an instance that excludes one starting value. This instance is finite and the beginning can be chosen arbitrarily. Thus, we can chain together multiple of these instances by scaling an instance for some set of starting values and modifying the beginning such that it contains an instance for an additional starting value. ◀

3.2 General Lower Bound

Now we want to employ the techniques we used to prove Lemma 17 and Proposition 3 in order to prove a lower bound on the competitive ratio of IncMaxCont. Let ρ^* be the unique real root $\rho \geq 1$ of the polynomial $-4\rho^6 + 24\rho^4 - \rho^3 - 30\rho^2 + 31\rho - 4$. As before, we need to show that a recursively defined sequence becomes negative at some point.

▶ **Lemma 18.** *For $\rho \in \mathbb{R}_{\geq 0}$ and $\epsilon > 0$, consider the recursively defined sequence $(t_n)_{n\in\mathbb{N}}$ with*

$$t_0 = 1, \qquad t_1 = \frac{1-\epsilon}{\rho}, \qquad t_n = \frac{1-\epsilon}{\frac{\rho}{t_{n-1}} - \frac{1}{t_{n-2}} - \frac{1}{\rho}\left(\sum_{j=0}^{n-3} \frac{(\rho+\epsilon)^{j+2-n}}{t_j}\right)} \quad \text{for all } n \in \mathbb{N}_{\geq 2}.$$

If $1 < \rho < \rho^*$, then there exists $\epsilon' > 0$ such that, for all $\epsilon \in [0, \epsilon']$, there is $\ell \in \mathbb{N}$ with $t_\ell < 0$.

The proof of this lemma is along the same lines as the proof of Lemma 17, with additional technical difficulties because the recurrence relation of the sequence is of order 3. With this lemma, we are ready to construct our lower bound on the competitive ratio of IncMaxCont and thus, via Propositions 11 and 13, of IncMax.

▶ **Theorem 4.** *The IncMax problem has a competitive ratio of at least* 2.246.

Proof sketch. We fix a competitive ratio $\rho < \rho^*$ and some small $\epsilon > 0$. Similarly to the construction in the proof of Proposition 3, the lower bound in Theorem 4 is a construction where we have intervals on which, alternatingly, either the density function or the value function is constant (cf. Figure 4). For $i \in \mathbb{N}$, on the $(2i)$-th interval, the value is constant and equals $(\rho+\epsilon)^{i-1}$. On the $(2i-1)$-th interval, the density is constant and equal to t_{i-1}, where $(t_n)_{n\in\mathbb{N}}$ is defined as in Lemma 18. Every solution that contains a size from an interval of constant value can be improved by picking the largest size from the preceding interval of constant density instead. This size has the same value and is smaller. Thus, we assume that algorithms only pick sizes from the intervals with constant density. We denote the solution by $(c_1, c_2, \dots)$. We have $d(c_1) = t_0 = 1$ because $t_1 < 1/\rho$ is too small. In order to be competitive for the first constant value interval of value 1, the solution has to satisfy $c_1 \geq 1/\rho$ to achieve a value of at least $1/\rho$. Then, the following recursive argument is made. Fix $i \in \mathbb{N}$. Whenever, for all $j \in \{1, \dots, i\}$, the solution satisfies $d(c_j) = t_{j-1}$ and $c_j \geq \frac{(\rho+\epsilon)^{i-1}}{\rho}$, then we have $d(c_{i+1}) = t_i$ and $c_{i+1} \geq \frac{(\rho+\epsilon)^i}{\rho}$. The equality $d(c_{i+1}) = t_i$ is due to the definition of the sequence $(t_n)_{n\in\mathbb{N}}$ and Lemma 15. The inequality $c_{i+1} \geq \frac{(\rho+\epsilon)^i}{t_i \rho}$ follows from the fact that, after the size c_{i+1} is added to the solution, the solution has to be competitive on the $(2i+2)$-th interval of value $(\rho+\epsilon)^i$. Since the sequence $(t_n)_{n\in\mathbb{N}}$ becomes negative at some point, the solution is not ρ-competitive. ◀

4 Randomized Incremental Maximization

We turn to analyzing randomized algorithms to solve the (discrete) IncMaxSep problem. In contrast to deterministic algorithms, we do not compare the value obtained by the algorithm to an optimum solution, but rather the expected value obtained by the algorithm. This enables us to find an algorithm with randomized competitive ratio smaller than the lower bound of 2.24 on the competitive ratio of deterministic algorithms in Theorem 4.

4.1 Randomized Algorithm

Scaling algorithms, i.e., algorithms where the size c_i is chosen such that $c_i = \delta c_{i-1}$ with an appropriate scaling factor $\delta > 1$, have been proven to perform well for the deterministic version of the problem. The best known algorithm is, in fact, a scaling algorithm [1]. In the analysis, it turns out that, on average, a scaling algorithm performs better than the actual competitive ratio, which is only tight for few sizes. By randomizing the initial size c_0, we manage to average out the worst-case sizes in the analysis.

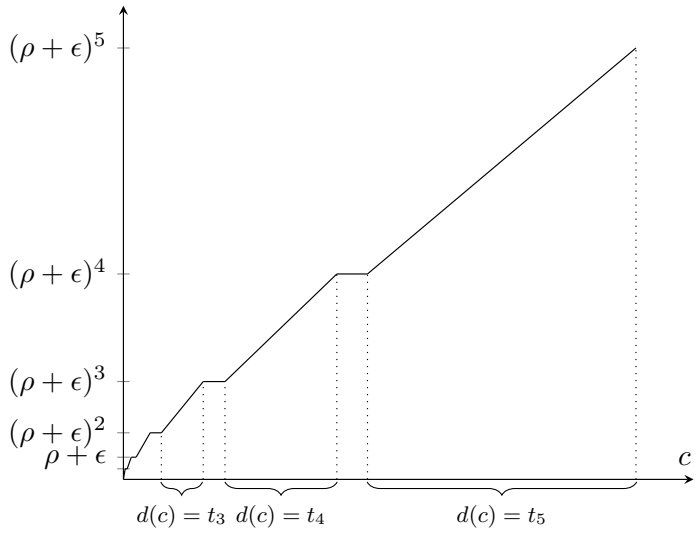

Figure 4 Lower bound construction for $\rho = 2.1$.

We describe the randomized algorithm RandomizedScaling for IncMaxSep. Let $r > 1$ be some scaling parameter to be determined later. The algorithm RandomizedScaling starts by choosing $\epsilon \in (0,1)$ uniformly at random. For all $i \in \mathbb{N}_0$, it calculates $\tilde{c}_i := r^{i+\epsilon}$ and $c_i := \lfloor \tilde{c}_i \rfloor$ and returns the solution $(c_0, c_1, c_2, \dots)$.[2] This approach is similar to a randomized algorithm to solve the CowPath problem in [16], which also calculates such a sequence with a different choice of $r \in \mathbb{R}$ in order to explore a star graph.

We define

$$\tilde{t}_i := \sum_{j=0}^{i} \tilde{c}_j = r^{\epsilon} \frac{r^{i+1}-1}{r-1} \qquad \text{and} \qquad t_i := \sum_{j=0}^{i} c_j.$$

For better readability, we let $\tilde{c}_{-1} = c_{-1} = \tilde{t}_{-1} = t_{-1} = 0$. Note that, for all $i \in \mathbb{N}_0$, we have

$$t_{i-1} \le \tilde{t}_{i-1} = r^{\epsilon} \frac{r^i - 1}{r-1} \overset{r>2}{\le} r^{i+\epsilon} - r^{\epsilon} \le r^{i+\epsilon} - 1 = \tilde{c}_i - 1 \le c_i. \tag{2}$$

For every size $c \in \mathbb{N}_0$, we denote the solution created by the algorithm RandomizedScaling by $X_{\text{ALG}}(c)$. Note that the optimum solution of size $c \in \mathbb{N}_0$ is given by the set R_c because $v_1 \le v_2 \le \dots$ and $d_1 \ge d_2 \ge \dots$. Thus, the value of the optimum solution of size c is v_c.

In order to find an upper bound on the randomized competitive ratio of RandomizedScaling, we need the following lemma. It gives an estimate on the expected value of the solution for a fixed size $C \in \mathbb{N}$ of RandomizedScaling depending on the interval in which C falls.

▶ **Lemma 19.** *Let $C \in \mathbb{N}$.*

1. *For $i \in \mathbb{N} \cup \{0\}$ with $\mathbb{P}[C \in (c_{i-1}, c_i]] > 0$, we have*

$$\mathbb{E}\big[f(X_{\text{ALG}}(C)) \mid C \in (c_{i-1}, c_i]\big] \ge \mathbb{E}\Big[\max\Big\{\frac{c_{i-1}}{C}, \frac{C - t_{i-1}}{\max\{C, c_i\}}\Big\} \;\Big|\; C \in (c_{i-1}, c_i]\Big] \cdot v_C.$$

[2] With this definition, the algorithm does not terminate on finite instances. To avoid this, it suffices to stop calculating the sizes c_i until they are larger than the number of elements in the instance.

2. *For $i \in \mathbb{N}$ with $\mathbb{P}[C \in (\tilde{c}_i, \tilde{t}_i - 1]] > 0$, we have*

$$\mathbb{E}\big[f(X_{ALG}(C)) \mid C \in (\tilde{c}_i, \tilde{t}_i - 1]\big] \geq \mathbb{E}\Big[1 - \frac{\tilde{t}_{i-1}}{C} \;\Big|\; C \in (\tilde{c}_i, \tilde{t}_i - 1]\Big] \cdot v_C.$$

3. *For $i \in \mathbb{N}$ with $\mathbb{P}[C \in (\tilde{t}_{i-1} - 1, \tilde{c}_i]] > 0$, we have*

$$\mathbb{E}\big[f(X_{ALG}(C)) \mid C \in (\tilde{t}_{i-1}{-}1, \tilde{c}_i]\big] \geq \mathbb{E}\Big[\max\Big\{\frac{\tilde{c}_{i-1} - 1}{C}, \frac{C - \tilde{t}_{i-1}}{\tilde{c}_i}\Big\} \;\Big|\; C \in (\tilde{t}_{i-1}{-}1, \tilde{c}_i]\Big] \cdot v_C.$$

By choosing $r \approx 5.1646$ to be the unique maximum of

$$\begin{aligned} g(x) \;=\; & \frac{1 - \sqrt{\big(\frac{x^3-1}{x-1}x^z - 1\big)^2 + 4x^{5+2z}}}{2\log(x)x^{3+z}} - (1-\delta)\frac{1-x^{-3}}{x-1} + z - \frac{1-x^{-3}}{2(x-1)\log(x)} \\ & - \Big(\frac{1-x^{-3}}{x-1} - \frac{1}{x^{3+z}}\Big)\Big(\log_x\Big(\sqrt{\big(\frac{x^3-1}{x-1}x^z - 1\big)^2 + 4x^{5+2z}} - \frac{x^3-1}{x-1}x^z + 1\Big) \\ & - \log_x(2) - 3\Big) - \frac{2x^{2+z}}{\Big(\sqrt{\big(\frac{x^3-1}{x-1}x^z - 1\big)^2 + 4x^{5+2z}} - \frac{x^3-1}{x-1}x^z + 1\Big)\log(x)} \\ & + \frac{2}{\log(x)} - \Big(1 + \frac{1}{x^{3+z}}\Big)\Big(\log_x(x^{3+z}+1) + \log_x(x-1) - \log_x(x^4-1)\Big), \end{aligned}$$

we can show that the following holds.

▶ **Lemma 20.** *Let $k \in \mathbb{N}$ and $\delta \in (0,1]$ such that $r^{k+\delta} \geq \sum_{i=0}^{3} r^i$. Then*

$$\begin{aligned} g(r) \leq I(k,\delta) := & \int_{\min\{1,\mu(k-1)\}}^{1} 1 - \frac{\tilde{t}_{k-2}}{r^{k+\delta}}\,d\epsilon + \int_{\min\{1,\nu(k-1)\}}^{\min\{1,\mu(k-1)\}} \frac{\tilde{c}_{k-1}-1}{r^{k+\delta}}\,d\epsilon \\ & + \int_{\delta}^{\min\{1,\nu(k-1)\}} \frac{r^{k+\delta} - \tilde{t}_{k-1}}{\tilde{c}_k}\,d\epsilon + \int_{\max\{0,\mu(k)\}}^{\delta} 1 - \frac{\tilde{t}_{k-1}}{r^{k+\delta}}\,d\epsilon \\ & + \int_{\max\{0,\nu(k)\}}^{\max\{0,\mu(k)\}} \frac{\tilde{c}_k - 1}{r^{k+\delta}}\,d\epsilon + \int_{0}^{\max\{0,\nu(k)\}} \frac{r^{k+\delta} - \tilde{t}_k}{\tilde{c}_{k+1}}\,d\epsilon \end{aligned}$$

where

$$\begin{aligned} \mu(i) &= \log_r(r^{k+\delta}+1) + \log_r(r-1) - \log_r(r^{i+1}-1), \\ \nu(i) &= \log_r\Big(\sqrt{\Big(r^{k+\delta}\frac{1-r^{-(i+1)}}{r-1} - 1\Big)^2 + 4r^{2k+2\delta-1}} - r^{k+\delta}\frac{1-r^{-(i+1)}}{r-1} + 1\Big) - \log_r(2) - i. \end{aligned}$$

With these lemmas, we are ready to prove an upper bound of $1/g(r) < 1.772$ on the randomized competitive ratio of RandomizedScaling.

▶ **Theorem 5.** *IncMax admits a 1.772-competitive randomized algorithm.*

Proof Sketch. In order to find this estimate, we start by fixing $k \in \mathbb{N}$ such that $C \in [r^k, r^{(k+1)})$. Then, depending on the value of ϵ, C is from one of the intervals

$$I_1 = (\tilde{c}_{k-1}, \tilde{t}_{k-1} - 1], \quad I_2 = (\tilde{t}_{k-1} - 1, \tilde{c}_k], \quad I_3 = (\tilde{c}_k, \tilde{t}_k - 1], \quad I_4 = (\tilde{t}_k - 1, \tilde{c}_{k+1}].$$

Yet, not all of these intervals are relevant to calculate the randomized competitive ratio. Depending on where in the interval $[r^k, r^{(k+1)})$ the value C lies, only 2 or 3 of the intervals I_1 to I_4 have a non-zero probability to contain C. Thus, we distinguish the different cases, where C lies in $[r^k, r^{(k+1)})$ and use Lemma 19 to calculate the randomized competitive ratio to be the integral expression in Lemma 20. Applying this lemma gives the desired bound on the randomized competitive ratio. ◀

4.2 Randomized Lower Bound

We turn to proving the lower bound in Theorem 6 for IncMaxSep.

▶ **Theorem 6.** *Every randomized IncMax algorithm has competitive ratio at least* 1.447.

Proof. We fix N to be the number of sets $R_1, \dots, R_N$, leaving $d_1, \dots, d_N$ as parameters to determine the instance; we denote the resulting instance by $I(d_1, \dots, d_N)$. Note that, given a probability distribution $p_1, \dots, p_N$ over the elements $\{1, \dots, N\}$ in addition, Yao's principle [24] yields

$$\inf_{\text{ALG} \in \mathcal{A}_N} \sum_{i=1}^{N} p_i \cdot \frac{i \cdot d_i}{\text{ALG}(I(d_1, \dots, d_N), i)}$$

as a lower bound on the randomized competitive ratio of the problem. Here, $\text{ALG}(I, i)$ denotes the value of the first i elements in the solution produced by ALG on instance I, and $\mathcal{A}_N$ is the set of all deterministic algorithms on instances with N sets $R_1, \dots, R_N$. As observed earlier, we may assume that

$$\mathcal{A}_N := \left\{ \text{ALG}_{c_1,\dots,c_\ell} \;\middle|\; 1 \le c_1 < \dots < c_\ell \le N, \sum_{i=1}^{\ell} c_i \le N \right\},$$

where $\text{ALG}_{c_1,\dots,c_\ell}$ is the algorithm that first includes all elements of R_{c_1} into the solution, then all elements of R_{c_2}, and so on. Once it has added the c_ℓ elements of R_{c_ℓ}, it adds some arbitrary elements from then onwards.

We can formulate the problem of maximizing the lower bound on the competitive ratio as an optimization problem:

$$\begin{aligned}
\max \quad & \rho \\
\text{s.t.} \quad & \rho \le \sum_{i=1}^{N} p_i \cdot \frac{i \cdot d_i}{\text{ALG}(I(d_1, \dots, d_N), i)} && \forall \text{ALG} \in \mathcal{A}_N, \\
& \sum_{i=1}^{N} p_i = 1, \\
& d_1, \dots, d_N \ge 0, \\
& p_1, \dots, p_N \ge 0.
\end{aligned}$$

Note that the expression $\text{ALG}_{c_1,\dots,c_\ell}(I(d_1, \dots, d_N), i)$ can also be written as a function of $c_1, \dots, c_\ell$, $d_1, \dots, d_N$, and i by taking the maximum over all sets from which $\text{ALG}_{c_1,\dots,c_\ell}$ selects elements:

$$\text{ALG}_{c_1,\dots,c_\ell}(I(d_1, \dots, d_N), i) = \max_{1 \le j \le \ell} \left\{ \max \left\{ i - \sum_{1 \le j' < j} c_{j'}, c_j \right\} \cdot d_{c_j} \right\}.$$

A feasible solution to the above optimization problem with $N = 10$ is given by

$$\begin{aligned}
&(\rho; d_1, \dots, d_{10}; p_1, \dots, p_{10}) \\
&= (1.447; 1, 1/2, 1/2, 1/2, 2/5, 1/3, 1/3, 1/3, 1/3, 1/3; 0.132, 0, 0, 0.395, 0, 0, 0, 0, 0, 0.473),
\end{aligned}$$

with objective value 1.447. ◀

Local Computation Algorithms for Hypergraph Coloring – Following Beck's Approach

Andrzej Dorobisz
Theoretical Computer Science Department, Faculty of Mathematics and Computer Science, Jagiellonian University, Kraków, Poland

Jakub Kozik
Theoretical Computer Science Department, Faculty of Mathematics and Computer Science, Jagiellonian University, Kraków, Poland

Abstract

We investigate local computation algorithms (LCA) for two-coloring of k-uniform hypergraphs. We focus on hypergraph instances that satisfy strengthened assumption of the Lovász Local Lemma of the form $2^{1-\alpha k}(\Delta+1)\mathrm{e}<1$, where Δ is the bound on the maximum edge degree. The main question which arises here is for how large α there exists an LCA that is able to properly color such hypergraphs in polylogarithmic time per query. We describe briefly how upgrading the classical sequential procedure of Beck from 1991 with Moser and Tardos' Resample yields polylogarithmic LCA that works for α up to $1/4$. Then, we present an improved procedure that solves wider range of instances by allowing α up to $1/3$.

1 Introduction

The problem of hypergraph coloring often serves as a benchmark for various probabilistic techniques. The task is to answer whether there exist (or to explicitly find) *a proper coloring*, that is, such an assignment of colors to the vertices of a hypergraph that no edge contains vertices all of the same color. In fact, the problem of two-coloring[1] of linear hypergraphs was one of the main motivations for introducing Local Lemma in the seminal paper of Erdős and Lovász [9]. It is well known that determining whether the given hypergraph admits proper two-coloring is NP-complete [15]. This result holds even for hypergraphs with all edges of size 3. In this work, we discuss sublinear algorithms for two-coloring of uniform hypergraphs within the framework of Local Computation Algorithms.

We are going to work with k-uniform hypergraphs[2]. For the rest of the paper, n is used to denote the number of vertices of considered uniform hypergraph, m its number of edges, and k size of the edges. We assume that k is fixed (but sufficiently large to avoid technical

[1] In two-coloring problem we can assign to each vertex one of two available colors.
[2] In *k-uniform hypergraph* each edge contains exactly k vertices.

details) and that n tends to infinity. For a fixed hypergraph, we denote by Δ its maximum edge degree. In the instances with which we are going to work, Δ is bounded by a function of k, so in terms of n it is $\mathcal{O}(1)$. This implies that the number of edges m is at most linear in n. We also assume that the considered hypergraphs do not have isolated vertices. Then, we also have $m = \Theta(n)$.

1.1 Local Computation Algorithms

Rubinfeld, Tamir, Vardi and Xie proposed in [21] a general model of sublinear sequential algorithms called Local Computation Algorithms (LCA). The model is intended to capture the situation where some computation has to be performed on a large instance but, at any specific time, only parts of the answer are required. The interaction with a local computation algorithm is organized in the sequence of queries about fragments of a global solution. The algorithm shall answer each consecutive query in sublinear time (wrt the size of the instance), systematically producing a partial answer that is consistent with some global solution. The model allows for randomness, and algorithm may occasionally fail.

For example, for the hypergraph two-coloring problem, the aim of an LCA procedure is to find a proper coloring of a given hypergraph. The algorithm can be queried about any vertex, and in response, it has to assign to the queried vertex one of the two available colors. For any sequence of queries, with high probability, it should be possible to extend the returned partial coloring to a proper one.

Formally, for a fixed problem, a procedure is a (t, s, δ)-*local computation algorithm*, if for any instance of size n and any sequence of queries, it can consistently answer each of them in time $t(n)$ using up to $s(n)$ space for computation memory. The time $t(n)$ has to be sublinear in n, but a polylogarithmic dependence is desirable. The value $\delta(n)$ shall bound the probability of failure for the whole sequence of queries. It is usually demanded to be small. The computation memory, the input, and the source of random bits are all represented as tapes with random access (the last two are not counted in $s(n)$ limit). The computation memory can be preserved between queries. In particular, it can store some partial answers determined in the previous calls. For the precise general definition of the model consult [21].

A procedure is called *query oblivious* if the returned solution does not depend on the order of the queries (i.e. it depends only on the input and the random bits). It usually indicates that the algorithm uses computation memory only to answer the current query and that there is no need to preserve information between queries. It is a desirable property, since it allows to run queries to algorithm in parallel. In a follow-up paper [3], Alon, Rubinfeld, Vardi, and Xie presented generic methods of removing query order dependence and reducing necessary number of random bits in LCA procedures. In the same paper, these techniques were applied to the example procedures (including hypergraph coloring) from [21] converting them to query oblivious LCAs. The improved procedures work not only in polylogarithmic time but also in polylogarithmic space. Mansour, Rubinstein, Vardi, and Xie in [16] improved analysis of this approach.

1.2 Constructive Local Lemma and LCA

The Lovász Local Lemma (LLL) is one of the most important tools in the field of local algorithms. In its basic form, it allows one to non-constructively prove the existence of combinatorial objects omitting a collection of undesirable properties, so-called bad events. A brief introduction to this topic and a summary of various versions of LLL can be found in the recent survey by Faragó [11].

For a fixed k-uniform hypergraph, let $p = 2^{-k}$ denote the probability that, in a uniformly random coloring, a fixed edge is monochromatic in a specific color. A straighforward application of the symmetric version of Local Lemma (see e.g., [11]) proves that the condition $2p\ (\Delta + 1)\ \mathrm{e} < 1$, is sufficient for a hypergraph with the maximum edge degree Δ, to be two-colorable.

For many years, Local Lemma resisted attempts to make it efficiently algorithmic. The first breakthrough came in 1991, when Beck [5], working on the example of hypergraph two-coloring, showed a method of converting some of LLL existence proofs into polynomial-time algorithmic procedures. However, in order to achieve that, the assumptions of Local Lemma had to be strengthened and took form

$$2\ p^{\alpha}\ (\Delta + 1)\ \mathrm{e} < 1. \tag{1}$$

For $\alpha = 1$ the inequality reduces to the standard assumption. The above inequality constraints Δ, and the constraint becomes more restrictive as α gets smaller. The original proof of Beck worked for $\alpha < 1/48$. From that time, a lot of effort has been put into studying applications to specific problems and pushing α forward, as close as possible to standard LLL criterion [2, 18, 7, 22, 19].

The next breakthrough was made by Moser in 2009. In cooperation with Tardos, Moser's ideas have been recasted in [20] into general constructive formulation of the lemma. They showed that, assuming so called variable setting of LLL, a natural randomized procedure called Resample[3] quickly finds an evaluation of involved random variables for which none of the bad events hold. They also proved that, in typical cases, the expected running time of the procedure is linear in the size of the instance. For the problem of two-coloring of k-uniform hypergraphs, the total expected number of resamplings is bounded by m/Δ (see Theorem 7 in [11]).

Adjusting constructive LLL to LCA model remains one of the most challenging problems in the area. It turns out, however, that previous results on algorithmization of Local Lemma can be adapted in the natural way. In fact, the first LCA algorithm for the hypergraph coloring from [21], is built on the variant of Beck's algorithm that is described in the book by Alon and Spencer [4]. That version works for $\alpha < 1/11$, and runs in polylogarithmic time per query. Later refinements focused on optimizing space and time requirements ([3], [16]), however, for polylogarithmic LCAs the bound on α has not been improved. In a recent work, Achlioptas, Gouleakis, and Iliopoulos [1] showed how to adjust Resample to LCA model. They did not manage, however, to obtain a polylogarithmic time. Their version answers queries in time $t(n) = n^{\beta(\alpha)}$. They establish some trade-off between the bound on α and the time needed to answer a query. In particular, when α approaches $1/2$ then $\beta(\alpha)$ tends to 1, which results in a very weak bound on the running time per query.

1.3 Main result

Our research focuses on the following general question in the area of local constructive versions of the Lovász Local Lemma: up to what value of α there exists a polylogarithmic LCA for the problem of two-coloring of k-uniform hypergraphs satisfying condition $2(\Delta + 1)\mathrm{e} < 2^{\alpha k}$. We prove the following theorem:

[3] As long as some bad events are violated, the procedure picks any such event and resamples all variables on which that event depends.

▶ **Theorem 1** (main result). *For every $\alpha < 1/3$ and all large enough k, there exists a local computation algorithm that, in polylogarithmic time per query, with probability $1 - O(1/n)$ solves the problem of two-coloring for k-uniform hypergraphs with maximum edge degree Δ, that satisfies $2\mathrm{e}(\Delta + 1) < 2^{\alpha k}$.*

Within the notation of [21] we present $(\mathrm{polylog}(n), \mathcal{O}(n), \mathcal{O}(1/n))$-local computation algorithm that properly colors hypergraphs that satisfy the above assumption. Our algorithm is not query oblivious. Moreover, typical methods of eliminating the dependence on the order of queried vertices do not seem to be applicable without sacrificing constant α. Consult the full version of this paper [8] for the complete proof of the theorem.

For comparison, Alon et al. [3] after Rubinfeld et al. [21] present a query oblivious $(\mathrm{polylog}(n), \mathrm{polylog}(n), \mathcal{O}(1/n))$-local computation algorithm working for hypergraphs satisfying

$$\begin{aligned} 16\,\Delta(\Delta-1)^3(\Delta+1) &< 2^{k_1}, \\ 16\,\Delta(\Delta-1)^3(\Delta+1) &< 2^{k_2}, \\ 2e(\Delta+1) &< 2^{k_3}, \end{aligned} \tag{2}$$

where k_1, k_2 and k_3 are positive integers such that $k = k_1 + k_2 + k_3$. These assumptions correspond to $\alpha < 1/11$.

The analysis of the LCA procedure from [3] guarantees only that the running time is of the order $\mathcal{O}\Big(\log^{\Delta}(n)\Big)$. Mansour et al. in [16] focus on improving time and space bounds within polylogarithmic class, removing the dependency on the maximal edge degree from the exponent. They obtain an LCA working in $\mathcal{O}\big(\log^4(n)\big)$ time and space, assuming that $k \geq 16\log(\Delta) + 19$, so it requires even stronger bound on α.

1.4 LOCAL distributed algorithms

The model of Local Computation Algorithms is related to the classical model of local distributed computations by Linial [14] (called LOCAL). For comparison of these two models, see work of Even, Medina, and Ron [10]. Chang and Pettie observed recently in [6] that within LOCAL model, the general problem of solving Local Lemma instances with a dependency graph of bounded degree is in some sense complete for a large class of problems (these are the problems which can be solved in sublogarithmic number of rounds). They also conjectured that for sufficiently strengthened condition of Local Lemma (like taking small enough α in (1)) there exists a distributed LOCAL algorithm that solves the problem in $\mathcal{O}(\log\log n)$ rounds. The straightforward simulation of such an algorithm within LCA framework would yield a procedure that, at least for fixed maximum degree, answers queries in polylogarithmic time.

Recently, progress towards this conjecture has been made by Fischer and Ghaffari [12], who proved that there exists an algorithm for Local Lemma instances that works in $2^{\mathcal{O}\left(\sqrt{\log\log n}\right)}$ rounds. The influence of the degree of underlying dependency graph on running time has been later improved by Ghaffari, Harris and Kuhn in [13]. In particular, for sufficiently constrained problem of hypergraph two-coloring, that result allows one to obtain an LCA procedure that answers queries in sublinear time. The time, however, would be superpolylogarithmic. Moreover, the necessary strengthening of Local Lemma assumptions appears to be much stronger than the one required to apply the result of Rubinfeld et al. [21].

The possibility of simulation of LOCAL algorithms within LCA model implies that if Chang and Pettie conjecture holds, then any problem satisfying sufficiently strengthened LLL conditions can be solved in LCA model in polylogarithmic time per query. We can therefore

formulate a weaker conjecture that for some α every such α-strengthened problem can be solved in LCA in polylogarithmic time per query. For the specific problem of hypergraph coloring, this property is known to hold. We can, however, ask what is the maximum such α for a fixed problem. That is precisely the general problem stated at the beginning of Section 1.3. It is interesting to note that our algorithms make essential use of the sequential nature of LCA. For that reason, they cannot be translated to $\mathcal{O}(\log \log n)$ LOCAL algorithms. This also illustrates an important difference between the models.

2 Main techniques and ideas of the proof

The algorithmic procedure of Beck [5] is divided into two phases. In the first one, which we call *the shattering phase*, it builds a random partial coloring that guarantees that a fraction of all edges are already properly colored. Moreover, the edges which are not yet taken care of have sufficiently many non-colored vertices to make sure that the partial coloring can be completed to a proper one. They also form connected components of logarithmic sizes which can be colored independently. Then, in the second phase, which we call *the final coloring phase*, an exhaustive search is used to complete the coloring of each component. This results in a sequential procedure with polynomial running time. In order to reduce the running time to almost linear, the shattering phase can be applied twice. Then, the final components w.h.p. are of size $\mathcal{O}(\log \log(n))$. The polylogarithmic LCA procedure for hypergraph coloring from [21] followed that approach and simulates locally two shattering phases and an exhaustive search when answering a single query. Division into these three phases is directly reflected in the conditions (2) required by the procedure.

While it is not known whether it is possible to design an LCA algorithm based solely on Resample, combining it with previous local algorithms brings significant improvements. It turns out that, within polylogarithmic time, after only one shattering phase, the coloring can be completed with the use of Resample. This simple modification, with slightly improved analysis, is sufficient to derive Theorem 1 for $\alpha \leq 1/4$. This is our first contribution. That procedure provides a reference point for explaining the intuitions and motivations that underlie the further improvements that we derive. In particular, we define a notion of *component-hypergraph* that allows for a more fine-grained analysis of the components of the residual hypergraph. For that reason, we present our base algorithm in detail in Section 3.

The first modification that we make in order to improve the base algorithm is that within the shattering phase we sample colors for all vertices. Then, for some vertices, the color is final, and for others, it is allowed to change the assigned color in the final coloring phase. Coloring all the vertices during the first phase somehow blurs the border between the shattering and final coloring phases. Its main purpose is to enable a more refined partition of the residual hypergraph into independent fragments. It also allows to determine some components of the residual hypergraph for which no recoloring would be necessary. This corresponds to a situation in which the first sampled colors in Resample happen to define a proper coloring. Altogether, we managed to significantly reduce the pessimistic size of the independent fragments colored in the final coloring phase, which enables further relaxation of the necessary conditions on α to $\alpha < 1/3$. The improved procedure is described in Section 4.

In order to analyze the procedures, we employ a common technique of associating some tree-like *witness structures* with components that require recoloring. Every such structure describes a collection of events associated with some edges of the hypergraph. All these events are determined by the colors assigned in the shattering phase. For the base algorithm, these structures are quite typical. However, in order to achieve the better bound on α, we

developed more sophisticated structures that are capable of tracking different kinds of events, which can also depend on the colors that are allowed to be recolored. Different kinds of events come with different bounds on probability. An important aspect of the analysis concerns amortization of different kinds of events within a single structure. The construction of these structures is our main technical contribution. Its detailed description can be found in the full version of this paper [8].

We finally note that, while our methods are not general enough to work for all instances satisfying the strengthened assumptions of LLL, they can be applied to a number of problems similar to hypergraph coloring, like, e.g. k-SAT.

3 Establishing base result

In this section we show how the Beck's algorithm can be combined with Resample to construct a local computation algorithm that works in polylogarithmic time per query for α up to $1/4$. In other words, we prove Theorem 1 under the stronger assumption that $\alpha \leq 1/4$. To keep the exposition simple, we first present a global randomized algorithm. Then, we comment on how to adapt this procedure to LCA model. The analysis of the procedure can be found in the full version of this paper [8].

Let $H = (V, E)$ be a hypergraph that satisfies the assumptions of Theorem 1 for a fixed $\alpha \leq 1/4$. For technical convenience, we assume that αk is an integer[4]. By assigning a random color, we mean choosing uniformly one of the two available colors. For a set of edges S, by $V(S)$ we mean all vertices covered by the edges from S. For an edge f, $N(f)$ denotes the set of edges intersecting f. We use a naming convention that is similar to other works on the subject – in particular, our view of Beck's algorithm is influenced by its descriptions by Alon and Spencer [4] and Molloy and Reed [17], as well as LCA realization given in [21].

3.1 Global coloring procedure

The algorithm starts with choosing an arbitrary order of vertices. Then, it proceeds in two phases: *the shattering phase* and *the final coloring phase*. The shattering phase colors some vertices of the input hypergraph and then splits the edges of the hypergraph that are not properly colored yet into *final components* – subhypergraphs that can be colored independently. The final coloring phase completes the coloring by considering the final components separately, one by one.

3.1.1 The shattering phase

The procedure processes vertices sequentially according to the fixed ordering. For every vertex, it either assigns a random color to the vertex or leave it non-colored in case it belongs to a *bad* edge. An edge is called *bad* if it contains $(1 - \alpha)k$ colored vertices and is still not colored properly (that is, all these vertices have the same color). Once an edge becomes bad, no more vertices from that edge will be colored – such vertices are called *troubled*. Vertices with assigned colors are called *accepted*.

Upon completion of the shattering phase, there are three types of edges:

- *safe edges* – properly colored by the accepted vertices,
- *bad edges* – containing exactly $(1 - \alpha)k$ accepted vertices, all of the same color,
- *unsafe edges* – containing fewer than $(1 - \alpha)k$ accepted vertices, all of the same color.

[4] In fact, for the given k it is only reasonable to take α in the form of t/k, where t is an integer $2 \leq t \leq k$.

Observe that in the resulting (partial) coloring, every edge that is not colored properly has at least αk troubled vertices, which will be colored in the next phase. Note also that it might happen that some unsafe edge has no colored vertices at all.

The colors of accepted vertices are not going to be changed, so the safe edges are already taken care of. Therefore, we focus on bad and unsafe edges. Let E_{bad} denote the set of all bad edges. Consider hypergraph $(V(E_{bad}), E_{bad})$. It is naturally decomposed into connected components.

▶ **Definition 2.** *Every component of the hypergraph* $(V(E_{bad}), E_{bad})$ *is called a* bad-component.

Note that every troubled vertex belongs to some bad-component. On top of them we build an abstract structure to express dependencies between bad-components through unsafe edges.

▶ **Definition 3.** *A* component-hypergraph *is constructed as follows: its vertices are bad-components of* H *and for every unsafe edge* f *intersecting more than one bad-component, an edge that contains all bad-components intersected by* f *is added to it.*

For each connected component of the component-hypergraph (that is, a maximal set of bad-components that is connected in the component-hypergraph) we construct a *final component* by taking the union of those bad-components (hence a final component is a subhypergraph of H). The shattering phase is *successful* if each final component contains at most $2(\Delta+1)\log(m)$ bad edges. If this is not the case, the procedure declares a failure. It turns out that this is very unlikely to happen.

3.1.2 The final coloring phase

For each final component $\mathcal{C}$ determined during the shattering phase, we add to $\mathcal{C}$ all unsafe edges intersecting it, and then, we restrict $\mathcal{C}$ to troubled vertices[5]. We obtain a hypergraph $\mathcal{C}'$ containing at most $2(\Delta+1)^2\log(m)$ edges, and each of them has at least αk vertices. The maximum edge degree in $\mathcal{C}'$ cannot be larger than Δ, which is the maximum edge degree in H. Since $2e(\Delta+1) < 2^{\alpha k}$ (by the assumptions of Theorem 1), Lovász Local Lemma ensures that $\mathcal{C}'$ is two-colorable. Hence, by the theorem of Moser and Tardos Resample finds a proper coloring of it using on average $|E(\mathcal{C}')|/\Delta$ resamplings (see Theorem 7 in [11]).

When the final coloring phase is over, all final components are properly colored. Since each bad or unsafe edge is dealt within some final component, and each safe edge was properly colored during the shattering phase, it is now guaranteed that the constructed coloring is proper for the whole H.

3.2 LCA realization

We employ quite standard techniques to obtain an LCA realization of the described algorithm. We articulate it below to provide a context for the description of our main algorithm. An important property of the described procedure is that the ordering of vertices does not have to be fixed a priori. In fact it can be even chosen in an on-line manner by an adversary. Following [21], we are going to exploit the freedom of choice of ordering. The LCA version of the algorithm is going to simulate the global version run with a specific ordering. That ordering is constructed dynamically during the evaluation and is driven by the queries. Apart

[5] Restriction of $H=(V,E)$ to $V'\subseteq V$ is defined as $H'=(V',\{e\cap V' |\ e\in E, e\cap V'\neq\emptyset\})$.

from some minor adjustment (resulting from adaptation to LCA model) when the algorithm is queried about vertex v, it performs all the work of the standard algorithm needed to assign a final color to v. The LCA version is presented in Listings 1, 2, 3, and 4. All colors assigned during work of the algorithm are stored in the computation memory (which is preserved between queries). For convenience, we also store there the status of each vertex – *uncolored*, *accepted* or *troubled*. Initially all vertices are uncolored.

Algorithm 1 LCA for uniform hypergraph coloring – main function.

```
1  Procedure QUERY(v - vertex):
2      if v is uncolored then
3          if all edges containing v are not bad then
4              assign a random color to v and mark it as accepted    // shattering
5          else mark v as troubled
6      if v is troubled then
7          C_v ← BUILD_FINAL_COMPONENT(v)                            // shattering
8          COLOR_FINAL_COMPONENT(C_v)                              // final coloring
9      return color assigned to v
```

3.2.1 query

When a vertex v has been already marked as accepted, its color is immediately returned. If it has not been processed before, the algorithm checks whether v belongs to any bad edge (that requires inspecting the current statuses of all the edges that contain v). If not, a random color is assigned to v, the vertex is marked as accepted, and the procedure returns the assigned color. On the other hand, when v belongs to a bad edge, it is marked as troubled. The algorithm then determines the final component containing v in procedure BUILD_FINAL_COMPONENT. These steps can be viewed as the shattering phase. Afterwards, the final coloring phase is performed for the final component in procedure COLOR_FINAL_COMPONENT.

Algorithm 2 Building the final component for v that belongs to some bad edge.

```
1  Procedure BUILD_FINAL_COMPONENT(v - troubled vertex):
2      B ← ∅                  // initialize set of bad edges of the component
3      U ← ∅                     // initialize set of unsafe edges to process
4      e ← any bad edge containing v
5      mark e as explored and run EXPAND_BAD_COMPONENT(e, B, U)
6      // process surrounding unsafe edges
7      while U is not empty do
8          f ← next edge from U (remove it from U)
9          EXPAND_VIA_UNSAFE(f, B, U)
10     // return hypergraph built on set of bad edges
11     return C = (V(B), B)
```

3.2.2 build_final_component

This procedure builds the set B of bad edges of the final component of v, exploring the line graph of H[6]. It uses a temporary flag *explored* to mark visited edges (this flag is not preserved between queries). The construction starts from a bad edge containing troubled vertex v and expands it to a bad-component. Then, as long as possible, set B is extended by edges of neighboring bad-components, which can be reached through unsafe edges adjacent to B. If at some point the number of bad edges in B exceeds the prescribed bound $2(\Delta+1)\log(m)$, then the procedure declares a failure (note that it cannot be restarted since LCA model does not allow to change colors returned for previous queries). Construction of the final component is done when there are no more bad edges to add. Then, the hypergraph $\mathcal{C} = (V(B), B)$ built on the collected bad edges is returned.

The expansion of bad-components is done within subprocedure `EXPAND_BAD_COMPONENT`. It starts from the given bad edge and explores the line graph by inspecting the adjacent edges. For each adjacent edge, its type (safe, unsafe, or bad) is determined using `DETERMINE_EDGE_STATUS`. Determining status of an edge may require processing some uncolored vertices of that edge. For each of them, the procedure check whether it is troubled. If it is not, a random color is assigned to the vertex and the vertex is marked as accepted.

Algorithm 3 Subprocedures for the final component construction.

```
1  Procedure EXPAND_BAD_COMPONENT(e - bad edge, B - bad edges, U - unsafe edges):
2      Q ← {e}                          // initialize set of bad edges to process
3      while Q is not empty do
4          f ← next edge from Q (remove it from Q)
5          add f to B and if |B| > 2(Δ + 1) log(m) then FAIL
6          for g ∈ N(f) which are not explored do
7              mark g as explored and DETERMINE_EDGE_STATUS(g)
8              if g is bad then add g to Q
9              if g is unsafe then add g to U
10
11 Procedure EXPAND_VIA_UNSAFE(f - unsafe edge, B - bad edges, U - unsafe edges):
12     for g ∈ N(f) which are not explored do
13         DETERMINE_EDGE_STATUS(g)
14         if g is bad then
15             mark g as explored and run EXPAND_BAD_COMPONENT(g, B, U)
16
17 Procedure DETERMINE_EDGE_STATUS(g - edge):
18     for each w in g that is uncolored unless g becomes safe do
19         if some edge containing w (including g) is bad then mark w as troubled
20         else assign a random color to w and mark it as accepted
21     count accepted vertices and check their colors to determine status of g
```

During the expansion through unsafe edges we keep a set U of not processed unsafe edges that intersects any edge of B. As long as U is not empty, we pick any unsafe f from U and process it by `EXPAND_VIA_UNSAFE`. Here we determine the statuses of all edges

[6] The line graph $L(H)$ is the graph built on $E(H)$ in which two distinct vertices (representing edges of H) are adjacent if the corresponding edges intersect.

adjacent to f and if we encounter a bad edge which is not in B, then we add it and expand a bad-component containing it. For technical convenience, during bad-component expansion we collect non-explored adjacent unsafe edges and add them to U.

Algorithm 4 Finding coloring inside the final component.

```
1  Procedure COLOR_FINAL_COMPONENT(C - hypergraph):
2      add to C all unsafe edges intersecting C
3      C' ← restriction of C to troubled vertices
4      t_e ← |E(C')|/Δ                    // expected time of one RESAMPLE trial
5      for trial = 1 to 2 log(m) do
6          // RESAMPLE with limited number of steps
7          assign random colors to V(C')
8          for step = 1 to 2t_e do
9              if there is monochromatic f ∈ E(C') then
10                 assign new random colors to all vertices of f
11             else
12                 // C' is properly colored
13                 mark all vertices of C' as accepted and return
14     FAIL
```

3.2.3 color_final_component

Final component $\mathcal{C}$ is extended with unsafe edges that intersect it. Then it is restricted to the set of its troubled vertices. The resulting hypergraph is denoted by $\mathcal{C}'$. The algorithm tries to find a proper coloring of $\mathcal{C}'$ using Resample procedure. To ensure polylogarithmic time, it is run only for the limited number of resampling steps. To decrease the probability of a failure, the procedure may be restarted a few times. When a proper coloring is found, each vertex of $\mathcal{C}'$ is marked as accepted. From now on, all edges of $\mathcal{C}$ are treated as safe. However, if all trials were unsuccessful, the procedure declares a failure.

4 Main result – algorithm

We show how to improve the base procedure described in the previous section to obtain an algorithm that can be used to prove Theorem 1, that is, an algorithm that works in polylogarithmic time per query on input hypergraphs that satisfy strengthened LLL condition (1) for $\alpha < 1/3$. Actually, our procedure can be used to find a proper coloring also for instances that satisfy that condition with any $\alpha \in (0, 1)$, but the running time is not guaranteed for $\alpha \geq 1/3$. We start with introducing the main ideas behind algorithm improvement and describe its global version. Then, we discuss how to adapt it to the model of the local computation algorithms, and finally we present a description of the LCA procedure. The analysis of the algorithm can be found in the full version of this paper [8].

4.1 A general idea

It is a common approach in randomized coloring algorithms to start from an initial random coloring and then make some correction to convert it to a proper one (like in Resample [20] or in Alon's parallel algorithm [2]). This is not the case of Beck's procedure, in which a

proper coloring is constructed incrementally, but coloring of some vertices (those marked as troubled) is postponed to the later phase. Our approach lies somewhere in between. We generally try to follow the latter one, but we sample colors for the troubled vertices already in the shattering phase. Such colors are considered as *proposed*, and we reserve the possibility of changing them in the final coloring phase. We use the information about the proposed colors to shrink the area that will be processed in the final coloring phase. In particular, if we look at the colors proposed for troubled vertices, then only those final components that contain a monochromatic edge require recoloring. Moreover, if we carefully track dependencies between bad-components (see Definition 2), it is also possible to decrease the sizes of the final components. We explain this idea in more detail in the following subsections.

4.1.1 Activation of bad-components

Imagine that all the vertices were colored in the shattering phase and we want to determine the final components. We look at the component-hypergraph (see Definition 3) and have to decide which of the bad-components should be recolored. We start from bad-components that are intersected by monochromatic edges - we mark them as *initially active* and treat them as seeds of final components. The remaining ones are currently *inactive*. Our intention is to recolor only active components in the final coloring phase. Note that it might not be sufficient to alter the coloring in a way that makes initially active components properly colored, because after their recoloring, it is possible that some unsafe edge which get both colors in the shattering phase becomes monochromatic. That is why the activation has to be propagated. We use the following *propagation rule*:

- let A_t be the set of troubled vertices that are covered by active bad-components, and f be an unsafe edge that intersects A_t; if $f \setminus A_t$ is monochromatic, then all inactive bad-components that intersect f become active and all bad-components that intersect f are merged into one (eventually final) component.

The above propagation rule is applied as long as possible. When it stops, it is guaranteed that all monochromatic edges are inside active components and all unsafe and bad edges outside of active components are properly colored by the vertices that are outside of active bad-components. In particular, we can accept all the colors proposed for inactive vertices.

4.1.2 Edge trimming

We employ an additional technique, which can further reduce the area of the final components. Observe that, in order to guarantee two-colorability of the final components, it is enough to ensure that each edge has at least αk vertices to recolor inside one final component. It means that if some active component already contains αk troubled vertices of some edge, then it is not necessary to propagate activation through that edge. Thus, we can improve the propagation rule in the following way. Consider an unsafe edge f for which $f \setminus A_t$ is monochromatic (recall that A_t denotes the set of currently active troubled vertices). If some active component contains at least αk troubled vertices of f, then f is trimmed to that active component. Otherwise, all bad-components intersected by f are activated and merged into one component (as described in the previous section).

We point out that the direct inspiration for this technique came from the work of Czumaj and Scheideler [7] in which the edge trimming is actively used during the construction of the area to be recolored. One of the consequences of using it is that the shapes of the final components depend on the specific order in which activation is propagated.

4.2 Global coloring procedure

Similarly to the base algorithm from Section 3.1, the improved procedure performs the shattering phase and then the final coloring phase. The former is modified according to the ideas described in the previous subsection. In particular, each vertex gets a color but we use the notions of *proposed* and *accepted* colors to distinguish colors that can be changed. The latter phase is almost the same. Pseudocode of the whole procedure can be found in Listing 5 in Appendix A.

4.2.1 The shattering phase

The procedure processes the vertices in a fixed order. For each vertex, it marks it as *accepted* or *troubled*, and then chooses a random color for it. A vertex is accepted if, at the time of processing, it does not belong to any of the bad edges. Otherwise, it is troubled. An edge becomes *bad* when its set of accepted vertices reaches size $(1-\alpha)k$ and is still monochromatic.

After processing all the vertices, *safe* and *unsafe* edges are determined in the same way as in the base algorithm. Additionally, by a *monochromatic* edge, we mean an edge for which all its vertices (accepted and troubled) have the same color. The colors of the accepted vertices are called *accepted colors*. The colors of the troubled vertices are called *proposed colors*. By accepting a color assigned to a vertex, we mean changing its status to accepted.

The next step involves determining the final components. We work with the component-hypergraph. We are going to mark some bad-components and unsafe edges as *active*. By an *active component*, we mean a maximal set of active bad-components which is connected in the component-hypergraph via active unsafe edges. We start with marking as active all monochromatic unsafe edges and all bad-components that are intersected by any (bad or unsafe) monochromatic edge. Let A_t denote the set of troubled vertices that are currently covered by active bad-components. Then, as long as there exists an inactive unsafe edge f satisfying the following conditions:

- f is monochromatic outside the active troubled area (i.e., $f \setminus A_t$ is monochromatic), and
- each active component contains less than αk troubled vertices of f,

we activate f and activate all bad-components intersected by f. When this propagation rule can no longer be applied, we accept the colors of all the troubled vertices from inactive bad-components. At that time, each active component determines a final component as the union of its bad-components. Just like in the base algorithm, the shattering phase is *successful* if each final component contains at most $2(\Delta+1)\log(m)$ bad edges. Otherwise, the procedure declares a failure.

4.2.2 The final coloring phase

We implement one modification at the beginning of the final coloring phase. For each final component $\mathcal{C}$, we add to $\mathcal{C}$ not all unsafe edges intersecting it, but only those that have at least αk troubled vertices in $V(\mathcal{C})$. Then, we proceed exactly as in the base algorithm: we restrict $\mathcal{C}$ to the troubled vertices and apply Resample.

4.3 Ideas behind LCA realization

In the base case, the conversion of the global algorithm to LCA is straightforward. In fact, the LCA version determines the same area to recolor (assuming that both versions process the vertices in the same order). For the improved algorithm described in the previous subsection, conversion to LCA is more complex and alters the behavior of the algorithm. The main

difficulty is that for a bad-component alone that is not initially active, it is not easy to quickly decide whether it is going to be activated or not. There might exist a long chain of activation leading to an activation of the considered bad-component, and we do not know in which direction to search for the sources of this eventual activation. Moreover, even if we find out that it will be activated, it is not obvious what the shape of the final component containing it will be, since it requires performing activation propagation and determining activation statuses of neighboring bad-components as well. To address these problems, when a troubled vertex of some bad-component is queried, we focus on finding an area containing that vertex that can be recolored independently from the remaining part of the input hypergraph. It means that from the beginning of the procedure the component of that vertex is treated as active and we allow trimming unsafe edges to that component. Moreover, we use additional techniques described below to limit the expansion of the processed area in a single query.

4.3.1 Trimming to bad-component

We extend edge trimming to the case when an unsafe edge f has at least αk troubled vertices in some bad-component S, and the set of those vertices together with the accepted vertices of f is not monochromatic. In such a case, f can be trimmed by removing from it the troubled vertices that do not belong to S. Note that we do not check here whether S is active or not. The idea behind this step is that from now on S is responsible for the proper coloring of f. If at some point, the colors of the vertices of S get accepted without any resamplings, then f will be obviously colored properly. Otherwise, if S becomes active, then f will be trimmed anyway, and S has enough troubled vertices of f to not break two-colorability of S.

4.3.2 Activation exclusion

The necessary condition for an inactive bad-component S to be activated is that there is an unsafe edge f whose accepted vertices and troubled vertices in $f \cap V(S)$ are of the same color. When there is no such edge or all such edges were trimmed to other components, then S cannot be activated. Therefore if it is not initially active, it stays inactive. In such a case, we can accept all the proposed colors for the vertices of S. As a result, some unsafe edges become properly colored, and we can treat them as safe. This, in turn, may enable proving that neighboring bad-components will also not be activated. The same reasoning can be applied to a set C of bad-components. If none of the bad-components in C is initially active and there are no unsafe edges intersecting some bad-component outside C that may activate bad-component from C, then we can conclude that all bad-components in C remain inactive.

4.3.3 Conditional expansion

The idea described in the previous subsection can be used for a bad-component to perform some kind of search for a potential reason of activation. If S_1 is not initially active, we inspect unsafe edges that may cause the activation of S_1. We can select any such f, and ask whether other bad-component S_2 intersected by f may become active. We can continue that procedure as long as there is a risk of activating any S_i from the group of bad-components visited so far. In the end, we either find some initially active component or we prove that all the considered bad-components cannot be activated. It turns out that, if we do not follow the edges that can be trimmed with the trimming to bad-component technique, then the processed area during such a search is unlikely to be large.

The possibility of finding an initially active bad-component can be used in expansion of the component to extend it by a neighboring area. For a selected bad-component adjacent to the currently constructed eventually final component, we launch a search and either we find

some monochromatic edge (initially active component) and extend the component with the whole searched area, or convince ourselves that this area cannot be activated. In the latter case we can simply accept the proposed colors in that area. In the former we can perform the expansion because the occurrence of a monochromatic edge, as an unlikely event, in a sense amortizes the expansion of the component. In fact, we can stop the search procedure not only when we find a monochromatic edge but also in a less restrictive case when we find an unsafe edge intersecting at least two disjoint bad edges outside the search area. This possibility follows from the technical details of the analysis.

4.4 LCA procedure

We describe the improved LCA procedure in reference to the base algorithm presented in Section 3.2. As previously, the ordering of the vertices is constructed dynamically and is driven by the queries and the work of the algorithm. For a set of edges S, by $V_t(S)$ we mean all troubled vertices in $V(S)$. For an edge f, we denote by $f|_t$ the set of troubled vertices of f, and by $f|_a$ the set of accepted vertices of f.

4.4.1 query

The main procedure is almost identical to its counterpart in the base algorithm (Listing 1). The only difference is that when processing a vertex v of a bad edge, it is not only marked as troubled, but also a random color is assigned to v.

4.4.2 build_final_component

This procedure is the heart of the algorithm and is substantially more complex than its analogue in the base version. It is presented in Listings 6 and 7 available in Appendix A. It also makes use of subprocedures defined earlier (see Listing 3), with one modification in `DETERMINE_EDGE_STATUS` – once a vertex w is marked as troubled, a random color is also assigned to w. As previously, the procedure works on the line graph of H and grows a set B of bad edges that will be converted to a final component at the end of the procedure. It always starts from the bad-component containing the queried vertex v, and expands it by neighbor bad-components via unsafe edges. The main change is that in the base algorithm each unsafe edge causes expansion of the component, here unsafe edges are processed more carefully. Throughout the procedure we make sure that the size of B does not exceed $2(\Delta+1)\log(m)$ bound on number of edges – if that happens, the procedure stops and declares a failure.

Let U be the set of not processed unsafe edges intersecting $V(B)$. If some edge can be trimmed to $V(B)$, it can be safely removed from U. Thus, we may assume that each f in U has fewer than αk troubled vertices in $V(B)$. Since every unsafe edge has more than αk troubled vertices, each f from U has to intersect at least one bad-component outside $V(B)$. The procedure applies the following *extension rules* as long as possible:

- (r1) if there exists f in U that intersects at least two disjoint bad edges outside B, or
- (r2) if there exists f in U for which all the vertices of f outside of $V_t(B)$ are monochromatic,

then B is extended with all bad edges from the bad-components intersected by f;

- (r3) if there are no edges in U that meet the conditions (r1) or (r2), but there exists f in U that has fewer than αk troubled vertices outside $V(B)$,

then call `EXPAND_OR_ACCEPT` procedure (described in the following subsection) for f, which implements the conditional expansion technique, and extend B with the returned set of bad edges (which may happen to be empty).

Note that, when there are no edges that meet conditions (r1) or (r2), then for any remaining f from U it is guaranteed that f intersects exactly one bad-component outside $V(B)$ and $f \setminus V_t(B)$ is not monochromatic. If such f does not satisfy condition (r3), it has at least αk troubled vertices in that external bad-component, so it can be trimmed to it (according to trimming to bad-component technique). Thus, f can be removed from U.

After each extension rule, the processed edge is removed from U. On the other hand, when B is extended, new unsafe edges may be added to U, but we remove those that can now be trimmed to $V(B)$. Since edges which do not fulfill any of the extension rules are also removed from U, finally U becomes empty and the procedure stops. At this point, B is a set of bad edges which are surrounded only by safe and trimmed unsafe edges.

4.4.3 expand_or_accept

This procedure is an implementation of the conditional expansion technique, through a given unsafe edge e. Similarly to BUILD_FINAL_COMPONENT, it grows a set A of bad edges, which we call a *search area*, and makes sure that its size does not exceed $2(\Delta+1)\log(m)$ bound (if that happens, the whole algorithm stops and declares a failure). Initially, A is empty. Then it becomes expanded by bad-components which may lead to initially active bad-component, starting from the not explored bad-component intersected by e. The expansion naturally stops when there are no more candidate bad-components. The procedure, however, can also stop earlier in case when some monochromatic edge or unsafe edge intersecting two disjoint not explored bad edges is found.

Let Q be the set of unsafe edges to be processed (initially it is empty). Let C be the set of bad edges of the currently expanded bad-component. Let U_C denote the set of unsafe edges intersecting $V(C)$ but not adjacent to the edges of B and A (these are simply those unsafe edges adjacent to the edges in C that were not explored before expansion of C). The procedure extends A with all edges from C, and then looks for the following *amortizing configuration*:

- (e1) if C contains monochromatic edge f

then the procedure stops and returns set A;

- (e2) if U_C contains a monochromatic edge f, or
- (e3) if U_C contains an edge f, which intersects at least two disjoint bad edges outside C,

then first set A is extended with all the bad edges of the bad-components intersected by f, and then the procedure stops and returns A.

When no such configuration is found, all unsafe edges in U_C are not monochromatic and, moreover, each intersects at most one bad-component outside A. We focus on the edges from U_C that can cause an activation of C – these are the edges whose troubled vertices in $V(C)$ together with accepted vertices are monochromatic. Each such an edge f has to intersect exactly one external bad-component and troubled vertices of that component together with $f|_a$ ensure a proper coloring of f. If there are at least αk troubled vertices of f in that external bad-component, f can be trimmed to it (according to the technique of trimming to bad-component). That is why we add to Q only those edges from U_C that may cause activation of C and have fewer than αk troubled vertices outside of $V(C)$.

When processing of C is finished, we pick any edge from Q (the set of unsafe edges to be processed) and repeat the above steps for the external bad-component intersected by the selected edge. It may happen that this component has already been added to A, in a such case the procedure continues picking edges from Q. When the procedure finishes without encountering amortizing configuration, there are no monochromatic edges in A and all unsafe edges intersecting $V(A)$ are either properly colored by the colors of the accepted vertices and

the vertices from $V_t(A)$, or are trimmed to bad-components outside it. Thus, an activation of whole A is excluded. Then we mark all vertices in $V_t(A)$ as accepted and treat edges properly colored by their colors as safe. In that case, the procedure returns the empty set.

Note that during this procedure, we do not apply edge trimming to $V(A)$ when it covers at least αk troubled vertices of some unsafe edge, since it can result in a false activation (in case the edge is monochromatic inside $V(A)$). We also ignore all unsafe edges intersecting $V(B)$ (they were explored before call to `EXPAND_OR_ACCEPT`) since, due to not satisfying (r1) and (r2) they cannot be used in an amortizing configuration or cause an activation (it is guaranteed that they are not monochromatic outside $V_t(B)$).

4.4.4 color_final_component

The last procedure is almost identical to its counterpart in the base algorithm (Listing 4). Recall that the only change is at the beginning of the procedure. Instead of extending $\mathcal{C}$ with all unsafe edges intersecting it, only those unsafe edges that have at least αk troubled vertices in $V(\mathcal{C})$ are added. Then we proceed as in the base algorithm.

4      U_s ← ∅                  // unprocessed unsafe edges able to launch search
5      e ← any bad edge containing v
6      mark e as explored and run EXPAND_BAD_COMPONENT(e, B, U)
7      // process surrounding unsafe edges according to extension rules
8      while U ≠ ∅ or U_s ≠ ∅ do
9          while U is not empty do
10             f ← next edge from U (remove it from U)
11             if f has < αk troubled vertices in V(B) then
12                 if f satisfies rule (r1) or (r2) then
13                     EXPAND_VIA_UNSAFE(f, B, U)
14                 else if f can satisfy rule (r3) then
15                     add f to U_s        // f \ V(B) has < αk troubled vertices
16         if U_s is not empty then
17             f ← next edge from U_s (remove it from U_s)
18             if f has < αk troubled vertices in V(B) then
19                 // f satisfies rule (r3)
20                 (A, U_A) ← EXPAND_OR_ACCEPT(f, B, U)
21                 B = B ∪ A and if |B| > 2(Δ + 1) log(m) then FAIL
22                 U = U ∪ U_A
23     // return hypergraph built on set of bad edges
24     return C = (V(B), B)
```

A.3 Listing of expand_or_accept (LCA)

Algorithm 7 Conditional expansion via unsafe edge e (exploring a search area).

```
1  Procedure EXPAND_OR_ACCEPT(e - unsafe edge):
2      A ← ∅                    // initialize set of bad edges of the search area
3      U_A ← ∅                  // initialize set of unsafe edges around search area
4      Q ← {e}                  // unprocessed unsafe edges allowing expansion
5      // process selected surrounding unsafe edges
6      while Q is not empty do
7          f ← next edge from Q (remove it from Q)
8          // expand with the external component to which leads f
9          (C, U_C) ← (∅, ∅)
10         EXPAND_VIA_UNSAFE(f, C, U_C)
11         A = A ∪ C and if |A| > 2(Δ + 1) log(m) then FAIL
12         U_A = U_A ∪ U_C
13         // inspect new edges - look for amortizing configuration
14         if (e1) is satisfied (there is a monochromatic edge in C) then
15             return (A, U_A)
16         else if there is an unsafe edge f in U_C satisfying (e2) or (e3) then
17             EXPAND_VIA_UNSAFE(f, A, U_A)
18             return (A, U_A)
19         // select edges that may cause an activation
20         else
21             for g in U_C do
22                 if g|_a ∪ (g|_t ∩ V(C)) is monochromatic then
23                     if g \ V(C) has < αk troubled vertices then add g to Q
24     // activation exclusion
25     mark all troubled vertices in V(A) as accepted
26     return (∅, ∅)
```

An EPTAS for Budgeted Matching and Budgeted Matroid Intersection via Representative Sets

Ilan Doron-Arad
Computer Science Department, Technion, Haifa, Israel

Ariel Kulik
CISPA Helmholtz Center for Information Security, Saarbrücken, Germany

Hadas Shachnai
Computer Science Department, Technion, Haifa, Israel

Abstract

We study the budgeted versions of the well known matching and matroid intersection problems. While both problems admit a *polynomial-time approximation scheme (PTAS)* [Berger et al. (Math. Programming, 2011), Chekuri, Vondrák and Zenklusen (SODA 2011)], it has been an intriguing open question whether these problems admit a *fully* PTAS (FPTAS), or even an *efficient* PTAS (EPTAS).

In this paper we answer the second part of this question affirmatively, by presenting an EPTAS for budgeted matching and budgeted matroid intersection. A main component of our scheme is a construction of *representative sets* for desired solutions, whose cardinality depends only on ε, the accuracy parameter. Thus, enumerating over solutions within a representative set leads to an EPTAS. This crucially distinguishes our algorithms from previous approaches, which rely on *exhaustive* enumeration over the solution set.

1 Introduction

A wide range of NP-hard combinatorial optimization problems can be formulated as follows. We are given a ground set E and a family $\mathcal{M}$ of subsets of E called the *feasible sets*. The elements in the ground set are associated with a cost function $c : E \to \mathbb{R}_{\geq 0}$ and a profit function $p : E \to \mathbb{R}$, and we are also given a budget $\beta \in \mathbb{R}_{\geq 0}$. A *solution* is a feasible set $S \in \mathcal{M}$ of bounded cost $c(S) \leq \beta$.[1] Generally, the goal is to find a solution S of maximum profit, that is:

$$\max p(S) \text{ s.t. } S \in \mathcal{M}, c(S) \leq \beta. \tag{1}$$

[1] For a function $f : A \to \mathbb{R}$ and a subset of elements $C \subseteq A$, we define $f(C) = \sum_{e \in C} f(e)$.

Notable examples include shortest weight-constrained path [7], constrained minimum spanning trees [16], and knapsack with a conflict graph [15]. In this work, we focus on two prominent problems which can be formulated as (1).

In the *budgeted matching (BM)* problem we are given an undirected graph $G = (V, E)$, profit and cost functions on the edges $p, c : E \to \mathbb{R}_{\geq 0}$, and a budget $\beta \in \mathbb{R}_{\geq 0}$. A *solution* is a *matching* $S \subseteq E$ in G such that $c(S) \leq \beta$. The goal is to find a solution S such that the total profit $p(S)$ is maximized. Observe that BM can be formulated using (1), by letting $\mathcal{M}$ be the set of matchings in G.

In the *budgeted matroid intersection (BI)* problem we are given two matroids $(E, \mathcal{I}_1)$ and $(E, \mathcal{I}_2)$ over a ground set E, profit and cost functions on the elements $p, c : E \to \mathbb{R}_{\geq 0}$, and a budget $\beta \in \mathbb{R}_{\geq 0}$. Each matroid is given by a membership oracle. A *solution* is a *common independent set* $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ such that $c(S) \leq \beta$; the goal is to find a solution S of maximum total profit $p(S)$. The formulation of BI as (1) follows by defining the feasible sets as all common independent sets $\mathcal{M} = \mathcal{I}_1 \cap \mathcal{I}_2$.

Let $\mathrm{OPT}(I)$ be the value of an optimal solution for an instance I of a maximization problem Π. For $\alpha \in (0, 1]$, we say that $\mathcal{A}$ is an α-approximation algorithm for Π if, for any instance I of Π, $\mathcal{A}$ outputs a solution of value at least $\alpha \cdot \mathrm{OPT}(I)$. A *polynomial-time approximation scheme* (PTAS) for Π is a family of algorithms $(A_\varepsilon)_{\varepsilon > 0}$ such that, for any $\varepsilon > 0$, A_ε is a polynomial-time $(1 - \varepsilon)$-approximation algorithm for Π. As ε gets smaller, a running time of the form $n^{\Theta\left(\frac{1}{\varepsilon}\right)}$ for a PTAS may become prohibitively large and thus impractical; therefore, it is natural to seek approximation schemes with better running times. Two families of such schemes have been extensively studied: an *efficient PTAS* (EPTAS) is a PTAS $(A_\varepsilon)_{\varepsilon > 0}$ whose running time is of the form $f\left(\frac{1}{\varepsilon}\right) \cdot n^{O(1)}$, where f is an arbitrary computable function, and n is the bit-length encoding size of the input instance. In a *fully PTAS* (FPTAS) the running time of A_ε is of the form $\left(\frac{n}{\varepsilon}\right)^{O(1)}$. For comprehensive surveys on approximation schemes see, e.g., [18, 19].

The state of the art for BM and BI is a PTAS developed by Berger et al. [1]. Similar results for both problems follow from a later work of Chekuri et al. [3] for the multi-budgeted variants of BM and BI. The running times of the above schemes are dominated by exhaustive enumeration which finds a set of $\Theta\left(\frac{1}{\varepsilon}\right)$ elements of highest profits in the solution. In this paper we optimize the enumeration procedure by substantially reducing the size of the domain over which we seek an efficient solution. Our main results are the following.

▶ **Theorem 1.** *There is an* EPTAS *for the budgeted matching problem.*

▶ **Theorem 2.** *There is an* EPTAS *for the budgeted matroid intersection problem.*

1.1 Related Work

BM and BI are immediate generalizations of the classic 0/1-knapsack problem. While the knapsack problem is known to be NP-hard, it admits an FPTAS. This raises a natural question whether BM and BI admit an FPTAS as well. The papers [1, 3] along with our results can be viewed as first steps towards answering this question.

Berger et al. [1] developed the first PTAS for BM and BI. Their approach includes an elegant combinatorial algorithm for *patching* two solutions for the *Lagrangian relaxation* of the underlying problem (i.e., BM or BI); one solution is feasible but has small profit, while the other solution has high profit but is infeasible. The scheme of [1] enumerates over solutions containing only high profit elements and uses the combinatorial algorithm to add low profit elements. This process may result in losing (twice) the profit of a low profit element, leading to a PTAS.

Chekuri et al. [3] developed a PTAS for multi-budgeted matching and a randomized PTAS for multi-budgeted matroid intersection; these are variants of BM and BI, respectively, in which the costs are d-dimensional, for some constant $d \geq 2$. They incorporate a non-trivial martingale based analysis to derive the results, along with enumeration to facilitate the selection of profitable elements for the solution. The paper [3] generalizes a previous result of Grandoni and Zenklusen [8], who obtained a PTAS for multi-budgeted matching and multi-budgeted matroid intersection in *representable matroids*.[2] For $d \geq 2$, the multi-budgeted variants of BM and BI generalize the two-dimensional knapsack problem, and thus do not admit an EPTAS unless W[1] = FPT [11].

An evidence for the difficulty of attaining an FPTAS for BM comes from the *exact* variant of the problem. In this setting, we are given a graph $G = (V, E)$, a cost function $c : E \to \mathbb{R}_{\geq 0}$, and a *target* $B \in \mathbb{R}_{\geq 0}$; the goal is to find a perfect matching $S \subseteq E$ with exact specified cost $c(S) = B$. There is a randomized pseudo-polynomial time algorithm for exact matching [13]. On the other hand, it is a long standing open question whether exact matching admits a deterministic pseudo-polynomial time algorithm [14]. Interestingly, as noted by Berger et al. [1], a deterministic FPTAS for BM would give an affirmative answer also for the latter question. A deterministic FPTAS for BI would have similar implications for the *exact* matroid intersection problem, which admits a randomized (but not a deterministic) pseudo-polynomial time algorithm for linear matroids [2]. While the above does not rule out the existence of an FPTAS for BM or BI, it indicates that improving our results from EPTAS to FPTAS might be a difficult task.

For the budgeted matroid independent set (i.e., the special case of BI with two identical matroids), the paper [6] gives an EPTAS using *representative sets* to enhance enumeration over elements of high profits. Their scheme exploits integrality properties of matroid polytopes under budget constraints (introduced in [8]) to efficiently combine elements of low profit into the solution.

1.2 Contribution and Techniques

Given an instance I of BM or BI, we say that an element e is *profitable* if $p(e) > \varepsilon \cdot \mathrm{OPT}(I)$; otherwise, e is *non-profitable*. The scheme for BM and BI of Berger et al. [1] distinguishes between profitable and non-profitable elements. In the main loop, the algorithm enumerates over all potential solutions containing only profitable elements.[3] Each solution is extended to include non-profitable elements using a combinatorial algorithm. The algorithm outputs a solution of highest profit. Overall, this process may lose at most twice the profit of a non-profitable element compared to the optimum, effectively preserving the approximation guarantee; however, an exhaustive enumeration over the profitable elements renders the running time $n^{\Omega(\frac{1}{\varepsilon})}$. In stark contrast, in this paper we introduce a new approach which enhances the enumeration over profitable elements, leading to an EPTAS.

We restrict the enumeration to only a small subset of elements called *representative set*; that is, a subset of elements $R \subseteq E$ satisfying the following property: there is a solution S such that the profitable elements in S are a subset of R, and the profit of S is at least $(1-O(\varepsilon))\cdot\mathrm{OPT}(I)$. If one finds efficiently a representative set R of cardinality $|R| \leq f\left(\frac{1}{\varepsilon}\right)$ for some computable function f, obtaining an EPTAS is straightforward based on the approach of [1].

[2] Representable matroids are also known as *linear matroids*.
[3] A similar technique is used also by Chekuri et al. [3].

Our scheme generalizes the *representative set* framework in [6], developed originally for budgeted matroid independent set. In [6], a representative set is a basis of minimum cost of a matroid, which can be found using a greedy algorithm. Alas, a greedy analogue for the setting of matching and matroid intersection fails; we give an example in Figure 1.[4] Hence, we take a different approach. Our main technical contribution is in the construction of representative sets for each of our problems.

For BM we design a surprisingly simple algorithm which finds a representative set using a union of multiple matchings. To this end, we partition the edges in G into *profit classes* such that each profit class contains edges of *similar* profits. We then use the greedy approach to repeatedly find in each profit class a union of disjoint matchings, where each matching has a bounded cardinality and is greedily selected to minimize cost. Intuitively, to show that the above yields a representative set, consider a profitable edge e in some optimal solution. Suppose that e is not chosen in our union of matchings, then we consider two cases. If each matching selected in the profit class of e contains an edge that is adjacent to (i.e., shares a vertex with) e, we show that at least one of these edges can be exchanged with e; otherwise, there exists a matching with no edge adjacent to e. In this case, we show that our greedy selection guarantees the existence of an edge in this matching which can be exchanged with e, implying the above is a representative set (see the details in Section 4).

For BI, we design a recursive algorithm that relies on an *asymmetric interpretation* of the two given matroids. We have learnt recently that a similar and more powerful construction was already proposed in [9]; we include the full details for completeness. In each recursive call of the algorithm, we are given an independent set $S \in \mathcal{I}_1$. The algorithm adds to the constructed representative set a minimum cost basis B_S of the second matroid $(E, \mathcal{I}_2)$, with the crucial restriction that any element $e \in B_S$ must satisfy $S \cup \{e\} \in \mathcal{I}_1$. Succeeding recursive calls will then use the set $S \cup \{e\}$, for every $e \in B_S$. Thus, we limit the search space to $\mathcal{I}_1$, while bases are constructed w.r.t. $\mathcal{I}_2$. To show that the algorithm yields a representative set, consider a profitable element f in an optimal solution. We construct a sequence of elements which are independent w.r.t. $\mathcal{I}_1$ and can be exchanged with f w.r.t. $\mathcal{I}_2$. Using matroid properties we show that one of these elements can be exchanged with f w.r.t. both matroids (see the details in Section 5).

Interestingly, our framework for solving BM and BI (presented in Section 3) can be extended to solve other problems formulated as (1) which possess similar *exchange properties*. We elaborate on that in Section 6.

Organization of the paper. In Section 2 we give some definitions and notation. Section 3 presents our framework that yields an EPTAS for each of the problems. In Sections 4 and 5 we describe the algorithms for constructing representative sets for BM and BI, respectively. We conclude in Section 6 with a summary and some directions for future work. Due to space constraints, some of the proofs are given in the full version of the paper [5].

2 Preliminaries

For simplicity of the notation, for any set A and an element e, we use $A + e$ and $A - e$ to denote $A \cup \{e\}$ and $A \setminus \{e\}$, respectively. Also, for any $k \in \mathbb{R}$ let $[k] = \{1, 2, \ldots, \lfloor k \rfloor\}$. For a function $f : A \to \mathbb{R}_{\geq 0}$ and a subset of elements $C \subseteq A$, let $f|_C : C \to \mathbb{R}_{\geq 0}$ be the *restriction* of f to C, such that $\forall e \in C : f|_C(e) = f(e)$.

[4] The example becomes clear once the reader is familiar with the definitions given in Section 3.

2.1 Matching and Matroids

Given an undirected graph $G = (V, E)$, a *matching* of G is a subset of edges $M \subseteq E$ such that each vertex appears as an endpoint in at most one edge in M, i.e., for all $v \in V$ it holds that $|\{\{u, v\} \in M \mid u \in V\}| \leq 1$. We denote by $V(M) = \{v \in V \mid \exists u \in V \text{ s.t. } \{u, v\} \in M\}$ the set of endpoints of a matching M of G.

Let E be a finite ground set and $\mathcal{I} \subseteq 2^E$ a non-empty set containing subsets of E called the *independent sets* of E. Then $\mathcal{M} = (E, \mathcal{I})$ is a *matroid* if it satisfies the following.

1. (Hereditary Property) For all $A \in \mathcal{I}$ and $B \subseteq A$, it holds that $B \in \mathcal{I}$.
2. (Exchange Property) For any $A, B \in \mathcal{I}$ where $|A| > |B|$, there is $e \in A \setminus B$ such that $B + e \in \mathcal{I}$.

A *basis* of a matroid $\mathcal{G} = (E, \mathcal{I})$ is an independent set $B \in \mathcal{I}$ such that for all $e \in E \setminus B$ it holds that $B + e \notin \mathcal{I}$. Given a cost function $c : E \to \mathbb{R}_{\geq 0}$, we say that a basis B of $\mathcal{G}$ is a *minimum* basis of $\mathcal{G}$ w.r.t. c if, for any basis A of $\mathcal{G}$ it holds that $c(B) \leq c(A)$. A minimum basis of $\mathcal{G}$ w.r.t. c can be easily constructed in polynomial-time using a greedy approach (see, e.g., [4]). In the following we define several matroid operations. Note that the structures resulting from the operations outlined in Definition 3 are matroids (see, e.g., [17]).

▶ **Definition 3.** *Let $\mathcal{G} = (E, \mathcal{I})$ be a matroid.*

1. *(restriction) For any $F \subseteq E$ define $\mathcal{I}_{\cap F} = \{A \in \mathcal{I} \mid A \subseteq F\}$ and $\mathcal{G} \cap F = (F, \mathcal{I}_{\cap F})$.*
2. *(thinning) For any $F \in \mathcal{I}$ define $\mathcal{I}/F = \{A \subseteq E \setminus F \mid A \cup F \in \mathcal{I}\}$ and $\mathcal{G}/F = (E \setminus F, \mathcal{I}/F)$.*[5]
3. *(truncation) For any $q \in \mathbb{N}$ define $\mathcal{I}_{\leq q} = \{A \in \mathcal{I} \mid |A| \leq q\}$ and $[\mathcal{G}]_{\leq q} = (E, \mathcal{I}_{\leq q})$.*

2.2 Instance Definition

We give a unified definition for instances of budgeted matching and budgeted matroid intersection. Given a ground set E of elements, we say that $\mathcal{C}$ is a *constraint* of E if one of the following holds.

- $\mathcal{C} = (V, E)$ is a *matching constraint*, where $\mathcal{C}$ is an undirected graph. Let $\mathcal{M}(\mathcal{C}) = \{M \subseteq E \mid M \text{ is a matching in } \mathcal{C}\}$ be the *feasible sets* of $\mathcal{C}$. Given a subset of edges $F \subseteq E$, let $E/F = \{\{u, v\} \in E \mid u, v \notin V(F)\}$ be the *thinning* of F on E, and let $\mathcal{C}/F = (V, E/F)$ be the *thinning* of F on $\mathcal{C}$.
- $\mathcal{C} = (\mathcal{I}_1, \mathcal{I}_2)$ is a *matroid intersection constraint*, where $(E, \mathcal{I}_1)$ and $(E, \mathcal{I}_2)$ are matroids. Throughout this paper, we assume that each of the matroids is given by an independence oracle. That is, determining whether $F \subseteq E$ belongs to $\mathcal{I}_1$ or to $\mathcal{I}_2$ requires a single call to the corresponding oracle of $\mathcal{I}_1$ or $\mathcal{I}_2$, respectively. Let $\mathcal{M}(\mathcal{C}) = \mathcal{I}_1 \cap \mathcal{I}_2$ be the collection of *feasible sets* of $\mathcal{C}$. In addition, given some $F \subseteq E$, let $\mathcal{C}/F = (\mathcal{I}_1/F, \mathcal{I}_2/F)$ be the *thinning* of F on $\mathcal{C}$. We say that $\mathcal{C}$ is a *single matroid constraint* if $\mathcal{I}_1 = \mathcal{I}_2$

When understood from the context, we simply use $\mathcal{M} = \mathcal{M}(\mathcal{C})$. Define an instance of the *budgeted constrained (BC)* problem as a tuple $I = (E, \mathcal{C}, c, p, \beta)$, where E is a ground set of elements, $\mathcal{C}$ is a constraint of E, $c : E \to \mathbb{R}_{\geq 0}$ is a cost function, $p : E \to \mathbb{R}_{\geq 0}$ is a profit function, and $\beta \in \mathbb{R}_{\geq 0}$ is a budget. If $\mathcal{C}$ is a matching constraint then I is a BM instance; otherwise, I is a BI instance. A *solution* of I is a feasible set $S \in \mathcal{M}(\mathcal{C})$ such that $c(S) \leq \beta$. The objective is to find a solution S of I such that $p(S)$ is maximized. Let $|I|$ denote the encoding size of a BC instance I, and $\text{poly}(|I|)$ be a polynomial size in $|I|$.

[5] Thinning is generally known as contraction; we use the term thinning to avoid confusion with edge contraction in graphs.

3 The Algorithm

In this section we present an EPTAS for the BC problem. Our first step is to determine the set of *profitable* elements in the constructed solution.[6] To this end, we generalize the *representative set* notion of [6] to the setting of BC. Our scheme relies on initially finding a set of profitable elements of small cardinality, from which the most profitable elements are selected for the solution using enumeration. Then, *non-profitable* elements are added to the solution using techniques of [1].

For the remainder of this section, fix a BC instance $I = (E, \mathcal{C}, c, p, \beta)$ and an error parameter $0 < \varepsilon < \frac{1}{2}$. Let $H(I, \varepsilon) = \{e \in E \mid p(e) > \varepsilon \cdot \mathrm{OPT}(I)\}$ be the set of *profitable* elements in I, and $E \setminus H(I, \varepsilon)$ the set of *non-profitable* elements; when understood from the context, we use $H = H(I, \varepsilon)$. Now, a representative set is a subset of elements which contains the profitable elements of an *almost* optimal solution. Formally,

▶ **Definition 4.** *Let $I = (E, \mathcal{C}, c, p, \beta)$ be a* BC *instance, $0 < \varepsilon < \frac{1}{2}$ and $R \subseteq E$. We say that R is a* representative set *of I and ε if there is a solution S of I such that the following holds.*

1. $S \cap H \subseteq R$.
2. $p(S) \geq (1 - 4\varepsilon) \cdot \mathrm{OPT}(I)$.

The work of [6] laid the foundations for the following notions of *replacements* and *strict representative sets (SRS)*, for the special case of BC where $\mathcal{C}$ is a single matroid constraint. Below we generalize the definitions of replacements and SRS.

Intuitively, a replacement of a solution S for I of bounded cardinality is another solution for I which preserves the attributes of the profitable elements in S (i.e., $S \cap H$). In particular, the profit of the replacement is close to $p(S \cap H)$, whereas the cost and the number of profitable elements can only be smaller. An SRS is a subset of elements containing a replacement for any solution for I of bounded cardinality.

The formal definitions of replacement and SRS for general BC instances are given in Definitions 5 and 6, respectively. Let $q(\varepsilon) = \left\lceil \varepsilon^{-\varepsilon^{-1}} \right\rceil$, and $\mathcal{M}_{\leq q(\varepsilon)} = \{A \in \mathcal{M} \mid |A| \leq q(\varepsilon)\}$ be all *bounded feasible sets* of $\mathcal{C}$ and ε. Recall that we use $\mathcal{M} = \mathcal{M}(\mathcal{C})$ for the feasible sets of $\mathcal{C}$; similar simplification in notation is used also for bounded feasible sets.

▶ **Definition 5.** *Given a* BC *instance $I = (E, \mathcal{C}, c, p, \beta), 0 < \varepsilon < \frac{1}{2}$, $S \in \mathcal{M}_{\leq q(\varepsilon)}$, and $Z_S \subseteq E$, we say that Z_S is a* replacement *of S for I and ε if the following holds:*

1. $(S \setminus H) \cup Z_S \in \mathcal{M}_{\leq q(\varepsilon)}$.
2. $c(Z_S) \leq c(S \cap H)$.
3. $p((S \setminus H) \cup Z_S) \geq (1 - \varepsilon) \cdot p(S)$.
4. $|Z_S| \leq |S \cap H|$.

▶ **Definition 6.** *Given a* BC *instance $I = (E, \mathcal{C}, c, p, \beta), 0 < \varepsilon < \frac{1}{2}$, and $R \subseteq E$, we say that R is a* strict representative set (SRS) *of I and ε if, for any $S \in \mathcal{M}_{\leq q(\varepsilon)}$, there is a replacement $Z_S \subseteq R$ of S for I and ε.*

Observe that given any solution S of I such that $|S| \leq q(\varepsilon)$, it holds that $S \cap H$ is a replacement of S; also, E is an SRS. In the next result, we demonstrate the power of SRS in solving BC. Specifically, we show that any SRS $R \subseteq E$ is also a representative set. Hence, using enumeration on subsets of R we can find a subset of elements that can be extended by only non-profitable elements to an *almost* optimal solution (see Algorithm 2).

[6] A similar approach is used, e.g., in [8, 1, 6].

▶ **Lemma 7.** *Let $I = (E, \mathcal{C}, c, p, \beta)$ be a* BC *instance, let $0 < \varepsilon < \frac{1}{2}$, and let R be an* SRS *of I and ε. Then R is a representative set of I and ε.*

The proof of Lemma 7 is given in [5]. We proceed to construct an SRS whose cardinality depends only on ε. First, we partition the profitable elements (and possibly some more elements) into a small number of *profit classes*, where elements from the same profit class have *similar* profits. The profit classes are derived from a 2-approximation α for $\mathrm{OPT}(I)$, which can be easily computed in polynomial time. Specifically, for all $r \in [\log_{1-\varepsilon}\left(\frac{\varepsilon}{2}\right) + 1]$ define the *r-profit class* as

$$\mathcal{K}_r(\alpha) = \left\{ e \in E \;\middle|\; \frac{p(e)}{2 \cdot \alpha} \in \left((1-\varepsilon)^r, (1-\varepsilon)^{r-1}\right] \right\}. \tag{2}$$

In the following we give a definition of an *exchange set* for each profit class. This facilitates the construction of an SRS. In words, a subset of elements X is an exchange set for some profit class $\mathcal{K}_r(\alpha)$ if any feasible set Δ and element $a \in (\Delta \cap \mathcal{K}_r(\alpha)) \setminus X$ can be replaced (while maintaining feasibility) by some element $b \in (X \cap \mathcal{K}_r(\alpha)) \setminus \Delta$, such that the cost of b is no larger than the cost of a. Formally,

▶ **Definition 8.** *Let $I = (E, \mathcal{C}, c, p, \beta)$ be a* BC *instance, $0 < \varepsilon < \frac{1}{2}$, $\frac{\mathrm{OPT}(I)}{2} \leq \alpha \leq \mathrm{OPT}(I)$, $r \in [\log_{1-\varepsilon}\left(\frac{\varepsilon}{2}\right) + 1]$, and $X \subseteq \mathcal{K}_r(\alpha)$. We say that X is an* exchange set *for I, ε, α, and r if:*

- *For all $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$ and $a \in (\Delta \cap \mathcal{K}_r(\alpha)) \setminus X$ there is $b \in (\mathcal{K}_r(\alpha) \cap X) \setminus \Delta$ satisfying*
  - *$c(b) \leq c(a)$.*
  - *$\Delta - a + b \in \mathcal{M}_{\leq q(\varepsilon)}$.*

The similarity between SRS and exchange sets is not coincidental. We show that if a set $R \subseteq E$ satisfies that $R \cap \mathcal{K}_r(\alpha)$ is an exchange set for any $r \in [\log_{1-\varepsilon}\left(\frac{\varepsilon}{2}\right) + 1]$, then R is an SRS, and thus also a representative set by Lemma 7. This allows us to construct an SRS using a union of disjoint exchange sets, one for each profit class.

▶ **Lemma 9.** *Let $I = (E, \mathcal{C}, c, p, \beta)$ be a* BC *instance, $0 < \varepsilon < \frac{1}{2}$, $\frac{\mathrm{OPT}(I)}{2} \leq \alpha \leq \mathrm{OPT}(I)$ and $R \subseteq E$. If for all $r \in [\log_{1-\varepsilon}\left(\frac{\varepsilon}{2}\right) + 1]$ it holds that $R \cap \mathcal{K}_r(\alpha)$ is an exchange set for I, ε, α, and r, then R is a representative set of I and ε.*

We give the formal proof in [5]. We now present a unified algorithm for finding a representative set for both types of constraints, namely, matching or matroid intersection constraints. This is achieved by taking the union of exchange sets of all profit classes. Nevertheless, for the construction of exchange sets we distinguish between the two types of constraints. This results also in different sizes for the obtained representative sets. Our algorithms for finding the exchange sets are the core technical contribution of this paper.

For matching constraints, we design an algorithm which constructs an exchange set for any profit class by finding multiple matchings of $\mathcal{C}$ from the given profit class. Each matching has a bounded cardinality, and the edges are chosen using a greedy approach to minimize the cost. We give the full details and a formal proof of Lemma 10 in Section 4.

▶ **Lemma 10.** *There is an algorithm* ExSet-Matching *that given a* BM *instance I, $0 < \varepsilon < \frac{1}{2}$, $\frac{\mathrm{OPT}(I)}{2} \leq \alpha \leq \mathrm{OPT}(I)$, and $r \in [\log_{1-\varepsilon}\left(\frac{\varepsilon}{2}\right) + 1]$, returns in time $q(\varepsilon) \cdot \mathrm{poly}(|I|)$ an exchange set X for I, ε, α, and r, such that $|X| \leq 18 \cdot q(\varepsilon)^2$.*

Our algorithm for matroid intersection constraints is more involved and generates an exchange set by an *asymmetric interpretation* of the two given matroids. As the technique was introduced by Huang and Ward [9], the proof of the next lemma follows immediately from Theorem 3.6 in [9]. For completeness, we give the full details in Section 5.

▶ **Lemma 11.** *There is an algorithm* ExSet-MatroidIntersection *that given a* BI *instance* I, $0 < \varepsilon < \frac{1}{2}$, $\frac{\mathrm{OPT}(I)}{2} \leq \alpha \leq \mathrm{OPT}(I)$, *and* $r \in [\log_{1-\varepsilon}\left(\frac{\varepsilon}{2}\right) + 1]$, *returns in time* $q(\varepsilon)^{O(q(\varepsilon))} \cdot \mathrm{poly}(|I|)$ *an exchange set* X *for* I, ε, α, *and* r, *such that* $|X| \leq q(\varepsilon)^{O(q(\varepsilon))}$.

Using the above, we design an algorithm that returns a representative set for both types of constraints. This is done by computing a 2-approximation α for $\mathrm{OPT}(I)$, and then finding exchange sets for all profit classes, for the corresponding type of constraint. Finally, we return the union of the above exchange sets. The pseudocode of our algorithm, RepSet, is given in Algorithm 1.

Algorithm 1 RepSet$(I = (E, \mathcal{C}, c, p, \beta), \varepsilon)$.

input : A BC instance I and error parameter $0 < \varepsilon < \frac{1}{2}$.
output : A representative set R of I and ε.

```
Compute a 2-approximation S* for I using a PTAS for BC with parameter ε' = 1/2.
Set α ← p(S*).
Initialize R ← ∅.
for r ∈ [log_{1−ε}(ε/2) + 1] do
    if I is a BM instance then
        R ← R ∪ ExSet-Matching(I, ε, α, r).
    else
        R ← R ∪ ExSet-MatroidIntersection(I, ε, α, r).
Return R.
```

▶ **Lemma 12.** *Given a* BC *instance* $I = (E, \mathcal{C}, c, p, \beta)$ *and* $0 < \varepsilon < \frac{1}{2}$, *Algorithm 1 returns a representative set* R *of* I *and* ε, *such that one of the following holds.*

- *If* $\mathcal{C}$ *is a matching constraint the running time is* $q(\varepsilon)^2 \cdot \mathrm{poly}(|I|)$, *and* $|R| \leq 54 \cdot q(\varepsilon)^3$.
- *If* $\mathcal{C}$ *is a matroid intersection constraint the running time is* $q(\varepsilon)^{O(q(\varepsilon))} \cdot \mathrm{poly}(|I|)$, *and* $|R| \leq q(\varepsilon)^{O(q(\varepsilon))}$.

The proof of the lemma is given in [5]. Next, we use a result of [1] for adding elements of smaller profits to the solution. The techniques of [1] are based on a non-trivial patching of two solutions of the Lagrangian relaxation of BC (for both matching and matroid intersection constraints). This approach yields a feasible set of almost optimal profit; in the worst case, the difference from the optimum is twice the maximal profit of an element in the instance. Since we use the latter approach only for non-profitable elements, this effectively does not harm our approximation guarantee. The following is a compact statement of the above result of [1].

▶ **Lemma 13.** *There is a polynomial-time algorithm* NonProfitableSolver *that given a* BC *instance* $I = (E, \mathcal{C}, c, p, \beta)$ *computes a solution* S *for* I *of profit* $p(S) \geq \mathrm{OPT}(I) - 2 \cdot \max_{e \in E} p(e)$.

Using the algorithm above and our algorithm for computing a representative set, we obtain an EPTAS for BC. Let R be the representative set returned by RepSet(I, ε). Our scheme enumerates over subsets of R to select profitable elements for the solution. Using algorithm NonProfitableSolver of [1], the solution is extended to include also non-profitable elements. Specifically, let $\frac{\mathrm{OPT}(I)}{2} \leq \alpha \leq \mathrm{OPT}(I)$ be a 2-approximation for the optimal profit for I. In addition, let $E(\alpha) = \{e \in E \mid p(e) \leq 2\varepsilon \cdot \alpha\}$ be the set including the non-profitable elements, and possibly also profitable elements $e \in E$ such that $p(e) \leq 2\varepsilon \cdot \mathrm{OPT}(I)$. Given a feasible set $F \in \mathcal{M}$, we define a residual BC instance containing elements which can *extend* F by adding elements from $E(\alpha)$. More formally,

▶ **Definition 14.** *Given a* BC *instance* $I = (E, \mathcal{C}, c, p, \beta)$, $\frac{\mathrm{OPT}(I)}{2} \leq \alpha \leq \mathrm{OPT}(I)$, *and* $F \in \mathcal{M}(\mathcal{C})$, *the* residual instance of F and α *for* I *is the* BC *instance* $I_F(\alpha) = (E_F, \mathcal{C}_F, c_F, p_F, \beta_F)$ *defined as follows.*

- $E_F = E(\alpha) \setminus F$.
- $\mathcal{C}_F = \mathcal{C}/F$.
- $p_F = p|_F$ *(i.e., the restriction of* p *to* F*).*
- $c_F = c|_F$.
- $\beta_F = \beta - c(F)$.

▶ **Observation 15.** *Let* $I = (E, \mathcal{C}, c, p, \beta)$ *be a* BC *instance,* $\frac{\mathrm{OPT}(I)}{2} \leq \alpha \leq \mathrm{OPT}(I)$, $F \in \mathcal{M}(\mathcal{C})$, *and let* T *be a solution for* $I_F(\alpha)$. *Then,* $T \cup F$ *is a solution for* I.

For all solutions $F \subseteq R$ for I with $|F| \leq \varepsilon^{-1}$, we find a solution T_F for the residual instance $I_F(\alpha)$ using Algorithm NonProfitableSolver and define $K_F = T_F \cup F$ as the *extended solution* of F. Our scheme iterates over the extended solutions K_F, for all such solutions F, and chooses an extended solution K_{F^*} of maximal total profit. The pseudocode of the scheme is given in Algorithm 2.

Algorithm 2 EPTAS$(I = (E, \mathcal{C}, c, p, \beta), \varepsilon)$.

input : A BC instance I and an error parameter $0 < \varepsilon < \frac{1}{2}$.
output : A solution for I.

```
Construct the representative set R ← RepSet(I, ε).
Compute a 2-approximation S* for I using a PTAS for BC with parameter ε' = 1/2.
Set α ← p(S*).
Initialize an empty solution A ← ∅.
for F ⊆ R s.t. |F| ≤ ε^{-1} and F is a solution of I do
    Find a solution for I_F(α) by T_F ← NonProfitableSolver(I_F(α)).
    Let K_F ← T_F ∪ F.
    if p(K_F) > p(A) then
        Update A ← K_F
Return A.
```

The running time of Algorithm 2 crucially depends on the cardinality of the representative set. Roughly speaking, the running time is the number of subsets of the representative set containing at most ε^{-1} elements, multiplied by a computation time that is polynomial in the encoding size of the instance. Moreover, since $R = \mathsf{RepSet}(I, \varepsilon)$ is a representative set (by Lemma 12), there is an almost optimal solution S of I such that the profitable elements in S are a subset of R. Thus, there is an iteration of the **for** loop in Algorithm 2 such that $F = S \cap H$. In the proof of Lemma 16 we focus on this iteration and show that it yields a solution K_F of I with an almost optimal profit.

▶ **Lemma 16.** *Given a* BC *instance* $I = (E, \mathcal{C}, c, p, \beta)$ *and* $0 < \varepsilon < \frac{1}{2}$, *Algorithm 2 returns a solution for* I *of profit at least* $(1 - 8\varepsilon) \cdot \mathrm{OPT}(I)$ *such that one of the following holds.*

- *If* I *is a* BM *instance the running time is* $2^{O\left(\varepsilon^{-2} \log \frac{1}{\varepsilon}\right)} \cdot \mathrm{poly}(|I|)$.
- *If* I *is a* BI *instance the running time is* $q(\varepsilon)^{O(\varepsilon^{-1} \cdot q(\varepsilon))} \cdot \mathrm{poly}(|I|)$, *where* $q(\varepsilon) = \left\lceil \varepsilon^{-\varepsilon^{-1}} \right\rceil$.

The proof of Lemma 16 is given in [5]. We are ready to prove our main results.

Proofs of Theorem 1 and Theorem 2. Given a BC instance I and $0 < \varepsilon < \frac{1}{2}$, using Algorithm 2 for I with parameter $\frac{\varepsilon}{8}$ we have by Lemma 16 the desired approximation guarantee. Furthermore, the running time is $2^{O\left(\varepsilon^{-2} \log \frac{1}{\varepsilon}\right)} \cdot \mathrm{poly}(|I|)$ or $q(\varepsilon)^{O(\varepsilon^{-1} \cdot q(\varepsilon))} \cdot \mathrm{poly}(|I|)$, depending on whether I is a BM instance or a BI instance, respectively. ◀

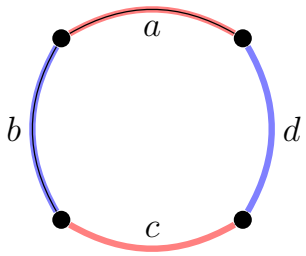

Figure 1 An example showing that bipartite matching may not yield an exchange set. Consider the two matchings $\Delta_1 = \{a, c\}, \Delta_2 = \{b, d\}$ marked in red and blue, and suppose that $\mathcal{K}_r(\alpha) = \{a, b\}$ is a profit class. The only exchange set for $\mathcal{K}_r(\alpha)$ is $\{a, b\}$, which is not a matching. Note that a bipartite matching can be cast as matroid intersection. For a bipartite graph $G = (L \cup R, E)$, define the matroids $\mathcal{M}_1 = (E, \mathcal{I}_1)$ and $\mathcal{M}_2 = (E, \mathcal{I}_2)$, where $\mathcal{I}_1 = \{F \subseteq E |\ \forall v \in L : |F \cap N(v)| \leq 1\}$, and $\mathcal{I}_2 = \{F \subseteq E |\ \forall v \in R : |F \cap N(v)| \leq 1\}$, where $N(v)$ is the set of neighbors of v. Thus, bipartite matching is a special case of both matching and matroid intersection.

4 Exchange Set for Matching Constraints

In this section we design an algorithm for finding an exchange set for a BM instance and a profit class, leading to the proof of Lemma 10. For the remainder of this section, fix a BM instance $I = (E, \mathcal{C}, c, p, \beta)$, an error parameter $0 < \varepsilon < \frac{1}{2}$, a 2-approximation for $\mathrm{OPT}(I)$, $\frac{\mathrm{OPT}(I)}{2} \leq \alpha \leq \mathrm{OPT}(I)$, and an index $r \in [\log_{1-\varepsilon}\left(\frac{\varepsilon}{2}\right) + 1]$ of the profit class $\mathcal{K}_r(\alpha)$.

We note that for a single matroid constraint an exchange set can be constructed by finding a minimum cost basis in the matroid [6]. More specifically, given a matroid $\mathcal{G} = (E, \mathcal{I})$, it is shown in [6] that a minimum cost basis in the matroid $[\mathcal{G} \cap \mathcal{K}_r(\alpha)]_{\leq q(\varepsilon)}$ is an exchange set for $\mathcal{K}_r(\alpha)$. Such exchange set can be easily computed using a greedy approach. An analogue for the setting of matching constraints is to find a matching of cardinality $\Omega(q(\varepsilon))$ and minimum total cost in $\mathcal{K}_r(\alpha)$. However, as shown in Figure 1, this idea fails. Thus, we turn to use a completely different approach.

A key observation is that even if a greedy matching algorithm may not suffice for the construction of an exchange set, applying such an algorithm multiple times can be the solution. Thus, as a subroutine our algorithm finds a matching using a greedy approach. The algorithm iteratively selects an edge of minimal cost while ensuring that the selected set of edges is a matching. This is done until the algorithm reaches a given cardinality bound, or no more edges can be added. The pseudocode of GreedyMatching is given in Algorithm 3.[7]

Algorithm 3 GreedyMatching$(G = (V, E), N, c)$.

input : A graph G, an integer $N \in \mathbb{N} \setminus \{0\}$, and a cost function $c : E \to \mathbb{R}_{\geq 0}$.
output : A matching M of G.

```
Initialize M ← ∅.
while |M| < N and E/M ≠ ∅ do
    Find e ∈ E/M of minimal cost w.r.t. c.
    Update M ← M + e.
Return M.
```

[7] Given a graph $G = (V, E)$ and a matching M of G, the definition of thinning E/M is given in Section 2.

Given a graph $G = (V, E)$ and two edges $a, b \in E$, we say that a, b are *adjacent* if there are $x, y, z \in V$ such that $a = \{x, y\}$ and $b = \{y, z\}$; for all $e \in E$, let $\mathsf{Adj}_G(e)$ be the set of edges adjacent to e in G. In the next result we show that if an edge a is not selected for the solution by GreedyMatching, then either the algorithm selects an adjacent edge of cost at most $c(a)$, or all of the selected edges have costs at most $c(a)$.

▶ **Lemma 17.** *Given a graph $G = (V, E)$, $N \in \mathbb{N} \setminus \{0\}$, and $c : E \to \mathbb{R}_{\geq 0}$, Algorithm 3 returns in polynomial time a matching M of G such that for all $a \in E \setminus M$ one of the following holds.*

1. *$|M| \leq N$ and there is $b \in \mathsf{Adj}_G(a) \cap M$ such that $c(b) \leq c(a)$.*
2. *$|M| = N$, for all $b \in M$ it holds that $c(b) \leq c(a)$, and $M + a$ is a matching of G.*

Proof. Clearly, Algorithm 3 returns in polynomial time a matching M of G. Observe that $|M| \leq N$ by Step 2. To prove that either 1. or 2. hold, we distinguish between two cases.

- $a \notin E/M$. Then $\mathsf{Adj}_G(a) \cap M \neq \emptyset$. Let e be the first edge in $\mathsf{Adj}_G(a) \cap M$ that is added to M in Step 4; also, let L be the set of edges added to M before e. Then $a \in E/L$, since L does not contain edges adjacent to a. By Step 3, it holds that $c(e) = \min_{e' \in E/L} c(e') \leq c(a)$.
- $a \in E/M$. Thus, $|M| = N$; otherwise, a would be added to M. Also, $M + a$ is a matching of G. Now, let $b \in M$, and let K be the set of edges added to M before b. Since $M + a$ is a matching of G, by the hereditary property of $(E, \mathcal{M}(G))$ it holds that $K + a$ is a matching of G; thus, $a \in E/K$ and by Step 3 it follows that $c(b) = \min_{e' \in E/K} c(e') \leq c(a)$. ◀

By Lemma 17, we argue that an exchange set can be found by using Algorithm GreedyMatching iteratively. Specifically, let $k(\varepsilon) = 6 \cdot q(\varepsilon)$ and $N(\varepsilon) = 3 \cdot q(\varepsilon)$. We run Algorithm GreedyMatching for $k(\varepsilon)$ iterations, each iteration with a bound $N(\varepsilon)$ on the cardinality of the matching. In iteration i, we choose a matching M_i from the edges of the profit class $\mathcal{K}_r(\alpha)$ and remove the chosen edges from the graph. Therefore, in the following iterations, edges adjacent to previously chosen edges can be chosen as well. A small-scale illustration of the algorithm is presented in Figure 2. The pseudocode of Algorithm ExSet-Matching, which computes an exchange set for the given profit class, is presented in Algorithm 4.

Algorithm 4 ExSet-Matching$(I = (E, \mathcal{C}, c, p, \beta), \varepsilon, \alpha, r)$.

input : a matching-BC instance I , $0 < \varepsilon < \frac{1}{2}$, $\frac{\mathrm{OPT}(I)}{2} \leq \alpha \leq \mathrm{OPT}(I)$, $r \in [\log_{1-\varepsilon}\left(\frac{\varepsilon}{2}\right) + 1]$.
output : An exchange set for I, ε, α, and r.

```
Initialize X ← ∅ and E_0 ← K_r(α).
for i ∈ {1, ..., k(ε)} do
    Define G_i = (V, E_{i−1}) where V is the vertex set of C.
    Compute M_i ← GreedyMatching(G_i, N(ε), c|_{E_{i−1}}).
    Update X ← X ∪ M_i and define E_i ← E_{i−1} \ M_i.
Return X.
```

Algorithm ExSet-Matching outputs a union X of disjoint matchings $M_1, \ldots, M_{k(\varepsilon)}$ taken from the edges of the profit class $\mathcal{K}_r(\alpha)$. For some $\Delta \in \mathcal{M}(\mathcal{C})$ and $a \in (\Delta \cap \mathcal{K}_r(\alpha)) \setminus X$, by Lemma 17, there are two options summarizing the main idea in the proof of Lemma 10.

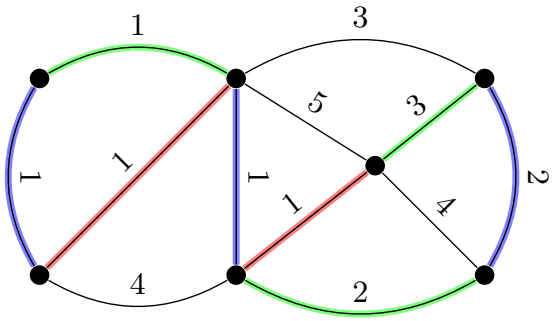

Figure 2 An execution of Algorithm ExSet-Matching with the (illegally small) parameters $N(\varepsilon) = k(\varepsilon) = 3$. The numbers by the edges are the costs. The edges chosen in iterations $i = 1, 2, 3$ are marked in blue, red, and green, respectively.

- all matchings M_i contain some b_i adjacent to a such that $c(b_i) \leq c(a)$. Then, as $k(\varepsilon)$ is sufficiently large, one such b_i is not adjacent to any edge in $\Delta - a$. Hence, $\Delta - a + b_i$ is a matching.
- One such M_i contains only edges of costs at most $c(a)$; as $N(\varepsilon)$ is sufficiently large, there is $b \in M_i$ such that $\Delta - a + b$ is a matching.

Proof of Lemma 10. For all $i \in \{1, \ldots, k(\varepsilon)\}$, let G_i and M_i be the outputs of Steps 3 and 4 in iteration i of the **for** loop in ExSet-Matching$(I, \varepsilon, \alpha, r)$, respectively. Also, let X be the output of the algorithm; observe that $X = \bigcup_{i \in [k(\varepsilon)]} M_i$. We show that X is an exchange set for I, ε, α and r (see Definition 8). Let $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$ and $a \in (\Delta \cap \mathcal{K}_r(\alpha)) \setminus X$. We use the next inequality in the claim below.

$$\frac{k(\varepsilon)}{2} = N(\varepsilon) = 3 \cdot q(\varepsilon) > 2 \cdot |\Delta| = |V(\Delta)|. \tag{3}$$

The inequality holds since $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$. The last equality holds since each vertex appears as an endpoint in a matching at most once.

▷ Claim 18. There is $b \in (X \cap \mathcal{K}_r(\alpha)) \setminus \Delta$ such that $\Delta - a + b \in \mathcal{M}_{\leq q(\varepsilon)}$, and $c(b) \leq c(a)$.

Proof. Let $a = \{x, y\}$, $I = (E, \mathcal{C}, c, p, \beta)$, and $\mathcal{C} = (V, E)$. Since $a \notin X$, for all $i \in \{1, \ldots, k(\varepsilon)\}$ it holds that $a \notin M_i$; thus, $a \in \mathcal{E}_i = \mathcal{E}_{i-1} \setminus M_i$. Hence, by Lemma 17, one of the following holds.

1. For all $i \in [k(\varepsilon)]$ there is $b_i \in \mathsf{Adj}_{G_i}(a) \cap M_i$ such that $c(b_i) \leq c(a)$. For $z \in \{x, y\}$ let

$$J_z = \{i \in [k(\varepsilon)] \mid \exists u \in V : \ b_i = \{z, u\}\}$$

be the set of indices of edges b_i neighboring to z. Since $b_i \in \mathsf{Adj}_{G_i}(a)$ it holds that $J_x \cup J_y = [k(\varepsilon)]$. Thus, there is $z \in \{x, y\}$ such that $|J_z| \geq \frac{k(\varepsilon)}{2} > |V(\Delta)|$, where the last inequality follows from (3). For any $i \in J_z$ let $v_i \in V$ be the vertex connected to z in b_i, that is $b_i = \{z, v_i\}$. Since the matchings $M_1, \ldots M_{k(\varepsilon)}$ are disjoint and $b_i \in M_i$ it follows that the vertices v_i for $i \in J_z$ are all distinct. As $|J_z| > |V(\Delta)|$ there is $i^* \in J_z$ such that $v_{i^*} \notin V(\Delta)$. Therefore, $\Delta - a + b_{i^*} \in \mathcal{M}_{\leq q(\varepsilon)}$ and $c(b_{i^*}) \leq c(a)$.
2. There is $i \in \{1, \ldots, k(\varepsilon)\}$ such that $|M_i| = N(\varepsilon)$, and for all $b \in M_i$ it holds that $c(b) \leq c(a)$. Then,

$$|M_i| = N(\varepsilon) > |V(\Delta)|. \tag{4}$$

The equality follows by the definition of M_i in Case 2. The inequality follows from (3). Since each vertex appears as an endpoint in a matching at most once, by (4) there is $b \in M_i$ such that both endpoints of b are not in $V(\Delta)$. Thus, $\Delta + b \in \mathcal{M}$; by the hereditary property and since $a \in \Delta$, it holds that $\Delta - a + b \in \mathcal{M}_{\leq q(\varepsilon)}$. ◁

By Claim 18 and Definition 8, we have that X is an exchange set for I, ε, α, and r as required. To complete the proof of the lemma we show (in [5]) the following.

▷ Claim 19. $|X| \leq 18 \cdot q(\varepsilon)^2$, and the running time of Algorithm 4 is $q(\varepsilon) \cdot \text{poly}(|I|)$. ◀

5 Exchange Set for Matroid Intersection Constraints

In this section we design an algorithm for finding an exchange set for a profit class in a BI instance. For the remainder of this section, fix a BI instance $I = (E, \mathcal{C}, c, p, \beta)$, an error parameter $0 < \varepsilon < \frac{1}{2}$, a 2-approximation for $\text{OPT}(I)$, $\frac{\text{OPT}(I)}{2} \leq \alpha \leq \text{OPT}(I)$, and an index $r \in [\log_{1-\varepsilon}(\frac{\varepsilon}{2}) + 1]$ of the profit class $\mathcal{K}_r(\alpha)$. Also, let $\mathcal{C} = (\mathcal{I}_1, \mathcal{I}_2)$ be the matroid intersection constraint $\mathcal{C}$ of I. For simplicity, when understood from the context, some of the lemmas in this section consider the given parameters (e.g., I) without explicit mention. The proofs of the lemmas in this section are given in the full version of the paper [5].

As shown in Figure 1, a simple greedy approach which finds a feasible set of minimum cost (within $\mathcal{K}_r(\alpha)$) in the intersection of the matroids may not output an exchange set for $\mathcal{K}_r(\alpha)$. Instead, our approach builds on some interesting properties of matroid intersection. The next definition presents a *shifting property* for a feasible set $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$ and an element $a \in \Delta \cap \mathcal{K}_r(\alpha)$ w.r.t. the two matroids. We use this property to show that our algorithm constructs an exchange set.

▶ **Definition 20.** *Let $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$, $a \in \Delta \cap \mathcal{K}_r(\alpha)$ and $b \in \mathcal{K}_r(\alpha) \setminus \Delta$. We say that b is a* shift *to a for Δ if $c(b) \leq c(a)$ and $\Delta - a + b \in \mathcal{M}_{\leq q(\varepsilon)}$. Furthermore, b is a* semi-shift *to a for Δ if $c(b) \leq c(a)$ and $\Delta - a + b \in \mathcal{I}_2$ but $\Delta - a + b \notin \mathcal{I}_1$.*

As a starting point for our exchange set algorithm, we show how to obtain small cardinality sets which contain either a shift or a semi-shift for every pair $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$ and $a \in \Delta \cap \mathcal{K}_r(\alpha)$.

▶ **Lemma 21.** *Let $U \subseteq \mathcal{K}_r(\alpha)$, $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$, and B be a minimum basis of $[(E, \mathcal{I}_2) \cap U]_{\leq q(\varepsilon)}$ w.r.t. c. Also, let $a \in (U \cap \Delta) \setminus B$. Then, there is $b \in B \setminus \Delta$ such that b is a semi-shift to a for Δ, or b is a shift to a for Δ.*

Observe that to obtain an exchange set, our goal is to find a subset of $\mathcal{K}_r(\alpha)$ which contains a shift for every pair $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$ and $a \in \Delta \cap \mathcal{K}_r(\alpha)$. Thus, using Lemma 21 we design the following recursive algorithm ExtendChain, which finds a union of minimum bases of matroids w.r.t $\mathcal{I}_2$, of increasingly restricted ground sets w.r.t. $\mathcal{I}_1$. The pseudocode of Algorithm ExtendChain is given in Algorithm 5.

We can view the execution of ExtendChain as a tree, where each node (called below a *branch*) corresponds to the subset $S \subseteq \mathcal{K}_r(\alpha)$ in a specific recursive call. We now describe the role of S in Algorithm ExtendChain. If $|S| \geq q(\varepsilon) + 1$, we simply return $\emptyset$; such a branch is called a *leaf*, and does not contribute elements to the constructed exchange set. Otherwise, define the *universe* of the branch S as $U_S = \{e \in \mathcal{K}_r(\alpha) \setminus S \mid S + e \in \mathcal{I}_1\}$; that is, elements in the universe of S which can be added to S to form an independent set w.r.t. $\mathcal{I}_1$. Next, we construct a minimum basis B_S w.r.t. c of the matroid $[(E, \mathcal{I}_2) \cap U_S]_{\leq q(\varepsilon)}$. Observe that B_S contains up to $q(\varepsilon)$ elements, selected from the universe of S, and that B_S is independent w.r.t. $\mathcal{I}_2$. Note that the definition of the universe relates to $\mathcal{I}_1$ while the construction of the bases to $\mathcal{I}_2$; thus, the two matroids play completely different roles in the algorithm.

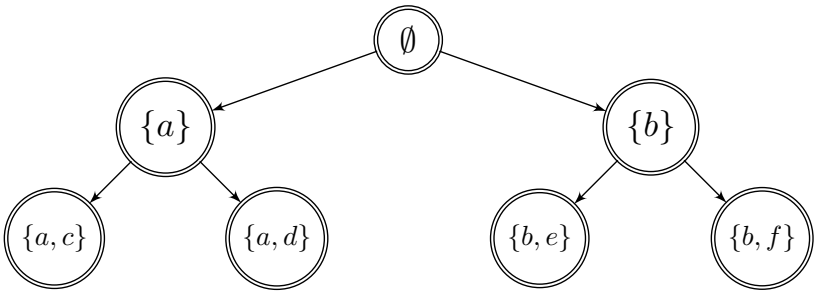

Figure 3 An illustration of the branches in Algorithm 5 for $S = \emptyset$. Note that $B_\emptyset = \{a, b\}$, $B_{\{a\}} = \{c, d\}$ and $B_{\{b\}} = \{e, f\}$. Also, $\{a, c\}$ and $\{a, d\}$ are the child branches of $\{a\}$.

For every element $e \in B_S$ we apply Algorithm ExtendChain recursively with $S' = S + e$ to find the corresponding basis B_{S+e}. The algorithm returns (using recursion) the union of the constructed bases over all branches. Finally, algorithm ExSet-MatroidIntersection constructs an exchange set for I, ε, α, and r by calling Algorithm ExtendChain with the initial branch (i.e., *root*) $S = \emptyset$:

$$\mathsf{ExSet\text{-}MatroidIntersection}(I, \varepsilon, \alpha, r) = \mathsf{ExtendChain}(I, \varepsilon, \alpha, r, \emptyset). \tag{5}$$

For an illustration of the algorithm, see Figure 3.

Algorithm 5 ExtendChain$(I = (E, \mathcal{C}, c, p, \beta), \varepsilon, \alpha, r, S)$.

input : a matroid-BC instance I , where $\mathcal{C} = (\mathcal{I}_1, \mathcal{I}_2)$, $0 < \varepsilon < \frac{1}{2}$, $\frac{\mathrm{OPT}(I)}{2} \leq \alpha \leq \mathrm{OPT}(I)$, $r \in [\log_{1-\varepsilon}\left(\frac{\varepsilon}{2}\right) + 1]$, and $S \subseteq E$.
output : (for $S = \emptyset$) An exchange set X for I, ε, α, and r.

```
if |S| ≥ q(ε) + 1 then
    Return ∅
Define U_S = {e ∈ K_r(α) \ S | S + e ∈ I_1}.
Compute a minimum basis B_S w.r.t. c of the matroid [(E, I_2) ∩ U_S]_{≤q(ε)}.
Return B_S ∪ (⋃_{e∈B_S} ExtendChain(I, ε, α, r, S + e)).
```

In the analysis of the algorithm, we consider branches with useful attributes, called *chains*; these are essentially sequences of semi-shifts to some $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$ and $a \in \Delta \cap \mathcal{K}_r(\alpha)$. Let $X = \mathsf{ExSet\text{-}MatroidIntersection}(I, \varepsilon, \alpha, r)$, and let $\mathcal{S}$ be the set of all branches $S \subseteq \mathcal{K}_r(\alpha)$ such that $\mathsf{ExtendChain}(I, \varepsilon, \alpha, r, S)$ is computed during the construction of X.

▶ **Definition 22.** *Let $S \in \mathcal{S}$, $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$, and $a \in (\mathcal{K}_r(\alpha) \cap \Delta) \setminus X$. We say that S is a* chain *of a and Δ if $a \in U_S$, and for all $e \in S$ it holds that e is a semi-shift to a for Δ.*

Note that there must be a chain for a and Δ since the empty set satisfies the conditions of Definition 22. Moreover, we can bound the cardinality of a chain by $q(\varepsilon)$ using the exchange property of the matroid $(E, \mathcal{I}_1)$. The above arguments are formalized in the next lemmas.

▶ **Lemma 23.** *For all $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$ and $a \in (\mathcal{K}_r(\alpha) \cap \Delta) \setminus X$ there is $S \subseteq X$ such that S is a chain of a and Δ.*

▶ **Lemma 24.** *For all $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$, $a \in (\mathcal{K}_r(\alpha) \cap \Delta) \setminus X$, and a chain S of a and Δ, it holds that $|S| \leq q(\varepsilon)$.*

For a chain S of a and Δ, let B_S be the result of the first computation of Step 4 (i.e., not within a recursive call) in $\mathsf{ExtendChain}(I, \varepsilon, \alpha, r, S)$. The key argument in the proof of Lemma 11 is that for a chain S^* of maximal cardinality, B_{S^*} contains a shift to a and Δ, using the maximality of S^* and Lemma 21.

▶ **Lemma 25.** *For all $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$, $a \in (\mathcal{K}_r(\alpha) \cap \Delta) \setminus X$, and a chain S^* of a and Δ of maximum cardinality, there is a shift $b^* \in B_{S^*}$ to a for Δ.*

In the proof of Lemma 11, for every $\Delta \in \mathcal{M}_{\leq q(\varepsilon)}$ and $a \in (\mathcal{K}_r(\alpha) \cap \Delta) \setminus X$, we take a chain S^* of a and Δ of maximum cardinality (which exists by Lemma 23 and Lemma 24). Then, by Lemma 25, there is a shift b^* to a for Δ, and it follows that X is an exchange set for I, ε, α, and r. The formal proof is given in [5].

6 Discussion

In this paper we present the first EPTAS for budgeted matching and budgeted matroid intersection, thus improving upon the existing PTAS for both problems. We derive our results via a generalization of the representative set framework in [6]; this ameliorates the exhaustive enumeration applied in similar settings [1, 3].

We note that the framework based on representative sets may be useful for solving other problems formulated as (1). Indeed, the proofs of Lemma 7 and Lemma 9, which establish the representative set framework, are oblivious to the exact type of constraints and only require having a *k-exchange system* for some constant k.[8]

Furthermore, our exchange sets algorithms can be applied with slight modifications to other variants of our problems and are thus of independent interest. In particular, we can use a generalization of Algorithm 4 to construct an exchange set for the *budgeted b-matching* problem. Also, using the techniques of [9], Algorithm 5 can be generalized to construct exchange sets for budgeted *multi-matroid intersection* for any constant number of matroids; this includes the *budgeted multi-dimensional matching* problem. While this problem does not admit a PTAS unless P=NP [10], our initial study shows that by constructing a representative set we may obtain an FPT-*approximation scheme* by parameterizing on the number of elements in the solution.[9]

Finally, to resolve the complexity status of BM and BI, the gripping question of whether the problems admit an FPTAS needs to be answered. Unfortunately, this may be a very difficult task. Even for special cases of a single matroid, such as graphic matroid, the existence of an FPTAS is still open. Moreover, a deterministic FPTAS for budgeted matching would solve deterministically the exact matching problem, which has been open for over four decades [14].

Abstract

Motivated by an application from geodesy, we study the *connected k-center problem* and the *connected k-diameter problem*. These problems arise from the classical k-center and k-diameter problems by adding a side constraint. For the side constraint, we are given an undirected *connectivity graph* G on the input points, and a clustering is now only feasible if every cluster induces a connected subgraph in G. Usually in clustering problems one assumes that the clusters are pairwise disjoint. We study this case but additionally also the case that clusters are allowed to be non-disjoint. This can help to satisfy the connectivity constraints.

Our main result is an $O(1)$-approximation algorithm for the disjoint connected k-center and k-diameter problem for Euclidean spaces of low dimension (constant d) and for metrics with constant doubling dimension. For general metrics, we get an $O(\log^2 k)$-approximation. Our algorithms work by computing a non-disjoint connected clustering first and transforming it into a disjoint connected clustering.

We complement these upper bounds by several upper and lower bounds for variations and special cases of the model.

Acknowledgements The authors thank anonymous reviewers of a previous draft for helpful comments and pointing out relevant related work. We thank Jürgen Kusche and Christian Sohler for raising the problem and for fruitful discussion on the modeling. We also thank Xiangyu Guo for the discussion on the algorithm design and analysis.

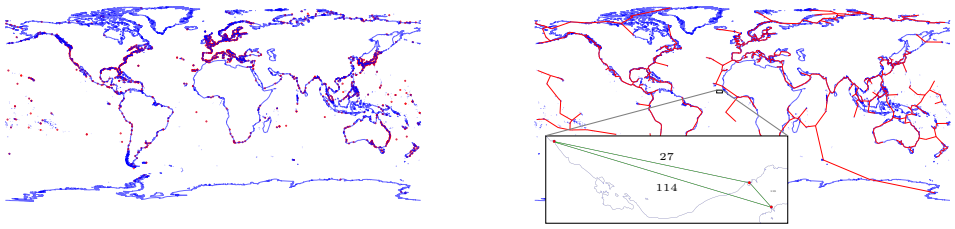

Figure 1 Gauge stations around the globe, with station location data from PSMSL (`http://www.psmsl.org/data/obtaining/`), plotted onto the map from the Natural Earth data set (`https://www.naturalearthdata.com/downloads/10m-physical-vectors/10m-coastline/`). Highlighted are three stations in Central America, and the numbers are Fréchet distances computed on the curves defined by sea levels between 1953 and 1968.

1 Introduction

Clustering problems occur in a wide range of application domains. Because of the general importance and interesting combinatorial properties, well-known k-clustering problems like k-center, k-median, and k-means have also been vastly studied in theory. These problems are NP-hard and APX-hard, but many constant-factor approximation algorithms for them are known. All k-clustering problems ask to partition a set of points (usually in a general metric space or in Euclidean space) into k clusters, often by picking k centers and assigning every point to its closest center. The clusters are then evaluated based on the distances between the points and their corresponding centers. For example in the case of k-center, the objective is to minimize the maximum distance between any point and its closest center.

In applications, clustering problems are often subject to side constraints. Consequently, clustering with side constraints has also become a thriving topic for designing approximation algorithms. Probably the most known example is clustering with capacities where the number of points in a cluster is limited. Notice how this constraint prevents us from assigning points to their closest center because there might not be enough space. So, for example, uniform capacitated (center-based) clustering consists of finding k centers and an assignment of points to those centers such that every center gets at most U points (and then evaluating the desired objective). Finding a constant factor approximation for uniform capacitated k-median clustering is a long standing open problem. Other constraints that have been studied are for example lower bounds (here, a cluster has to have a certain minimum number of points, so it may be beneficial to open less than k clusters) and clustering with outliers (here we are allowed $k + z$ clusters, but z of them have to be singletons, i.e. outliers). There are also results on constraints that restrict the choice of centers, for example by demanding that the centers satisfy a given matroid constraint. Among the newer clustering problems with constraints are those that evolve around aspects of fairness. These constraints are typically more complex and can either be point-based or center-based. Each constrained clustering problem, old or new, comes with a unique combinatorial structure, giving rise to a plethora of insights on designing approximation algorithms.

In this paper, we study a constraint that stems from the area of sea level geodesy but which is also of interest for other domains (discussed briefly below). For the application that motivated our work, consider the left picture in Figure 1. We see the location of tide gauge stations around the globe from the PSMSL data set [13, 9]. At every station, sea level heights have been collected over the years, constituting monthly time series. These records

can be used to reconstruct regional or global mean sea levels. However, the tide gauges have usually been constructed for practical purposes and not for sea level science. As a result, they are unevenly distributed over the globe. One way out of this is to replace clusters of tide gauges by representative records to thin out the data set. Our general goal is therefore to cluster the tide gauges into a given number k of clusters. However, the objective is not based on the gauge stations' geographic distance but on the time series. We wish to combine gauge stations with similar time series into one, i.e., when we cluster, we want to find clusters where the center's time series is similar to the records collected at the tide gauges represented by that center. We can model the distance between time series by a metric distance measure for time series or curves (like the Fréchet distance). As the objective we pick k-center, so we want to minimize the maximum distance between the center and the points that are replaced by it. Now we get to the complication: The gauge stations are *also* points on the map. We do not want to have points in the same cluster that are geographically very far away.

It is not immediately clear how to best model this scenario. We could resort to bicriteria approximation and look for solutions where both the time series of points in a cluster are similar and the radius of clusters is small, by either looking at the Pareto front or weighting the two objectives. Alternatively, we could fix a threshold and limit the geographic distance between centers and points, i.e., demand that a point x can only be assigned to center c if its geographic distance is at most some T. Both modelings have the drawback that they really only capture the distance on the map, while in reality, we would like to have somewhat coherent clusters that correspond to non-overlapping areas on the map. Indeed, we might be fine with having points of large geographic distance in the same cluster if all points 'between' them are also in the same cluster (i.e., that larger area of the sea behaves very similar with respect to the gauge station measurements).

The modeling that we study incorporates this via a preprocessing step. We assume that the points have been preprocessed such that we get a connectivity graph like shown on the right in Figure 1. The graph on the map was computed by finding a minimum spanning tree of the points, but it could be computed in other ways, too. The important part is that it captures a neighborhood structure. To model coherence, we now demand that clusters are *connected* in this graph. Figure 2 gives an example.

▶ **Problem 1.** *In a connected k-clustering problem, we are given points V, a metric d on V, a number k, and an unweighted and undirected connectivity graph $G = (V, E)$. A feasible solution is a partitioning of V into k clusters $C_1, \dots, C_k$ which satisfies that for every $i \in \{1, \dots, k\}$ the subgraph of G induced by C_i is* connected.

For the connected k-center problem, a solution also contains centers $c_1, \dots, c_k$ corresponding to the clusters $C_1, \dots, C_k$ and the objective is to minimize the maximum radius $\max_{i\in[k], x\in C_i} d(x, c_i)$. For the connected k-diameter problem the objective is to minimize the maximum diameter $\max_{i\in[k]} \max_{x,y\in C_i} d(x, y)$. It is easy to see that the connected k-clustering problem generalizes the classic k-center and k-diameter problem whose connectivity graph G is a complete graph.

Interestingly, the connected k-center problem was independently defined in an earlier paper by Ge et al. [4] (previously unknown to us. We thank the anonymous reviewer who pointed us to this reference). In that paper, connected clustering is motivated in the context of applications where both attribute and relationship data is present. It is applied to scenarios of community detection and gene clustering, showing the wide applicability of the modeling. We discuss their work further in the related work section.

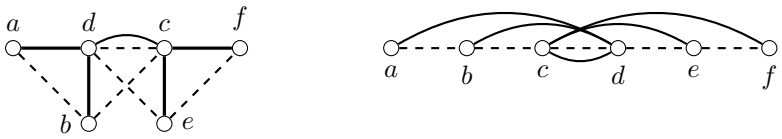

Figure 2 An example. The solid edges form the metric: Vertices connected by a solid edge have distance 1 and all other distances are 2. The dashed edges form the connectivity graph. Both pictures show the same graph. The optimal k-center solution with centers $\{c, d\}$ and clusters $\{a, b, d\}$ and $\{c, e, f\}$ is not connected. Any optimal (disjoint) connected k-center solution has radius 2.

Disjoint vs non-disjoint clusters, restricted graph classes

Notice that we demand that the C_i are *disjoint*. For some clustering problems with constraints the objective value can be decreased when we are allowed to assign points to more than one cluster: For example, lower bounds are easier to satisfy when points can be reused. The same is true for connected clustering: It is easier to satisfy connectivity when we can put important points into multiple clusters. For our application, we want to have disjoint clusters, but we still study the variation for completeness and also since it allows for better approximation algorithms that can be at least tested for their usefulness in the application (e.g., leaving it to the user to resolve overlaps). Notice that in Figure 2, allowing non-disjoint clusters enables the solution $\{c, d\}$ with clusters $\{a, b, c, d\}$, $\{c, d, e, f\}$ which has cost 1.

▶ **Definition 2.** *We distinguish between connected k-clustering* with disjoint clusters *and* with non-disjoint *clusters, referring to whether the clusters C_i have to be pairwise disjoint or not.*

Finally, we observe that in our application the connectivity graph is not necessarily arbitrary. Depending on the way that we build the graph, it could be a tree (the minimum spanning tree) or even a line (if we follow the coast line). Thus, we are interested in the problem on restricted graph classes as well.

Results and techniques

Our main result is an approximation algorithm that works for both the disjoint connected k-center problem and the disjoint connected k-diameter problem for general connectivity graphs G. For general metrics, the algorithm computes an $O(\log^2 k)$-approximation. If the metric has bounded doubling dimension D, the approximation ratio improves to $O(2^{3 \cdot D})$, and for Euclidean spaces, to $O(d \cdot 2^d)$. To obtain these results we first compute a non-disjoint clustering. Then we develop a method using a concept of a layered partitioning (see Definition 10) to make the clusters disjoint. We show how to obtain such a partitioning for different metrics. Both steps are novel and form the main contribution of this paper. In addition, in the full version of this paper we study how to compute well-separated partitions if the number of clusters is small, particularly when $k = 2$.

We also study restricted connectivity graphs (lines, stars and trees) and also the easier case of non-disjoint connected clustering. In this context we discuss greedy algorithms and obtain hardness results via reductions. The rest hardness proof in the full version of this paper is technically more involved. An overview of our results is given in Table 1, the more details are given in Section 2.

Table 1 An overview of the bounds shown in this paper and the literature for connected k-clustering. The notation $[\ell, u]$ stands for a lower bound ℓ and an upper bound u on the best possible approximation factor (achievable in polynomial time and assuming $P \neq NP$). Results marked by "*" are proven in the full version of this paper.

Related work

The k-center problem and the k-diameter problem are both NP-hard to approximate better than by a factor of 2 (see [10, 7] for k-center, k-diameter follows along the same lines). There are two popular 2-approximation algorithms for k-center which both also work for k-diameter with the same approximation guarantee [5, 8]. There are various results on side constraints for k-center and related k-clustering problems, including [1, 2, 3, 11] and many others. A more extensive list of results is contained in the full version of this paper, and we only review closely related work in the following. The connected k-center problem with disjoint clusters has been introduced and studied by Ge et al. [4][1]. Besides other results, Ge et al. present a greedy algorithm for the problem and claim that it computes a 6-approximation. In the full version of this paper we present an example showing that this greedy algorithm actually only obtains an $\Omega(k)$-approximation. The greedy algorithm is based on the approach of transforming a non-disjoint clustering into a disjoint one. In this transformation, it does not change the centers, i.e., it uses the given centers of the non-disjoint clustering also as centers for the disjoint clustering. In addition, we prove in the full version of this paper a lower bound showing that no algorithm based on transforming a non-disjoint clustering into a disjoint one with the same centers can compute an $O(1)$-approximation. Hence, without fundamental changes of the algorithm, no $O(1)$-approximation can be obtained. We even show that in general the optimal non-disjoint clustering can be better than the optimal disjoint clustering by a factor of $\Omega(\log \log k)$. Hence, if one uses only the radius of an optimal non-disjoint clustering as a lower bound for the radius of an optimal disjoint clustering, one cannot show a better approximation factor than $\Omega(\log \log k)$. To the best of our knowledge, no other approximation algorithms with provable guarantees for the connected k-center or k-diameter problem are known.

Ge et al. introduce the connected k-center problem to model clustering problems where both attribute and relationship data is present. They perform experiments in the context of gene clustering and community detection and demonstrate that for both these applications modelling them as connected clustering problems leads to superior results compared to standard clustering formulations without connectivity constraint. For community detection for example, they construct datasets from DBLP[2] where researchers are supposed to be

[1] We thank an anonymous reviewer for pointing us to this reference
[2] https://dblp.org/

clustered according to their main research area. Based on keyword frequencies they defined a distance measure for the researchers. At the same time, the coauthor network can be used as a connectivity graph. The advantage of connected clustering compared to traditional models is that it naturally takes into account both the distance measure and the coauthor network. For their experiments, Ge et al. develop a heuristic called NetScan for the connected k-center problem with disjoint clusters, which is reminiscent of the k-means method, and efficient on large datasets. In their experiments, the outcomes of this heuristic were significantly better than the outcomes of state-of-the-art clustering algorithms that take into account either only the distance measure or only the coauthor network. The work of Ge et al. has attracted some attention and it is cited in many other articles on community detection and related subjects.

Furthermore, Ge et al. show that already for $k = 2$, the connected k-center problem with disjoint clusters is NP-hard. They also argue that it is even NP-hard to obtain a $(2 - \epsilon)$-approximation for any $\epsilon > 0$. Additionally they give an algorithm based on dynamic programming with running time $O(n^2 \log n)$ that solves the connected k-center problem with disjoint clusters optimally when the connectivity graph is a tree.

Gupta et al. [6] study the connected k-median and k-means problem and prove upper and lower bounds on their approximability. Related to our motivation, Liao and Peng [12] consider the connected k-means problem to model clustering of spatial data with a geographic constraint. They develop a local-search based heuristic and conduct an experimental evaluation.

Outline

In Section 2 we discuss the general setting and results for restricted graph classes. Section 3 covers the case of non-disjoint connected clustering. Then in Section 4, we show the results on the connected clustering problems for general connectivity graphs and disjoint clusterings.

2 Setup and review of results on restricted graph classes

For all approximation algorithms in this paper, we use the following well-known framework for k-center approximation due to Hochbaum and Shmoys [8]. It is built upon the following fact: For the k-diameter or k-center problem (connected or not), the value of the cost function is always equal to one of the at most n^2 different distances between two points in V where $n = |V|$. This is true because it is either the distance between two points in the same cluster (k-diameter) or it is the distance between a point and its center (k-center). Thus, a standard scheme to follow is to sort these distances in time $O(n^2 \log n)$ and then search for the optimum value by binary search. The problem then reduces to finding a subroutine for the following task.

▶ **Problem 3.** *If there is a solution which costs r for a given r, find a solution that costs at most $\alpha \cdot r$. Otherwise, report that r is too small.*

An algorithm that solves this task can easily be turned into an α-approximation by searching for the smallest r for which the algorithm returns a solution. The running time of the resulting algorithm is $O(n^2 \log n)$ for the preprocessing plus $O(\log n)$ times the running time of the subroutine.

Lines, stars and trees

Connected k-clustering demands that the clusters are connected in a given connectivity graph G. How tricky is this condition? Maybe it can actually *help* to solve the problem? This is true if G is very simple, i.e., a line. We include the following proof as a warm-up.

▶ **Corollary 4.** *When the connectivity graph G is a line graph, then the connected k-center problem and the connected k-diameter problem can be solved optimally in time $O(n^2 \log n)$ both with disjoint and non-disjoint clusters. This is true even if the distances are not a metric.*

Proof. We only show how to solve the connected k-center problem with non-disjoint clusters. The full proof can be found in the full version of this paper. The line graph G is defined by vertices $V = \{v_1, v_2, ..., v_n\}$ and edges $E = \{\{v_i, v_{i+1}\} \mid i \in \{1, \dots, n-1\}\}$. Assume that r is given.

Notice that any connected cluster is a subpath of G. We start by precomputing for every v_i how far a cluster with center at v_i can stretch to the left and right: Let a_i be the smallest ℓ such that $d(v_j, v_{j'}) \leq r$ for all $j, j' \in \{\ell, \dots, i\}$ and let b_i be the largest ℓ such that $d(v_j, v_{j'}) \leq r$ for all $j, j' \in \{i, \dots, \ell\}$. We can compute all a_i and all b_i in time $O(n^2)$. Now we cut the line into clusters. We start by finding an index i with $a_i = 1$ for which b_i is as large as possible because we have to cover the first vertex and want to cover as many other vertices as possible. We place a center at v_i and know that all vertices until v_{b_i} are covered by the cluster. Now we know that the next cluster has to contain v_{b_i+1}, so we search for an i' which satisfies $b_i + 1 \in \{a_{i'}, \dots, b_{i'}\}$, if there are multiple, we take the one with maximum $b_{i'}$. This finds the center which covers v_{b_i+1} and the largest number of additional vertices. We place a center at $v_{i'}$. It may be that $i' < i$ as in Figure 2) and thus the clusters have to overlap (recall that we are in the non-disjoint case). The process is iterated until v_n is covered. If the number of clusters is more than k, we report that r was too small, otherwise, we report the clustering. This way we solve Problem 3 for $\alpha = 1$ in time $O(n^2)$. ◀

For trees, k-center and k-diameter differ. Surprisingly, the connected k-diameter problem is already NP-hard if G is a star. We prove the following lemma by a reduction from the uniform minimum multicut problem on stars in the full version of this paper.

▶ **Lemma 5.** *Let $\epsilon > 0$. Assuming $P \neq NP$, there is no $(2 - \epsilon)$-approximation algorithm for the connected k-diameter problem with disjoint clusters even if G is a star.*

Notice how the connected k-diameter problem with G being a star is thus very different from the k-diameter problem where the *metric* is given by a graph metric that is a star. The latter problem can be solved optimally by sorting the edges by weight and then deleting the $k - 1$ most expensive edges to form k connected components which form an optimal clustering. Say we have distances $d(e_1) \geq d(e_2) \geq \dots \geq d(e_n)$, then this optimal clustering has cost $d(e_k) + d(e_{k+1})$. However, any clustering that keeps an edge from $\{e_1, \dots, e_{k-1}\}$ costs at least $d(e_{k+1}) + d(e_{k-1}) \geq d(e_k) + d(e_{k+1})$ since it deletes at most $k - 1$ edges.

Ge et al. [4] show that the connected k-center problem is still solvable optimally for trees by dynamic programming.

▶ **Theorem 6** (Ge et al. [4])**.** *When the connectivity graph G is a tree, then the connected k-center problem with disjoint clusters can be solved optimally in time $O(n^2 \log n)$. This is true even if the distances are not a metric.*

It follows immediately that the connected k-diameter problem with disjoint clusters on trees can be 2-approximated by the same algorithm because the diameter of the produced solution is always at most twice the radius. This is interesting because our reduction in Lemma 5 shows that this is tight, i.e., using the dynamic programming algorithm for k-diameter achieves the best possible approximation ratio (assuming $P \neq NP$).

3 General G, non-disjoint clusters

The connected k-center and k-diameter problems with non-disjoint clusters behave similarly to the unconstrained versions. On the positive side, there is a 2-approximation; on the negative side, it is NP-hard to approximate these problems better than 2. In contrast to the case of disjoint clusters, APX-hardness starts with stars for *both* k-center and k-diameter. We show this via reductions from clique cover and set cover in the full version of this paper.

▶ **Corollary 7.** *Let $\epsilon > 0$. Assuming $P \neq NP$, there is no $(2-\epsilon)$-approximation algorithm for the connected k-diameter problem with non-disjoint clusters, even if G is a star. The same is true for the connected k-center problem with non-disjoint clusters.*

For the positive result, the classical result by Hochbaum and Shmoys [8] can be used. We discuss it in detail because we need it as a basis for our algorithms. For the unconstrained k-center problem, Problem 3 for $\alpha = 2$ can be solved as follows: Given input V, k, and a radius r, one picks an arbitrary point $x \in V$ and puts all nodes within distance $2r$ of x into one cluster. When r is at least the radius of the optimal k-clustering, this cluster will contain all nodes that are in the same optimal cluster as x. The cluster is then removed from V and the process is repeated until all nodes are covered. If the number of clusters is at most k, the solution is returned, otherwise, it is reported that r was too small.

This algorithm can easily be adapted to the connected k-center problem with non-disjoint clusters by the following observation: Let x and y be two nodes from the same optimal cluster with center c and radius r. Then x and y are connected in the connectivity graph by a path that contains only nodes within distance $2r$ from x and y. So the algorithm is: When a node x is selected, put all nodes into a cluster that have distance at most $2r$ from x and are reachable from x in the connectivity graph via a path on which all nodes have a distance of at most $2r$ from x. This set can be determined by the BFS-type algorithm `ComputeCluster` (see Algorithm 1 with $R = 2r$). Say the resulting cluster is T. Do not remove T from G

Algorithm 1 ComputeCluster(G, M, R, c).

Input: points V, graph $G = (V, E)$, metric $M = (V, d)$, radius R, node $c \in V$
$T \leftarrow \{c\}$;
$N \leftarrow \{u \in V \setminus T \mid \exists v \in T, (v, u) \in E : d(u, c) \leq R\}$;
while $N \neq \emptyset$ **do**
  $T \leftarrow T \cup N$;
  $N \leftarrow \{u \in V \setminus T \mid \exists v \in T, (v, u) \in E : d(u, c) \leq R\}$;
Output: cluster T

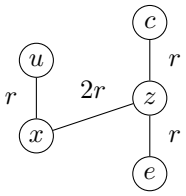
but only mark all nodes in T as covered. As long as there are uncovered nodes, pick an arbitrary such node and form a cluster of radius $2r$ around it (in general this cluster will also contain nodes that are already covered). This will result in at most k connected clusters with radius $2r$ if r is at least the radius of an optimal connected k-clustering. We call this algorithm `GreedyClustering` and we give its pseudocode as Algorithm 2. In general, the sets T_c computed by this algorithm are not disjoint but the centers are pairwise distinct.

▶ **Lemma 8.** *Let r^* denote the radius of an optimal connected k-center clustering with non-disjoint clusters. For $r \geq 2r^*$, Algorithm 2 computes a center set C with $|C| \leq k$.*

Proof. Consider a node $c \in V$ that is chosen as a center by the algorithm and the optimal cluster O node c is contained in. This cluster is centered around some node c' and has a radius of at most r^*. Hence, by the triangle inequality all nodes in O have a distance of at

Algorithm 2 GreedyClustering(G, M, r).

Input: graph $G = (V, E)$, metric $M = (V, d)$, radius r
$C \leftarrow \emptyset$; `// center nodes`
$V' \leftarrow V$; `// uncovered nodes`
while $V' \neq \emptyset$ **do**
  select a node $c \in V'$ and add it to C;
  $T_c \leftarrow$ ComputeCluster(G, M, r, c);
  $V' \leftarrow V' \setminus T_c$;
Output: centers C, sets T_c for all $c \in C$



The optimal connected 2-clustering has centers x and z with clusters $\{x, u\}$ and $\{z, c, e\}$ and a radius of r. The greedy algorithm started with x forms $\{x, u, z\}$ as the first cluster. After that, only c and e remain. Without z, they are not connected anymore and have to go into different clusters.

Figure 3 An example where greedy disconnects an optimum cluster.

most $2r^*$ from c. Also since O is connected, all nodes in O are reachable from c. In particular, all nodes in O are reachable from c on paths that contain only nodes within distance $2r^*$ of c. This implies that for $r \geq 2r^*$, the set T_c is a superset of the optimal cluster O. Since the centers in Algorithm 2 are chosen among the uncovered nodes, all chosen centers must be from distinct optimal clusters. This implies that there can be at most k centers in C. ◀

The same algorithm works for the connected k-diameter problem when `ComputeCluster` is evoked with $R = r$ (not $2r$) if r is at least the optimal diameter. By adding all points in distance r to the cluster of the chosen center x, it is ensured that the optimum cluster is added if r is at least the optimum value (since the distance between two points is then at most r). Furthermore, the resulting cluster has diameter at most $2r$ by the triangle inequality.

▶ **Lemma 9.** *There exists a 2-approximation algorithm for the connected k-center problem with non-disjoint clusters and also for the connected k-diameter problem with non-disjoint clusters.*

4 General G, disjoint clusters

The disjoint case for general connectivity graphs is more challenging. To keep the presentation simple, we focus in the following on the connected k-center problem: Given an unweighted graph $G = (V, E)$ and a metric space $M = (V, d)$ with $d : V \times V \to \mathbb{R}$, find k node-disjoint connected subgraphs of G (clusters) that cover all vertices and minimize the maximum radius of these subgraphs. An adaptation to the connected k-diameter problem can be found in the full version of this paper.

We start with the algorithm `GreedyClustering` from the previous section on the non-disjoint case. Notice that in general, the output of this algorithm is not node-disjoint. We could opt to delete the nodes in T computed by Algorithm 1 to enforce disjointness, however, the problem is this: The first cluster that the algorithm forms around a vertex x is guaranteed to be a superset of the optimal cluster that x is contained in. It might be a strict superset and contain a node that belongs to a different optimal cluster. This node will get removed from G together with all other nodes in the cluster around x. However, its removal might

make the optimal cluster it is contained in unconnected. This is problematic because then k connected clusters might not suffice anymore to cover all points from G even if we guessed the optimal radius r correctly. See Figure 3 for an example where this happens.

4.1 Making the clusters disjoint

In this section we describe how to transform the set of non-disjoint clusters computed by `GreedyClustering` into a set of pairwise disjoint clusters that cover all points at the cost of increasing the radius or diameter. This transformation has to be performed very carefully in order to not increase the radius or diameter by too much.

Let C with $|C| \leq k$ denote the set of centers around which the non-disjoint clusters have been formed by the algorithm and let r denote their radius. The following two observations are helpful: (1) When two centers are more than $2r$ apart then their corresponding clusters are disjoint. (2) If a set of centers have pairwise distance at most L then merging the corresponding clusters results in a single cluster with radius at most $r + L$ and diameter at most $2r + L$.

If it is possible to partition the centers into groups such that all centers within the same group have a distance of at most L and all centers from different groups have a distance of more than $2r$, we could make the clusters disjoint as follows: as long as there are two non-disjoint clusters whose centers are in the same group of the partition, merge them into a single cluster. In the end, the algorithm will return no more than $|C| \leq k$ clusters. By isolating some singletons as new clusters, we obtain a solution with exactly k clusters as required without worsening the solution. After this, all clusters whose centers are in the same group are disjoint (if not they would have been merged) and clusters whose centers are in different groups are disjoint because their centers are far enough from each other. Hence, such a partition results in a solution with disjoint clusters with radius $r + L$ and diameter $2r + L$. A key idea in our algorithm for the general case is to find such a partition of the centers in C with small L. However, observe that this is not possible in general. A simple counterexample would be that all centers are equally spaced on a line with distance r between two consecutive centers. Then all centers have to be in the same group and L would be $(k-1)r$, resulting in an approximation factor of $\Omega(k)$.

To circumvent this problem, we do not partition all centers from C at once but we start with a partition of a subset of C that satisfies the properties above (i.e., centers in the same group have distance at most L, while centers in different groups have a distance of more than $2r$). We call this the first layer of the partition. Then we remove all centers contained in the first layer from C and proceed with the remaining centers analogously: Let C' denote the set of centers not contained in the first layer. We find a partition of a subset of C' that satisfies the properties above and call this the second layer of the partition. We repeat this process until all points from C are in some layer. We call such a partition a *well-separated partition*. Figure 4 shows possible partitions for the example above.

▶ **Definition 10.** *Let $M = (C, d)$ be a metric and $r > 0$. An* r-well-separated partition *with $\ell \in \mathbb{N}$ layers and with parameters $(h_1, \ldots, h_\ell)$ is a partition of C into groups $\{C_{1,1}, \ldots, C_{1,\ell_1}\}, \{C_{2,1}, \ldots, C_{2,\ell_2}\}, \ldots, \{C_{\ell,1}, \ldots, C_{\ell,\ell_\ell}\}$ with the following properties.*

- **(i)** *The groups cover all points from C, i.e., $\bigcup_{i\in[\ell], j\in[\ell_i]} C_{i,j} = C$.*
- **(ii)** *The groups are pairwise disjoint, i.e., $\forall i, i', j, j'$ with $i \neq i'$ or $j \neq j'$, $C_{i,j} \cap C_{i',j'} = \emptyset$.*
- **(iii)** *For $i \in [\ell]$, we call the sets $C_{i,1}, \ldots, C_{i,\ell_i}$ the* sets on layer i. *Two different sets from the same layer are more than $2r$ away, i.e., $\forall i \in [\ell], v \in C_{i,j}, v' \in C_{i,j'}$ with $j \neq j'$, $d(v, v') > 2r$.*
- **(iv)** *For $i \in [\ell]$, the maximum diameter of a group on layer i is at most h_i, i.e., $\max_j \max_{v,v'\in C_{i,j}} d(v, v') \leq h_i$.*

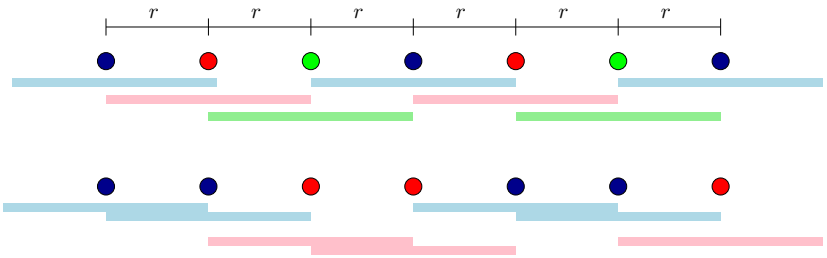


Figure 4 We consider an instance with 7 centers on a line where consecutive centers have a distance of r. The top figure shows a well-separated partition of this instance with $L = 0$ and $\ell = 3$ layers. The colors depict the different layers and the colored rectangles depict the clusters of radius R around these centers. On the blue layer there are, e.g., three groups where each group consists of a single blue center. The bottom figure shows a well-separated partition of the same instance with $L = r$ and $\ell = 2$. The blue layer contains two groups of two centers each, while the red layer contains two groups, one with two centers and one with only one center.

It is not clear at first glance why a well-separated partition is helpful for obtaining a solution with disjoint clusters. For every layer of the partition, we can use the reasoning above. That is, we merge all non-disjoint clusters whose centers are in the same group to obtain disjoint clusters with radius $r + L$ and diameter $2r + L$. However, a cluster is then only disjoint from all clusters on the same layer but in general not from clusters on other layers (see Figure 4). A main ingredient of our algorithm is a non-trivial way to merge clusters on different layers. For this, we add the layers one after another. Consider the case of two layers. The clusters from the first layer are disjoint from each other. We add the clusters of the second layer one after another. For each cluster from the second layer, we first check with which clusters from the first layer it overlaps. If there is more than one, we split the cluster from the second layer into multiple parts and merge the parts with different clusters from the first layer with which they overlap. This is done in such a way that the final result is a set of disjoint connected clusters. We prove with an inductive argument that the radius and diameter of these clusters is $O(\ell \cdot L)$, where ℓ denotes the number of layers of the well-separated partition.

The following lemma describes an algorithm that adjusts the clusters layer by layer to make them pairwise disjoint.

▶ **Lemma 11.** *Consider an instance $(G = (V, E), M = (V, d), k)$ of the connected k-center problem and assume that Algorithm 2 computes a center set $C \subseteq V$ with $|C| \leq k$ for some radius r. Furthermore, let an r-well-separated partition of C with ℓ layers and parameters $(h_1, \ldots, h_\ell)$ be given. Then we can efficiently find a feasible solution for the connected k-center problem with disjoint clusters with radius at most $(2\ell - 1)r + \sum_{i=1}^{\ell} h_i$.*

Proof. According to Definition 10 and Algorithm 2, we have the following properties:

(i) $\bigcup_{i\in[\ell],j\in[\ell_i]} C_{i,j} = C$
(ii) $\forall i, i', j, j'$ with $i \neq i'$ or $j \neq j'$: $C_{i,j} \cap C_{i',j'} = \emptyset$
(iii) $\forall i \in [\ell], c \in C_{i,j}, c' \in C_{i,j'}$ with $j \neq j'$: $d(c, c') > 2r$ and $T_c \cap T_{c'} = \emptyset$
(iv) $\forall i \in [\ell]$, $j \in [\ell_i]$, $c, c' \in C_{i,j}$: $d(c, c') \leq h_i$
(v) $\bigcup_{i\in[\ell],j\in[\ell_i]} \bigcup_{c\in C_{i,j}} T_c = V$

In the first step, we adjust the clusters by merging all non-disjoint clusters whose centers belong to the same group. To be precise, for each group $C_{i,j}$ we do the following: As long as there are two different centers $c \in C_{i,j}$ and $c' \in C_{i,j}$ with $T_c \cap T_{c'} \neq \emptyset$, we remove c' from

$C_{i,j}$ and replace T_c by $T_c \cup T_{c'}$. That is, we merge the two clusters T_c and $T_{c'}$ and define c as its center. Since centers in the same group on layer i have a distance of at most h_i, after this step the clusters in each group $C_{i,j}$ are pairwise disjoint and have a radius of at most $r + h_i$ and a diameter of at most $2r + h_i$. They are still connected because we only merge connected clusters that have at least one node in common.

Since clusters in different groups of the same layer are pairwise disjoint anyway, all clusters on the same layer are pairwise disjoint after this step. Hence, in the next step we only need to describe how clusters from different layers can be made disjoint. For this, it will be helpful to view the clusters as trees. To make this more precise, consider a cluster T_c with center c. We know that the subgraph of G induced by T_c is connected. For any cluster T_c we choose an arbitrary spanning tree in this induced subgraph and consider c to be the root of this tree. Let $\mathcal{T}_i$ denote the set of all such trees in the i-th layer for $i \in [\ell]$. In the following we will use the terms clusters and trees synonymously. By abuse of notation we will use T_c to denote both the cluster with center c and the spanning tree with root c, depending on the context.

For every $i \in [\ell]$, all trees in $\mathcal{T}_i$ are node-disjoint. We will now describe how to ensure that trees on different layers are also node-disjoint. For this, we will go through the layers $i = 1, 2, \ldots, \ell$ in this order and replace $\mathcal{T}_i$ by an adjusted set of trees $\mathcal{T}'_i$. We will construct these trees so that at each step $i \in [\ell]$ all trees from $\cup_{j\in[i]}\mathcal{T}'_j$ are pairwise disjoint. Furthermore, at step i the radius of any tree from $\cup_{j\in[i]}\mathcal{T}'_j$ will be bounded from above by $(2i-1)r + \sum_{j\in[i]} h_j$. Finally, our construction ensures that in the end, the trees in $\cup_{i\in[\ell]}\mathcal{T}'_i$ cover all nodes in V. Hence, these trees form a feasible solution to the connected k-center problem with disjoint clusters with the desired radius.

We set $\mathcal{T}'_1 = \mathcal{T}_1$. Then for $i = 1$, the desired properties are satisfied because the trees on layer 1 are pairwise disjoint and have a radius of at most $r + h_1$. Now assume that the properties are true for some i and let us discuss how to ensure them also for $i + 1$. We start with $\mathcal{T}'_{i+1} = \emptyset$ and add trees to it one after another. Consider an arbitrary tree $T \in \mathcal{T}_{i+1} = (V', E')$ with center c and let $V^* \subseteq V'$ denote the nodes that also occur in some tree $T' \in \mathcal{T}'_j$ for some $j \in [i]$. Observe that any node from V^* can be contained in at most one such tree T' because by the induction hypothesis all trees in $\cup_{j\in[i]}\mathcal{T}'_j$ are pairwise disjoint. If V^* is empty then the tree T is disjoint from all trees in $\cup_{j\in[i+1]}\mathcal{T}'_j$ and does not need to be adjusted. In this case we simply add it to $\mathcal{T}'_{i+1}$.

If V^* contains only a single node v then we merge the tree T with the unique tree T' from $\mathcal{T}'_j$ for some $j \leq i$ that also contains node v, i.e., we replace T' by $T \cup T'$ in $\mathcal{T}'_j$. Tree T' has a radius of at most $(2i-1)r + \sum_{j\in[i]} h_j$. Since the diameter of T is at most $2r + h_{i+1}$, the radius of the union of T and T' with respect to the center of T' is at most (see Figure 5)

$$(2r + h_{i+1}) + (2i-1)r + \sum_{j\in[i]} h_j = (2(i+1)-1)r + \sum_{j\in[i+1]} h_j. \tag{1}$$

Now consider the case that V^* contains more than one node. In this case we cannot simply merge T with some tree from $\cup_{j\in[i]}\mathcal{T}'_j$ because the resulting tree would not be disjoint from the other trees. We also cannot merge all trees that contain nodes from V' into a single cluster because the radius of the resulting cluster could be too large. Instead we split the tree T into multiple components and we merge these components separately with different trees from $\cup_{j\in[i]}\mathcal{T}'_j$. For each node $v \in V^*$ that is not the root c of T we consider the path from c to v and let e denote the last edge on this path (i.e., the edge leading to v). We remove edge e from the tree T and thereby split the tree T into two components. Since we do this for every node from $V^* \setminus \{c\}$, the tree T will be split into $|V^* \setminus \{c\}| + 1$ pairwise disjoint connected components. Each of these components that does not contain the root c contains

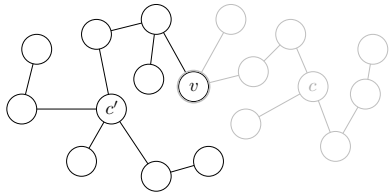

Figure 5 This figure shows the tree T' with center c' in black and the tree T with center c in gray. These trees have node v in common. When T and T' are merged into a single tree, the radius of this new tree with respect to c' is larger than the radius of T' by at most the diameter of T.

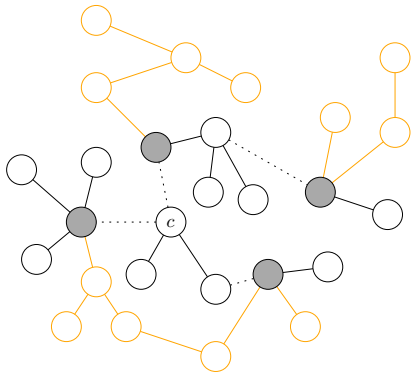

Figure 6 This figure shows the tree T in black. The nodes in V^* are marked gray and the edges that are removed from T are shown dotted. The orange trees depict the trees on lower layers that contain the nodes from V^* and with which the corresponding components are merged.

exactly one node from V^*. Hence, for each of these components there is a unique tree from $\cup_{j\in[i]}\mathcal{T}'_j$ from which it is non-disjoint. We merge every component with the tree from which it is non-disjoint (see Figure 6). In the component that contains the root, only the root might belong to V^*. If this is the case, we merge it with the unique tree from $\cup_{j\in[i]}\mathcal{T}'_j$ from which it is non-disjoint. Otherwise, we add this component to $\mathcal{T}'_{i+1}$. Since T has a diameter of at most $2r + h_{i+1}$, the same is true for each of the components. By the induction hypothesis, each tree from $\cup_{j\in[i]}\mathcal{T}'_j$ has a radius of at most $(2i-1)r + \sum_{j\in[i]} h_j$. Hence, as in (1), the radius of the merged clusters is bounded from above by $(2(i+1)-1)r + \sum_{j\in[i+1]} h_j$. ◀

▶ **Corollary 12.** *If there exists a polynomial-time algorithm that computes for any metric (C, d) and any r an r-well-separated partition with ℓ layers and parameters $(h_1, \ldots, h_\ell)$ then there exists an approximation algorithm for the connected k-center problem with disjoint clusters that achieves an approximation factor of $4\ell - 2 + 2\sum_{i=1}^{\ell} h_i/r$.*

Proof. To obtain the desired approximation factor, we first determine the smallest r for which Algorithm 2 returns a center set C with $|C| \leq k$. Due to Lemma 8, this radius r will be at most $2r^*$, where r^* denotes the radius of an optimal connected k-clustering with non-disjoint clusters. Let r^*_D denote the radius of an optimal connected k-clustering with disjoint clusters. Then $r^*_D \geq r^* \geq r/2$. According to Lemma 11, the polynomial-time algorithm for computing an r-well-separated partition can then be used to compute a connected k-clustering with disjoint clusters and radius at most $(2\ell-1)r + \sum_{i\in[\ell]} h_i$. The approximation factor of this k-clustering is

$$\frac{(2\ell-1)r + \sum_{i\in[\ell]} h_i}{r^*_D} \leq \frac{(2\ell-1)r + \sum_{i\in[\ell]} h_i}{r/2} = 4\ell - 2 + 2\sum_{i\in[\ell]} \frac{h_i}{r}.$$ ◀

The same algorithm that we developed in this sections for the connected k-center problem can also be used for the connected k-diameter problem without any modifications. Only the analysis of the approximation factor needs to be adapted slightly.

Lemma 8 is changed as follows.

▶ **Lemma 13.** *Let r^* denote the diameter of an optimal connected k-diameter clustering with non-disjoint clusters. For $r \geq r^*$, Algorithm 2 computes a center set C with $|C| \leq k$.*

Observe that the diameter of the clusters T_c that are computed by Algorithm 2 for some r can be at most $2r$.

A straightforward adaption of Lemma 11 yields the following result.

▶ **Lemma 14.** *Consider an instance $(G = (V, E), M = (V, d), k)$ of the connected k-diameter problem and assume that Algorithm 2 computes a center set $C \subseteq V$ with $|C| \leq k$ for some radius r. Furthermore, let an r-well-separated partition of C with ℓ layers and parameters $(h_1, \ldots, h_\ell)$ be given. Then we can efficiently find a feasible solution for the connected k-diameter problem with disjoint clusters with diameter at most $(4\ell - 2)r + h_1 + 2\sum_{i=2}^{\ell} h_i$.*

Overall we obtain the following corollary.

▶ **Corollary 15.** *If there exists a polynomial-time algorithm that computes for any metric (C, d) and any r an r-well-separated partition with ℓ layers and parameters $(h_1, \ldots, h_\ell)$ then there exists an approximation algorithm for the connected k-diameter problem with disjoint clusters that achieves an approximation factor of $4\ell - 2 + h_1/r + 2\sum_{i=2}^{\ell} h_i/r$.*

4.2 Finding well-separated partitions

With the discussion above, finding a good approximation algorithm is reduced to finding an efficient algorithm for computing an r-well-separated partition with small L and few layers. For general metrics, we present an efficient algorithm that computes a well-separated partition with $L = O(r \cdot \log k)$ and $\ell = O(\log k)$. This yields a clustering of radius and diameter $O(r \cdot \log^2 k)$. Details can be found in the proof of Theorem 18 in the next section. We give better results for computing well-separated partitions for L_p-metrics and metric spaces with bounded doubling dimension in Theorem 20 and Theorem 23. Overall, we get the following results.

▶ **Theorem 16.** *There exists an $O(\log^2 k)$-approximation algorithm for the connected k-center problem with disjoint clusters and for the connected k-diameter problem with disjoint clusters. The approximation ratio improves*

- *to $O(2^{3 \cdot \dim(M)})$ if the metric space has bounded doubling dimension $\dim(M)$, and*
- *to $O(d \cdot 2^d)$ if the distance is an L_p-metric in $\mathbb{R}^d$.*

It is an intriguing question if better well-separated partitions exist for general metrics and for the special metrics that we have considered. By our framework, better partitions would immediately give rise to better approximation factors.

We prove in the full version a lower bound of $\Omega(\log \log k)$ for our algorithmic framework. To be precise, we construct an instance in a general metric space together with a set of k centers C that could be produced by the algorithm `GreedyClustering` such that even the optimal disjoint solution with centers C is worse than the optimal disjoint solution for arbitrary centers by a factor of $\Omega(\log \log k)$. Hence, to prove a constant-factor approximation in general metric spaces, one cannot rely on the centers chosen by `GreedyClustering`.

4.2.1 Well-separated partitions in general metrics

According to Corollaries 12 and 15, we only need to find an efficient algorithm for computing an r-well-separated partition to obtain an approximation algorithm for the connected k-center and k-diameter problem.

Algorithm 3 computes an r-well separated partition layer by layer. For each layer it creates the groups in a greedy fashion: At the beginning of a layer i, the set U' of all nodes that are not assigned to previous layers is considered. The goal is to assign as many of these nodes to the current layer i as possible. For this, we start with an arbitrary node $u \in U'$ that is not assigned to any previous layer and we create a group around u. First the group consists only of u itself. Then we iteratively augment the group by adding all nodes to the group that have a distance of at most $2r$ from some node that already belongs to the group. We repeat this augmentation step multiple times one after another. We stop when the number of new nodes that join the group is smaller than twice the number of nodes that have already been added to the group for the first time. Then the group around u is finished and added to layer i. All nodes in the group are removed from U'. Furthermore, we also remove all nodes that have a distance of at most $2r$ from this group from U'. These nodes have to be assigned to other layers that are created later to ensure property (iii) in Definition 10. As long as U' is not empty, we repeat the process to create another group on layer i. The pseudocode is shown as Algorithm 3.

Algorithm 3 PartitionGeneralMetric$((C, d), r)$.

Input: metric (C, d), radius r
$U \leftarrow C$; // nodes that still have to be assigned
$i \leftarrow 0$;
while $U \neq \emptyset$ **do**
  $i \leftarrow i + 1$; // start a new layer
  $j \leftarrow 0$;
  $U' \leftarrow U$; // nodes that could still be assigned on i-th layer
  while $U' \neq \emptyset$ **do**
    $j = j + 1$; // create a new group in i-th layer
    select a node $u \in U'$, $C_{i,j} \leftarrow \{u\}$ and $N_0(u) \leftarrow \{u\}$;
    $U' \leftarrow U' \setminus \{u\}$;
    $U \leftarrow U \setminus \{u\}$;
    $s = 1$;
    while $s \neq 0$ *and* $U' \neq \emptyset$ **do**
      $N_s(u) \leftarrow \{x \in U' \mid \exists v \in N_{s-1}(u) : d(v, x) \leq 2r\}$;
      // nearby nodes of nodes $C_{i,j}$ in U'
      if $|N_s(u)| \geq 2 \cdot |C_{i,j}|$ **then**
        $C_{i,j} \leftarrow C_{i,j} \cup N_s(u)$; // add nearby nodes to $C_{i,j}$
        $U' \leftarrow U' \setminus N_s(u)$;
        $U \leftarrow U \setminus N_s(u)$;
        $s = s + 1$;
      else
        $U' \leftarrow U' \setminus N_s(u)$; // nearby nodes cannot be on i-th layer
        $s = 0$; // end group of node u
Output: $\{C_{1,1}, C_{1,2}, \ldots\}, \{C_{2,1}, C_{2,2}, \ldots\}, \ldots$

▶ **Lemma 17.** *Let (C, d) be an arbitrary metric with $k := |C|$ and $r > 0$. Let $\ell = 1 + \lfloor \log_{\frac{3}{2}}(k) \rfloor$ and $h = 4r\lfloor \log_3 k \rfloor$. The output of Algorithm 3 is an r-well-separated partition with at most ℓ layers and parameters $(h, \dots, h)$.*

Proof. Let $\{C_{1,1}, \dots, C_{1,\ell_1}\}, \{C_{2,1}, \dots, C_{2,\ell_2}\}, \dots, \{C_{\ell,1}, \dots, C_{\ell,\ell_\ell}\}$ denote the output of Algorithm 3. The algorithm ensures that every point from C is contained in exactly one group $C_{i,j}$ because when nodes are deleted from U in Line 18 they have been added to $C_{i,j}$ in Line 16. Furthermore U' is always a subset of U and so no node can be assigned to multiple clusters. Furthermore, Lines 14 and 21 ensure that nodes in different groups of the same layer are more than $2r$ apart. This shows that the properties (i), (ii), and (iii) in Definition 10 are satisfied.

Next we show property (iv) that the maximum diameter of every group is h. As long as the number of nearby nodes in $N_s(u)$ is at least twice the number of the previously grouped nodes in $\cup_{t=1}^{s-1} N_t(u)$, we add these nearby nodes to the current group. As long as this is true we have

$$|N_s(u)| \geq 2 \cdot \sum_{t=0}^{s-1} |N_t(u)|.$$

Together with $|N_0(u)| = 1$, this implies $|\cup_{t=1}^{s} N_t(u)| \geq 3^s$ for every s by a simple inductive argument. Since this set cannot contain more than $k = |C|$ nodes, we have $C_{i,j} = \bigcup_{s=1}^{h} N_s(u)$ for some $h \leq \lfloor \log_3 k \rfloor$. For any $s \geq 1$, any node in $N_s(u)$ has a distance of at most $2r$ from some node in $N_{s-1}(u)$. Since u is the only node in $N_0(u)$, this implies that any node has a distance of at most $2rh$ from u. Hence, the diameter of every group is at most $4rh \leq 4r\lfloor \log_3 k \rfloor$. This shows property (iv) in Definition 10.

Now it only remains to bound the number of layers of the partition. When a new layer is started, U' is set to U, the set of yet unassigned nodes in Line 6. When a group is formed then its current neighbors $N_s(u)$ get removed from U' in Line 21. These are exactly the nodes that do not get assigned to the current layer and have to be assigned to other layers afterwards. Since line 21 is only reached if $|N_s(u)|$ is smaller than twice $|C_{i,j}|$, at least one third of the initially unassigned nodes get assigned to groups on the current layer and at most two thirds are postponed to other layers afterwards. This implies that after ℓ layers, there are no more than $(\frac{2}{3})^\ell \cdot k$ nodes left to be assigned. Hence, the number of layers cannot be more than $1 + \lfloor \log_{\frac{3}{2}}(k) \rfloor$. ◀

Based on Corollaries 12 and 15, it is now easy to prove the following theorem.

▶ **Theorem 18.** *There exists an $O(\log^2 k)$-approximation algorithm for the connected k-center problem and for the connected k-diameter problem with disjoint clusters.*

Proof. According to Lemma 17, one can efficiently compute for any metric an r-well-separated partition with at most ℓ layers and parameters $(h, \dots, h)$ for $\ell = 1 + \lfloor \log_{\frac{3}{2}}(k) \rfloor = O(\log k)$ and $h = 4r\lfloor \log_3 k \rfloor = O(r \cdot \log k)$.

By Corollary 12 this implies that we can efficiently find a solution for the connected k-center problem with disjoint clusters with approximation factor

$$4\ell - 2 + 2\sum_{i=1}^{\ell} h/r = O(\ell + \ell h/r) = O(\log k + \log^2 k) = O(\log^2 k).$$

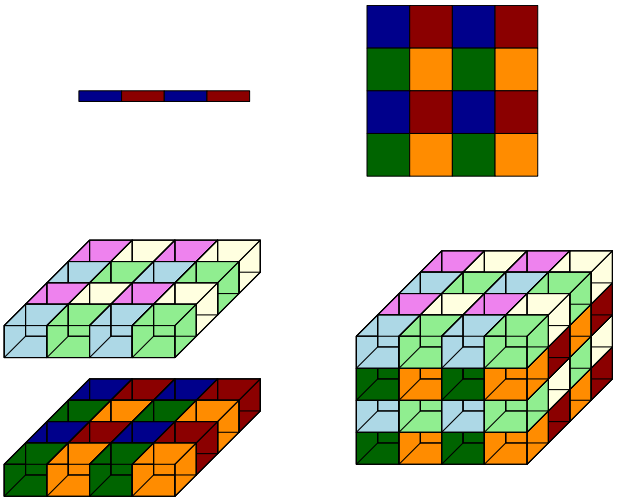

Figure 7 In the upper row, colorings for $d = 1$ and $d = 2$ are shown. In the lower row on the right, a coloring for $d = 3$ is shown. It is composed of alternatingly using the 2-dimensional colorings shown on the left.

By Corollary 15, it also implies that we can efficiently find a solution for the connected k-diameter problem with disjoint clusters with approximation factor

$$4\ell - 2 + h_1/r + 2\sum_{i=2}^{\ell} h_i/r = O(\ell + \ell h/r) = O(\log k + \log^2 k) = O(\log^2 k). \quad \blacktriangleleft$$

4.2.2 Well-separated partitions in Euclidean metrics

In this section, we study how to compute an r-well-separated partition if the metric is an L_p-metric in the d-dimensional space $\mathbb{R}^d$ for some $p \in \{1, 2, \ldots, \infty\}$.

▶ **Lemma 19.** *For any L_p-metric in $\mathbb{R}^d$, an r-well-separated partition with 2^d layers and parameters $(h, \ldots, h)$ with $h = 3d^{1/p}r$ can be computed in polynomial time.*

Proof. First we partition the space $\mathbb{R}^d$ into d-dimensional hypercubes with side length $3r$. These hypercubes are chosen such that they are pairwise disjoint and that they cover the entire space. Then we color these hypercubes such that no two neighboring hypercubes get the same color where also diagonal neighbors are taken into account (see Figure 7). Based on this coloring we create the following r-well-separated partition: each color corresponds to one layer of the partition and within a layer all nodes that belong to the same hypercube form a group. Since the distance of two hypercubes of the same color is at least $3r$, property (iii) of Definition 10 is satisfied. Properties (i) and (ii) are satisfied because the hypercubes partition the space $\mathbb{R}^d$. Finally, the diameter of any of the hypercubes is bounded from above by $(\sum_{i=1}^{d}(3r)^p)^{1/p} = 3d^{1/p}r$, which also proves property (iv).

It remains to bound the number of layers, i.e., the number of different colors necessary to color the hypercubes. One can prove by induction that 2^d colors are sufficient. For $d = 1$, one simply colors the hypercubes alternatingly with two different colors. For $d \geq 2$, we first pick two different colorings of $\mathbb{R}^{d-1}$ with 2^{d-1} colors each such that the two colorings do not have a color in common. Then we color the hypercubes in $\mathbb{R}^d$ by alternatingly using one of the two $(d-1)$-dimensional colorings. This way, we obtain a coloring of the hypercubes in $\mathbb{R}^d$ with 2^d colors (see Figure 7). ◀

Based on Corollaries 12 and 15, it is now easy to prove the following theorem.

▶ **Theorem 20.** *For any L_p-metric in $\mathbb{R}^d$, there exists an $O(d \cdot 2^d)$-approximation algorithm for the connected k-center problem and for the connected k-diameter problem with disjoint clusters.*

Proof. According to Lemma 19, we can efficiently compute an r-well-separated partition with 2^d layers and parameters $(h, \dots, h)$ for $h = 3d^{1/p}r$.

By Corollary 12 this implies that we can efficiently find a solution for the connected k-center problem with disjoint clusters with approximation factor

$$4\ell - 2 + 2\sum_{i=1}^{\ell} h/r = O(d \cdot 2^d).$$

By Corollary 15, it also implies that we can efficiently find a solution for the connected k-diameter problem with disjoint clusters with approximation factor

$$(4\ell - 2) + h_1/r + 2\sum_{i=2}^{\ell} h_i/r = O(d \cdot 2^d).$$ ◀

4.2.3 Well-separated partitions in metrics with small doubling dimension

In this section, we study how to compute an r-well-separated partition if the metric has constant doubling dimension. This generalizes Lemma 19 for Euclidean spaces.

▶ **Definition 21** (doubling dimension)**.** *The* doubling constant *of a metric space $M = (X, d)$ is the smallest number k such that for all $x \in X$ and $r > 0$, the ball $B_r(x) := \{y \in X \mid d(x, y) \leq r\}$ can be covered by at most k balls of radius $r/2$, i.e.,*

$$\forall x \in X : \forall r > 0 : \exists Y \subseteq X, |Y| \leq k : B_r(x) \subseteq \bigcup_{y \in Y} B_{r/2}(y).$$

The doubling dimension *of M is defined as* $\dim(M) = \lceil \log_2 k \rceil$.

▶ **Lemma 22.** *For any metric $M = (X, d)$ with doubling dimension $\dim(M)$, an r-well-separated partition with $2^{3 \cdot \dim(M)}$ layers and parameters $(h, \dots, h)$ with $h = 2r$ can be computed in polynomial time.*

Proof. First we partition X greedily into balls of radius r: As long as not all points of X are covered, we choose arbitrarily an uncovered point x from X and put x into one group together with all uncovered points that have a distance of at most r from x. This way, we get a partition of X into groups with radius at most r.

Next, we try to reduce the number of groups by local improvements. We say that two groups are neighboring if the distance of their centers is at most $4r$. As long as there is a group that has at least $2^{3 \cdot \dim(M)}$ neighbors, we replace this group and its neighbors by $2^{3 \cdot \dim(M)}$ groups as follows: Let x be a center of a group that has at least $2^{3 \cdot \dim(M)}$ neighbors, and let the centers of the neighbors be $Y \subseteq X$. Since x has a distance of at most $4r$ from all centers in Y, we have

$$B_r(x) \cup_{y \in Y} B_r(y) \subseteq B_{5r}(x).$$

By definition of the doubling dimension, the ball $B_{5r}(x)$ can be covered by $2^{\dim(M)}$ balls of radius $5r/2$, each of these can be covered by $2^{\dim(M)}$ balls of radius $5r/4 < 2r$, and each of these can be covered by $2^{\dim(M)}$ balls of radius $5r/8 < r$. Hence, the points in

$B_r(x) \cup_{y \in Y} B_r(y)$ can be covered by $2^{3 \cdot \dim(M)}$ balls of radius r. In our partition, we replace the groups around x and around $y \in Y$ by the groups induced by these balls. Since this reduces the number of groups by at least one, after a linear number of these local improvements, no local improvement is possible anymore, i.e., every group has less than $2^{3 \cdot \dim(M)}$ neighbors.

We have obtained a partition of X into groups, where each group has a radius of at most r. Furthermore, each group has a center and two groups are neighbors if their centers have a distance of at most $4r$. Furthermore, every group has less than $2^{3 \cdot \dim(M)}$ neighbors. The groups will form the groups in the r-well-separated partition. Since points from groups that are not neighbored have a distance of more than $2r$, two groups that are not neighbored can be on the same layer of the partition without contradicting property (iii) from Definition 10. The diameter of each group is at most $h = 2r$. It remains to distribute the groups to the different layers of the partition. For this we find a coloring of the groups such that neighboring groups get different colors. The neighborhood defines implicitly a graph with the groups as vertices with degree at most $2^{3 \cdot \dim(M)} - 1$. Any such graph can be colored with $2^{3 \cdot \dim(M)}$ colors by a greedy algorithm. Now we assign the groups according to the colors to different layers, resulting in an r-well-separated partition with at most $2^{3 \cdot \dim(M)}$ layers. ◀

Based on Corollaries 12 and 15, it is now easy to prove the following theorem.

▶ **Theorem 23.** *For any metric $M = (X, d)$ with doubling dimension $\dim(M)$, there exists an $O(2^{3 \cdot \dim(M)})$-approximation algorithm for the connected k-center problem and for the connected k-diameter problem with disjoint clusters.*

Proof. According to Lemma 19, we can efficiently compute an r-well-separated partition with $2^{3 \cdot \dim(M)}$ layers and parameters $(h, \dots, h)$ for $h = 2r$.

By Corollary 12 this implies that we can efficiently find a solution for the connected k-center problem with disjoint clusters with approximation factor

$$4\ell - 2 + 2 \sum_{i=1}^{\ell} h/r = O(2^{3 \cdot \dim(M)}).$$

By Corollary 15, it also implies that we can efficiently find a solution for the connected k-diameter problem with disjoint clusters with approximation factor

$$4\ell - 2 + h_1/r + 2 \sum_{i=2}^{\ell} h_i/r = O(2^{3 \cdot \dim(M)}).$$ ◀

5 Conclusions

We studied the connected k-center and k-diameter problem and proved several new results on the approximability of different variants of these problems. In particular, we developed a general framework to obtain approximation algorithms for the disjoint versions of these problems that relies on the existence of well-separated partitions. While we obtain constant-factor approximations for L_p-metrics in constant dimension and metrics with constant doubling dimension, our general upper bound is $O(\log^2 k)$. Since all our lower bounds are constant, an obvious open question is to close the gaps between the upper and lower bounds. One possibility to approach this would be to derive better well-separated partitions. However, we also show that with our approach no bound better than $O(\log \log k)$ can be shown.

Abstract

Motivated by recent progress on stochastic matching with few queries, we embark on a systematic study of the sparsification of stochastic packing problems more generally. Specifically, we consider packing problems where elements are independently active with a given probability p, and ask whether one can (non-adaptively) compute a "sparse" set of elements guaranteed to contain an approximately optimal solution to the realized (active) subproblem. We seek structural and algorithmic results of broad applicability to such problems. Our focus is on computing sparse sets containing on the order of d feasible solutions to the packing problem, where d is linear or at most polynomial in $\frac{1}{p}$. Crucially, we require d to be independent of the number of elements, or any parameter related to the "size" of the packing problem. We refer to d as the "degree" of the sparsifier, as is consistent with graph theoretic degree in the special case of matching.

First, we exhibit a generic sparsifier of degree $\frac{1}{p}$ based on contention resolution. This sparsifier's approximation ratio matches the best contention resolution scheme (CRS) for any packing problem for additive objectives, and approximately matches the best monotone CRS for submodular objectives. Second, we embark on outperforming this generic sparsifier for additive optimization over matroids and their intersections, as well as weighted matching. These improved sparsifiers feature different algorithmic and analytic approaches, and have degree linear in $\frac{1}{p}$. In the case of a single matroid, our sparsifier tends to the optimal solution. In the case of weighted matching, we combine our contention-resolution-based sparsifier with technical approaches of prior work to improve the state of the art ratio from 0.501 to 0.536. Third, we examine packing problems with submodular objectives. We show that even the simplest such problems do not admit sparsifiers approaching optimality. We then outperform our generic sparsifier for some special cases with submodular objectives.

1 Introduction

Our starting point for this paper is the beautiful line of recent work on variants of the stochastic matching problem, seeking approximate solutions with limited query access to the (stochastic) data [9, 3, 2, 4, 8, 7, 6, 5]. Notably, many of the algorithms in these works are non-adaptive, and can therefore be interpreted as "sparsifiers" for the stochastic problem.

These works feature powerful new algorithmic and analytic sparsification techniques of possibly more general interest, suggesting that effective sparsifiers might exist well beyond matching and closely related problems.

Our goal in this paper is to coalesce a broader agenda on the sparsification of combinatorial stochastic optimization problems more generally, beginning with the natural and broad class of packing problems. We ask, and make progress on, the fundamental questions: For which stochastic packing problems is effective sparsification possible? What are the algorithmic techniques and blueprints which are broadly applicable? What are the barriers to progress?

Concretely, we examine stochastic packing problems (SPPs) of the following (fairly general) form. We are given a set system $(E, \mathcal{I})$, where E is a finite set of *elements* and $\mathcal{I} \subseteq 2^E$ is a downwards-closed family of *feasible sets* (often also referred to as *independent sets*, in particular for matroids). Also given is an objective function $f : 2^E \to \mathbb{R}_+$, which we assume to be either additive (a.k.a. modular) or submodular. The stochastic uncertainty is described by a given probability $p \in [0, 1]$: We assume that each element of E is *active*, i.e., viable for being selected, independently with probability p. The goal of the SPP is to select a feasible set of active elements maximizing the objective function.

When the set R of active elements is given, or can be queried without restriction, this reduces to non-stochastic optimization for the induced subproblem on R. We refer to the output of such an omniscient [approximation] algorithm as an [approximate] *stochastic optimum solution*. We are instead concerned with algorithms that approximate the stochastic optimum by querying the activity status of only a small, a.k.a. "sparse", set of elements $Q \subseteq E$. In particular, as in much of the prior work we require the queried set Q to be chosen non-adaptively. Such algorithms can equivalently be thought of as factoring into two steps: First, a *sparsification algorithm* (or *sparsifier* for short) computes a (possibly random) set of elements Q. Second, we learn $R \cap Q$, and an [approximate] optimization algorithm is applied to the (now fully-specified) subproblem induced by $R \cap Q$. Since the second (optimization) step is familiar and well-studied, our focus is on the first step, namely sparsification.

We evaluate a sparsifier by two quantities. The first quantity is a familiar one, namely its *approximation ratio*. Specifically, a sparsifier is α-approximate if it guarantees an α-approximation to the stochastic optimum solution when combined with a suitable algorithm in the second (optimization) step. The second quantity is a measure of the "sparsity" of the set Q selected by the sparsifier. We say our sparsifier is of *degree* d if it guarantees $\mathbb{E}[|Q|] \leq d \cdot r$, where $r = \max\{|S| : S \in \mathcal{I}\}$ is the *rank* of the set system $(E, \mathcal{I})$. Intuitively, the sparsification degree refers to the level of "contingency" or "redundancy" in the sparsified instance, relative to the size of maximal feasible solutions. Loosely speaking, the degree of a sparsifier roughly measures "how many" feasible solutions are maintained to account for uncertainty in the problem. Somewhat fortuitously, our definition of degree specializes to the (average) graph-theoretic degree in the special case of matching, lending consistency with prior work on stochastic matching with few queries.

We study sparsifiers whose degree admits an upperbound that is independent of the size of the system; The degree bound can not depend on the number of elements or the rank of the set system, for example. We focus especially on the "polynomial regime", where the degree is restricted to be at most polynomial in $\frac{1}{p}$. We pursue sparsifiers which are constant-approximate, or in the best case $(1 - \epsilon)$-approximate for arbitrarily small $\epsilon > 0$.

Results and Techniques

We begin with the observation that a degree of at least $\frac{1}{p}$ is necessary for constant-approximate sparsification, even for the simplest of packing problems: a rank one matroid and the unweighted additive objective. We then establish a "baseline" of possibility for all stochastic

packing problems, through a generic sparsifier with this same degree $\frac{1}{p}$. This sparsifier is simple: it computes (or estimates) the marginals $\{q_e\}_{e \in E}$ of the stochastic optimum solution, and outputs a set Q which includes each element e independently with probability $\frac{q_e}{p}$. For SPPs with an additive objective, we show that this sparsifier's approximation ratio matches the balance ratio of the best contention resolution scheme (CRS)[1]. for the set system. When the objective is submodular, we approximately match the balance ratio of the best *monotone* CRS up to a factor of $1 - \frac{1}{e}$. We note that contention resolution is only used as a proof tool to certify our sparsifier's approximation guarantee, and is not invoked algorithmically. In settings where the marginals $\{q_e\}_{e \in E}$ are intractable to compute, this sparsifier can be made computationally efficient by resorting to approximation, in which case its approximation ratio degrades in the expected manner. This generic result yields constant-approximate sparsifiers of degree $\frac{1}{p}$ for a large variety of set systems for which contention resolution has been studied, including matroids and their intersections.

Next, we embark on "beating" this contention resolution baseline for natural SPPs. We succeed at doing so for additive (weighted) optimization over matroids, matroid intersections, and matchings. For a single matroid, we derive a simple greedy sparsifier which is $(1 - \epsilon)$-approximate and has degree $\frac{1}{p} \cdot \log(1/\epsilon)$. This sparsifier repeatedly adds a maximum weight independent set of the matroid to the sparse set Q, and removes it from the matroid, until the desired degree is reached. Though our sparsifier is simple, its analysis is (we believe necessarily) less so.

For matroid intersections, we first argue that adaptations of our single-matroid sparsifier cannot succeed, due to feasible sets not "combining well" as they do in the case of a single matroid. Instead, our sparsifier for matroid intersections repeatedly samples the stochastic optimum solution and adds it to the sparse set Q, for a degree of $O(\frac{1}{p\epsilon} \cdot \log(1/\epsilon))$. The approximation ratio of our sparsifier for the intersection of k matroids is $\frac{1-\epsilon}{k+1/(k+1)}$, which beats the best known bound on the correlation gap of $1/(k+1)$ [1]. The analysis of this sparsifier is again nontrivial, and utilizes basis exchange maps.

For matroids and matroid intersections, we note that analysis techniques employed by prior work on matching do not appear to suffice. In particular, prior work on matching often employs concentration arguments on the active degree of matroid "flats" containing an element; this is sufficient in the case of matching, since each element is in at most two binding flats (one for each partition matroid). For general matroids, such concentration arguments fail to bound the degree in a manner independent of the number of elements, necessitating alternative proof approaches like ours.

For general (non-bipartite) matching, we augment our contention-resolution-baseline sparsifier with samples from the stochastic optimum solution, for a total degree of $O(1/p)$. We show that the samples from the stochastic optimum combine well with our baseline sparsifier. We obtain an approximation ratio which is a function of the (as yet not fully known) correlation gap of the matching polytope. This function exceeds the identity function everywhere, implying that our sparsifier strictly improves on the contention resolution baseline. Plugging in the best known lowerbound of 0.474 on the correlation gap from [17], we guarantee that our sparsifier is 0.536 approximate. This improves on the state of the art in the polynomial regime, 0.501-approximate sparsifier of degree poly $(1/p)$ due to [8]. In addition, assuming the conjecture from [20] which states the existence of 0.544 balanced CRS for general matching polytope implies that our sparsifier is 0.598 approximate.

[1] This is equal to the set system's *correlation gap*, as shown by [12].

Table 1 Summary of information theoretic sparsifiers for additive objectives. Here, n is the number of elements and W is the maximum element weight.

	Previous Results		This Work	
Constraint	**Approx. Ratio**	**Sparsification Degree**	**Approx. Ratio**	**Sparsification Degree**
Matroid	$1-\epsilon$ [14]	$O\left(\frac{1}{p}\log\frac{\mathbf{Rank}}{\epsilon}\right)$	$1-\epsilon$	$\frac{1}{p}\cdot\log\left(\frac{1}{\epsilon}\right)$
k-Matroid Intersection	$\frac{1-\epsilon}{2k}$ [18]	$O\left(\frac{W}{p}\log n\log\left(\frac{n}{\epsilon}\right)\frac{k}{\epsilon^3}\right)$	$\frac{1-\epsilon}{k+\frac{1}{k+1}}$	$\frac{1}{\epsilon\cdot p}\cdot\log\left(\frac{1}{\epsilon}\right)$
General Matching	$1-\epsilon$ [6]	$O\left(\exp(\exp(\exp(1/p)))\right)$	0.536	$O\left(\frac{1}{p}\right)$
General Matching	0.501 [8]	$O\left(\frac{1}{p}\right)$	0.536	$O\left(\frac{1}{p}\right)$

Finally, we further examine stochastic packing problems with submodular objectives. Our $(1-\epsilon)$-approximate sparsifier for weighted matroid optimization might tempt one to conjecture a similar result for submodular optimization over simple enough set systems. However, we show by way of an information-theoretic impossibility result that no sparsifier with degree bound independent of the number of elements can beat $(1-1/e)$, even for optimizing a coverage function subject to a uniform matroid constraint. We complement this impossibility result with algorithmic sparsification results for optimizing coverage functions over matroids, improving over the guarantees provided by our baseline generic sparsifier. Due to limited space, the results for submodular SPPs are detailed in the full version of this paper [13](Section 8).

Additional Discussion of Related Work

The exploration of sparsifying SPPs was initiated by [9], who focus on the unweighted stochastic matching problem. This problem has since been studied extensively in a series of works [4, 8, 7, 6] which attempt to beat the benchmark set by [9]. In the "polynomial-degree regime", the state-of-the-art sparsifier for unweighted stochastic matching is a 0.66-approximation due to [2]. Recent work by [5] improves this approximation to $\frac{e}{e+1}$ for unweighted bipartite matching. For weighted stochastic matching in the polynomial-degree regime, the current best known sparsifier is a 0.501-approximation due to [8]. Going beyond polynomial degree, [7, 6] constructed a $(1-\epsilon)$-approximate sparsifier with degree $\exp(\exp(\exp(1/p)))$the weighted general matching problem. The sparsifiers designed for the stochastic matching problems rely heavily on structural properties particular to matching. Our techniques, on the other hand, are targeted at more general packing problems.

To the best of our knowledge, the work of [18, 19] stands alone in directly studying the sparsification of SPPs beyond matching. In [18], they proposed a general framework for solving stochastic packing integer programs. As a corollary of their techniques, they obtain non-adaptive sparsifiers for several additive SPPs. However, the degree of their sparsification algorithms intrinsically depends on the number of elements in settings where a single element may be in an exponential number of binding constraints (as is the case for matroids). Our work, in contrast, proposes several algorithmic techniques that yield approximate sparsifiers with degree independent of the number of elements.

Also related is the work of [14], which studies the covering analogue of our question for matroids. They show how to construct a set of size $O(\frac{\mathbf{Rank}}{p}\log\frac{\mathbf{Rank}}{\epsilon})$ which is guaranteed to contain a minimum-weight base of the matroid with high probability. This implicitly

Table 2 Summary of information theoretic sparsifiers for monotone submodular objectives. All mentioned results are shown in this paper.

Constraint	Approximation Ratio	Sparsification Degree	Note
r-Uniform Matroid	$\left(1-\frac{1}{e}\right)\cdot\left(1-\frac{1}{\sqrt{r+3}}\right)$	$\frac{1}{p}$	$\left(1-\frac{1}{e}\right)$ upperbound, Optimal when $r\to\infty$
Matroid	$\left(1-\frac{1}{e}\right)^2$	$\frac{1}{p}$	$1-\frac{1}{e}$ upperbound
k-Matroid Intersection	$\left(1-\frac{1}{e}\right)\cdot\frac{1}{k+1}$	$\frac{1}{p}$	

implies an $O(\frac{1}{p}\log\frac{\mathbf{Rank}}{\epsilon})$-degree sparsifier for weighted stochastic packing on matroids. Their analysis is tight for the covering setting, and it appears nontrivial to adapt their techniques for the packing setting in order to remove the degree's dependence on the rank. We compare our results for additive SPPs with prior work in Table 1.

The manuscript [19] proposes sparsifiers for SPPs with a monotone submodular objectives. However, their sparsification algorithms are intrinsically adaptive in nature. To the best of our knowledge, ours is the first work that analyzes SPPs with submodular objectives in the non-adaptive setting. We summarize our results for submodular SPPs in Table 2.

2 Problem Definition

We consider packing problems of the form $\langle E,\mathcal{I},f\rangle$ where E is a ground set of *elements* with cardinality n, $f:2^E\to\mathbb{R}_{\geq 0}$ is an objective function, and $\mathcal{I}\subseteq 2^E$ is a downwards-closed family of *independent sets* (a.k.a. *feasible sets*). We use $r=\text{argmax}\{|I|:I\in\mathcal{I}\}$ to denote the *rank* of the set system $\mathcal{I}$. The aim of the packing problem is to select an independent set $O\in\mathcal{I}$ that maximizes $f(O)$.

In this paper, we study packing problems in a particular setting with uncertainty parametrized by $p\in[0,1]$. In a *stochastic packing problem (SPP)* $\langle E,\mathcal{I},f,p\rangle$, nature selects a random set $R\subseteq E$ of *active elements* such that $\mathbf{Pr}[e\in R]=p$ independently for all $e\in E$. We are then tasked with solving the induced (random) packing problem on the active elements, namely $\langle R,\mathcal{I}|R,f|R\rangle$ where $\mathcal{I}|R$ and $f|R$ denote the restriction of $\mathcal{I}$ and f to subsets of R, respectively. We refer to an [approximately] optimum solution to $\langle R,\mathcal{I}|R,f|R\rangle$ as an [approximate] *stochastic optimum solution*. We use **OPT** to denote the expected value of a stochastic optimum solution, i.e.,

$$\mathbf{OPT}(E,\mathcal{I},f,p)=\mathbb{E}_R\left[\max_{\substack{T\in\mathcal{I}\\T\subseteq R}}f(T)\right],$$

where $R\subseteq E$ is the random set which each element of E independently with probability p.

We assume that the set R of active elements is a-priori unknown, and that we can *query* elements in E to check their membership in R. Motivated by settings in which queries are costly, we seek algorithms which query a small (we say "sparse") subset of the elements, and moreover choose those queries non-adaptively. Such non-adaptive algorithms can be thought of as factoring into two steps: A *sparsification* step which selects the small set $Q\subseteq E$ of queries, and an *optimization* step which solves the packing problem $\langle R\cap Q,\mathcal{I}|R\cap Q,f|R\cap Q\rangle$ induced by the queried active elements. For the optimization step, we assume access to a traditional [approximation] algorithm. Our focus is on algorithms for the sparsification step, which we define formally next.

A *sparsification algorithm* (or *sparsifier* for short) $\mathcal{A}$ takes as input an SPP $J = \langle E, \mathcal{I}, f, p \rangle$ from some family of SPPs, and outputs a (possibly random) set of elements $Q \subseteq E$. The twin goals here are for Q to be "sparse" in a quantified formal sense we describe shortly, while guaranteeing that optimally solving the "sparsified" SPP $J|Q = \langle Q, \mathcal{I}|Q, f|Q, p \rangle$ yields an approximate solution to the original SPP J. We say that the sparsification algorithm $\mathcal{A}$ is α-*approximate* if it guarantees $\mathbf{OPT}(J|Q) \geq \alpha\, \mathbf{OPT}(J)$ – i.e., an optimal solution to the sparsified SPP is an α-approximate solution to the original SPP. We sometimes identify the sparsified SPP $J|Q$ with Q when J is clear from the context.

To quantify sparsity, we say that $\mathcal{A}$ has *sparsification degree* d if it guarantees that $\frac{\mathbb{E}[|Q|]}{r} \leq d$, where r is the rank of the set system $\mathcal{I}$, and expectation is over the internal random coins of $\mathcal{A}$. Intuitively, the degree of sparsification refers to the level of "contingency" or "redundancy" in the sparsified instance, relative to the size of maximal feasible solutions. Loosely speaking, the degree of a sparsifier roughly measures "how many" feasible solutions it maintains to account for uncertainty in the problem.

In the absence of a bound on degree, an approximation factor of $\alpha = 1$ is trivially achievable. We aim to construct approximate sparsifiers of low degree for natural classes of SPPs. We begin by observing that a degree of $\Omega(1/p)$ is necessary for constant approximation, even for the simplest of constraints.

▶ **Example 1.** Consider the SPP with n elements, the unweighted additive objective function $f(S) = |S|$, a rank-one matroid constraint, and activation probability $p = 1/n$. There is at least one active element with probability $1 - (1-p)^n \geq 1 - 1/e$, therefore $\mathbf{OPT} \geq 1 - 1/e$. On the other hand, a set of elements Q will contain no active elements with probability $(1-p)^{|Q|} \geq 1 - |Q| \cdot p = 1 - \frac{|Q|}{n}$. When $|Q| = o(1/p) = o(n)$, there are no active elements in Q with probability $1 - o(1)$. Therefore, any constant-approximate sparsifier must have degree $\Omega(1/p)$.

We also show in in the full version of this paper [13] that, unsurprisingly, there exist stochastic packing problems which do not admit constant approximate sparsifiers with degree $\text{poly}(1/p)$. Given these simple impossibility results, we ask a natural question:

▶ **Question 2.** *Which stochastic packing problems admit constant approximate sparsifiers of degree* $O\left(\frac{1}{p}\right)$*, or more loosely* $\text{poly}\left(\frac{1}{p}\right)$*?*

In this paper, we focus on designing sparsification algorithms for stochastic packing problems with additive or nonnegative monotone submodular objectives.

A Note on Input Representation

Many of our results are information theoretic, and therefore make no assumptions on how a stochastic packing problem is represented. Most of our algorithmic results, on the other hand, only require solving realized (non-stochastic) instances of the packing problem, possibly approximately. Specifically, for a stochastic packing problem $\langle E, \mathcal{I}, f, p \rangle$ we often assume access to a [β-approximate] *stochastic optimal oracle*. Such an oracle samples a [β-approximate] solution to the (random) packing problem $\langle R, \mathcal{I}|R, f|R \rangle$, where R includes each element of E independently with probability p, and $\mathcal{I}|R$ and $f|R$ denote the restriction of $\mathcal{I}$ and f to R respectively. For our algorithmic results on matroids, we additionally assume access to an independence oracle, as is standard.

3 Sparsification from Contention Resolution

In this section, we show how to generically derive a sparsifier for a stochastic packing problem from bounds on contention resolution for the associated set system. First, we recall the relevant definition of contention resolution.

▶ **Definition 3** ([12]). *Let $(E, \mathcal{I})$ be a set system, and let $P_{\mathcal{I}} = \text{convexhull}\{\mathbb{1}_I : I \in \mathcal{I}\}$ denote the associated polytope. A* Contention Resolution Scheme (CRS) *π for $P_{\mathcal{I}}$ is a (randomized) algorithm which takes as input a point $x \in P_{\mathcal{I}}$ and a set of* active *elements $R(x) \subseteq E$, including each element $i \in E$ independently with probability x_i, and outputs a feasible subset $\pi_x(R(x)) \subseteq R(x)$, $\pi_x(R(x)) \in \mathcal{I}$. For $b, c \in [0, 1]$, we say a CRS is* (b, c)-balanced *if for all $i \in E$ and $x \in b \cdot P_{\mathcal{I}}$, $\mathbf{Pr}[i \in \pi_x(R(x)) \mid i \in R(x)] \geq c$. A CRS π is* monotone *if for every $S \subseteq T \subseteq E$ we have that $\mathbf{Pr}[i \in \pi(S) \mid i \in S] \geq \mathbf{Pr}[i \in \pi(T) \mid i \in T]$.*

Our generic sparsifier is randomized, has degree $\frac{1}{p}$, and is shown in Algorithm 1. Our sparsifier computes estimated marginals $\mathbf{q}$ for the stochastic optimum solution. For an information-theoretic result, we can assume these to be exact. Then it samples each element $e \in E$ in a sparse set Q with probability $\frac{q_e}{p}$.

When the objective function f is additive, our sparsifier has an approximation factor that matches the balance ratio of the best CRS for $P_{\mathcal{I}}$.[2] For nonnegative monotone submodular functions, the approximation factor matches the balance ratio of the best monotone CRS for $P_{\mathcal{I}}$. This is due to the observation that each element $e \in E$ is included in the active subset of the sparse set Q with probability q_e and the fact that $\mathbf{q} \in P_{\mathcal{I}}$. The detailed proof for Theorem 4 can be found in the full version [13].

Algorithm 1 Generic Sparsifier for a Stochastic Packing Problem $\langle E, \mathcal{I}, f, p \rangle$.

Input: Stochastic packing problem $\langle E, \mathcal{I}, f, p \rangle$

Compute the marginals $\mathbf{q}$ of the stochastic optimum solution, or an approximation thereof.
$Q \leftarrow \emptyset$;
for all $e \in E$ **do**
  Add e to Q with probability $\frac{q_e}{p}$ (independently)
end for
Output: Sparse set Q.

▶ **Theorem 4.** *Consider Algorithm 1, implemented with exact (possibly non-polynomial-time) computation of the marginals $\mathbf{q}$. When f is additive, and $P_{\mathcal{I}}$ admits a c-balanced CRS, the algorithm is a c-approximate sparsifier of degree $\frac{1}{p}$. When f is a nonnegative monotone submodular, and $P_{\mathcal{I}}$ admits a c-balanced monotone CRS, the algorithm is a $c\left(1 - \frac{1}{e}\right)$-approximate sparsifier of degree $\frac{1}{p}$.*

To make our sparsifier algorithmically efficient, $\mathbf{q}$ may be estimated by sampling from a (possibly approximate) stochastic optimum oracle, in which case our guarantees degrade in the expected manner due to sampling errors and/or the approximation inherent to the oracle. We present the detailed analysis with approximate stochastic optimal oracles in Appendix B in the full version [13]. Theorem 4 and Theorem 4.3 (In full version [13]) together with contention resolution schemes from prior work [1, 12, 17] and approximate stochastic optimal oracles that employ approximation algorithms from [11, 16], imply constant approximate sparsifier for a broad class of packing constrains summarized in Table 3.

[2] This balanced ratio is equal to the *correlation gap* of the set system $\mathcal{I}$, as per [12].

Table 3 Approximation Ratio of Generic Sparsifier of degree $\frac{1}{p}$ for various packing constraint families with additive and non-negative monotone submodular function.

	Additive Objective		**Submodular Objective**	
Constraint	Information Theoretic	Poly-Time	Information Theoretic	Poly-Time
Matroid	$\left(1-\frac{1}{e}\right)$	$(1-\epsilon)\cdot\left(1-\frac{1}{e}\right)$	$\left(1-\frac{1}{e}\right)^2$	$(1-\epsilon)\cdot\left(1-\frac{1}{e}\right)^3$
k-matroid intersection	$\frac{1}{k+1}$	$(1-\epsilon)\cdot\frac{1}{k^2-1}\cdot$	$\frac{1-1/e}{k+1}$	$(1-\epsilon)\cdot\frac{1-1/e}{k^2-1}\cdot$
Matching	0.474	$(1-\epsilon)\cdot 0.474$	$(1-\frac{1}{e})\cdot 0.43$	$(1-\frac{1}{e})^2\cdot 0.43$

The following proposition (whose proof is delegated to the full version [13]) shows that Algorithm 1 is optimal for matroids and additive objectives among sparsifiers of degree $1/p$. This strongly suggests that sparsification is intimately tied to contention resolution when the degree is restricted to $1/p$. In particular, exceeding degree $1/p$ appears necessary for outperforming the correlation gap of a set system in general.

▶ **Proposition 5.** *Consider the family of stochastic packing problems with matroid constraints and additive objectives. There is no degree $\frac{1}{p}$ sparsifier for this family that achieves an approximation ratio $1-1/e+\Omega(1)$.*

We note that $1-1/e$ is the best possible balance ratio for contention resolution on the rank one matroid, as shown in [12] through the correlation gap. Given the above discussion, it is natural to ask whether we can design sparsifiers of degree $O(1/p)$, or even poly$(1/p)$, whose approximation ratio α exceeds the best CRS balance ratio c, i.e., can we have $\alpha > c$ with degree linear or polynomial in $1/p$? Recent progress on this question for bipartite matching constraints came in a pair of recent works. Behnezhad et.al. [5] designed a $\frac{e}{e+1}\approx 0.731$-approximate sparsifier with degree poly$(1/p)$ for unweighted bipartite matching. Their approximation factor is strictly better than a known upper bound of 0.544 on the correlation gap (and hence the best balance ratio) of bipartite matching, due to [15]. To our knowledge, this is the only sparsifier in the literature with degree polynomial in $\frac{1}{p}$ and approximation ratio provably exceeding the correlation gap of the set system. Another recent result due to Behnezhad et al [7] achieves a 0.501-approximate sparsification with degree polynomial in $1/p$ for *weighted* matching. This outperforms the best *known* contention resolution scheme for matching[10], though not clearly the best possible. Prior to our work, there was no known sparsifier for any *weighted* stochastic packing problem which provably outperforms the correlation gap using degree poly$(1/p)$.

In the following sections, we will construct degree $O(1/p)$ sparsifiers for matroids, matroid intersections, and matching which improve on the contention-resolution-based guarantees provided in this section. For matroids and matchings, our sparsifiers provably outperform contention resolution. For matroid intersections, we outperform the best *known* CRS.

4 Additive Optimization over a Matroid

In this section, we design an improved sparsifier for the stochastic packing problem $\langle E,\mathcal{I},f,p\rangle$ when $\mathcal{M}=(E,\mathcal{I})$ is a matroid and f is additive. For an arbitrary $\epsilon>0$, our sparsifier is $(1-\epsilon)$-approximate and has degree $\frac{1}{p}\log\frac{1}{\epsilon}$. Throughout, we use $\{w_e\}_{e\in E}$ to denote the weights associated with the additive function f, and use $R\subseteq E$ to denote the (random) set of active elements which includes each $e\in E$ independently with probability p. We also sometimes use r as shorthand for $\mathbf{Rank}(\mathcal{M})$. We present basic preliminaries of matroid theory in the full version [13]

▶ **Theorem 6.** *Let $\mathcal{M} = (E, \mathcal{I})$ be a matroid, f be an additive function and $p \in [0,1]$. Algorithm 2 is a $(1-\epsilon)$-approximate polynomial time sparsifier for the stochastic packing problem $\langle E, \mathcal{I}, f, p\rangle$ with sparsification degree $\frac{1}{p} \cdot \log\left(\frac{1}{\epsilon}\right)$.*

Previously, the best known sparsifer for matroid was $(1-\epsilon)$-approximate with degree $O\left(1/p \log\left(\mathbf{Rank}/\epsilon\right)\right)$ implicit in [14]. In contrast, the sparsification degree of our algorithm is independent of the "size" of the matroid. As we argued in introduction, such a size-independent guarantee appears to be beyond the techniques used in earlier works [14, 18].

Algorithm 2 Sparsifier for $(\mathcal{M}, f, p)$, when $\mathcal{M}$ is a matroid and f is additive.

Set $\mathcal{M}_0 = \mathcal{M}$ and $Q = \emptyset$.
for t in $\{1, \ldots, \tau\}$ where $\tau = \frac{1}{p} \cdot \log(\frac{1}{\epsilon})$
  Let $I_t \leftarrow \text{argmax}_{I \in \mathcal{I}_{t-1}} f(I)$, where $\mathcal{I}_{t-1}$ is the collection of independent sets in $\mathcal{M}_{t-1}$.
  Update $\mathcal{M}_t \leftarrow \mathcal{M}_{t-1} \setminus I_t$.
Output: $Q = \bigcup_{t=1}^{\tau} I_t$.

It is clear that the sparsifier in Algorithm 2 has degree $\tau = \frac{1}{p} \cdot \log(\frac{1}{\epsilon})$, and can be implemented in polynomial time given an independence oracle for the matroid $\mathcal{M}$. The remainder of this section is devoted to proving that it is $(1-\epsilon)$-approximate, as needed to complete the proof of Theorem 6. Our proof will consist of two parts. First, we will analyze Algorithm 2 in the special case of unit weights (a.k.a. unweighted). Second, we reduce the analysis of the weighted problem to that of the unweighted problem.

4.1 Special Case: Unweighted Optimization

In this subsection, we assume that elements of the matroid $\mathcal{M}$ all have unit weight. In this case, observe that Algorithm 2 repeatedly removes an arbitrary basis of the matroid and adds it to the sparse set Q. More precisely, in iteration t the set I_t is a basis of the remaining matroid $\mathcal{M}_{t-1} := \mathcal{M} \setminus \bigcup_{j=1}^{t-1} I_j$.

In this unweighted case, the stochastic optimal value is the expected rank of the active elements R, and our claimed approximation guarantee can be expressed as $\mathbb{E}[\mathbf{Rank}(Q \cap R)] \geq (1-\epsilon)\,\mathbb{E}[\mathbf{Rank}(R)]$. To establish this, consider the following informal (but ultimately flawed) argument, starting with the observation that $I_t \cap R$ spans a p fraction of the rank of the remaining matroid $\mathcal{M}_{t-1}$ in expectation. This observation suggests that the rank of elements not spanned by $Q \cap R$ should shrink by a factor of $(1-p)$ with each iteration. Induction would then guarantee that after $\frac{1}{p} \cdot \log\left(\frac{1}{\epsilon}\right)$ iterations we have covered a $(1-\epsilon)$ fraction of the rank of the matroid.

The above rough argument is a good starting point. Indeed, it succeeds when all (or many) of the bases $I_1, \ldots, I_\tau$ are full-rank or close to it. These are precisely the scenarios in which $\mathbb{E}[\mathbf{Rank}(R)] \approx \mathbf{Rank}(\mathcal{M})$. However, in general $\mathbf{OPT} = \mathbb{E}[\mathbf{Rank}(R)]$ can be significantly smaller than $\mathbf{Rank}(\mathcal{M})$ – in the worst case up to a factor of p smaller – in which case the the rank of I_t may drop precipitously with t and the above inductive analysis falls apart. Such scenarios are not simply outliers that we can assume away: they are unavoidable products of the weighted-to-unweighted reduction we present in the next subsection, and can account for a large fraction of the weighted stochastic optimal. This seems to necessitate a more nuanced proof approach in which we compare $\mathbb{E}[\mathbf{Rank}(Q \cap R)]$ with $\mathbb{E}[\mathbf{Rank}(R)]$. We present such a proof next, built upon the following definitions and structural properties.

▶ **Definition 7.** *A* nested system of spanning sets (NSS) *for a matroid $\mathcal{M}$ is a sequence $I_1, I_2, \dots I_\tau$ of sets such that for any $j \in [\tau]$, I_j is a full rank set of elements in $\mathcal{M} \setminus I_{1:j-1}$, where $I_{1:j-1} = \bigcup_{\ell=1}^{j-1} I_\ell$.*

▶ **Observation 8.** *The sets $I_1, \dots, I_\tau$ from Algorithm 2 are an NSS of $\mathcal{M}$.*

The following lemma states that the property of being an NSS is preserved under contraction.

▶ **Lemma 9.** *Let $\mathcal{M} = (E, \mathcal{I})$ be a matroid and let $I_1, \dots I_\tau$ be an NSS of $\mathcal{M}$. For an arbitrary independent set S of $\mathcal{M}$, let $I'_j = I_j \setminus S$ for all j. Then, the sequence $I'_1, \dots I'_\tau$ is an NSS of $\mathcal{M}/S$.*

Proof. Fix an arbitrary $j \in \{1, \dots, \tau\}$. It is clear that I'_j is a subset of the elements of $\mathcal{M}/S \setminus I'_{1:j-1}$. It remains to show that I'_j is full rank in $\mathcal{M}/S \setminus I'_{1:j-1}$, as follows.

$$\begin{aligned}
\mathbf{Rank}^{\mathcal{M}/S}(I'_j) &= \mathbf{Rank}^{\mathcal{M}}(I_j \cup S) - |S| && \text{(By (2) and definition of } I'_j\text{)} \\
&= \mathbf{Rank}^{\mathcal{M}}((E \setminus I_{1:j-1}) \cup S) - |S| && (I_j \text{ is full rank in } \mathcal{M} \setminus I_{1:j-1}) \\
&= \mathbf{Rank}^{\mathcal{M}}((E \setminus S \setminus I'_{1:j-1}) \cup S) - |S| && \text{(By definition of } I'_j\text{)} \\
&= \mathbf{Rank}^{\mathcal{M}/S}(E \setminus S \setminus I'_{1:j-1}) && \text{(By (2))} \\
&= \mathbf{Rank}(\mathcal{M}/S \setminus I'_{1:j-1}) && \blacktriangleleft
\end{aligned}$$

▶ **Observation 10.** *If $I_1, \dots, I_\tau$ is an NSS of $\mathcal{M}$, then $I_2, \dots I_\tau$ is an NSS of $\mathcal{M} \setminus I_1$.*

Now, we will prove the desired result for unweighted matroids.

▶ **Lemma 11.** *Let $\mathcal{M}$ be a matroid, and let $I_1, \dots I_\tau$ be an NSS of $\mathcal{M}$. Then,*

$$\mathbb{E}[\boldsymbol{Rank}(I_{1:\tau} \cap R)] \geq (1 - (1-p)^\tau) \cdot \mathbb{E}[\boldsymbol{Rank}(R)]$$

Proof. Let E denote the elements of $\mathcal{M}$. We will apply induction on τ to prove this result. The base case of $\tau = 0$ is trivial.

Consider $\tau \geq 1$. Let S be an arbitrary maximal independent subset of $R \cap I_1$, and let $\mathbf{Rank}'$ denote the rank function of the (random) matroid $\mathcal{M}' = \mathcal{M}/S \setminus I_1$ with elements $E \setminus I_1$. Using (2) we can write

$$\mathbf{Rank}(R \cap I_{1:\tau}) = \mathbf{Rank}(R \cap I_1) + \mathbf{Rank}'(R \cap I_{2:\tau}) \tag{1}$$

The expectation of the first term is $\mathbb{E}[\mathbf{Rank}(R \cap I_1)] = r \cdot p$. To bound the expectation of the second term, we first condition on $R \cap I_1$, which also fixes S and $\mathcal{M}'$. It follows from Lemma 9 and Observation 10, as well as the fact that $S \subseteq I_1$ is disjoint from $I_{2:\tau}$, that $I_2, \dots I_\tau$ is an NSS of $\mathcal{M}'$. This allows us to invoke the inductive hypothesis to obtain

$$\mathbb{E}[\mathbf{Rank}'(R \cap I_{2:\tau})] \geq (1 - (1-p)^{\tau-1}) \cdot \mathbb{E}[\mathbf{Rank}'(R \setminus I_1)].$$

We use a well-known fact about the rank function of the contracted matroid given by

$$\mathbf{Rank}^{\mathcal{M}/S}(T) = \mathbf{Rank}^{\mathcal{M}}(T \cup S) - \mathbf{Rank}^{\mathcal{M}}(S) = \mathbf{Rank}^{\mathcal{M}}(T \cup S) - |S|. \tag{2}$$

Equation (2) and the definition of S implies that $\mathbf{Rank}'(R \setminus I_1) = \mathbf{Rank}((R \setminus I_1) \cup S) - \mathbf{Rank}(S) = \mathbf{Rank}(R) - \mathbf{Rank}(R \cap I_1)$. Also using the fact $\mathbb{E}[\mathbf{Rank}(R \cap I_1)] = r \cdot p$, we obtain

$$\begin{aligned}\mathbb{E}[\mathbf{Rank}'(R \cap I_{2:\tau})] &\geq (1-(1-p)^{\tau-1}) \cdot \mathbb{E}[\mathbf{Rank}'(R \setminus I_1)] \\ &= (1-(1-p)^{\tau-1})(\mathbb{E}[\mathbf{Rank}(R)] - \mathbb{E}[\mathbf{Rank}(R \cap I_1)]) \\ &= (1-(1-p)^{\tau-1})\,\mathbb{E}[\mathbf{Rank}(R)] - (1-(1-p)^{\tau-1}) \cdot r \cdot p \end{aligned} \tag{3}$$

Finally, we combine (1), and (3) to conclude

$$\begin{aligned}\mathbb{E}[\mathbf{Rank}(R \cap I_{1:\tau})] &\geq (1-(1-p)^{\tau-1})\,\mathbb{E}[\mathbf{Rank}(R)] + (1-p)^{\tau-1} \cdot r \cdot p \\ &\geq (1-(1-p)^{\tau-1} + p(1-p)^{\tau-1})\,\mathbb{E}[\mathbf{Rank}(R)] \\ &= (1-(1-p)^{\tau})\,\mathbb{E}[\mathbf{Rank}(R)] \end{aligned}$$

◀

By observation 8, we get the following corollary of Lemma 11.

▶ **Corollary 12.** *Consider a stochastic matroid optimization problem $\langle E, \mathcal{I}, f, p\rangle$ for $p \in [0,1]$ and $f(S) = |S|$ for all $S \subseteq E$. Algorithm 2 is a $(1-\epsilon)$-approximate sparsifier with degree $\frac{1}{p} \cdot \log\left(\frac{1}{\epsilon}\right)$.*

4.2 Proof of Theorem 6

In this section, we will complete the proof of Theorem 6 by reducing the analysis for a general (weighted) additive function to that of the unweighted case. We order the elements $e_1, \ldots e_n$ in decreasing order of their weights $w_1 \geq \ldots \geq w_n$. Without loss of generality we assume $w_n > 0$, and for notational convenience we define $w_{n+1} = 0$. The following lemma says that if a sparsifier is α-approximate for the unweighted problem on elements above any given weight threshold, then it is also α-approximate for the weighted problem.

▶ **Lemma 13.** *For all $j \in [n]$ with $w_j > w_{j+1}$, if a set $Q \subseteq E$ satisfies*

$$\mathbb{E}[\boldsymbol{Rank}(Q \cap R \cap \{e_1, \ldots e_j\})] \geq (1-\epsilon)\,\mathbb{E}[\boldsymbol{Rank}(R \cap \{e_1, \ldots e_j\})], \tag{4}$$

then $\mathbb{E}[f(\mathrm{opt}(Q \cap R))] \geq (1-\epsilon)\,\mathbb{E}[f(\mathrm{opt}(R))]$. Here, we denote $\mathrm{opt}(S) \in \operatorname{argmax}_{\substack{I \subseteq S \\ I \in \mathcal{I}}} f(I)$, with ties broken arbitrarily.

The above lemma follows from the optimality of the greedy algorithm for weighted optimization over matroids. We relegate the (fairly standard) proof to the full version [13].

To conclude the proof of Theorem 6, we show in the following lemma that the output of Algorithm 2 satisfies condition (4).

▶ **Lemma 14.** *For all $j \in [n]$ with $w_j > w_{j+1}$, the output set Q of Algorithm 2 satisfies*

$$\mathbb{E}[\boldsymbol{Rank}(Q \cap R \cap \{e_1, \ldots, e_j\})] \geq (1-(1-p)^{\tau})\,\mathbb{E}[\boldsymbol{Rank}(R \cap \{e_1, \ldots, e_j\})]$$

To provide more intuition, let $I_1, \ldots, I_\tau$ be the sets defined in Algorithm 2, and $\overline{E} = \{e_1, \ldots e_j\}$ be the top weight j elements. It is sufficient to show that the sets $I_t \cap \overline{E}$ form a sequence of nested spanning sets for the restricted matroid $\overline{\mathcal{M}}$ on elements $\overline{E}$. The optimal choice of of I_t in Algorithm 2, together with the matroid structure, implies that $I_t \cap \overline{E}$ has full rank in $\overline{\mathcal{M}} \setminus I_{1:t-1}$. We complete the proof in the in the full version [13]. Combining Lemmas 13 and 14 completes the proof of Theorem 6.

5 Improved Sparsifier for Stochastic Weighted Matching

In the instance of stochastic weighted matching $\langle E, \mathcal{I}, f, p\rangle$, the elements E are the edges of a known weighted graph $G := (V, E, w)$, $\mathcal{I}$ is the set of all matchings in the graph G, and f is an additive function with element weights $\{w_e\}_{e\in E}$. For simplicity, we sometimes denote the stochastic matching instance $\langle E, \mathcal{I}, f, p\rangle$ by $\langle G, p\rangle$ when it is clear from the context.

The aim of a sparsifier for this problem is to query a poly $(1/p)$-degree subgraph H of G such that the expected weight of the maximum matching on active edges of H approximates the optimum value of $\langle G, p\rangle$. The current state-of-the-art poly $(1/p)$-degree sparsifier for the stochastic weighted matching problem achieves a 0.501 approximation ratio due to [8][3]. In this section, we present a new poly$(1/p)$-degree sparsifier for the stochastic weighted matching that improves the approximation ratio to 0.536.

Our sparsifier for the stochastic weighted matching problem consists of two phases. In the first phase, it samples a set of edges $Q_{\texttt{CRS}}$ using the generic sparsifier described in Algorithm 1. In the second phase, we independently select T samples $Q_1, \ldots, Q_T$ from the stochastic optimum oracle $\mathcal{D}_{\text{opt}}$, which is similar to the method used in [8]. This second phase alone already provides a 0.501 approximation, but by incorporating the edges sampled in the first phase, we are able to improve the approximation ratio to 0.536. The main result of this section is presented in the following theorem.

Algorithm 3 Sparsifier for Weighted Stochastic Matching Problem $\langle G, p\rangle$.

1: Compute the marginals $\mathbf{q}$ of the stochastic optimum solution.
2: Add each edge $e \in E$ to the set $Q_{\texttt{CRS}}$ independently with probability $\frac{q_e}{p}$.
3: Sample $Q_1, \ldots, Q_T \sim D_{\text{opt}}$ independently and add them to $Q_{\texttt{Greedy}}$ for $T = 1/\epsilon^8 p$.
4: **Output:** $Q = Q_{\texttt{CRS}} \cup Q_{\texttt{Greedy}}$.

▶ **Theorem 15.** *Let $G = (V, E, w)$ be a weighted graph and $p \in (0, 1)$. If the matching polytope of G admits an α-balanced contention resolution scheme, then Algorithm 3 is the $(1 - O(\epsilon)) \cdot \max\left\{\frac{1}{2}, \left(\frac{1+\alpha e^2}{1+e^2}\right)\right\}$-approximate polynomial time sparsifier for the stochastic weighted matching problem $\langle G, p\rangle$ with sparsification degree $O(1/\epsilon^8 p)$.*

Our theorem combined with 0.474-balanced CRS for machining polytope from [17] implies 0.536-approximate sparsifier for stochastic weighted matching. Assuming the conjecture from [20] which states the existence of 0.544 balanced CRS for general matching polytope implies that Algorithm 3 is ~ 0.6 approximate.

The proof of Theorem 15 relies on p being small. So, before we prove the theorem, in Lemma 16, we show that for any $\epsilon > 0$ (constant), without loss of generality we can assume $p \le \epsilon^4$. The proof of this part is rather technical and, we defer it to the full version [13] due to space constraints.

▶ **Lemma 16** (Reduction Lemma). *If there exists an α-approximate sparsifier with degree d/p for the class of stochastic weighted matching with $p \le \epsilon^4$ then there exists an α-approximate sparsifier for the same problem class and arbitrary $p \in (0, 1)$ with sparsification degree $\frac{d}{p\cdot\epsilon^4}$.*

For the rest of the section, we assume that $p \le \epsilon^4$. We first define the set of crucial edges and non-crucial edges formally in the following definition.

[3] Recent work by [6] constructs $(1-\epsilon)$-approximate sparsifier with degree $\exp(\exp(\exp(1/\epsilon, 1/p)))$, however, in this work, we focus on sparsifiers with degree poly$(1/p)$

▶ **Definition 17.** *Given $\langle G, p\rangle$, let q_e be the probability of an edge e being in the stochastic optimum solution. We define* crucial edges *as* $\mathtt{C} := \{e \in E \ : \ q_e \geq \tau(\epsilon)\}$ *and* non-crucial edges *as* $\mathtt{NC} := \{e \in E \ : \ q_e < \tau(\epsilon)\}$ *where* $\tau(\epsilon) := \frac{\epsilon^3 p}{20 \cdot \log \frac{1}{\epsilon}}$ *is the threshold.*

Given $\langle G, p\rangle$ and set of crucial and non-crucial edges $\mathtt{C}$ and $\mathtt{NC}$, we let $\mathbf{OPT}_{\mathtt{C}}$ and $\mathbf{OPT}_{\mathtt{NC}}$ be the contributions of crucial and non-crucial edges in the stochastic optimum, i.e. $\sum_{e \in \mathtt{C}} w_e \cdot q_e$ and $\sum_{e \in \mathtt{NC}} w_e \cdot q_e$. Note that

$$\mathbf{OPT} = \mathbf{OPT}_{\mathtt{C}} + \mathbf{OPT}_{\mathtt{NC}}\,.$$

In order to prove Theorem 15, we provide a procedure to construct a matching $M \subseteq Q \cap R$ such that $\mathbb{E}\left[\sum_{i \in M} w_e\right] \geq (1 - O(\epsilon)) \cdot \max\left\{\frac{1}{2}, \left(\frac{1+\alpha e^2}{1+e^2}\right)\right\} \cdot \mathbf{OPT}$. Our procedure constructs three matchings $M_{\mathtt{C}}, M_{\mathtt{NC}}, M_{\mathtt{AUG}} \subseteq R \cap Q$ and then picks the matching with the maximum weight. We construct matchings $M_{\mathtt{C}}, M_{\mathtt{NC}}$ on the queried active crucial and non-crucial edges in $Q_{\mathtt{Greedy}}$ similar to the [8] which satisfies the desired properties described in Lemma 18 and Lemma 19. First, we state that each crucial edge $e \in \mathtt{C}$ appears in the $Q_{\mathtt{Greedy}}$ with probability $1 - \epsilon$ which shows the existence of matching $M_{\mathtt{C}} \subseteq Q \cap R \cap \mathtt{C}$ with expected weight at least $(1 - \epsilon) \cdot \mathbf{OPT}_{\mathtt{C}}$.

▶ **Lemma 18** (Crucial Edge Lemma [8])**.** *Given a stochastic weighted matching instance $\langle G, p\rangle$ and $Q_{\mathtt{Greedy}}$ is the set defined in Algorithm 3, let $M_{\mathtt{C}}$ be the maximum weight matching in the graph $Q_{\mathtt{Greedy}} \cap \mathtt{C} \cap R$, then $\mathbb{E}\left[\sum_{e \in M_{\mathtt{C}}} w_e\right] \geq (1 - \epsilon) \cdot \boldsymbol{OPT}_{\mathtt{C}}$.*

Now, following the [8, Lemma 4.7], in Lemma 19, we construct a matching $M_{\mathtt{NC}} \subseteq R \cap Q_{\mathtt{Greedy}} \cap \mathtt{NC}$ on active queried non-crucial edges, such that each $e \in \mathtt{NC}$ is present in $M_{\mathtt{NC}}$ with probability at least $(1 - O(\epsilon)) \cdot q_e$. We further prove an important property of $M_{\mathtt{NC}}$ that states that for any non-crucial edge $e \in \mathtt{NC}$, the probability of $e \in M_{\mathtt{NC}}$ can not decrease when we condition on the events that some of the neighbors of e are inactive[4].

▶ **Lemma 19** (Non-Crucial Edges)**.** *Given a stochastic weighted matching instance $\langle G, p\rangle$, let $Q_{\mathtt{Greedy}}$ be the set defined in Algorithm 3. There exists a matching $M_{\mathtt{NC}} \subseteq Q_{\mathtt{Greedy}} \cap \mathtt{NC} \cap R$ such that for any non-crucial edge $e \in \mathtt{NC}$, $\mathbf{Pr}[e \in M_{\mathtt{NC}}] \geq (1 - 12\epsilon) \cdot q_e$. This implies that, $\mathbb{E}\left[\sum_{e \in M_{\mathtt{NC}}} w_e\right] \geq (1 - 12\epsilon) \cdot \boldsymbol{OPT}_{\mathtt{NC}}$. Moreover, for any subset $S \subseteq N(e)$ where $N(e)$ is the set of edges incident to e in graph G, we have*

$$\mathbf{Pr}[e \in M_{\mathtt{NC}} \mid S \cap R = \emptyset] \geq (1 - 12 \cdot \epsilon) \cdot q_e. \tag{5}$$

The proof of the lemma is technically involved and therefore it is delegated to the full version [13]. Lemma 18 and Lemma 19 together imply that our sparsifier is at least 1/2 approximate.

We note that $Q_{\mathtt{CRS}}$ is the output of generic sparsifier discussed in Algorithm 1 (Section 3). Let $M_{\mathtt{CRS}} := \pi(Q_{\mathtt{CRS}} \cap R)$ be the matching constructed by an α-balanced CRS π which ensures $\mathbf{Pr}[e \in M_{\mathtt{CRS}}] \geq \alpha \cdot q_e$ for all $e \in E$. We refer $M_{\mathtt{CRS}}$ as `CRS-BaseMatching`. Crucially, $M_{\mathtt{CRS}}$ is independent of the edges sampled in $Q_{\mathtt{Greedy}}$ as well as $M_{\mathtt{NC}}$ and $M_{\mathtt{C}}$. Using Independence between $M_{\mathtt{CRS}}$ and $M_{\mathtt{NC}}$, we construct the third matching $M_{\mathtt{AUG}}$ on the set of edges $Q_{\mathtt{CRS}} \cup (Q_{\mathtt{Greedy}} \cap \mathtt{NC}) \cup R$. Our augmentation simply adds a non-crucial edge $e \in M_{\mathtt{NC}}$ to `CRS-BaseMatching` if both endpoints of the edge e are unmatched in `CRS-BaseMatching`. Algorithm 4 describes our augmentation procedure in detail.

[4] We noticed a bug in the proof of a similar lemma presented in [8], further used in [7, 6]. In order to prove the lemma and the monotonicity property (5), we require slightly different proof techniques.

Our key observation is that any non-crucial edge $e \in \texttt{NC}$ has a small probability of being sampled in the set $Q_{\texttt{CRS}}$. However, with some non-trivial probability, both endpoints of the edge e will be unmatched in `CRS-BaseMatching`. More formally, first we show that for any non-crucial edge $e := (u, v) \in \texttt{NC}$, both endpoints of e are unmatched in the `CRS-BaseMatching` with probability at least $1/e^2$. The intuition here is that as $p \leq \epsilon^4$, the number of incident edges on the endpoints of the edge e in the set $Q_{\texttt{CRS}}$ are concentrated around $2/p$ with high probability. Such a property ensures that if all these incident edges are inactive, then both endpoints of e are unmatched in `CRS-BaseMatching`.

Later, we use the property (5) of $M_{\texttt{NC}}$ from Lemma 19 to guarantee that when a non-crucial edge $e \notin Q_{\texttt{CRS}}$ and both endpoints of e are unmatched in `CRS-BaseMatching`, we can guarantee that $e \in M_{\texttt{NC}}$ with probability approximately q_e. Therefore, we can add such a non-crucial edge e to `CRS-BaseMatching` with probability approximately $\frac{q_e}{e^2}$. Combining this intuition, we prove the following key lemma whose proof is delegated to the full version [13].

▶ **Lemma 20.** *Let M_{AUG} be the output of the procedure described in Algorithm 4 then,*

$$\mathbf{Pr}[e \in M_{AUG}] \geq q_e \cdot \alpha \ \forall e \in \mathcal{C} \qquad \text{and} \qquad \mathbf{Pr}[e \in M_{AUG}] \geq q_e \cdot \left(\alpha + \frac{1 - O(\epsilon)}{e^2}\right) \ \forall e \in \mathit{NC}.$$

Algorithm 4 Construction of the matching $M_{\texttt{AUG}}$ on $Q \cap R$.

1: $M_{\texttt{NC}}$ be the matching on $Q_{\texttt{Greedy}} \cap R \cap \texttt{NC}$ satisfying property of stated Lemma 19.
2: $M_{\texttt{CRS}} \leftarrow \pi(Q_{\texttt{CRS}} \cap R)$ be the matching produced by α-balanced truncated CRS.
3: $M_{\texttt{AUG}} \leftarrow M_{\texttt{CRS}}$.
4: $\forall e \in M_{\texttt{NC}}$, add e to the matching $M_{\texttt{AUG}}$ if both endpoints of e are unmatched in $M_{\texttt{AUG}}$.

Combining Lemma 18, Lemma 19 and Lemma 20, we show that the expected weight of the best matching among $M_{\texttt{CRS}}, M_{\texttt{NC}}$, and $M_{\texttt{AUG}}$ exhibits the desired approximation ratio. We complete the proof of Theorem 15 in the full version [13].

6 Additive Optimization over the Intersection of k Matroids

Given our $(1 - \epsilon)$-approximate sparsifier for additive optimization over a single matroid constraint, a natural question is whether the natural generalization of this algorithm to the intersection of matroids is $(1 - \epsilon)$-approximate. This turns out to not be the case even for bipartite matching (the intersection of two partition matroids) due to [9]. The main challenge here is that, unlike for a single matroid, multiple solutions for matroid intersection do not always "combine" well. In this section, we prove a slightly weaker sparsification result for additive optimization over the intersection of k matroid constraints, which nevertheless beats the best known bound of $1/(k + 1)$ on the correlation gap of k-matroid intersection (see [1]), and therefore outperforms our generic sparsifier for this problem. The following theorem is the main result of this section.

▶ **Theorem 21.** *For each $\epsilon > 0$, there is a $\frac{(1-\epsilon)}{k+\frac{1}{k+1}}$-approximate sparsifier of degree $O\left(\frac{1}{\epsilon \cdot p} \log \frac{1}{\epsilon}\right)$ for stochastic packing problem $\langle E, \mathcal{I}, f, p\rangle$ when $(E, \mathcal{I})$ is the intersection of k matroids and f is additive.*

Our sparsifier samples $Q_1, \ldots, Q_\tau$ independently from stochastic optimum oracle $\mathcal{D}_{\text{opt}}$ as a sparsifier. Similar algorithms with degree poly$(1/p)$ have been considered for the stochastic matching [8, 7], and were shown to be 0.6568-approximate for the unweighted and 0.501-approximate for a weighted matching with degree poly$(1/p)$.

Algorithm 5 Sparsifier for additive optimization over the intersection of k matroid constraints.

Input: $\langle E, \mathcal{I}, f, p\rangle$ with the intersection of k matroids constraints and additive f; $D_{\mathbf{OPT}}$
Sample $Q_1, \ldots, Q_\tau \sim D_{\mathbf{OPT}}$ independently for $\tau \leftarrow \frac{2}{\epsilon p} \log \frac{2}{\epsilon}$;
Output: $Q = \cup_{i=1}^{\tau} Q_i$.

In order to prove Theorem 21, we provide a procedure for constructing a feasible solution $I \subseteq Q \cap R$ such that $\mathbb{E}[\sum_{i\in I} w_e] \geq \frac{(1-\epsilon)}{k+1/(k+1)}\,\mathbf{OPT}$. The backbone of our analysis lies in Lemma 22. As a first step, let S_1 and S_2 be two independent sets of the same matroid and $R \subseteq E$ be the (random) set of active elements with parameter p. We propose a procedure (details in Algorithm 6 in the full version [13]) that swaps active elements from S_1, i.e. $S_1 \cap R$, with elements of S_2 such that each element of S_2 is "protected" independently with probability $1-p$. Hence, the expected value of updated set S_2 is $\geq \mathbb{E}[f(S_1 \cap R)] + (1-p)\cdot f(S_2)$.

The key intuition here is that the exchange property of matroids allows us to swap any element $e \in S_1$ with a different element $f \in S_2$ without violating the feasibility of S_2. Therefore, if e is inactive then e can not swap out f from S_2 and hence we "protect" f in S_2 with probability $1-p$. However, the main challenge here is after a single swap between e and f, sets S_1 and S_2 get updated and f can potentially be swapped with some $f' \in S_2$. Our procedure overcomes this challenge by carefully choosing swaps of elements between S_1 and S_2 while maintaining feasibility.

We extend this idea to when S_1 and S_2 are two independent sets in the intersection of k matroids. We run the procedure described in Algorithm 6 in the full version [13] for each matroid and obtain sets T feasible in the intersection of all matroids such that each element of S_2 is added to T independently with probability $(1-p)^k$. The details of procedure and proof of Lemma 22 is relegated to the full version of the paper [13]

▶ **Lemma 22.** *Let $\mathcal{M}_1, \ldots \mathcal{M}_k$ be matroids with $\mathcal{M}_\ell = (E, \mathcal{I}_\ell)$, and let $\mathcal{I} = \bigcap_{\ell=1}^{k} \mathcal{I}_\ell$ be their common independent sets. Let S_1 and S_2 be in $\mathcal{I}$. Let $R \subseteq E$ include each element of E independently with probability p. Let $T(\ell) \in \mathcal{I}_\ell$ be the output of Algorithm 6 in full version [13] for matroid $\mathcal{M}_\ell$, for each $\ell \in [k]$. The set $T := \bigcap_{\ell=1}^{k} T(\ell)$ satisfies:*

1. *$S_1 \cap S_2 \subseteq T$ with probability 1.*
2. *$T \in \mathcal{I}$ with probability 1.*
3. *$(S_1 \setminus S_2) \cap R \subseteq T$, i.e. $\mathbf{Pr}[e \in T] = p$ for all $e \in S_1 \setminus S_2$.*
4. *$\mathbf{Pr}[f \in T] \geq (1-p)^k$ for all $f \in S_2 \setminus S_1$*

We utilize the above lemma and propose a procedure to construct a feasible set $I \subseteq Q \cap R$. At a high level, our procedure iteratively observes active elements in the set Q_i and swaps elements in $Q_{i+1}, \ldots, Q_n$ by $Q_i \cap R$ using Lemma 22. To this end, Lemma 22 ensures that each element in Q_j for $j > i$ is not swapped ("protected") with probability at least $(1-p)$. Using this argument inductively, we prove the following lemma that lower bounds the probability of selecting each element $e \in Q$ whose proof is in the full version [13]. We then use the lemma and carefully analyze the probability of each element $e \in E$ in the constructed set $I \subseteq R \cap Q$ to conclude the proof of Theorem 21.

▶ **Lemma 23.** *Let $I^* = I(\tau)$ be the output of Algorithm 7 in full version [13]. For any $e \in E$, we have*

$$\mathbf{Pr}[e \in I^* \mid e \in Q_i \setminus \cup_{\ell=1}^{i-1} Q_i] \geq p \cdot (1-p)^{k(i-1)}$$

7 Open Questions

- We believe that our results portend a deeper connection between the sparsification and contention resolution. The results of Section 3 show that contention resolution serves to lower-bound the sparsification ratio. We ask whether the connection goes both ways. In particular, does the existence of a c-sparsifier of degree $1/p$ imply a contention resolution scheme with balance c? This is intimated by Proposition 5. Does the existence of a c-sparsifier of degree $\text{poly}(1/p)$ imply a contention resolution scheme with balance $\Omega(c)$ (or some other expression involving c and the degree)? Formalizing a tighter connection between sparsification and contention resolution (equivalently, the correlation gap) might lead to new structural and computational insights for the latter.
- In Section 4, we show that a greedy sparsifier $1-\epsilon$ approximate with degree $O(1/p)$ for additive optimization subject to a matroid constraint. We conjecture that a similar greedy sparsifier exists for the intersection of k matroids, obtaining a $\frac{1-\epsilon}{k}$-approximation with degree $O(1/p)$. A similar greedy sparsifier, albeit with degree $O(1/p^{1/\epsilon})$, was shown to be 1/2-approximate for the special case of unweighted bipartite matching in [9].
- Our results in Section 5 improve the state of the art sparsifier for weighted (non-bipartite) matching in the polynomial degree regime. Moreover, since our approximation guarantee is a function of the correlation gap, progress on the correlation gap of the matching polytope will lead to further improved sparsifiers. Finding the best possible sparsification ratio in the polynomial degree regime remains open, however, with $1-\epsilon$ still on the table. Beyond polynomial degree, a $1-\epsilon$ approximate sparsifier with degree $\exp(\exp(\exp(1/p)))$ was already shown by [6].

Abstract

Many deployments of differential privacy in industry are in the local model, where each party releases its private information via a differentially private randomizer. We study triangle counting in the noninteractive and interactive local model with edge differential privacy (that, intuitively, requires that the outputs of the algorithm on graphs that differ in one edge be indistinguishable). In this model, each party's local view consists of the adjacency list of one vertex.

In the noninteractive model, we prove that additive $\Omega(n^2)$ error is necessary, where n is the number of nodes. This lower bound is our main technical contribution. It uses a reconstruction attack with a new class of linear queries and a novel mix-and-match strategy of running the local randomizers with different completions of their adjacency lists. It matches the additive error of the algorithm based on Randomized Response, proposed by Imola, Murakami and Chaudhuri (USENIX2021) and analyzed by Imola, Murakami and Chaudhuri (CCS2022) for constant ε. We use a different postprocessing of Randomized Response and provide tight bounds on the variance of the resulting algorithm.

In the interactive setting, we prove a lower bound of $\Omega(n^{3/2})$ on the additive error. Previously, no hardness results were known for interactive, edge-private algorithms in the local model, except for those that follow trivially from the results for the central model. Our work significantly improves on the state of the art in differentially private graph analysis in the local model.

1 Introduction

Triangle counting is a fundamental primitive in graph analysis, used in numerous applications and widely studied in different computational models [3, 12, 26, 37, 7, 44, 45, 48, 50]. Statistics based on triangle counts reveal important structural information about networks (as discussed, e.g., in [30, 46, 51]). They are used to perform many computational tasks on social networks, including community detection [49], link prediction [25], and spam filtering [5]. See [1] for a survey on algorithms for and applications of triangle counting.

In applications where a graph (e.g., a social network) holds sensitive information, the algorithm that computes on the graph has to protect personal information, such as friendships between specific individuals. Differential privacy [22] has emerged as the standard of rigorous privacy guarantees. See [53] for a survey of differentially private graph analysis. The most investigated setting of differential privacy is called the *central model*. It implicitly assumes a curator that collects all the data, computes on it, and provides data releases. In some situations, however, it might be undesirable to collect all information in one place, for instance, because of trust or liability issues. To address this, the *local model* of differential privacy was proposed [29, 22, 40] and is now used in many industry deployments [28, 8, 14, 2, 17].

In this model, each party releases its private information via a differentially private randomizer. Then the algorithm processes the information and, in the case of the local *noninteractive* model, outputs the answer. In the case of the local *interactive* model, the algorithm may have multiple rounds where it asks all parties to run different randomizers on their private data. These randomizers can have arbitrary dependencies on previous messages. Differential privacy in the local model is defined with respect to the whole transcript of interactions between the parties and the algorithm. In the local model applied to graph data, each vertex represents a party. It receives the list of its neighbors as input and applies local randomizers to it. In contrast to the typical datasets, where information belongs to individual parties, in the graph setting, each pair of parties (vertices) share the information of whether there is an edge between them.

Differential privacy, intuitively, guarantees that, for any two neighboring datasets, the output distributions of the algorithm are roughly the same. There are two natural notions of neighboring graphs: *edge-neighboring* and *node-neighboring*. Two graphs are edge-neighboring if they differ in one edge; they are node-neighboring if they differ in one node and its adjacent edges. Edge differential privacy is, in general, easier to attain, but node differential privacy provides stronger guarantees. Edge differential privacy was introduced and first applied to triangle counting in [47]. The edge-differentially private algorithm from [47] was generalized and implemented in [38]. The first node-differentially private algorithms appeared in [9, 41, 13], and all three of these articles considered the problem of triangle counting. Edge differential privacy in the local model has been studied in [52, 31, 54, 56, 33, 34, 16] with most of the listed articles focusing on triangle counting.

In this work, we investigate edge differentially private algorithms for estimating the number of triangles in a graph in the local model. Our goal is to understand the additive error achievable by such algorithms both in the noninteractive and in the interactive model. For the noninteractive model, we provide upper and lower bounds on additive error. Our bounds are tight in terms of n, the number of nodes in the input graph. For the interactive model, we provide the first lower bound specific to local, edge differentially private (LEDP) algorithms. There are trivial lower bounds for the central model (based on global sensitivity) which apply to the local model, but no lower bounds specific to the local model were previously known for any graph problem, even for 2-round algorithms. Together, our results improve our understanding of both noninteractive and interactive LEDP algorithms.

1.1 Results

Our results and comparison to previous work are summarized in Table 1.

Table 1 Summary of lower and upper bounds on the additive error for triangle counting in the noninteractive and interactive models. Note that the largest value of $C_4(G)$ is $\binom{n}{4} = \Theta(n^4)$. For ease of comparison, the results of [33] and [34] are stated for graphs with $d_{max} = \Theta(n)$.

Model		Previous Results		Our Results	
Non-interactive	Lower Bound	$\Omega(n^{3/2})$	[33]	$\Omega(n^2)$	Thm. 1.1
	Upper Bound	$O(n^2)$ (constant ε)	[35]	$O\left(\frac{\sqrt{C_4(G)}}{\varepsilon} + \frac{n^{3/2}}{\varepsilon^3}\right)$	Thm. 1.2
Interactive	Lower Bound	$\Omega(n)$	easy	$\Omega(\frac{n^{3/2}}{\varepsilon})$	Thm. 1.3
	Upper Bound	$O\left(\frac{\sqrt{C_4(G)}}{\varepsilon} + \frac{n^{3/2}}{\varepsilon^2}\right)$	[34]		

1.1.1 Lower Bound for the Noninteractive Local Model

Our main technical contribution is a lower bound in the noninteractive setting. It uses a reconstruction attack (for the central model) with a new class of linear queries and a novel mix-and-match strategy of running local randomizers with different completions of their adjacency lists. While reconstruction attacks are a powerful tool in proving lower bounds in the central model of differential privacy, they have not been used to obtain bounds in the local model. Previous lower bounds in the local model are based on quite different techniques – typically, information-theoretic arguments (see, for example, [40, 6, 19] and many subsequent works).

▶ **Theorem 1.1** (Noninteractive Lower Bound, informal version). *Let $\varepsilon \in (0, 1/20)$ and $\delta \geq 0$ be a sufficiently small constant. There exists a family of graphs such that every noninteractive (ε, δ)-local edge differentially private algorithm that gets an n-node graph from the family as input and approximates the number of triangles in the graph within additive error at most α (with sufficiently high constant probability) must have $\alpha = \Omega(n^2)$.*

Our lower bound holds for all small $\delta \geq 0$ (the case referred to as "approximate" differential privacy). Observe that such lower bounds are stronger than those for $\delta = 0$ (the case referred to as "pure" differential privacy), because they include $\delta = 0$ as a special case. The only previously known lower bound, due to Imola et al. [33], showed that noninteractive algorithms must have error $\Omega(\sqrt{n} \cdot d_{max})$.

To prove the lower bound in Theorem 1.1, we develop a novel mix-and-match technique for noninteractive local model. For a technical overview of the proof of Theorem 1.1, see Section 1.2.

Our lower bound matches the upper bound of $O(n^2)$ proved by [35, Theorem G.3] (for constant ε) for an algorithm based on randomized response. In this work, we give a simpler variant of the algorithm and a more refined analysis, which works for all ε.

1.1.2 Tight Analysis of Randomized Response

The most natural algorithm for the noninteractive model is Randomized Response, which dates back to Warner [55]. In this algorithm, each bit is flipped with probability $\frac{1}{e^{\varepsilon}+1}$, where ε is the privacy parameter. In the case of graphs, each bit represents a presence or absence of an edge. An algorithm based on Randomized Response for triangle counting was first analyzed by [33] for the special case of Erdős-Rényi graphs, and then [35] proved that this algorithm has $O(n^2)$ additive error for constant ε for general graphs. These works first compute the number of triangles and other induced subgraphs with three vertices as though the noisy edges are real edges and then appropriately adjust the estimate using these counts to make it unbiased.

We use a different postprocessing of Randomized Response. We rescale the noisy edges right away, so we need not compute counts for graphs other than triangles, which makes the analysis much simpler. We obtain tight upper and lower bounds on the variance of the resulting algorithm that hold for all ε. Our bounds are more refined, as they are stated in terms of $C_4(G)$, the number of four cycles in the graph.

▶ **Theorem 1.2** (Analysis of Randomized Response). *For all $\varepsilon > 0$, there exists a noninteractive ε-LEDP algorithm based on Randomized Response that gets an n-node graph as input and returns an unbiased estimate $\hat{T}$ of the number of triangles in a graph that has variance $\Theta\Big(\frac{C_4(G)}{\varepsilon^2} + \frac{n^3}{\varepsilon^6}\Big)$.*

In particular, with high constant probability, $\hat{T}$ has additive error $\alpha = O\Big(\frac{\sqrt{C_4(G)}}{\varepsilon} + \frac{n^{3/2}}{\varepsilon^3}\Big)$.

Note that for constant ε, Theorem 1.2 implies an upper bound of $O(n^2)$ on the additive error of the algorithm's estimate. Thus, Randomized Response is optimal for graphs that have $C_4 = \Theta(n^4)$ by our lower bound in Theorem 1.1. Also, observe that Randomized Response achieves pure differential privacy (with $\delta = 0$), whereas the lower bound in Theorem 1.1 holds even for approximate differential privacy. Even though allowing $\delta > 0$ results in better accuracy for many problems, it does not give any additional utility for noninteractive triangle counting. The proof of Theorem 1.2 is deferred to the full version.

1.1.3 Lower Bound for the Interactive Local Model

Next, we investigate triangle counting in the interactive setting. Imola et al. [33] present an ε-LEDP for triangle counting in the interactive model with additive error of $O\big(\sqrt{C_4(G)}/\varepsilon + \sqrt{n} \cdot d_{max}/\varepsilon^2\big)$, where d_{max} is an upper bound on the maximum degree.

We give a lower bound on the additive error of LEDP algorithms for triangle counting in the interactive model. Note that $\Omega(n)$ additive error is unavoidable for triangle counting even in the central model, because the (edge) global sensitivity of the number of triangles is $n-2$ (and this lower bound is tight in the central model). There were no previously known lower bounds for this problem (or any other problem on graphs) specific to the interactive LEDP model that applied to even 2-round algorithms. Our lower bound applies to interactive algorithms with *any* number of rounds.

▶ **Theorem 1.3** (Interactive Lower Bound). *There exist a family of graphs and a constant $c > 0$ such that for every $\varepsilon \in (0,1)$, $n \in \mathbb{N}, \alpha \in (0, n^2]$ and $\delta \in \Big[0, \frac{1}{10^5} \cdot \frac{\varepsilon^3 \alpha_0^2}{n^5 \ln(n^3/\varepsilon\alpha_0)}\Big]$, every (potentially interactive) (ε, δ)-local edge differentially private algorithm that gets an n-node graph from the family as input and approximates the number of triangles in the graph with additive error at most α (with probability at least 2/3) must have $\alpha \geq c \cdot \frac{n^{3/2}}{\varepsilon}$.*

Our lower bound is obtained via a reduction from the problem of computing the summation of n randomly sampled bits in $\{0,1\}$ in the LDP model, studied in a series of works [6, 10, 20, 36]. Our lower bound matches the upper bound of [33] for constant ε and for graphs where $d_{max} = \Theta(n)$ and $C_4(G) = O(n^3)$. It is open whether additive error of $o(n^2)$ can be achieved for general graphs.

1.2 Technical Overview of the Noninteractive Lower Bound

Typical techniques for proving lower bounds in the local model heavily rely on two facts that hold for simpler datasets: first, each party's information is not seen by other parties; second, arbitrary changes to the information of one party have to be protected. Both of these conditions fail for graphs in the LEDP model: each edge is shared between two parties, and only changes to one edge are protected in the strong sense of neighboring datasets, imposed by differential privacy.

To overcome these difficulties, we develop a new lower bound method, based on reconstruction attacks in the central model. Such attacks use accurate answers to many queries to reconstruct nearly all the entries of a secret data set [18, 23, 24, 42, 43, 15]. They are usually applied to algorithms that release many different values. However, a triangle-estimation algorithm returns a single number. Consider a naïve attempt to mount an attack using the algorithm as a black box, that is, by simulating every query using a separate invocation of the triangle counting algorithm. This would require us to run the local randomizers many times, degrading their privacy parameters and making a privacy breach vacuous.

To overcome this difficulty, in our attack, we use the noninteractive triangle-estimation algorithm as a *gray box*. Since the algorithm is noninteractive, it is specified by local randomizers for all vertices and a postprocessing algorithm that runs on the outputs of the randomizers. We use a secret dataset X to create a secret subgraph, run the randomizers for the vertices in the secret subgraph only twice, and publish the results. By properties of the randomizers and by composition, the resulting procedure is differentially private. In the next phase, we postprocess the published information to complete the secret subgraph to different graphs corresponding to the queries needed for our attack. Then we feed these graphs to the triangle approximation algorithm, except that for the vertices in the secret subgraph, we rely only on the published outputs. If the triangle counting algorithm is accurate, we get accurate answers to our queries. Even though the randomness used to answer different queries is correlated, we show that a good approximation algorithm for triangle counts allows us to get most of the queries answered correctly. Finally, we use a novel anti-concentration bound (Lemma 1.4, below) to demonstrate that our attack succeeds in reconstructing most of the secret dataset with high probability. This shows that the overall algorithm we run in this process is not differentially private, leading to the conclusion that a very accurate triangle counting algorithm cannot exist in the noninteractive LEDP setting.

We call the queries used in our attack *outer-product queries*. The queries are linear, but their entries are dependent. To define this class of queries, we represent the secret dataset X with n^2 bits as an $n \times n$ matrix. An outer-product query to X specifies two vectors A and B of length n with entries in $\{-1,1\}$ and returns $A^T X B$, that is, $\sum_{i,j\in[n]} A_i X_{ij} B_j$.

To analyze our reconstruction attack, we prove the following anti-concentration bound for random outer-product queries, which might be of independent interest.

▶ **Lemma 1.4** (Anti-concentration for random outer-product queries). *Let M be an $n \times n$ matrix with entries $M_{ij} \in \{-1,0,1\}$ for all $i,j \in [n]$ and m be the number of nonzero entries in M. Let A and B be drawn uniformly and independently from $\{-1,1\}^n$. If $m \geq \gamma n^2$ for some constant γ, then*

$$\Pr\left[|A^T M B| > \frac{\sqrt{m}}{2}\right] \geq \frac{\gamma^2}{16}.$$

The literature on reconstruction attacks describes other classes of dependent queries [42]; the outer-product queries arising here required a new and qualitatively different analysis.

1.3 Additional Related Work

One of the difficulties with proving lower bounds in the local model is that Randomized Response, despite providing strong privacy guarantees, supplies enough information to compute fairly sophisticated statistics. For example, Gupta, Roth and Ullman [32] show how the output of Randomized Response can be used to estimate the density of all cuts in a graph. Karwa et al. [39] show how to fit exponential random graph models based on randomized response output. For certain model families, this would entail estimation of the number of triangles; however, they provide no theoretical error analysis, only experimental evidence for convergence. Randomized Response has also been studied in the statistics literature with a focus on small probabilities of flipping an edge. Balachandran et al. [4] analyze the distribution of the naive estimator that counts the number of triangles in the randomized responses (when flip probabilities are very low). Chang et al. [11] give estimation strategies for settings where the flip rate is unknown but multiple replicates with independent noise are available. To the best of our understanding, these works do not shed light on the regime most relevant to privacy, where edge-flip probabilities are close to 1/2.

A number of works have looked at triangle counting and other graph problems in the empirical setting [54, 52, 31, 56] in "decentralized" privacy models. In all but [54], the local view consists of the adjacency list. The local views in Sun et al. [54] consist of two-hop neighborhoods. Such a model results in less error since nodes can see all of their adjacent triangles and can report their adjacent triangles using the geometric mechanism.

1.4 Organization

Various models of differential privacy, including LEDP, are defined in Section 2. Our proof of the lower bound for the noninteractive model, Theorem 1.1, appears in Section 3. The anti-concentration lemma for out-product queries (Lemma 1.4) is proved in Section 3.2. Our analysis of Randomized Response and the proof of Theorem 1.2 appears in the full version [27]. The proof of Theorem 1.3 for the interactive LEDP model appears in Section 4.

2 Background on Differential Privacy

We begin with the definition of differential privacy that applies to datasets represented as vectors as well as to graph datasets.

▶ **Definition 2.1** (Differential Privacy [22, 21]). *Let $\varepsilon > 0$ and $\delta \in [0, 1)$. A randomized algorithm $\mathcal{A}$ is* (ε, δ)-differentially private (DP) *(with respect to the neighbor relation on the universe of the datasets) if for all events S in the output space of $\mathcal{A}$ and all neighboring datasets X and X',*

$$\Pr[\mathcal{A}(x) \in S] \leq \exp(\varepsilon) \cdot \Pr[\mathcal{A}(X') \in S] + \delta.$$

When $\delta = 0$, the algorithm is ε-differentially private (sometimes also called "purely differentially private").

Differential privacy can be defined with respect to any notion of neighboring datasets. When datasets are represented as vectors, datasets X and Y are consider neighbors if they differ in one entry. In the context of graphs, there are two natural notions of neighboring graphs that can be used in the definition: edge-neighboring and node-neighboring. We use predominantly the former, but define both to make discussion of previous work clear.

▶ **Definition 2.2.** *Two graphs $G = (V, E)$ and $G' = (V', E')$ are **edge-neighboring** if G and G' differ in exactly one edge, that is, if $V = V'$ and E and E' differ in exactly one element. Two graphs are **node-neighboring** if one can be obtained from the other by removing a node and its adjacent edges.*

If the datasets are graphs with edge (respectively, node) neighbor relationship, we call a differentially private algorithm simply *edge-private* (respectively, *node-private*).

2.1 The local model

The definition of differential privacy implicitly assumes a trusted curator that has access to the data, runs a private algorithm on it, and releases the result. This setup is called the *central model* of differential privacy. In contrast, in the *local model* of differential privacy, each party participating in the computation holds its own data. The interaction between the parties is coordinated by an algorithm $\mathcal{A}$ that accesses data via *local randomizers*. A local randomizer is a differentially private algorithm that runs on the data of one party. In the context of graph datasets, the input graph is distributed among the parties as follows: each party corresponds to a node of the graph and its data is the corresponding row in the adjacency matrix of the graph. In each round of interaction, the algorithm $\mathcal{A}$ assigns each party a local randomizer (or randomizers) that can depend on the information obtained in previous rounds.

We adapt the definition of local differential privacy from [36, 40] to the graph setting. Consider an undirected graph $G = ([n], E)$ represented by an $n \times n$ adjacency matrix A. Each party $i \in [n]$ holds the i-th row of A, denoted $\mathbf{a}_{i*}$. We sometimes refer to $\mathbf{a}_{i*}$ as the *adjacency vector* of party i. Entries of A are denoted a_{ij} for $i, j \in [n]$.

▶ **Definition 2.3** (Local Randomizer)**.** *Let $\varepsilon > 0$ and $\delta \in [0, 1)$. An (ε, δ)-**local randomizer** $R : \{0,1\}^n \to \mathcal{Y}$ is an (ε, δ)-edge DP algorithm that takes as input the set of neighbors of one node, represented by an adjacency vector $\mathbf{a} \in \{0,1\}^n$. In other words, $\mathsf{Pr}[R(\mathbf{a}) \in Y] \leq e^\varepsilon \cdot \mathsf{Pr}[R(\mathbf{a}') \in Y] + \delta$ for all $\mathbf{a}$ and $\mathbf{a}'$ that differ in one bit and all sets of outputs $Y \subseteq \mathcal{Y}$. The probability is taken over the random coins of R (but* not *over the choice of the input). When $\delta = 0$, we say that R is an ε-local randomizer.*

A randomized algorithm $\mathcal{A}$ on a distributed graph is (ε, δ)-LEDP if it satisfies Definition 2.4.

▶ **Definition 2.4** (Local Edge Differential Privacy)**.** *A **transcript** π is a vector consisting of 5-tuples $(S_U^t, S_R^t, S_\varepsilon^t, S_\delta^t, S_Y^t)$ – encoding the set of parties chosen, set of randomizers assigned, set of randomizer privacy parameters, and set of randomized outputs produced – for each round t. Let S_π be the collection of all transcripts and S_R be the collection of all randomizers. Let $\perp$ denote a special character indicating that the computation halts. An **algorithm** in this model is a function $\mathcal{A} : S_\pi \to (2^{[n]} \times 2^{S_R} \times 2^{\mathbb{R}^{\geq 0}} \times 2^{\mathbb{R}^{\geq 0}}) \cup \{\perp\}$ mapping transcripts to sets of parties, randomizers, and randomizer privacy parameters. The length of the transcript, as indexed by t, is its round complexity.*

*Given $\varepsilon \geq 0$ and $\delta \in [0,1)$, a randomized algorithm $\mathcal{A}$ on a (distributed) graph G is (ε,δ)-**locally edge differentially private (LEDP)** if the algorithm that outputs the entire transcript generated by $\mathcal{A}$ is (ε,δ)-edge differentially private on graph G. When $\delta = 0$, we say that $\mathcal{A}$ is an ε-LEDP.*

*If $t = 1$, that is, if there is only one round, then $\mathcal{A}$ is called **noninteractive**. Otherwise, $\mathcal{A}$ is called **interactive**.*

Observe that a noninteractive LEDP algorithm is specified by a local randomizer for each node and a postprocessing algorithm $\mathcal{P}$ that takes the outputs of the local randomizers as input.

We use a local algorithm known as *randomized response*, initially due to [55], but since adapted to differential privacy [40].

▶ **Definition 2.5** (Randomized Response). *Given a privacy parameter $\varepsilon > 0$ and a k-bit vector $\mathbf{a}$, the algorithm $\mathsf{RandomizedResponse}_\varepsilon(\mathbf{a})$ outputs a k-bit vector, where for each $i \in [k]$, bit i is a_i with probability $\frac{e^\varepsilon}{e^\varepsilon+1}$ and $1-a_i$ otherwise.*

▶ **Theorem 2.6** (Randomized Response is ε-LR). *Randomized response is an ε-local randomizer.*

Additional privacy tools are described in the full version of this paper.

3 The Noninteractive Lower Bound

In this section, we prove Theorem 1.1, which we restate formally here.

▶ **Theorem 3.1.** *There exists a family of graphs, such that every noninteractive (ε,δ)-LEDP algorithm with $\varepsilon \in (0, \frac{1}{20})$ and $\delta \in [0, \frac{1}{100})$ that gets an n-node graph from the family as an input and approximates the number of triangles in the graph within additive error α with probability at least $1 - \frac{1}{3^6 \cdot 2^7}$, must have $\alpha = \Omega(n^2)$.*

At a high level, the lower bound is proved by showing that a noninteractive local algorithm for counting triangles can be used to mount a reconstruction attack on a secret dataset X in the central model of differential privacy. A groundbreaking result of Dinur and Nissim [18] – generalized in subsequent works [23, 24, 42, 43, 15] – shows that if an algorithm answers too many random linear queries on a sensitive dataset of N bits too accurately then a large constant fraction of the dataset can be reconstructed. This is referred to as a "reconstruction attack". Specifically, Dinur and Nissim show that N random linear queries answered to within $\pm O(\sqrt{N})$ are sufficient for reconstruction. It is well known that if the output of an algorithm on a secret dataset can be used for reconstruction, then this algorithm is not differentially private. This line of reasoning leads to a lower bound of $\Omega(\sqrt{N})$ on the additive error of any differentially private algorithm answering N random linear queries.

Suppose we could show that an LEDP triangle counting algorithm with $O(n^2)$ additive error can be used to construct a DP algorithm for answering n linear queries with $O(\sqrt{n})$ additive error on some data set of size n – then by the above, we reach a contradiction to the privacy of the algorithm. While indeed a triangle counting algorithm can be used to answer a *single* linear query, the main challenge is that the Dinur-Nissim reconstruction attack requires answering not one, but rather n, linear queries on the same dataset. Let $\mathcal{A}$ be an (ε,δ)-LEDP triangle counting algorithm. If we naively try to answer each linear query to X using a new invocation of the triangle counting algorithm in a black-box manner, this would result in n invocations of $\mathcal{A}$. This in turn would cause the privacy parameters to grow linearly with n, making the privacy breach vacuous. That is, the result would be of

the following sort. An (ε, δ)-LEDP algorithm for triangle counting with low additive error implies an $(O(\varepsilon n), O(n\delta))$-DP algorithm for answering linear queries with low additive error. Since the latter statement is too weak to be used with the results of Dinur and Nissim, we take a different approach.

In order to avoid making n invocations of a triangle counting algorithm, we develop a new type of reconstruction attack on a secret dataset X, where the set of allowed linear queries has a special combinatorial structure. We call the new type of queries *outer-product queries*. We show that, given access to an (ε, δ)-LEDP algorithm $\mathcal{A}$ that approximates the number of triangles up to $O(n^2)$ additive error, we can design a $(2\varepsilon, 2\delta)$-DP algorithm $\mathcal{B}$ for answering $\Theta(n^2)$ outer-product queries on dataset X of size $N = n^2$, so that a constant fraction of them is answered with $O(n)$ additive error. (The dataset size is n^2, so asymptotically the number of random queries and the required accuracy are the same as in the Dinur-Nissim attack.) The main insight is that instead of using $\mathcal{A}$ as a black-box, we use it in a "gray-box" manner. This allows us to answer all $\Theta(n^2)$ queries without degrading the privacy parameters of $\mathcal{B}$. This in turn allows us to reconstruct X, which is a contradiction to the privacy of algorithm $\mathcal{B}$, and thus also to the privacy of algorithm $\mathcal{A}$. Hence, we conclude that any LEDP triangle-counting algorithm must have $\Omega(n^2)$ additive error.

The rest of Section 3.1 is organized as follows. In Section 3.1, we define outer-product queries, and show that an (ε, δ)-DP algorithm $\mathcal{A}$ for triangle-counting with low additive error can be used to construct a $(2\varepsilon, 2\delta)$-DP algorithm $\mathcal{B}$ for answering outer-product queries with low additive error. In Section 3.2, we prove an anti-concentration result for random outer-product queries. In Section 3.3, we use the anti-concentration result to show that an algorithm $\mathcal{B}$ that accurately answers $\Theta(n^2)$ outer-product queries on a sensitive data set $X \in \{0,1\}^{n \times n}$ can be used to reconstruct most of X and complete the proof of Theorem 3.1.

3.1 Reduction from Outer-product Queries to Triangle Counting

In this section, we prove Lemma 3.3, which is at the heart of our reduction. It shows that, given access to an (ε, δ)-LEDP algorithm $\mathcal{A}$ for approximating the number of triangles with low additive error, we can construct an $(2\varepsilon, 2\delta)$-DP algorithm $\mathcal{B}$ (in the central model) that accurately answers $\Theta(n^2)$ outer-product queries on a sensitive data set X. We start by formally defining this new class of queries.

▶ **Definition 3.2** (Outer-product queries). *Let $X \in \{0,1\}^{n \times n}$. An* outer-product query *to X specifies two vectors A and B of length n with entries in $\{-1, 1\}$ and returns $A^T X B$, that is, $\sum_{i,j \in [n]} A_i X_{ij} B_j$.*

Let γ be the desired reconstruction parameter that indicates that the attack has been successful if we reconstruct at least $(1-\gamma)n^2$ bits of X correctly. (Later, in Section 3.3, γ will be set to $\frac{1}{9}$ and the number of queries, k, will be set to $\Theta(n^2)$.)

▶ **Lemma 3.3** (Answering Outer-product Queries via Triangle Counting). *Let $\varepsilon, \delta > 0$ and $\gamma \in (0, 1/2)$. Assume that there is a noninteractive (ε, δ)-LEDP algorithm $\mathcal{A}$ that, for every $3n$-node graph, approximates the number of triangles with probability at least $1 - \frac{\gamma^2}{9 \cdot 128}$ and has additive error at most $\frac{\sqrt{\gamma} n^2}{20}$. Then there is an $(2\varepsilon, 2\delta)$-DP algorithm $\mathcal{B}$ in the central model that, for every secret dataset $X \in \{0,1\}^{n \times n}$ and every set of k outer-product queries $(A^{(1)}, B^{(1)}), \ldots, (A^{(k)}, B^{(k)})$, gives answers $a_1, \ldots, a_k$ satisfying*

$$\Pr\left[\left|\left\{\ell \in [k] : \left|(A^{(\ell)})^T X B^{(\ell)} - a_\ell\right| > \frac{\sqrt{\gamma} n}{4}\right\}\right| > \frac{\gamma^2 k}{64}\right] \leq \frac{1}{6}.$$

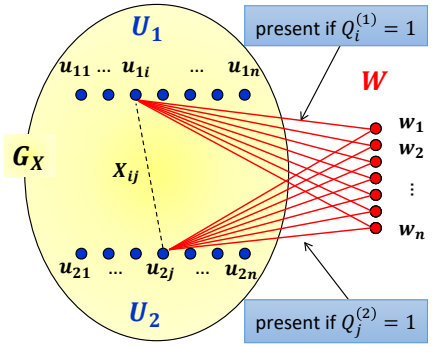

Figure 1 The construction of the query graph $G_{X,Q}$. Each of the parts U_1, U_2, W consists of n nodes. The dashed line is an edge iff $X_{ij} = 1$. Only the subgraph G_X (induced by $U_1 \cup U_2$) holds secret information.

That is, with probability at most $5/6$*, for every dataset* X *and a set of* k *outer-product queries, Algorithm* $\mathcal{B}$ *answers inaccurately at most* $\frac{\gamma^2 k}{64}$ *of the* k *queries, where by inaccurately we mean with additive error more than* $\frac{\sqrt{\gamma}n}{4}$*.*

Proof. Consider an algorithm $\mathcal{A}$ described in the premise of the lemma. Since $\mathcal{A}$ is local noninteractive, it is specified by a local randomizer $R_v(\mathbf{a})$ for each vertex v, as well as a postprocessing algorithm $\mathcal{P}$. Each randomizer takes an adjacency vector $\mathbf{a} \in \{0,1\}^n$ as input and passes its output to $\mathcal{P}$. Next, we define algorithm $\mathcal{B}$ that, given a sensitive dataset X and a set of k outer-product queries, uses the randomizers and the postprocessing algorithm as subroutines to obtain accurate answers to the outer-product queries.

Fix a dataset $X \in \{0,1\}^{n \times n}$. For each outer-product query (A, B), algorithm $\mathcal{B}$ constructs several corresponding *query* graphs. All query graphs are on the same vertex set V of size $3n$, partitioned into three sets U_1, U_2, and W of size n. The vertices in U_t for $t \in \{1,2\}$ are denoted $u_{t1}, \ldots, u_{tn}$. The vertices of W are denoted $w_1, \ldots, w_n$. See Figure 1 for an illustration.

Algorithm $\mathcal{B}$ first forms a bipartite graph G_X with parts U_1 and U_2 with X as the adjacency matrix; that is, it adds an edge (u_{1i}, u_{2j}) for each $i, j \in [n]$ with $X_{ij} = 1$. We call G_X the *secret subgraph*, because it will be included as a subgraph in every query graph and it will be the only part of that graph that contains any information about the original sensitive dataset X. Note that G_X does not depend on the outer-product query. The remaining edges of each query subgraph are between $U_1 \cup U_2$ and W and are specific to each query graph, so that overall the resulting graph is tripartite. For each $v \in U_1 \cup U_2$, let $\Gamma_X(v)$ denote the neighbors of v in the secret subgraph G_X. A key idea in the construction is that every node in the secret subgraph G_X will have one of only two possible neighborhoods in each query graph. This allows algorithm $\mathcal{B}$ to simulate triangle-counting computations on all query graphs by invoking a local randomizer on each vertex in $U_1 \cup U_2$ only twice. For each vertex $v \in U_1 \cup U_2$, algorithm $\mathcal{B}$ runs its local randomizer $R_v(\cdot)$ twice: once with the adjacency list specified by $\Gamma_X(v)$ and once with the adjacency list specified by $\Gamma_X(v) \cup W$. Algorithm $\mathcal{B}$ then records the output of the former invocation as as $r_0(v)$, and the latter as $r_1(v)$.

By the composition property of differential privacy, the algorithm that simply outputs the vector of all $4n$ responses of the local randomizers is $(2\varepsilon, 2\delta)$-DP by composition, because each bit of X is encoded as a potential edge and used in two executions of the randomizers for its endpoints, where each execution (of all randomizers) is (ε, δ)-LEDP. In the remaining steps, algorithm $\mathcal{B}$ only postprocesses the vector of responses, and thus it is $(2\varepsilon, 2\delta)$-DP.

Next, we describe how to postprocess the vector of responses to obtain an answer to an outer-product query (A, B). To answer each outer-product query, algorithm $\mathcal{B}$ will first obtain answers to three linear queries that we call *submatrix queries*. Submatrix queries are defined the same way as outer-product queries, except that vectors A and B have entries in $\{0, 1\}$ instead of $\{-1, 1\}$. Next, we explain how to answer submatrix queries on X, deferring to Claim 3.5 the description of the simulation of each outer-product query with submatrix queries.

To answer a submatrix query $Q = (Q^{(1)}, Q^{(2)})$ on dataset X, algorithm $\mathcal{B}$ completes the secret subgraph G_X to a query graph $G_{X,Q}$ as follows. For each vertex $u_{ti} \in U_1 \cup U_2$, where $t \in \{1, 2\}$ and $i \in [n]$, it adds edges determined by $Q^{(t)}$: specifically, if $Q_i^{(t)} = 1$, it adds edges from u_{ti} to all vertices in W. Next claim states the relationship between the number of triangles in $G_{X,Q}$ and the answer to the submatrix query Q.

▷ Claim 3.4. The number of triangles in graph $G_{X,Q}$ is equal to $n \cdot (Q^{(1)})^T X Q^{(2)}$.

Proof. Observe that $G_{X,Q}$ is tripartite with parts (U_1, U_2, W), so all triangles must have one vertex in each part. The answer to the submatrix query $Q = (Q^{(1)}, Q^{(2)})$ is

$$(Q^{(1)})^T X Q^{(2)} = \sum_{i,j \in [n]} Q_i^{(1)} Q_j^{(2)} X_{ij}.$$

For each term in the sum, both u_{1i} and u_{2j} are adjacent to all nodes in W iff $Q_i^{(1)} = Q_j^{(2)} = 1$. If the edge (u_{1i}, u_{2j}) is present in the graph, then this results in n triangles. Thus, each term where $Q_i^{(1)} = Q_j^{(2)} = X_{ij} = 1$ corresponds to n triangles of the form (u_{1i}, u_{2j}, w_ℓ), where $\ell \in [n]$. All other terms create no triangles, since either $X_{ij} = 0$, in which case the edge (u_{1i}, u_{2j}) is not present in the graph, or either $Q_i^{(1)} = 0$ or $Q_j^{(2)} = 0$, in which case u_{1i} and u_{2j} do not have common neighbors. ◁

To answer a submatrix query Q, algorithm $\mathcal{B}$ simulates a call to the triangle-counting algorithm $\mathcal{A}$ on the corresponding query graph $G_{X,Q}$. First, $\mathcal{B}$ runs the local randomizers for the vertices in W with their adjacency vectors specified by the graph $G_{X,Q}$. Note that these vertices do not have access to any private information, so this operation does not affect privacy. For each vertex $u_{ti} \in U_1 \cup U_2$, where $t \in \{1, 2\}$ and $i \in [n]$, algorithm $\mathcal{B}$ uses the result $r_b(u_{ti})$ from the previously run randomizer, where $b = Q_i^{(t)}$. E.g., if $Q_i^{(1)} = 0$, then $\mathcal{B}$ uses the result $r_0(u_{1i})$, and if $Q_i^{(1)} = 1$, it uses the result $r_1(u_{1i})$. Now algorithm $\mathcal{B}$ has results from all vertex randomizers on the graph $G_{X,Q}$ and it simply runs the postprocessing algorithm $\mathcal{P}$ on these results. To obtain the answer to the submatrix query, $\mathcal{B}$ divides the output of $\mathcal{P}$ by n.

Finally, algorithm $\mathcal{B}$ answers each outer-product query as specified in the following claim, by getting answers to three submatrix queries.

▷ Claim 3.5. An outer-product query to X can be simulated with three submatrix queries to X. Moreover, if all three submatrix queries are answered with additive error at most α, then the outer product query can be answered with additive error at most 5α.

Proof. Consider an outer-product query to an $n \times n$ matrix X specified by $A, B \in \{-1, 1\}^n$. Define n-bit vectors $A' = \frac{1}{2}(A + \vec{1})$ and $A'' = \frac{1}{2}(-A + \vec{1})$, where $\vec{1}$ denotes a vector of 1s of length n. Define B' and B'' analogously. Then, as illustrated in Figure 2,

$$A^T X B = 2((A')^T X B' + (A'')^T X B'') - \vec{1}^T X \vec{1}.$$

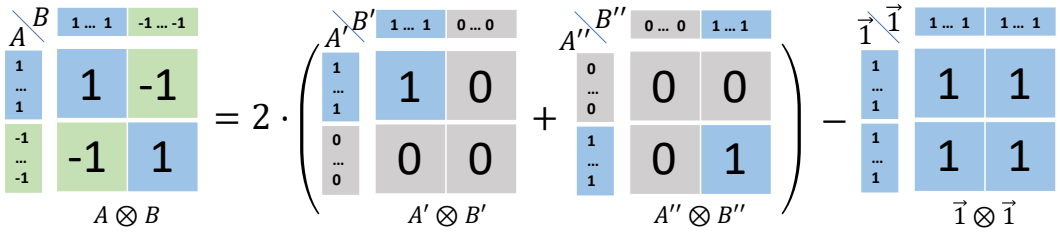

Figure 2 Every outer-product query can be simulated using three submatrix queries. For the illustration, the entries of all vectors are rearranged to group the same values together. The outer product is denoted $\otimes$.

That is, the answer to the outer-product query (A, B) can be computed from the answers to the submatrix queries $(A', B'), (A'', B'')$, and $(\vec{1}, \vec{1})$, and the additive error increases from α to 5α, as stated. ◁

It remains to prove the following claim.

▷ Claim 3.6. Let $\mathcal{A}$ be as in the premise of Lemma 3.3. For every secret dataset $X \in \{0,1\}^{n \times n}$ and every set of k outer-product queries $\{(A^{(\ell)}, B^{(\ell)})\}_{\ell \in [k]}$, algorithm $\mathcal{B}$ gives answers $a_1, \ldots, a_k$ satisfying

$$\Pr\left[\left|\left\{\ell \in [k] : \left|(A^{(\ell)})^T X B^{(\ell)} - a_\ell\right| > \frac{\sqrt{\gamma}n}{4}\right\}\right| > \frac{\gamma^2 k}{64}\right] \leq \frac{1}{6}.$$

That is, the number of "incorrectly" answered outer-product queries exceeds $\frac{\gamma^2 k}{64}$ with probability at most $1/6$.

Proof. By the assumption on $\mathcal{A}$, for every graph G, algorithm $\mathcal{A}$ returns the number of triangles in G within an additive error at most $\frac{\sqrt{\gamma}n^2}{20}$ with probability at least $1 - \frac{\gamma^2}{9 \cdot 128}$.

Given a secret dataset X and k outer-product queries, algorithm $\mathcal{B}$ first creates k triples of submatrix queries corresponding to the outer-product queries. Then $\mathcal{B}$ uses $\mathcal{A}$ as a gray box, to answer all $3k$ submatrix queries simultaneously. Recall that this is achieved by invoking the local randomizers on vertices holding private information (that is, vertices in parts U_1, U_2) twice, once for each potential value of the bit that corresponds to this vertex in a specific query. Then for each individual submatrix query, one local randomizer is invoked on each of the n vertices in W with the adjacency list that corresponds to that specific query graph. Then, to answer each specific submatrix query, algorithm $\mathcal{B}$ combines the new outputs of the vertices from W with the stored outputs from running randomizers on $U_1 \cup U_2$ that correspond to that specific query, and invokes the postprocessing algorithm $\mathcal{P}$ on this vector of $3n$ outputs. Finally, $\mathcal{B}$ divides $\mathcal{P}$'s answer by n to obtain the answer to the submatrix query.

Each invocation of $\mathcal{P}$ by $\mathcal{B}$ simulates one triangle-counting computation. Overall, we have $3k$ (*dependent*) simulated triangle-counting computations. By the assumption on $\mathcal{A}$, stated in the premise of Lemma 3.3, the postprocessing algorithm $\mathcal{P}$ answers each simulated triangle-counting computation inaccurately (i.e., with additive error exceeding $\frac{\sqrt{\gamma}n^2}{20}$) with probability at most $\frac{\gamma^2}{9 \cdot 128}$ (where this probability is taken over the random coins of the individual $3n$ local randomizers, as well as the random coins of $\mathcal{P}$). Overall, there are $3k$ (dependent) simulations, and so the expected number of simulated triangle-counting computations for which $\mathcal{A}$ returns additive error greater than $\frac{\sqrt{\gamma}n^2}{20}$ is at most $\frac{\gamma^2 \cdot (3k)}{9 \cdot 128} = \frac{\gamma^2 \cdot k}{6 \cdot 64}$. Hence, by Markov's inequality, the probability that the number of inaccurate simulated triangles queries exceeds $\frac{\gamma^2 \cdot k}{64}$ is at most $\frac{1}{6}$.

Condition on the event that at most $\frac{\gamma^2 \cdot k}{64}$ of the triangle-counting computations are answered inaccurately, so that the remaining computations are answered with error at most $\alpha = \frac{\sqrt{\gamma} n^2}{20}$, and denote this even by E. Recall that each triangle-counting computation is used to answer a single submatrix query, and that by Claim 3.4, if a triangle-counting computation is answered with additive error α, then the corresponding submatrix query is answered with additive error α/n. Hence, by the above conditioning, at most $\frac{\gamma^2 \cdot k}{64}$ of the submatrix queries are answered with additive error greater than α/n. Each inaccurate answer to a triangle-counting computation can spoil the answer to at most one outer-product query. Furthermore, by Claim 3.5, if all three submatrix queries used to compute a single outer-product query are answered to within additive error α/n, then the outer-product query is answered to within additive error $5\alpha/n$. Hence, by the above conditioning, at most $\frac{\gamma^2 \cdot k}{64}$ of the outer-product queries are answered with additive error greater than $5\alpha/n = \frac{\sqrt{\gamma} n}{4}$. Since event E occurs with probability at least $5/6$, we get that with probability at least $5/6$, the fraction of outer-product queries that is answered with additive error greater than $\frac{\sqrt{\gamma} n}{4}$ is at most $\frac{\gamma^2 \cdot k}{64}$, so that Claim 3.6 holds. ◁

This completes the proof of Lemma 3.3. ◀

3.2 Anti-Concentration for Random Outer-Product Queries

In this section, we prove Lemma 1.4. To analyze our reconstruction attack, we will consider the differences between the true dataset X and a potential reconstructed dataset Y. Let M denote $X - Y$. Then, for an outer-product query (A, B), the difference between the answers to this query on dataset X and on dataset Y is $A^T X B - A^T Y B = A^T M B$. The main result of this section shows that if X and Y differ on many entries (that is, M has lots of nonzero entries) then a random outer-product query is likely to produce significantly different answers on X and Y.

Proof of Lemma 1.4. Let $Z_{ij} = A_i B_j$ for all $i, j \in [n]$, and $U = A^T M B$. We prove the lemma by computing the expectation and the second and the fourth moments of U, and then apply the Paley-Zigmund inequality to U^2.

By independence of A_i and B_j for all $i, j \in [n]$, we have $\mathbb{E}[Z_{ij}] = \mathbb{E}[A_i] \cdot \mathbb{E}[B_j] = 0$ and $\mathrm{Var}[Z_{ij}] = \mathbb{E}[Z_{ij}^2] = \mathbb{E}[A_i^2 B_j^2] = 1$. By definition of U and the linearity of expectation,

$$\mathbb{E}[U] = \mathbb{E}[A^T M B] = \mathbb{E}\Big[\sum_{i,j \in [n]} M_{i,j} Z_{i,j}\Big] = \sum_{i,j \in [n]} M_{i,j} \mathbb{E}[Z_{i,j}] = 0.$$

Note that random variables Z_{ij} are pairwise independent. This is an important feature of random outer-product queries and the main reason to use them instead of the submatrix queries. This feature greatly simplifies the analysis. Since U is unbiased, $\mathbb{E}[U^2] = \mathrm{Var}[U]$. By pairwise independence of Z_{ij},

$$\mathrm{Var}[U] = \mathrm{Var}\Big[\sum_{i,j \in [n]} M_{ij} Z_{ij}\Big] = \sum_{i,j \in [n]} M_{ij}^2 \, \mathrm{Var}[Z_{ij}] = \sum_{i,j \in [n]} M_{ij}^2 = m.$$

Next, we give an upper bound on the 4th moment of U.

▷ Claim 3.7. $\mathbb{E}[U^4] \leq 9n^4$.

Proof. We use the definition of U, write it out as a sum, and multiply out the terms of the product:

$$\begin{aligned}\mathbb{E}[U^4] = \mathbb{E}[(A^T MB)^4] &= \mathbb{E}\Big[\Big(\sum_{i,j\in[n]} M_{ij}Z_{ij}\Big)^4\Big] \\ &= \sum_{(i_1,j_1),\ldots,(i_4,j_4)\in[d]\times[d]} M_{i_1j_1}M_{i_2j_2}M_{i_3j_3}M_{i_4j_4}\ \mathbb{E}[Z_{i_1j_1}Z_{i_2j_2}Z_{i_3j_3}Z_{i_4j_4}], \qquad (1)\end{aligned}$$

where Equation (1) is obtained by using the linearity of expectation. Next, we evaluate the expectation of the product in Equation (1):

$$\begin{aligned}\mathbb{E}[Z_{i_1j_1}Z_{i_2j_2}Z_{i_3j_3}Z_{i_4j_4}] &= \mathbb{E}[A_{i_1}B_{j_1}A_{i_2}B_{j_2}A_{i_3}B_{j_3}A_{i_4}B_{j_4}] \\ &= \mathbb{E}[A_{i_1}A_{i_2}A_{i_3}A_{i_4}]\ \mathbb{E}[B_{j_1}B_{j_2}B_{j_3}B_{j_4}],\end{aligned}$$

where the last equality follows by independence of A_i and B_j for all $i, j \in [n]$. The expression $\mathbb{E}[A_{i_1}A_{i_2}A_{i_3}A_{i_4}]$ is 0 if at least one of the indices appears only once in the tuple (i_1, i_2, i_3, i_4), since, in this case, we can use the independence of the corresponding factor A_i from the remaining factors to represent this expression as $\mathbb{E}[A_i]$ multiplied by the expectation of the product of the remaining factors. Since $\mathbb{E}[A_i] = 0$ for all $i \in [n]$, the overall expression evaluates to 0.

Note that if one of the factors appears exactly three times, then another factor appears exactly once. Therefore, the remaining case is when each factor appears an even number of times. If there are two factors, say A_i and A_j that appear twice, then the expression evaluates to $\mathbb{E}[A_i^2 A_j^2] = 1$. It also evaluates to 1 when $i = j$.

Thus, each term in Equation (1) is either 0 or 1. By symmetry, it can potentially be 1 only if each index in the tuple (i_1, i_2, i_3, i_4) and each index in the tuple (j_1, j_2, j_3, j_4) appears an even number of times. It remains to give an upper bound on the number of such terms. There are $\binom{n}{2}$ ways to choose two distinct i-indices and $\binom{4}{2} = 6$ possible positions for them in the 4-tuple. In addition, there are n ways to choose an index that appears 4 times in the 4-tuple. So, the number of possibilities for nonzero $\mathbb{E}[A_{i_1}A_{i_2}A_{i_3}A_{i_4}]$ is at most $3n^2$. The same bounds holds for $\mathbb{E}[B_{j_1}B_{j_2}B_{j_3}B_{j_4}]$. Consequently, the number of terms equal to 1 in Equation (1) is at most $9n^4$. Thus, the sum evaluates to at most $9n^4$. This completes the proof of Claim 3.7. ◁

Since U^2 is a nonnegative random variable with finite variance, the Paley-Zygmund inequality gives that, for all $\theta \in [0, 1]$,

$$\Pr\left[U^2 > \theta\ \mathbb{E}[U^2]\right] \geq (1-\theta)^2 \frac{(\mathbb{E}[U^2])^2}{\mathbb{E}[U^4]} \geq (1-\theta)^2 \frac{m^2}{9n^4} \geq (1-\theta)^2 \frac{(\gamma n^2)^2}{9n^4} = (1-\theta)^2 \frac{\gamma^2}{9},$$

where the last inequality uses the bound $m \geq \gamma n^2$ stated in the lemma. Finally, we set $\theta = 1/4$ and get:

$$\Pr\left[|A^T MB| > \frac{\sqrt{m}}{2}\right] = \Pr\left[|U| > \frac{\sqrt{m}}{2}\right] = \Pr\left[U^2 > \frac{m}{4}\right] \geq \frac{3^2}{4^2}\frac{\gamma^2}{9} = \frac{\gamma^2}{16},$$

completing the proof of Lemma 1.4. ◀

3.3 Reconstruction Attack Using Outer-Product Queries

To simplify notation in this section, we represent our datasets and outer-product queries as vectors. Formally, X here denotes the vectorization of the original sensitive dataset, i.e., a vector in $\{0,1\}^{n^2}$. For an outer-product query (A, B), we let $Q \in \{0,1\}^{n^2}$ represent the vectorization of $A \otimes B$, the outer product of A and B. (In other words, Q is the Kronecker product of A and B.) Then the answer to the query is the dot product $Q \cdot X$.

In this section, we define and analyze the attacker's algorithm $\mathcal{C}$ and complete the proof of Theorem 3.1. The attacker $\mathcal{C}$ runs algorithm $\mathcal{B}$ from Section 3.1 on the sensitive dataset X and a set of k random outer-product queries $Q_1, \ldots, Q_k$ to obtain answers $a_1, \ldots, a_k$. For all $\ell \in [k]$, we call the answer a_ℓ *accurate for a dataset* Y if $|Q_\ell \cdot Y - a_\ell| \leq \frac{\sqrt{\gamma}n}{4}$; otherwise, we call a_ℓ *inaccurate for* Y. The attacker $\mathcal{C}$ outputs any dataset $Y^* \in \{0,1\}^{n^2}$ for which at most $\frac{\gamma^2 k}{64}$ answers among $a_1, \ldots, a_k$ are inaccurate for Y^*. By Lemma 3.3, the probability that X satisfies this requirement is at least $\frac{5}{6}$. If this event occurs, algorithm $\mathcal{C}$ will be able to output some Y^*. (Otherwise, the attack fails.)

Next, we analyze the attack. Let $\|X - Y\|_1$ denote the Hamming distance between datasets X and Y. Call a dataset Y *bad* if $\|X - Y\|_1 > \gamma n^2$, i.e., if it differs from X on more than γn^2 entries. We will show that $\mathcal{C}$ is unlikely to choose a bad data set as Y^*. Fix a bad dataset Y. Let $M = X - Y$, and observe that M has $m > \gamma n^2$ nonzero entries. We say that a set of queries $\{Q_1, \ldots, Q_k\}$ *catches* the dataset Y if more than $\frac{\gamma^2 k}{32}$ entries in $(|Q_1 \cdot M|, \ldots, |Q_k \cdot M|)$ exceed $\frac{\sqrt{\gamma}n}{2}$.

▶ **Lemma 3.8.** *Suppose the attacker $\mathcal{C}$ makes $k = \frac{128n^2}{\gamma^2}$ uniformly random outer-product queries. Then the probability that there exists a bad dataset not caught by the attacker's set of queries is at most $\frac{1}{6}$.*

Proof. Consider a set of k uniformly random outer-product queries $\{Q_\ell\}_{\ell \in [k]}$. Fix a bad dataset Y. Then $\|X - Y\|_1 > \gamma n^2$. Let $M = X - Y$.

For every $\ell \in [k]$, let $\chi_\ell = 1$ if $|Q_\ell \cdot M| > \frac{\sqrt{\gamma}n}{2}$, and otherwise let $\chi_\ell = 0$. Also, let $\chi = \sum_{\ell=1}^{k} \chi_\ell$. By definition, the difference vector $M = X - Y$ has more than γn^2 nonzero entries. By the anti-concentration bound in Lemma 1.4, $\Pr\left[|Q_\ell \cdot M| > \frac{\sqrt{\gamma}n}{2}\right] \geq \frac{\gamma^2}{16}$. Therefore, $\mathbb{E}[\chi_\ell] \geq \frac{\gamma^2}{16}$. By the Chernoff bound, we have that for $k = \frac{128n^2}{\gamma^2}$ and for $n \geq 3$,

$$\Pr\left[\chi \leq \frac{\gamma^2 \cdot k}{32}\right] \leq \exp\left(-\frac{\gamma^2 k}{128}\right) = \exp\left(-n^2\right) < \frac{1}{6 \cdot 2^{n^2}}.$$

Hence, the set $\{Q_\ell\}_{\ell \in [k]}$ fails to catch each specific bad dataset with probability at most $\frac{1}{6 \cdot 2^{n^2}}$. By a union bound over at most 2^{n^2} bad datasets, the probability that there exists a bad dataset not caught by the attacker's queries is at most $1/6$. ◀

▶ **Lemma 3.9** (Reconstruction Lemma)**.** *If algorithm $\mathcal{B}$ has additive error at most $\frac{\sqrt{\gamma}n}{4}$ on all but at most $\frac{\gamma^2 k}{64}$ answers, and the set of queries it uses catches all bad datasets Y, then the reconstruction attack is successful, that is, the attacker $\mathcal{C}$ outputs Y^* that differs from X on at most γn^2 entries, i.e., $\|X - Y^*\|_1 \leq \gamma n^2$.*

Proof. By the first premise of the lemma, the dataset X "disagrees" with at most $\frac{\gamma^2 k}{64}$ of the answers a_ℓ. Hence, necessarily, the attacker $\mathcal{C}$ outputs some dataset Y^*. Assume towards a contradiction that Y^* is a bad dataset. Let $\{Q_\ell\}_{\ell \in [k]}$ be the set of queries chosen by $\mathcal{B}$. Let $M^* = X - Y^*$ be the difference vector. By the triangle inequality, $|Q_\ell M^*| = |Q_\ell X - Q_\ell Y^*| \leq |Q_\ell X - a_\ell| + |Q_\ell Y^* - a_\ell|$. From the first assumption in the

lemma, $|Q_\ell X - a_\ell| \le \frac{\sqrt{\gamma}n}{4}$ for all but at most $\frac{\gamma^2 k}{64}$ of the queries. By the description of the attack $\mathcal{C}$, the output Y^* is such that for all but at most $\frac{\gamma^2 k}{64}$ of the queries, $|Q_\ell Y^* - a_\ell| \le \frac{\sqrt{\gamma}n}{4}$. Therefore, for all but at most $\frac{\gamma^2 k}{32}$ of the queries, $|Q_\ell M^*| \le |Q_\ell X - a_\ell| + |Q_\ell Y^* - a_\ell| \le \frac{\sqrt{\gamma}n}{2}$. Since $\{Q_\ell\}_{\ell\in[k]}$ catches all bad datasets, it in particular catches Y^*, because Y^* is bad. By definition of catching, $|Q_\ell M^*| > \frac{\sqrt{\gamma}n}{2}$ for more than $\frac{\gamma^2 k}{32}$ of the values $Q_\ell M^*$. Hence, we have reached a contradiction, implying that Y^* is a good dataset. ◀

The final ingredient for proving Theorem 3.1 is the following lemma, which is based on an argument of [15]. Any algorithm that outputs a large fraction of its secret dataset is definitely not private, for any reasonable notion of privacy. Lemma 3.10 states that such an algorithm is not differentially private.

▶ **Lemma 3.10.** *Let $\mathcal{C}$ be an algorithm that takes as input a secret data set X in $\{0,1\}^N$ and outputs a vector in the same set, $\{0,1\}^N$. If $\mathcal{C}$ is (ε,δ)-differentially private and X is uniformly distributed in $\{0,1\}^N$, then*

$$\mathbb{E}\left[\|\mathcal{C}(X) - X\|_1\right] \ge e^{-\varepsilon}\left(\tfrac{1}{2} - \delta\right)N\,.$$

Lemma 3.10 above only bounds the expectation of $\|\mathcal{C}(X) - X\|_1$. The more sophisticated argument in [15] yields much tighter concentration results. We use the simpler version here since it allows for a self-contained presentation.

Proof. Fix an index $i \in [N]$ and a bit $r \in \{0,1\}$. Let $X_{i\to r}$ denote the vector obtained by replacing the i-th entry of X with the bit r.

Consider the pair of random variables $(X, \mathcal{C}(X))$. Because $\mathcal{C}$ is (ε,δ)-differentially private, this is distributed similarly to the pair $(X_{i\to R}, \mathcal{C}(X))$, where R is a uniformly random bit independent of the other values. Specifically, for any event $E \subseteq \{0,1\}^N \times \{0,1\}^N$,

$$\Pr[(X_{i\to R}, \mathcal{C}(X)) \in E] \le e^{\varepsilon} \Pr[(X, \mathcal{C}(X)) \in E] + \delta.$$

Applying this inequality to the event $E_i = \{(x,y) : x_i \ne y_i\}$ shows that

$$\tfrac{1}{2} = \Pr[\mathcal{C}(X)_i \ne R] \le e^{\varepsilon} \Pr[\mathcal{C}(X)_i \ne X_i] + \delta \quad \text{and thus} \quad \Pr[\mathcal{C}(X)_i \ne X_i] \ge e^{-\varepsilon}(\tfrac{1}{2} - \delta)\,.$$

The Hamming distance $\|\mathcal{C}(X) - X\|_1$ is the sum of the indicator random variables for the events $\mathcal{C}(X)_i \ne X_i$. By linearity of expectation, the expected Hamming distance is at least $e^{-\varepsilon}\left(\frac{1}{2} - \delta\right)N$. ◀

Finally, we use Lemmas 3.3 and 3.8–3.10 to compete the proof of the main theorem.

Proof of Theorem 3.1. We set $\gamma = \frac{1}{9}$. Assume towards a contradiction that for some ε and δ as in the statement of the theorem, there exists an (ε,δ)-LEDP algorithm $\mathcal{A}$ that for every $3n$-node graph approximates the number of triangles in the graph up to additive error $\alpha = \frac{\sqrt{\gamma}n^2}{20}$ with probability at least $1 - \frac{\gamma^2}{9\cdot 128} = 1 - \frac{1}{3^6\cdot 2^7}$. Then by Lemma 3.3, there exists a $(2\varepsilon, 2\delta)$-DP algorithm $\mathcal{B}$ that, for every secret dataset X and every set of k outer-product queries, answers inaccurately (i.e., with additive error more than $\frac{\sqrt{\gamma}n}{4}$) on at most $\frac{\gamma^2 k}{64}$ of the k queries with probability at least $\frac{5}{6}$. By Lemma 3.8, the probability that a set of $k = \frac{128n^2}{\gamma^2}$ random outer-product queries chosen by the attacker $\mathcal{C}$ does not catch all bad datasets is at most $\frac{1}{6}$. By a union bound, with probability at least $\frac{2}{3}$, the attacker $\mathcal{C}$ satisfies the premise of Lemma 3.9 and the set of chosen queries catches all bad data sets. Hence, with probability at least $\frac{2}{3}$, the attacker $\mathcal{C}$ outputs a dataset Y^* which coincides with X on at least $(1-\gamma)n^2$ entries. The expected Hamming distance $\mathbb{E}[\|X - Y^*\|_1]$ is therefore at most $\frac{2}{3}\cdot\gamma n^2 + \frac{1}{3}n^2 = \frac{1+2\gamma}{3}n^2$. When $\gamma = \frac{1}{9}$, the expected distance is less than $0.41n^2$.

Recall that the attacker $\mathcal{C}$ runs $(2\varepsilon, 2\delta)$-DP algorithm $\mathcal{B}$ on a secret dataset X and then post processes the output of $\mathcal{B}$. Thus, $\mathcal{C}$ is $(2\varepsilon, 2\delta)$-DP, and we can apply Lemma 3.10 to conclude that the expected Hamming distance $\mathbb{E}\|\mathcal{C}(X) - X\|_1$ is at most $e^{-2\varepsilon}(\frac{1}{2} - 2\delta)n^2$. Since, by assumption, $\varepsilon \leq 1/20$ and $\delta \leq 1/100$, we have $\mathbb{E}\|\mathcal{C}(X) - X\|_1 \geq 0.43n^2$. This contradicts the upper bound of $0.41n^2$ above. ◀

4 The Interactive Lower Bound

In this section, we present an $\Omega\left(\frac{n^{3/2}}{\varepsilon}\right)$ lower bound on the additive error of every ε-LEDP algorithm for estimating the number of triangles in a graph, stated formally in Theorem 1.3. We reduce from the problem of computing the summation in the LDP model.

▶ **Definition 4.1** (Summation function). *Let SUM_n be the following function. For all $x_1, \ldots, x_n \in \{0,1\}$, $SUM_n(x_1, \ldots, x_n) = \sum_{i=1}^{n} x_i$.*

This problem was shown to have an additive error lower bound of $\Omega(\sqrt{n}/\varepsilon)$ [36, Theorem 5.3 of arxiv v2]. We substitute $\alpha = \alpha_0/n$ and $\beta = \varepsilon\alpha_0/n$ to obtain the following lemma.

▶ **Lemma 4.2** ([10, 6, 36]). *There exists a constant $c > 0$ such that for every $\varepsilon \in (0,1)$, $n \in \mathbb{N}, \alpha_0 \in (0,n]$ and $\delta \in \left[0, \frac{1}{10^5} \cdot \frac{\varepsilon^3\alpha_0^2}{n^3 \ln(n^2/\varepsilon\alpha_0)}\right]$, if $\mathcal{B}$ is an (ε,δ)-LDP algorithm where each party i receives input $x_i \in \{0,1\}$ and $\mathcal{B}$ estimates SUM_n up to additive error α_0 with probability at least $2/3$, then $\alpha_0 \geq c \cdot \sqrt{n}/\varepsilon$.*

Proof of Theorem 1.3. We reduce from SUM_n in the local model. By Lemma 4.2, every (potentially interactive) algorithm that approximates SUM_n with additive error at most α_0 (with sufficiently high constant probability) must have $\alpha_0 = \Omega(\frac{\sqrt{n}}{\varepsilon})$. In our reduction, we will set the additive error of the triangle-counting algorithm, $\alpha = \alpha_0 n$.

Our reduction is black-box. Given an instance of SUM_n, where each local party holds one bit X_i of the vector $(X_1, \ldots, X_n)$, the parties implicitly create the following graph G. The vertex set consists of two sets of nodes, V_1 and V_2, where V_1 has size n and V_2 has size $2n$. The nodes in V_1 will not have any secret information and can be simulated by any local party. The nodes in V_2 are $[2n]$, and each party $i \in [n]$ is responsible for simulating nodes $2i-1$ and $2i$ in V_2. To create the edges of G, we add edges of the complete bipartite graph between V_1 and V_2. In addition, each pair of nodes $(2i-1, 2i)$ in V_2 has an edge between them if and only if $x_i = 1$. See Figure 3 for an illustration.

Let $S = x_1 + \ldots x_n$. Observe that any triangle in G must have two vertices in V_2 and an edge between a pair of matched nodes. Any such edge contributes exactly n triangles. So, the total number of triangles in G is $T = Sn$.

For the sake of contradiction, suppose there is an (ε,δ)-LEDP algorithm $\mathcal{A}$ that estimates the number of edges with error $o(\frac{n^{3/2}}{\varepsilon})$. We run it on G. By construction, party i can simulate the two nodes assigned to it, and anybody can simulate nodes in V_1. When the algorithm gets an estimate $\widehat{T}$ for the number of triangles, it outputs $\hat{S} = \widehat{T}/n$. If $\widehat{T} = T \pm o(\frac{n^{3/2}}{\varepsilon})$, then $\hat{S} = \widehat{T}/n = T/n \pm o(\frac{\sqrt{n}}{\varepsilon}) = S \pm o(\frac{\sqrt{n}}{\varepsilon})$, which is a contradiction to Lemma 4.2.

Moreover, if $\mathcal{A}$ is (ε,δ)-LEDP, then the reduction algorithm is (ε,δ)-LDP with respect to the secret dataset X. However, the latter contradicts Lemma 4.2. Thus, $\mathcal{A}$ cannot exist. ◀

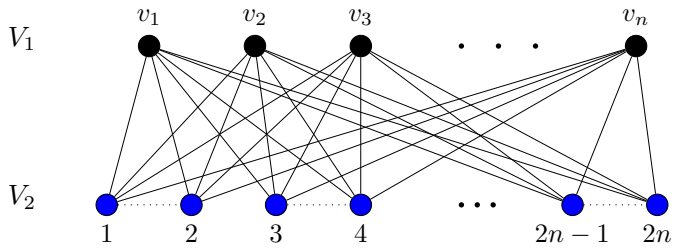

Figure 3 An instance of the interactive $\Omega(n^{3/2})$ lower bound consists of a complete bipartite graph with parts V_1, V_2 of sizes n and $2n$, respectively; in addition, there is an edge between each pair $\{2i-1, 2i\}$ iff the secret input bit $X_i = 1$.

Abstract

Single-hop radio networks (SHRN) are a well studied abstraction of communication over a *wireless* channel. In this model, in every round, each of the n participating parties may decide to *broadcast* a message to all the others, potentially causing collisions. We consider the SHRN model in the presence of *stochastic message drops* (i.e., *erasures*), where in every round, the message received by each party is *erased* (replaced by $\perp$) with some small constant probability, independently.

Our main result is a *constant rate coding scheme*, allowing one to run protocols designed to work over the (noiseless) SHRN model over the SHRN model with erasures. Our scheme converts any protocol Π of length at most exponential in n over the SHRN model to a protocol Π' that is resilient to constant fraction of erasures and has length linear in the length of Π.

We mention that for the special case where the protocol Π is *non-adaptive*, i.e., the order of communication is fixed in advance, such a scheme was known. Nevertheless, adaptivity is widely used and is known to hugely boost the power of wireless channels, which makes handling the general case of adaptive protocols Π both important and more challenging. Indeed, to the best of our knowledge, our result is the first constant rate scheme that converts adaptive protocols to noise resilient ones in any multi-party model.

1 Introduction

Over the last decades, wireless communication found many applications and has transformed technology. On the theoretical side, wireless systems were studied by numerous works, many of which consider the *single-hop radio networks* (SHRN) model of Chlamtac and Kutten [7], which abstracts a simple broadcast channel.

The classical model of SHRN assumes that the communication is *noiseless*, guaranteeing that (if no "collisions" occur) the message broadcast in a round will be received correctly by all the parties. In contrast, recently, Censor-Hillel, Haeupler, Hershkowitz, and Zuzic [6],

initiated the study of the radio networks model under *stochastic message drops* (*a.k.a*, *stochastic erasures*). In their model, each party only gets the message that was broadcast with probability $1-\epsilon$, independently, for some small constant ϵ. Otherwise, the round is "erased" for this party, meaning that it is received as a silent round, as if nothing was broadcast.

While the (noiseless) radio networks model is, by now, mostly well understood, and while noise is inherent in almost all communication systems, the relative power of noisy radio networks is far less explored. In this work we study the power of the SHRN model under the message drop noise of [6].

1.1 Our Result

Our main result is that the model of SHRN with message drops is as powerful as that of (noiseless) SHRN, in the sense that any protocol that was designed to work over the latter can be made to work over the former with a small overhead to the communication. An informal statement of our main result is in Theorem 1 (see Theorem 2 for a formal statement, the assumed model is discussed next).

▶ **Theorem 1.** *Let $n \in \mathbb{N}$ be the number of participants, $\epsilon \in (0,1)$ be the noise rate, and Γ be a non-empty alphabet set. For any protocol Π of length $T \leq 2^n$ over the (n,Γ)-broadcast channel, there is a protocol Π' with $\mathcal{O}(T)$ rounds over the (n,ϵ,Γ)-noisy broadcast channel that simulates[1] Π, and errs with probability polynomially small in T.*

We mention that our scheme works for protocols of length $T \leq 2^n$, as, if T is much larger than 2^n, there will be rounds where the messages received by all parties are erased (see Section 2.4). We also mention that our scheme uses a combinatorial building block called a *tree code* (see Section 2.2), and like other works that use tree codes, it is not computationally efficient, as no efficient tree code construction is known. Whether or not longer protocols can be handled with constant rate, and whether computationally efficient schemes are possible, are two intriguing questions we leave open.

The *collision-as-silence-as-erasures* SHRN model

We next overview the noise model of [6] used by Theorem 1 (for formal definitions, see Section 3): A protocol over the (n,ϵ,Γ)-*noisy broadcast channel* is a communication protocol between n communicating parties that proceeds in synchronous rounds. In each round, each party can decide to either broadcast a symbol from Γ or stay silent. If more than one party broadcasts in a given round (a *collision*), or none of the parties broadcast (a *silent round*), then the "$\perp$" symbol is received by all the parties[2]. Otherwise, exactly one of the parties broadcasts a symbol, and each party receives the broadcast symbol with probability $1-\epsilon$, and $\perp$ with probability ϵ, independently[3]. A protocol over the (n,Γ)-*broadcast channel* is a protocol over the $(n,0,\Gamma)$-noisy broadcast channel, i.e., one where erasures do not occur.

---

[1] By "Π' that simulates Π", we mean that a transcript for Π can be retrieved from a transcript for Π', see Theorem 2.

[2] The name *collision-as-silence* is because the same $\perp$ symbol is received in both collision and silent rounds. This model is, perhaps, the most common model in the literature. Another very popular model is the *collision detection* model, where collision and silence are perceived as different symbols. Theorem 1 is stated for the collision-as-silence model, but applies to the collision detection model as well.

[3] Modeling erasures as the same symbol as collisions/silences only makes our result stronger. As explained in Section 2.3, this makes our erasure model closer to the corruption model.

1.2 Corruption Noise and Adaptivity

The corruption noise model

One of the original motivations for our work was exploring the power of the SHRN model under stochastic *corruption noise*, a noise model that received quite a bit of attention over the last few years (see, e.g., [10, 11]). In this model, in every round, each party receives the correct symbol output by the channel with probability $1 - \epsilon$, and receives one of the other symbols with probability ϵ, independently[4]. Observe that protecting protocols against corruptions is at least as hard as protecting them against message drops.

Adaptivity and the [10] scheme

An encouraging piece of evidence, indicating that it may be possible to make SHRN protocols resilient to corruption noise with small overhead, was recently given by Efremenko, Kol, and Saxena [10], who designed such a scheme for a restricted set of protocols called *non-adaptive* protocols. Still, our initial belief was that such a scheme is impossible in the general case of *adaptive* protocols.

Non-adaptive (*a.k.a*, *oblivious* or *static*) protocols are a restricted set of protocols where it is known ahead of time which party broadcasts in what round, while adaptive protocols allow the parties to decide whether or not they wish to broadcast at a given round based on their input and their received transcript up until the current round.

While non-adaptive protocols are useful, they do not fully utilize the power of the wireless channel, and communication-efficient protocols for some central problems are, in fact, adaptive (e.g., the celebrated Decay protocol for computing the size of a network [3]). This additional power of adaptive protocols is what makes their conversion to noise-resilient ones more challenging, and, indeed, the [10] scheme may fail when applied to adaptive protocols Π.

When starting this project, we identified two inherent reasons (see Section 2.1) for the failure of [10] when applied to adaptive protocols and hoped to show that these must lead to a blowup of $\tilde{\Omega}(\log n)$ in the communication. As most interactive coding lower bounds for multi-party protocols also extend to the message drop model (e.g., [4, 11]), as a first step, we attempted to convince ourselves that no constant rate simulation scheme exists even for the SHRN model with message drop noise.

To our surprise, we were able to overcome both problems in the message drop model and design a scheme that also works for adaptive protocols. As far as we know, the scheme converting noiseless to noise-resilient protocols we construct in our proof of Theorem 1 is the first constant overhead scheme that handles adaptive protocols in any multi-party setting.

We are still very interested in the more general question of making SHRN protocols resilient to corruption noise, as we believe it is a basic and "clean" coding question. Our result can be interpreted as saying that (at least for protocols that are not extremely long) either a high-rate scheme is possible or a novel lower bound approach is required.

1.3 Related Work

Interactive coding. *Interactive error correcting codes* encode interactive communication protocols designed to work over noiseless channels to protocols that also work over noisy channels. The study of interactive codes was initiated by a seminal paper of Schulman [25]

[4] Care needs to be taken while defining an error model for corruptions, as some definitions may allow for signaling-based protocols [20].

that considered two-party protocols, which was also the topic of many follow-up works. Interactive codes for multi-party distributed channels received quite a bit of attention over the last few years. These include codes for *peer-to-peer* channels [24, 21, 20, 1, 4, 16, 17] and codes for various *wireless* channels [5, 10, 6, 11, 12, 2, 8].

Coding for wireless systems. The models of wireless communication considered in the context of noise-resilience differ on a few axes. The first axis is the *adaptivity* of the simulation protocol: in some papers the target simulation protocol is allowed to be adaptive and in others it must be non-adaptive. (Of course, if the noiseless protocols considered are adaptive, the simulation needs to be adaptive. However, simulations of non-adaptive noiseless protocols by adaptive noise-resilient protocols have been considered). The second axis is whether *single or multi-hop* networks are considered. Finally, the last axis is whether the noise is modeled as stochastic *erasures* (message drops) or stochastic *corruptions* (change of symbols).

Non-adaptive simulations. The study of noise in wireless systems can be traced back to [14] that answered an open problem of [15] by giving an $\mathcal{O}(n \log \log n)$ length communication protocol for the *bit exchange* problem (all n parties have an input bit and all parties want to know the input of all the other parties). The underlying model was the *noisy broadcast channel*, which is a non-adaptive, single-hop model with corruption errors. A matching lower bound for this problem was later given by [18]. The communication complexity of other specific n-bit functions, like the *OR*, *majority*, and *parity* functions, were studied under related models by [27, 22, 13, 23, 18]. The non-adaptive single-hop model was studied under erasure noise by [19], where an $\mathcal{O}(n \log^* n)$ protocol is given for the bit exchange problem, breaking the $\Omega(n \log \log n)$ lower bound proved for corruption errors. The general case of simulating *any* non-adaptive protocol by an noise resilient non-adaptive protocol was very recently studied by [9]. Their main result is that, for protocols of length polynomial in n, such a simulation requires $\tilde{\Theta}(\sqrt{\log n})$ multiplicative overhead in the communication complexity.

Adaptive simulations. The work of [10] gave a scheme for converting any non-adaptive noiseless protocol to an adaptive noise-resilient one with only a constant multiplicative overhead, over a single-hop network with corruption errors (in particular, implying an adaptive noise-resilient bit exchange protocol with $\mathcal{O}(n)$ communication).

Multi-hop radio networks. The work of [10] (and our current work) consider the setting where the parties are connected in a *clique* (a *single-hop* network), as it is assumed that when a party transmits, all other parties can hear the transmission. As mentioned above, this topology is the single most extensively studied, as it represents the simplest broadcast channel. However, wireless systems can have arbitrary topologies.

In contrast to [10], in [11] it is shown that such a scheme is impossible over general multi-hop networks, where each of the n communicating parties is associated with a node in the graph, and when a party broadcasts, its message is only received by its neighbors in the graph (if there are no collisions). Specifically, [11] shows that in some networks, the cost of noise-resilience is $\Omega(\log n)$, even for simulating non-adaptive protocols by adaptive protocols. A matching $\mathcal{O}(\log n)$-overhead scheme for converting any noiseless protocol to a noise resilient one over any network is also given by [11].

The recent work of [6], considered general radio networks under message drop noise. They show that any protocol over any network can be converted to a noise resilient one with a multiplicative $\mathcal{O}(\Delta \log^2 \Delta)$ overhead to the communication, where Δ is the maximum degree of a node in the network. For the special case in which the noiseless protocol we wish to convert is non-adaptive, a scheme with an improved overhead of

$\text{poly}(\log\Delta, \log\log n)$ is shown [6]. For networks with small Δ, this implies an efficient simulation of noiseless protocols. However, for networks with large Δ, the [6] simulation can have a huge overhead. This is not for no reason, as the $\Omega(\log n)$ lower bound of [11] mentioned above also applies to the message drop noise and implies that there exist network topologies with large Δ for which an $\Omega(\log\Delta)$ overhead is necessary. Our result shows for the important single-hop topology, these communication overheads can be avoided altogether.

2 Proof Sketch

In this section, we give a detailed sketch of our protocol.

As mentioned in Section 1.2, one of the main motivations for our work was studying the rate of interactive codes over the SHRN model with corruptions. The restricted case where the protocol Π to be simulated is non-adaptive was studied by [10], but their scheme fails for adaptive protocols. We next explain the inherent reasons for this failure and then outline our solutions for erasure noise.

2.1 The [10] Scheme

The rewind-if-error framework

The [10] scheme utilizes the *rewind-if-error* framework, which was initially designed for the two-party setting [25]. Rewind-if-error coding schemes consist of many iterations, where each iteration consists of two phases: a *simulation phase*, where a small number of rounds of the noiseless protocol Π are executed, and a *consistency check phase* where the parties attempt to check if they have the same received transcript or whether an error occurred (e.g., by comparing hashes of their received transcripts). If the check phase passes, parties continue the simulation, otherwise they *rewind* and re-simulate the last few rounds.

A careful examination of the [10] scheme shows that it breaks down when applied to adaptive protocols for the following two fundamental reasons:

Repeated rewinds. The first problem is that with noise rate ϵ, we should expect about ϵn parties to experience message drops in every round of the simulation phase. Since ϵ is constant, $\epsilon n \gg 1$. This implies that the consistency check phase will almost always fail and trigger a rewind, and no progress will ever be made. This situation can be trivially corrected by repeating each broadcast symbol $\mathcal{O}(\log n)$ times, and thereby effectively reducing the noise rate to less than $\frac{1}{n}$. However, this is unaffordable for a constant overhead simulation.

We note that this repeated rewinds problem is avoided by [10] as, although the total number of parties n is large, the assumed non-adaptivity of Π can be used to determine a small subset S of parties that *critically* need to know the simulated transcript. These are the parties that will broadcast in the rounds immediately following the current one. The remaining parties broadcast later in the future and therefore have more time to decode the symbol broadcast in the current round. Then, [10] show that it is enough to make sure that parties in S are not experiencing message drops, which helps reduce overhead down to a constant. Since in the adaptive case, it is possible that *any* of the n parties broadcasts next, this approach cannot be implemented.

Message certification. An even bigger problem we encounter when attempting to run the [10] scheme on adaptive protocols is that it crucially uses the fact that the symbol received from the channel in every round can be *certified* by at least one of the parties: Since Π is

assumed to be non-adaptive, it can also be assumed that a single party broadcasts in every round (collisions and silences can be eliminated ahead of time). Furthermore, this party (and all other parties) knows that it is the only one to broadcast. Therefore, if party i broadcast the symbol σ in round t of Π and some claimed transcript of Π has a symbol different from σ in round t, party i can "object" to this transcript to trigger a rewind.

The adaptive setting is different though. Consider, for example, the case where Π is adaptive and in some rounds has multiple parties broadcasting simultaneously, causing a collision. We call such collisions *intended collisions*. Suppose, however, that in round t, party i was the only one to broadcast, but the claimed transcript for Π has $\perp$ in round t. Since party i may no longer know that it is the only one to broadcast in this round, it may deem it possible that others have broadcast as well, leading to an intended collision, and thus will not object. The other, silent, parties may not object either as they may think that this is a collision or a silent round.

2.2 Avoiding The Repeated Rewinds Problem

A protocol Π exhibiting repeated rewinds

To explain how our scheme handles the first (and easier) repeated rewinds problem described above, consider the following protocol Π that exhibits it (the second, message certification problem, does not occur): The protocol is played over an underlying complete binary tree of depth $T < 2^n$. Each of the n parties gets as input, one symbol $b_v \in \{0, 1, \star\}$ for each vertex v in the tree, where the inputs are sampled as follows: First, we select one of the root-to-leaf paths in the tree uniformly at random and call it the "*correct path*". We assign each of the vertices v on this path to exactly one of the n parties uniformly at random. Here, by "assigning vertex v to party i" we mean that party i gets a bit $b_v \in \{0, 1\}$ for vertex v. If vertex v is not assigned to party i, party i gets $b_v = \star$. Additionally, each of the vertices v outside this path is assigned to many parties, say, to a set of $\frac{n}{2}$ parties selected uniformly at random.

In the noiseless protocol Π, all parties start from the root of the tree, and, upon reaching node v, a party that was not assigned v (has $b_v = \star$) stays silent, and a party that was assigned v broadcasts its bit b_v. Since each of the vertices on the correct path was assigned to exactly one party, exactly one party broadcasts a bit, and all parties then progress to the child of v indicated by this bit (that is, if 0 is broadcast they update v to be the left child of v, otherwise to the right child). This is done until a leaf is reached, which is also the output of the protocol.

Observe that since on every vertex of the correct path a single party broadcasts (and the parties know that this is the case), the message certification problem does not occur. However, since any of the n parties may potentially be the one to broadcast in the next round, the repeated rewinds problem occurs.

The *play-it-safe* simulation scheme

To avoid repeated rewinds in our simulation of Π, we make sure that parties never go off the correct path (i.e., no party ever reaches a vertex v that is not on the correct path) by guaranteeing that the parties never broadcast when it is not their turn to broadcast. To this end, our policy for the parties is that they always *play it safe* and *never broadcast unless they know the entire transcript so far.*

Of course, it may be the case that the received transcript of the party who should broadcast next contains erasures, causing it to refrain from broadcasting. Since no other party broadcasts, this will be a silent round and all parties will receive $\perp$. Upon receiving $\perp$, parties do not update their current node v in the tree. Thus, no progress is made in this round, where progress is measured as the number of steps taken on the correct path (the depth of v in the tree). Note, however, that indeed in this protocol parties never go off the correct path.

To allow progress to resume, we need to ensure that the erasures in the transcript of the party that should broadcast next are resolved (hopefully, within a few rounds). To this end, we pick one of the parties (say, the first party) to be the *leader*. After every communication round, this leader re-broadcasts the symbol it received from the channel on a *tree code* [26]. A tree code is essentially an error correcting code that can be computed "online" and ensures that the messages sent until round t will *eventually* be decoded correctly, where the probability of correct decoding greatly increases with the number of rounds that have passed since round t. Thus, parties that suffer an erasure will be able to recover the missing symbol over the next few iterations by observing what was received from the leader on the tree code. This means that, while progress may pause, it will resume within a few rounds.

2.3 Avoiding The Message Certification Problem

A harder-to-simulate protocol Π

Now let us address the second (and more severe) problem of message certification. Observe that in our simulation of the above protocol Π we did not encounter this problem. The reason is that on every vertex on the correct path a single party is scheduled to broadcast. We now consider the more general case where some of the vertices on the correct path are given to more than one party. For concreteness, say that a quarter of the vertices v on the correct path are given to exactly 2 parties, and an additional quarter is given to $\frac{n}{2}$ parties (that is, in total, there is an intended collision on half of the vertices on the correct path). Additionally, assume that the underlying tree is ternary (instead of binary), and the children of every non-leaf vertex are labeled by $\{0, 1, \perp\}$. In a case of an intended collision, the $\perp$ child of the current vertex should be taken.

Erasures can cause errors

Observe that the play-it-safe simulation protocol we had before has to change: When designing it, we assumed that there are no collisions on the correct path, thus progress was paused when a $\perp$ symbol was received (that is, the parties did not update their current vertex v in the tree). As intended collisions are now possible, we ask that, upon receiving $\perp$, the parties update v to the $\perp$ child of v.

Observe however, that since the parties are *unable to differentiate intended collisions from erasures*, as both are received as $\perp$, they may go off the correct path and will need to eventually detect the error and rewind. We note that working in the erasure model typically means that a party that does not have the correct transcript knows that it does not have the correct transcript. However, as is evident here, this reasoning does not apply to our erasure model. In this sense, our model is *closer to the corruptions model* than other erasure models.

In our simulation, parties can go off the correct path in round t if the party that was supposed to broadcast in round t (say party i) did not do so as it did not know the full transcript so far. By not broadcasting, party i potentially converts the output of the channel in round t from a bit to $\perp$ (this happens when party i was supposed to be the only one

to broadcast) or from $\perp$ to a bit (this happens when one additional party was supposed to broadcast). Recall that, owing to the usage of a tree code, party i eventually learns the complete transcript until the missed round t. When this happens, we can have party i object in the next consistency check in order to trigger a rewind. However, because the rate of erasures is constant and parties broadcast very often (recall that a quarter of the vertices on the correct path are given to $\frac{n}{2}$ parties), there are likely to be too many missed rounds and such objections will once again cause repeated rewinds.

Critical parties

To implement a rewind-if-error mechanism without repeated rewinds, we observe that rewinds are required only when the output symbol was changed due to party i (a party that was scheduled to broadcast in round t) not broadcasting in round t. Note that this only happens if the output symbol in round t is not a collision. In this case, we say that party i is *critical*[5] for round t. We use the policy that party i only objects to round t if it is critical to round t[6]. Note that this policy does not cause repeated rewinds: if many parties were supposed to broadcast in round t, none of them is critical (this round will be a collision round even if one of these parties will not broadcast). Otherwise, if few parties were supposed to broadcast in round t, then there is a good chance that round t is not erased in any of the received transcripts of these parties.

Collision-*not*-as-silence

To be able to implement the policy, party i needs to know if it was critical to the round t that it missed. Observe that if round t was a collision round even without party i broadcasting, then party i is not critical for round t, and no rewind is necessary. It is not hard to see that this is in fact the only case where a party who missed a round is not critical for this round. This means that testing criticality boils down to the ability to differentiate a collision round from a silent round.

To differentiate collision rounds from silent rounds, we use a known radio networks *collision detection* trick. Assume for the purposes of this sketch that there is some player, say the leader, that is known to not broadcast in this round[7]. We "run" the round twice, once in a black-box way (without the leader broadcasting), and once again while having the leader broadcast. If the round was a silent round, then the parties receive a $\perp$ in the first run, and a bit (non-$\perp$ symbol) in the second, while if the round was a collision, they will receive $\perp$ in both the runs. As they receive a different combination of symbols, they can distinguish between collisions and silences[8]. Note that the argument above assumes sender collision-detection, i.e., the parties that are transmitting also receive a symbol in that round. However, this assumption is not needed, see Footnote 10 and Remark 3.

---

[5] We mention that this definition differs slightly from the technical sections, but implements a similar idea.

[6] Observe that a priori, it is not clear if the parties know they are critical. We deal with this later in this section. We also note that the notion of critical parties does not appear in the algorithm description and is used only in the analysis.

[7] This assumption can easily be removed by, *e.g*, running the round an extra time where only the leader will broadcast.

[8] We note that noise can erase the symbol broadcast by the leader in the second run and effectively erase a silence out to look like a collision. We distinguish between these and regular collisions using the method described in Section 2.4.

2.4 Erasures *To* And *From* The Leader

Recall from Section 2.2 that after every round the leader re-transmits the symbol that it received from the channel in this round. We next discuss issues that can arise when the communication to/from the leader is erased.

Erasures *to* the leader

Consider the case where the true output of the channel in a given round is a bit, but the leader receives $\perp$ due to an erasure (re-transmitting this $\perp$ may cause the execution of the protocol to go off the correct path). However, since erasures are assumed to happen independently, then with probability exponentially small in n, at least one of the other parties receives the erased bit and can object in the next consistency check to trigger a rewind. Using the assumption that the length of the protocol is at most exponential in n, we get that all such leader errors will be corrected with high probability. We mention that this is the only place in our proof where we use the bound on the length of the protocol.

Erasures *from* the leader: Collision-as-silence-*not*-as-erasures

Now consider the situation where the leader receives a bit and re-transmits it, but, due to erasures, some parties receive a $\perp$. By updating their current node v using this $\perp$, these parties may fall off the correct path. As mentioned in Section 2.3, this type of error occurs as the channel does not distinguish between erasures and collisions/silences.

To circumvent this problem, we convert our collision-as-silence-as-erasures channel to a collision-as-silence-*not*-as-erasures channel. This is done by having the leader broadcast a special symbol[9] other than 0, 1, and $\perp$, in the case it receives $\perp$. As the other parties know that the leader never broadcasts $\perp$, they can deduce that any $\perp$ they may receive from it is due to an erasure. On the other hand, if they receive the special symbol, they can conclude that the round is a collision/silence.

2.5 Implementing Check Phases

The simulation scheme we discuss so far is in the rewind-if-error framework. In this sketch we attempted to show that whenever the parties go off the correct path due to erasures, at least one of the parties is able to detect the problem and object in the next check phase.

To implement a check phase, we ask parties that wish to object to broadcast a bit (say, 1), and ask all other parties to keep silent. Then, the collision detection subroutine described above allows the parties to tell whether 0, 1, or more than 1 parties were broadcasting, and thus also allows them to tell whether there exists an objecting party and a rewind should take place.

3 The Model

In this paper, we study the broadcast channel with random erasures, assuming the *collision-as-silence-as-erasures* model. To define the model and throughout this paper, we will use the following notation. For a string s, we shall use $|s|$ to denote the length of s. For $i \in [|s|]$, let s_i denote the i^{th} coordinate of s and $s_{<i}, s_{\leq i}$ denote the prefix of the first $i-1$ and i

[9] The actual proof does not require an additional symbol. Rather, we encode every symbol by two symbols.

coordinates of s, respectively. For two strings s, t over the same alphabet, denote by $\Delta(s,t)$ the Hamming distance between s and t, by $\mathsf{LCP}(s,t)$ the longest common prefix of the strings s and t, and by $s \| t$ the concatenation of s and t.

The (n, ϵ, Γ)-*noisy broadcast channel* is defined by a number $n \geq 0$ of parties, an error parameter $\epsilon > 0$, and an alphabet set Γ satisfying $|\Gamma| > 1$. We shall refer to player 1 as the *leader* Ld, use $\perp$ to denote a special symbol not in Γ (this symbol will represent collisions, silences, and deletions), and define $\Gamma_c = \Gamma \cup \{\perp\}$. We also define the (n, Γ)-*broadcast channel* to be the *noiseless* version of this channel, i.e., when $\epsilon = 0$.

Definition of a protocol

A (deterministic) *protocol* Π over the (n, ϵ, Γ)-noisy broadcast channel is defined as:

$$\Pi = \left(T, \{\mathcal{X}^i\}_{i\in[n]}, \mathcal{Y}, \{M_j^i\}_{i\in[n], j\in[T]}, \mathsf{out}\right). \tag{1}$$

Here, $T = \|\Pi\|$ is the number of rounds (or the *length*) of the protocol, $\mathcal{X}^i$ is the input space for player i, $\mathcal{Y}$ is the output space of the protocol, $M_j^i : \mathcal{X}^i \times \Gamma_c^{j-1} \to \Gamma_c$ is the function player i uses to determine what message to send in round j, and $\mathsf{out} : \Gamma_c^T \to \mathcal{Y}$ is the function the leader uses to determine the output from its received transcript. As usual, we define a *randomized protocol* to be a distribution over (deterministic) protocols.

Execution of a protocol

The protocol Π starts with all players $i \in [n]$ having an input $x^i \in \mathcal{X}^i$ and proceeds in T rounds, maintaining the invariant that before round j, for all $j \in [T]$, all players i have a transcript $\pi^i_{<j} \in \Gamma_c^{j-1}$. In round j, player i broadcasts $z^i = M_j^i(x^i, \pi^i_{<j}) \in \Gamma_c$. Define the function:

$$\mathtt{combine}(z^1, \cdots, z^n) = \begin{cases} z^i, & \text{if } \exists \text{ unique } i \in [n] \text{ such that } z^i \neq \perp \\ \perp, & \text{otherwise} \end{cases}. \tag{2}$$

Now, the symbol π^i_j received by player i in round j equals $\mathtt{combine}(z^1, \cdots, z^n)$, with probability $1-\epsilon$, and equals $\perp$, with probability ϵ, independently for all $i \in [n]$ and $j \in [T]$.[10] In the latter case, we say the message to player i in round j was *erased* by the noise. Player i appends π^i_j to $\pi^i_{<j}$ to get a transcript $\pi^i_{\leq j}$ and continues the execution of the protocol.

After T rounds, the leader outputs $\Pi^{\mathsf{Ld}}(X) = \mathsf{out}(\pi^{\mathsf{Ld}}_{\leq T}) \in \mathcal{Y}$. (Note that using only $\mathcal{O}(\max\{T, \log n\})$ additional transmissions, the leader can communicate the output to all the other parties in a reliable manner by encoding with a standard error correcting code.) We shall sometimes omit Ld when the channel is noiseless, as in this case, all the players receive the same transcript and can compute the output.

4 Our Simulation Protocol

We formalize Theorem 1 as Theorem 2 (below). (Note that by having the parties repeat every round of the original protocol Π constantly many times and taking the majority of the outputs, we get the channel noise rate to be smaller than 10^{-10}).

[10] We remark that in the literature (e.g., [6]), the broadcast channel (single-hop radio networks) is often defined such that a player that broadcasts a symbol (other than $\perp$) in a round does not receive any symbol from the channel in that round (in other words, there is no sender collision-detection). However, for simplicity of presentation, in this paper we assume this stronger model. We explain how to make our protocol work with no sender collision-detection in Remark 3.

▶ **Theorem 2** (Formal Version of Theorem 1). *There exists a constant C such that the following holds: Fix $\epsilon = 10^{-10}$, $n > 0$, an alphabet set Γ satisfying $|\Gamma| > 1$. For any protocol Π of length $T \leq 2^n$ in the (n, Γ)-broadcast channel, there is a protocol Π' over the (n, ϵ, Γ)-noisy broadcast channel, with $\|\Pi'\| \leq CT$, and such that for all inputs $X = \left(x^1, x^2, \cdots, x^n\right)$ for the players, we have:*

$$\Pr\left(\Pi'^{\mathsf{Ld}}(X) \neq \Pi(X)\right) \leq 2^{-\min(n,T)},$$

where the probability is over the noise in the channel.

We note that when n is small, so is T, so Π can be simulated by simply repeating each round sufficiently many times. As such, without loss of generality, we may assume that n is large.

The proof of Theorem 2 spans the rest of this paper. In this section we give the simulation protocol Π', and in Appendix B we give its analysis.

Let n, ϵ, Γ be as in the theorem statement and assume without loss of generality that $\Gamma = [|\Gamma|]$. Fix a protocol Π. Observe that fixing Π also fixes $T, \left\{\mathcal{X}^i\right\}_{i\in[n]}, \left\{M_j^i\right\}_{i\in[n],j\in[T]}$, etc. as in Equation (1). As a randomized protocol is simply a distribution over deterministic protocols, we can assume without loss of generality, that the protocol Π is deterministic. We also assume without loss of generality that the output of Π is just its transcript. In order to define the protocol Π', we first set up some notation.

Protocol notation

Define the sets $\mathcal{P}^{\mathsf{Ld}} = [n]$ (all parties including the leader), and $\mathcal{P} = \{2, 3, \ldots, n\}$ (all parties excluding the leader).

As motivated in Section 2, our protocol shall implicitly implement a collision detection model, having two separate symbols for collisions and silences. We shall use a special symbol $\perp_C \notin \Gamma$ to denote a collision and $\perp_S \notin \Gamma$ to denote a silence. Define $\Gamma_{cs} = \Gamma \cup \{\perp_C, \perp_S\}$.

Additionally let $\mathsf{R} \notin \Gamma$ be a special symbol indicating that the leader wants to rewind a round, and denote by $\Gamma_{csr} = \Gamma_{cs} \cup \{\mathsf{R}\}$. We shall treat both $\perp_C$ and $\perp_S$ as $\perp$ in our protocol, and output a string in Γ_{cs}^T. We also redefine the message functions, M_j^i, to take inputs from Γ_{cs}^{j-1} instead of Γ_c^{j-1}, treating both $\perp_C$ and $\perp_S$ as $\perp$, e.g., $M_j^i(x^i, \perp_C \| \perp_S) = M_j^i(x^i, \perp \| \perp)$. For simplicity, we shall pad the protocol Π with $\perp$ infinitely many times and correspondingly define, for all $i \in [n]$, $j > T$, the value $M_j^i(\cdot, \cdot) = \perp$.

Our protocol will use a $(\Gamma_{csr}, \Gamma, R_{\mathsf{TC}}, 0.4)$-tree code TC, where $R_{\mathsf{TC}} \geq \max\left(10^5, 10R\right)$ is a sufficiently large constant and R is as promised by Theorem 5. This tree code will only be written to by the leader, and will be used to log the leader's simulated transcript. In our protocol, when we say *the leader writes $s \in \Gamma_{csr}$ to the tree code*, we mean that it computes and broadcasts $\mathsf{TC}(\rho \| s)$, where ρ is the string of all the symbols it wrote to the tree code before the current s. We shall also use $\mathsf{D\text{-}TC}$ to denote the tree code decoding function from Definition 6.

We give a formal description of our protocol Π' in Algorithm 1.

▶ Remark 3. Recall from Footnote 10 that we are assuming a broadcast model with sender collision-detection. In other words, we assume that players that are talking (broadcasting a symbol other than $\perp$) also receive an output symbol from the channel. We next claim that our simulation protocol Π' can be made to work over the channel with no sender collision-detection, that is, when only players that listen (broadcast $\perp$), get the output symbol from the channel.

Algorithm 1 The simulation protocol Π'.

Input: Each party $i \in \mathcal{P}^{\mathsf{Ld}}$ holds an input $x^i \in \mathcal{X}^i$.
Output: The leader outputs $\pi \in \Gamma_{cs}^T$, that represents a transcript for Π.

1: **for** $t \in \left[10^5 T\right]$ **do**
2: Each player $i \in \mathcal{P}^{\mathsf{Ld}}$ runs parse on τ^i to get output $\left(\pi^i, r^i\right)$, where:
- τ^i, for $i \in \mathcal{P}$, is the concatenation of all messages received by player i at Line 8 up to this point (possibly none).
- τ^{Ld} is the concatenation of all messages broadcast (as opposed to received) by the leader at Line 8 up to this point (possibly none).

3: Each player $i \in \mathcal{P}^{\mathsf{Ld}}$ computes $z^i \leftarrow M^i_{|\pi^i|+1}\left(x^i, \pi^i\right)$. Set $z^i \leftarrow \perp$ if $\pi^i = \mathsf{fail}$.
4: The parties run detect-collisions, using z^i as the input for player $i \in \mathcal{P}$.
Let w^i be the output for player $i \in \mathcal{P}^{\mathsf{Ld}}$.
5: The leader represents $w^{\mathsf{Ld}} \in \Gamma_{cs}$ as an element of Γ^4 and broadcasts it in 4 rounds.
Let $\tilde{w}^i$ be the symbol decoded by player $i \in \mathcal{P}$, or $\perp$ if the player fails to decode.
6: Each player $i \in \mathcal{P}$ sets a flag $e^i \in \{1, \perp\}$ as follows:

$$e^i \leftarrow \begin{cases} 1, & \text{if } r^i = \mathsf{true} \text{ or } \tilde{w}^i = \perp_C \neq w^i \\ \perp, & \text{otherwise} \end{cases}.$$

7: The parties run detect-collisions, using e^i as the input for player $i \in \mathcal{P}$.
Let e^{Ld} be the output for the leader.
8: The leader writes $s^{\mathsf{Ld}} \in \Gamma_{csr}$ to the tree code, where

$$s^{\mathsf{Ld}} \leftarrow \begin{cases} \mathsf{R}, & \text{if } e^{\mathsf{Ld}} \neq \perp_S \\ w^{\mathsf{Ld}}, & \text{else if } z^{\mathsf{Ld}} = \perp \\ z^{\mathsf{Ld}}, & \text{else if } w^{\mathsf{Ld}} = \perp_S \\ \perp_C, & \text{otherwise} \end{cases}.$$

9: **end for**
10: The leader runs parse on τ^{Ld} to get output $\left(\pi^{\mathsf{Ld}}, r^{\mathsf{Ld}}\right)$, where τ^{Ld} is as in Line 2. The leader then outputs $\pi^{\mathsf{Ld}}_{\leq T}$.

Algorithm 2 Algorithm detect-collisions, that distinguishes between collisions and silence.

Input: Each player $i \in \mathcal{P}$ has a symbol $z^i \in \Gamma_c$ that it wishes to broadcast in this round.
Output: Each player $i \in \mathcal{P}^{\mathsf{Ld}}$ outputs a guess $w^i \in \Gamma_{cs}$ for the combined symbol.

11: In one round of communication, each player $i \in \mathcal{P}$ broadcasts z^i and the leader broadcasts $\perp$.
Let u^i be the symbol heard by player $i \in \mathcal{P}^{\mathsf{Ld}}$.
12: In one round of communication, each player $i \in \mathcal{P}$ broadcasts z^i and leader broadcasts 1.
Let $\overline{u}^i$ be the symbol heard by player $i \in \mathcal{P}^{\mathsf{Ld}}$.
13: Each player $i \in \mathcal{P}^{\mathsf{Ld}}$ returns w^i, where

$$w^i \leftarrow \begin{cases} u^i, & \text{if } u^i \neq \perp \\ \perp_S, & \text{else if } \overline{u}^i \neq \perp \\ \perp_C, & \text{otherwise} \end{cases}.$$

Algorithm 3 Algorithm parse, run locally by a player $i \in \mathcal{P}^{\mathsf{Ld}}$ to decode and parse the tree code.

Input: Player i has $\tau \in \Gamma_c^*$, its view of the symbols encoded over the tree code.
Output: Player i outputs a transcript $\pi \in \Gamma_c^*$ or fail if it failed to decode the tree code, and a rewind flag $r \in \{\mathsf{true}, \mathsf{false}\}$ which is true if the player found a problem with π.

14: Initialize π to be the empty string, $\ell \leftarrow \infty$.
15: Let $\rho \leftarrow \mathsf{D\text{-}TC}(\tau)$.
16: If $\rho = \mathsf{fail}$, terminate and return $(\mathsf{fail}, \mathsf{false})$.
17: **for** $k \in [|\rho|]$ **do**
18: **if** $\rho_k = \mathsf{R}$ **then**
19: $\pi \leftarrow \pi_{<|\pi|}$.
20: **if** $|\pi| < \ell$ **then**
21: $\ell \leftarrow \infty$.
22: **end if**
23: **else**
24: $\pi \leftarrow \pi \| \rho_k$.
25: **if** $\mathsf{D\text{-}TC}\left(\tau_{\leq (k-1)R_{\mathsf{TC}}}\right) = \mathsf{fail}$ **and** $M^i_{|\pi|}\left(x^i, \pi_{<|\pi|}\right) \neq \perp$ **and** $\rho_k \neq \perp_C$ **then**
26: $\ell \leftarrow \min(\ell, |\pi|)$.
27: **end if**
28: **end if**
29: **end for**
30: Return $(\pi, \ell \neq \infty)$.

There are two sources of problems if we assume no sender collision-detection. The first is that players $i \in \mathcal{P}$ are expected to get their own w^i at Line 4, which they use to detect erasures experienced by the leader (compute e^i in Line 6). However, as erasures are one-sided, if at least two different players $i \neq i' \in \mathcal{P}$ talk in the same round, the leader and all listening players will receive the correct symbol, i.e., $\perp_C$, as the value of w^i. As such, if an erasure causes the leader to get an incorrect w^{Ld}, there is at most one player $i \in \mathcal{P}$ who is talking. Thus, almost all players in $\mathcal{P}$ are listening, so they will have their own w^i, and this erasure is likely to be detected.

The second issue that arises is that the leader is expected to both talk and listen at Line 12. Recall that the purpose of algorithm detect-collisions is to run a round of the original protocol and essentially tell whether 0, 1, or ≥ 2 players in $\mathcal{P}$ are talking. The leader acts as a "noisemaker" in Line 12 to distinguish the case of 0 talking players from the case of ≥ 2 talking players. However, the role of a noisemaker can be handled by any other player, as long as that player would never have talked in this round otherwise.

This gives rise to the following modification of algorithm detect-collisions: We partition the parties in $\mathcal{P}$ into two non-empty sets $\mathcal{P}_1$ and $\mathcal{P}_2$. We then have parties in $\mathcal{P}_1$ perform algorithm detect-collisions with an arbitrary player in $\mathcal{P}_2$ acting as a noisemaker, and vice versa. This allows the leader to determine whether there were 0, 1, or ≥ 2 players talking in $\mathcal{P}_1$ and in $\mathcal{P}_2$, from which they can tell if there were 0, 1, or ≥ 2 players talking in $\mathcal{P}$.

As there are no other cases in the protocol Π' where a player both talks and uses the value given to it by the channel, these changes are sufficient to make the algorithm work with no sender collision-detection.

A Technical Preliminaries

A.1 Tree Codes

Our algorithms make use of *tree codes*, first introduced in [26].

▶ **Definition 4** (Tree Codes). *Let $\mathcal{X}$ and Γ be two alphabet sets, $R_{\mathsf{TC}} > 0$ be an integer, and $\delta \in (0,1)$. An $(\mathcal{X}, \Gamma, R_{\mathsf{TC}}, \delta)$-*tree code *is a function $\mathsf{TC} : \mathcal{X}^* \to \Gamma^{R_{\mathsf{TC}}}$ such that for any integer $k \geq 0$ and strings $x, x' \in \mathcal{X}^k$, defining $\overline{\mathsf{TC}}(x) = \mathsf{TC}(x_{\leq 1}) \| \mathsf{TC}(x_{\leq 2}) \| \cdots \| \mathsf{TC}(x)$, we have:*

$$\Delta\big(\overline{\mathsf{TC}}(x), \overline{\mathsf{TC}}(x')\big) \geq \delta R_{\mathsf{TC}} \cdot (k - |\mathsf{LCP}(x, x')|).$$

▶ **Theorem 5** ([26]). *There exists a constant $R \geq 0$ such that for any alphabet sets $\mathcal{X}$, Γ and all $R_{\mathsf{TC}} \geq R \cdot \frac{\log|\mathcal{X}|}{\log|\Gamma|}$, there exists an $(\mathcal{X}, \Gamma, R_{\mathsf{TC}}, 0.4)$-tree code.*

We will also need a way of decoding tree codes from erasures. Recall the notation $\Gamma, \perp, \Gamma_c$ from above, and let $w_{i,j} = (w_i)_j$.

▶ **Definition 6** (Decoding from Erasures). *Let TC be an $(\mathcal{X}, \Gamma, R_{\mathsf{TC}}, \delta)$-tree code. The* decoding function of TC, *denoted $\mathsf{D\text{-}TC} : (\Gamma_c^{R_{\mathsf{TC}}})^* \to \mathcal{X}^* \cup \{\mathsf{fail}\}$, is given by the following: For an integer $k \geq 0$ and $w \in (\Gamma_c^{R_{\mathsf{TC}}})^k$,*

$$\mathsf{D\text{-}TC}(w) = \begin{cases} z, & \text{if } \exists \text{ unique } z \in \mathcal{X}^k : \forall i \in [k], j \in [R_{\mathsf{TC}}] : w_{i,j} \in \{\perp, \mathsf{TC}_j(z_{\leq i})\} \\ \mathsf{fail}, & \text{otherwise} \end{cases}.$$

▷ Claim 7. Let TC be an $(\mathcal{X}, \Gamma, R_{\mathsf{TC}}, \delta)$-tree code and let $\mathsf{D\text{-}TC}$ be its decoding function. Let $k \geq 0$ be an integer and let $z \in \mathcal{X}^k$. Then, for any $\tilde{\tau} \in \left(\Gamma_c^{R_{\mathsf{TC}}}\right)^k$ such that $\forall i \in [k], j \in [R_{\mathsf{TC}}] : \tilde{\tau}_{i,j} \in \{\perp, \mathsf{TC}_j(z_{\leq i})\}$, it holds that $\mathsf{D\text{-}TC}(\tilde{\tau}) \in \{z, \mathsf{fail}\}$.

B Analyzing the Protocol

In this section we prove that the simulation protocol Π' given in Section 4 satisfies Theorem 2.

We omit the proofs of lemmas in this section for space. They can be found in the full version of the paper.

Iterations and rounds

Observe that our protocol Π' has $T' = 10^5 T$ *iterations* and each iteration has $R' = R_{\mathsf{TC}} + 8$ *rounds* of communication: 2 rounds in the call to detect-collisions in Line 4, 4 rounds in Line 5, 2 rounds in the call to detect-collisions in Line 7, and R_{TC} rounds in Line 8.

The noise indicator

For $t \in [T']$, $r \in [R']$, and $i \in [n]$, we define the indicator random variable $\mathsf{N}_{t,r,i}$ to be 1 if and only if the message received by player i in the r^{th} round of communication in iteration t is erased due to noise. For a set $S \subseteq [T']$, we shall use N_S to denote the collection $\mathsf{N} = \{\mathsf{N}_{t,r,i}\}_{t\in S, r\in[R'], i\in[n]}$ and sometimes abbreviate $\mathsf{N}_{[T']}$ as N and $\mathsf{N}_{[t]}$ as $\mathsf{N}_{\leq t}$ for all $t \in [T']$. Observe that our definition implies that the variables in N are mutually independent and identically distributed, and take the value 1 with probability ϵ.

Note that fixing any instantiation N of N together with the inputs X to the parties fixes the entire execution of Π'. In fact, for all $t \in [T']$, fixing any instantiation $N_{\leq t}$ of $\mathsf{N}_{\leq t}$ fixes the execution of the first t iterations of Π'. This means that it also fixes the values of all the variables in these iterations.

Variables

For $i \in [n]$ and a variable *var* in Algorithms 1 and 3,[11] we shall use $var_t^i(N)$ to denote the value of variable *var* as seen by player i at the end of iteration t when the noise is N. We shall use $t = 0$ to denote the values at the start of the execution and drop N when it is clear from context. As explained above, these values are determined by $N_{\leq t}$. We also use $\pi^{\mathsf{Ld}}_{T'+1}(N)$ to refer to the leader's π^{Ld} at Line 10.

The collision-not-as-silence model

To help with our analysis, we define a function `combine-CD` that intuitively captures the behavior of a broadcast channel with collision-detection. Formally, we have, for $z^1, z^2, \cdots, z^n \in \Gamma_c^*$,

$$\texttt{combine-CD}\big(z^1, \cdots, z^n\big) = \begin{cases} \perp_S, & \text{if } \forall i \in [n] : z^i = \perp \\ z^i, & \text{if } \exists \text{ unique } i \in [n] \text{ such that } z^i \neq \perp \\ \perp_C, & \text{otherwise} \end{cases}. \tag{3}$$

For the rest of the text, fix inputs $X = \big(x^1, x^2, \cdots, x^n\big)$ for the players. We abuse notation slightly and denote by $\Pi = \Pi(X)$ the transcript of the noiseless protocol Π when the inputs to the parties are as in X and the model uses `combine-CD` in place of `combine` (thus, $\Pi \in \Gamma_{cs}^T$). This is without loss of generality as a transcript in the collision-not-as-silence model only has more information than one in the collision-as-silence model.

B.1 Technical Lemmas and One-Sided Error

A key property of our model is the fact that our noise is one-sided: After collisions are resolved, the resulting symbol will either be received correctly, or will be replaced by a $\perp$. This means that if a player hears a symbol that is not $\perp$, that player will accurately know that that is the "correct" symbol, and that they were not affected by noise.

[11] We do not use this notation for variables in Algorithm 2 as that is invoked twice in every iteration.

This property means that we can make several very useful claims, which we use throughout the rest of this paper.

▶ **Lemma 8.** *For all $t \in [T']$, all $i \in [n]$, and all instantiations N of* N*,*

$$\pi_t^i(N) \in \left\{\mathsf{fail}, \pi_t^{\mathsf{Ld}}(N)\right\}.$$

As a player $i \in [n]$ sets z^i as a deterministic function of x^i and π^i at Line 3, we also directly get the following corollary.

▶ **Corollary 9.** *For all $t \in [T']$, all $i \in [n]$, and all instantiations N of* N*,*

$$z_t^i(N) \in \left\{\perp, M^i_{|\pi_t^{\mathsf{Ld}}(N)|+1}\left(x^i, \pi_t^{\mathsf{Ld}}(N)\right)\right\}.$$

Likewise, we can also analyse the behaviour of Algorithm 2, during the two calls at Line 4 and Line 7, to see the way the noise can affect the executions of this algorithm.

▶ **Lemma 10.** *For all $t \in [T']$, all $i \in [n]$, and all instantiations N of* N*,*

$$w_t^i(N) \in \left\{\perp_C, \texttt{combine-CD}\left(\perp, z_t^2(N), \ldots, z_t^n(N)\right)\right\}.$$

▶ **Lemma 11.** *For $t \in [T']$ and any instantiation N of* N*, we have:*

$$e_t^{\mathsf{Ld}}(N) = \perp_S \implies \texttt{combine-CD}\left(\perp, e_t^2(N), e_t^3(N), \cdots, e_t^n(N)\right) = \perp_S.$$

We also show some properties of the symbol s^{Ld}, and how it relates to the transcript that players maintain.

▶ **Lemma 12.** *For all $t \in [T']$ and any instantiation N of* N *such that $e_t^{\mathsf{Ld}}(N) = \perp_S$ and $w_t^{\mathsf{Ld}}(N) = \texttt{combine-CD}\left(\perp, z_t^2(N), \ldots, z_t^n(N)\right)$, we have*

$$s_t^{\mathsf{Ld}}(N) = \texttt{combine-CD}\left(z_t^{\mathsf{Ld}}(N), z_t^2(N), \ldots, z_t^n(N)\right).$$

We also analyse the behaviour of Algorithm 3, and in particular how π and ρ behave in that algorithm.

▶ **Lemma 13.** *For all $t \in [T']$ and all instantiations N of* N*,*

$$\rho_t^{\mathsf{Ld}}(N) = s_1^{\mathsf{Ld}}(N) \| \cdots \| s_{t-1}^{\mathsf{Ld}}(N).$$

▶ **Lemma 14.** *For all $t \in [T']$, all $i \in [n]$, and all instantiations N of* N*,*

- *If $s_t^{\mathsf{Ld}}(N) \neq \mathsf{R}$, then*

$$\pi_{t+1}^{\mathsf{Ld}}(N) = \pi_t^{\mathsf{Ld}}(N) \| s_t^{\mathsf{Ld}}(N).$$

- *If $s_t^{\mathsf{Ld}}(N) = \mathsf{R}$, then*

$$\pi_{t+1}^{\mathsf{Ld}}(N) = \left(\pi_t^{\mathsf{Ld}}(N)\right)_{<|\pi_t^{\mathsf{Ld}}(N)|}.$$

B.2 Bad Events

B.2.1 Noise Events

Next, we define and analyze some events based on the variable N.

The event $\mathcal{E}^{\mathsf{wo}}_{t,r}$

For $t \in [T']$, $r \in [R']$, the event $\mathcal{E}^{\mathsf{wo}}_{t,r}$ occurs if the communication in round r in iteration t is erased for a significant fraction of the players (it is "wiped out"). Formally, we have:

$$\mathcal{E}^{\mathsf{wo}}_{t,r} \coloneqq \left(\sum_{i \in [n]} \mathsf{N}_{t,r,i} \geq \frac{n}{10} \right). \tag{4}$$

The event $\mathcal{E}^{\mathsf{dc}}_{t,i}$

For $t \in [T']$, $i \in [n]$, the event $\mathcal{E}^{\mathsf{dc}}_{t,i}$ occurs if the communication in the first execution of detect-collisions, i.e., at least one of rounds 1 and 2, in iteration t is erased for player i. Formally, we have:

$$\mathcal{E}^{\mathsf{dc}}_{t,i} \coloneqq (\exists r \in [2] : \mathsf{N}_{t,r,i} = 1). \tag{5}$$

The event $\mathcal{E}^{\mathsf{or}}_{t}$

For $t \in [T']$, we define the event $\mathcal{E}^{\mathsf{or}}_{t}$ to occur if the communication in the second execution of detect-collisions (which effectively computes a logical OR of the e^i's), i.e., in at least one of rounds 7 and 8 in iteration t is erased for the leader. Formally, we have:

$$\mathcal{E}^{\mathsf{or}}_{t} \coloneqq (\exists r \in \{7, 8\} : \mathsf{N}_{t,r,\mathsf{Ld}} = 1). \tag{6}$$

The event $\mathcal{E}^{\mathsf{tc}}_{t',t,i}$

For $0 \leq t' < t \leq T'$ and $i \in [n]$, define the following event concerning the rounds 9 to R' in each iteration, i.e., the rounds where the leader broadcasts on the tree code:

$$\mathcal{E}^{\mathsf{tc}}_{t',t,i} \coloneqq \left(\sum_{s=t'+1}^{t} \sum_{r=9}^{R'} \mathsf{N}_{s,r,i} \geq \frac{2R_{\mathsf{TC}}}{5} \cdot (t - t') \right). \tag{7}$$

B.2.2 Bad Iterations

We now define sets of "bad" iterations for a given execution. Intuitively, these are iterations where our protocol does not make progress. For an instantiation N of N, we have:

$$\begin{aligned} \mathcal{B}^{\mathsf{wo}}(N) &= \left\{ t \in [T'] \mid \exists r \in [R'] : N \in \mathcal{E}^{\mathsf{wo}}_{t,r} \right\}. \\ \mathcal{B}^{\mathsf{dc}}(N) &= \left\{ t \in [T'] \mid N \in \mathcal{E}^{\mathsf{dc}}_{t,\mathsf{Ld}} \right\}. \\ \mathcal{B}^{\mathsf{or}}(N) &= \{ t \in [T'] \mid N \in \mathcal{E}^{\mathsf{or}}_{t} \}. \end{aligned} \tag{8}$$

▶ **Lemma 15.** *It holds that:*

1. $\Pr(\mathcal{B}^{\mathsf{wo}}(\mathsf{N}) \neq \emptyset) \leq 2.25^{-n}$.
2. $\Pr\left(\left| \mathcal{B}^{\mathsf{dc}}(\mathsf{N}) \cup \mathcal{B}^{\mathsf{or}}(\mathsf{N}) \right| \geq \frac{T'}{50} \right) \leq \mathrm{e}^{-\frac{T'}{100}}$.

We note that our assumption that $T \leq 2^n$ is only used in Item 1 of Lemma 15.

B.3 Bad Intervals

B.3.1 Critical Players

We now define and show results about players "critical" to the protocol, i.e., those needed to make sure we make progress in our simulation. For a set S of integers and an integer k define $S_{\leq k}$ to be the set consisting of the k smallest elements of S. If $|S| \leq k$, we define $S_{\leq k} = S$. For a transcript $\pi \in \Gamma^*_{cs}$, we define the set $\mathcal{S}(\pi)$ to be the set of all non-leader players who would broadcast in the noiseless protocol when their received transcript is π. Formally,

$$\mathcal{S}(\pi) = \left\{ i \in \mathcal{P} \mid M^i_{|\pi|+1}(x^i, \pi) \neq \perp \right\}.$$

▶ **Definition 16** (Critical Players). *For $\pi \in \Gamma^*_{cs}$, we define the set of players that are π-*critical *as* $\mathsf{Crit}(\pi) = \mathcal{S}(\mathsf{LCP}(\pi, \Pi))_{\leq 2}$.

We note that this definition is made for analysis purposes and no single player can necessarily compute the set $\mathsf{Crit}(\cdot)$.

B.3.2 Bad Intervals

Next, we define the set of possible augmented transcripts and bad intervals.

▶ **Definition 17.** *For $0 \leq t' \leq t \leq T'$ and an instantiation $N_{\leq t'}$ of $\mathsf{N}_{\leq t'}$, define the set:*

$$\mathsf{Aug}_t(N_{\leq t'}) = \left\{ \pi \in \Gamma^*_{cs} \mid \exists N_{(t',t]} : \pi^{\mathsf{Ld}}_t(N_{\leq t}) = \pi \right\}.$$

▶ **Definition 18.** *Let N be an instantiation of N. We define $\mathcal{B}^\dagger(N)$ to be the set of all intervals $(t', t]$ satisfying $0 \leq t' < t \leq T'$ for which there exists $\pi \in \mathsf{Aug}_t(N_{\leq t'})$ and $i \in \mathsf{Crit}(\pi)$ such that $\mathcal{E}^{\mathsf{tc}}_{t',t,i}$ occurs when $\mathsf{N} = N$. We also define:*

$$\mathcal{B}(N) = \bigcup_{(t',t] \in \mathcal{B}^\dagger(N)} (t', t].$$

▶ **Lemma 19.** *It holds that:*

$$\Pr\left(|\mathcal{B}(\mathsf{N})| \geq \frac{T'}{50} \right) \leq 10^{-\frac{T'}{50}}.$$

To finish this subsection, we show that $\mathcal{B}(\cdot)$ has all the iterations where a critical player fails to decode the tree code.

▶ **Lemma 20.** *For any instantiation N of N and all $t \notin \mathcal{B}(N)$, for all $i \in \mathsf{Crit}(\pi^{\mathsf{Ld}}_t(N))$, we have $\pi^i_t(N) = \pi^{\mathsf{Ld}}_t(N)$.*

B.4 A Potential Function

We now define the potential function that we shall use in the analysis. For $t \in \{0\} \cup [T']$ and an instantiation N of N, we define:

$$\Phi_t(N) = 2 \cdot \left| \mathsf{LCP}\left(\pi^{\mathsf{Ld}}_{t+1}(N), \Pi\right) \right| - \left| \pi^{\mathsf{Ld}}_{t+1}(N) \right|. \tag{9}$$

Our definition clearly implies $\Phi_0(N) = 0$ and $\Phi_t(N) \leq \left| \mathsf{LCP}\left(\pi^{\mathsf{Ld}}_{t+1}(N), \Pi\right) \right|$ for all N. Moreover, as either one symbol is appended to or removed from the end of π^{Ld} in every iteration, we have that $\Phi_t(N) \geq \Phi_{t-1}(N) - 1$ for all N and $t \in [T']$. In Lemma 25 we will now show that if t is not in one of the bad sets defined above, then the potential increases by at least 1. But first, we state some helpful lemmas.

▶ **Lemma 21.** *For any instantiation N of N and any $t \notin \mathcal{B}^{\mathsf{wo}}(N)$, we have:*

$$s_t^{\mathsf{Ld}}(N) \in \left\{\mathsf{R}, \texttt{combine-CD}\left(z_t^{\mathsf{Ld}}(N), z_t^2(N), \ldots, z_t^n(N)\right)\right\}$$

For $i \in [n]$, define the variable $\hat{r}^i$ to be the value of r output by Algorithm 3, when run by player i, with Line 15 replaced[12] by $\rho \leftarrow \mathsf{D\text{-}TC}\left(\tau^{\mathsf{Ld}}\right)$. This value is only used for analysis purposes and cannot be computed by the player during the execution of the protocol (as they may not know τ^{Ld}). We now claim several useful properties of $\hat{r}_t^i$, and how it relates to r_t^i.

▶ **Lemma 22.** *For $t \in [T']$ and any instantiation N of N such that $\mathcal{B}^{\mathsf{wo}}(N) = \emptyset$, we have:*

$$\left(\nexists j \in \left[\left|\pi_t^{\mathsf{Ld}}(N)\right|\right] : \left(\pi_t^{\mathsf{Ld}}(N)\right)_j \neq \Pi_j\right) \implies \left(\nexists i \in \mathcal{P} : \hat{r}_t^i(N) = \mathsf{true}\right).$$

We also prove a modified converse version of the previous lemma.

▶ **Lemma 23.** *For $t \in [T']$ and any instantiation N of N such that $\mathcal{B}^{\mathsf{wo}}(N) = \emptyset$, we have:*

$$\left(\exists j \in \left[\left|\pi_t^{\mathsf{Ld}}(N)\right|\right] : \left(\pi_t^{\mathsf{Ld}}(N)\right)_j \neq \Pi_j\right) \implies \left(\exists i \in \mathsf{Crit}(\pi_t^{\mathsf{Ld}}(N)) : \hat{r}_t^i(N) = \mathsf{true}\right),$$

▶ **Lemma 24.** *For $t \in [T']$, $i \in [n]$ and any instantiation N of N, $r_t^i(N) \in \left\{\hat{r}_t^i(N), \mathsf{false}\right\}$. Furthermore, if $\pi_t^i(N) = \pi_t^{\mathsf{Ld}}(N)$, then $r_t^i(N) = \hat{r}_t^i(N)$.*

▶ **Lemma 25.** *For $t \in [T']$ and any instantiation N of N such that $\mathcal{B}^{\mathsf{wo}}(N) = \emptyset$, we have:*

$$t \notin \mathcal{B}^{\mathsf{dc}}(N) \cup \mathcal{B}^{\mathsf{or}}(N) \cup \mathcal{B}(N) \implies \Phi_t(N) \geq \Phi_{t-1}(N) + 1.$$

B.5 Finishing the proof of Theorem 2

We are now ready to finish the proof of Theorem 2.

Proof of Theorem 2. Let $C \geq 100 R_{\mathsf{TC}}$. Fix ϵ, n and Γ as in the statement of the theorem. We claim that the algorithm provided in Algorithm 1 satisfies all the properties claimed by the theorem. It can be observed that Algorithm 1 takes at most CT rounds of communication, so it just suffices to just show that $\Pr\left(\Pi'^{\mathsf{Ld}}(X) \neq \Pi(X)\right) \leq 2^{-\min(n,T)}$.

By Lemmas 15 and 19 and a union bound, we get that an instantiation N of N satisfies $\left|\mathcal{B}^{\mathsf{dc}}(N) \cup \mathcal{B}^{\mathsf{or}}(N) \cup \mathcal{B}(N)\right| \leq \frac{T'}{25}$ and $\mathcal{B}^{\mathsf{wo}}(N) = \emptyset$ except with probability at most

$$10^{-\frac{1}{50}T'} + \mathrm{e}^{-\frac{1}{100}T'} + 2.25^{-n} \leq 2^{-\min\left(n, \frac{1}{100}T'\right)} \leq 2^{-\min(n,T)}.$$

Lemma 25 then states that for all such N, for all $t \notin \mathcal{B}^{\mathsf{dc}}(N) \cup \mathcal{B}^{\mathsf{or}}(N) \cup \mathcal{B}(N)$, $\Phi_t(N) \geq \Phi_{t-1}(N) + 1$. At the same time, we recall that Equation (9) also gives that for all $t \in [T']$, $\Phi_t(N) \geq \Phi_{t-1}(N) - 1$. Thus, we see that

$$\Phi_{T'}(N) \geq \left(T' - \frac{T'}{25}\right) - \frac{T'}{25} \geq \frac{9}{10}T' \geq T.$$

Furthermore, we consult Equation (9) to get that

$$\left|\mathsf{LCP}\left(\pi_{T'+1}^{\mathsf{Ld}}(N), \Pi\right)\right| \geq \Phi_{T'}(N) \geq T,$$

which implies that $\left(\pi_{T'+1}^{\mathsf{Ld}}(N)\right)_{\leq T} = \Pi_{\leq T}$. so the leader's output at Line 10 is equal to $\Pi_{\leq T}$.

As this happens except with probability at most $2^{-\min(n,T)}$, this concludes the proof. ◀

[12] We stress that Line 25 still uses τ^i and *not* τ^{Ld}.

On the Mixing Time of Glauber Dynamics for the Hard-Core and Related Models on $G(n, d/n)$

Charilaos Efthymiou
Computer Science, University of Warwick, Coventry, UK

Weiming Feng
School of Informatics, University of Edinburgh, Edinburgh, UK

Abstract

We study the single-site Glauber dynamics for the fugacity λ, Hard-Core model on the random graph $G(n, d/n)$. We show that for the typical instances of the random graph $G(n, d/n)$ and for fugacity $\lambda < \frac{d^d}{(d-1)^{d+1}}$, the mixing time of Glauber dynamics is $n^{1+O(1/\log\log n)}$.

Our result improves on the recent elegant algorithm in [Bezáková, Galanis, Goldberg and Štefankovič; ICALP'22]. The algorithm there is an MCMC-based sampling algorithm, but it is not the Glauber dynamics. Our algorithm here is *simpler*, as we use the classic Glauber dynamics. Furthermore, the bounds on mixing time we prove are smaller than those in Bezáková et al. paper, hence our algorithm is also *faster*.

The main challenge in our proof is handling vertices with unbounded degrees. We provide stronger results with regard the spectral independence via branching values and show that the our Gibbs distributions satisfy the approximate tensorisation of the entropy. We conjecture that the bounds we have here are optimal for $G(n, d/n)$.

As corollary of our analysis for the Hard-Core model, we also get bounds on the mixing time of the Glauber dynamics for the Monomer-Dimer model on $G(n, d/n)$. The bounds we get for this model are slightly better than those we have for the Hard-Core model

1 Introduction

The Hard-Core model and the related problem of the geometry of independent sets on the sparse random graph $G(n, d/n)$ is a fundamental area of study in discrete mathematics [17, 11], in computer science they are studied in the context of the random *Constraint Satisfaction Problems* [10, 20], while in statistical physics they are studied as instances of *disordered systems*. Using the so-called *Cavity method* [25, 2], physicists make some impressive

predictions about the independent sets of $G(n, d/n)$, such as higher order replica symmetry breaking etc. Physicists' predictions are (typically) mathematically non-rigorous. Most of these predictions about independent sets still remain open as basic natural objects in the study such as the partition function, or the free energy are extremely challenging to analyse.

The Hard-Core model with fugacity $\lambda > 0$, is a distribution over the *independent sets* of an underlying graph G such that every independent set σ is assigned probability measure $\mu(\sigma)$ which is proportional to $\lambda^{|\sigma|}$, where $|\sigma|$ is the cardinality of σ. Here, we consider the case where the underlying graph is a typical instance of the sparse random graph $G(n, d/n)$. This is the random graph on n vertices, while each edge appears independently with probability $p = d/n$. The quantity $d > 0$ corresponds to the *expected degree*. For us here the expected degree is a bounded constant, i.e., we have $d = \Theta(1)$, hence the graph is sparse.

Our focus is on approximate sampling from the aforementioned distribution using *Glauber dynamics*. This is a classic, very popular, algorithm for approximate sampling. The popularity of this process, mainly, is due to its simplicity and the strong approximation guarantees that provides. The efficiency of Glauber dynamics for sampling is studied by means of the *mixing time*.

Recently, there has been an "explosion" of results about the mixing time of Glauber dynamics for *worst-case* instances the problem, e.g. [1, 9, 8, 12]. Combined with the earlier hardness results in [29, 30, 19] one could claim that for worst-case instances the behaviour of Glauber dynamics for the Hard-Core model, but also the related approximate sampling-counting problem, is well understood. Specifically, for the graphs of maximum degree Δ, Glauber dynamics exhibits $O(n \log n)$ mixing time for any fugacity $\lambda < (\Delta-1)^{\Delta-1}/(\Delta-2)^{\Delta}$, while the hardness results support that this region of λ is best possible.

The aforementioned upper bound on λ coincides with the *critical point* for the uniqueness/non-uniqueness phase transition of the Hard-Core model on the infinite Δ-regular tree [24]. At this point in the discussion, perhaps, it is important to note the dependency of the critical point on the *maximum degree*. This is the point where the situation with the random graph $G(n, d/n)$ differentiates from the worst case one.

For $G(n, d/n)$ and for the range of the expected degree d we consider here, typically, almost all of the vertices in the graph, e.g., say 99%, are of degree very close to d. On the other hand, the maximum degree of $G(n, d/n)$ is as large as $\Theta(\frac{\log n}{\log \log n})$, i.e., it is *unbounded*. In light of this observation, it is natural to expect that the Glauber dynamics on the Hard-Core model mixes fast for values of the fugacity that depend on the *expected degree*, rather the maximum degree. Note that, this implies to use Glauber dynamics to sample from the Hard-Core model with fugacity λ taking *much larger* values than what the worst-case bound implies.

For $d > 1$, let $\lambda_c(d) = \frac{d^d}{(d-1)^{(d+1)}}$. One of the main result in our paper is as follows: we show that for any $d > 1$ and for typical instances of $G(n, d/n)$, the Glauber dynamics on the Hard-Core with any fugacity $\lambda < \lambda_c(d)$, exhibits mixing time which is $n^{1+\frac{C}{\log \log n}} = n^{1+o(1)}$, for some absolute constant $C > 0$ which depends only on λ and d.

It is our *conjecture* that the bound on the mixing time for the hard-core is tight. Furthermore, following intuitions from [10], as well as from *statistical physics* predictions in [2], it is our *conjecture* that the bound $\lambda_c(d)$ on the fugacity λ is also tight, in the following sense: for $\lambda > \lambda_c(d)$ it is not precluded that there is a region where efficient approximate sampling is possible, however, the approximation guarantees are *weaker* than those we have here.

Our result improves on the elegant sampling algorithm that was proposed recently in [3] for the same distribution, i.e., the Hard-Core model on $G(n, d/n)$. That algorithm, similarly to the one we consider here, relies on the Markov Chain Monte Carlo method. The authors

use Spectral Independence [1, 9] to show that the underlying Markov chain exhibits mixing time which is $O\left(n^{1+\theta}\right)$ for any $\lambda < \lambda_c(d)$ and arbitrary small consant $\theta > 0$. The idea that underlies the algorithm in [3] is reminiscent of the *variable marking* technique that was introduced in [26] for approximate counting with the Lovász Local Lemma, and was further exploited in [14, 16, 21, 18]. Here, we use a different, more straightforward, approach and analyse directly the Glauber dynamics.

Note that both algorithms, i.e., here and in [3], allow for the same range for the fugacity λ. On the other hand, the algorithm we study here is the (much simpler) Glauber dynamics, while the running time guarantees we obtain here are asymptotically better.

Previous works in the area, i.e., even before [3], in order to prove their results and avoid the use of maximum degree, have been focusing on various parameters of $G(n, d/n)$ such as the expected degree [13], or the connective constant [28]. Which, as it turns out are not that different with each other. Here, we utilise the notion of *branching value*, which is somehow related to the previous ones.

The notion of the branching value as well as its use for establishing Spectral Independence was introduced in [3]. Unfortunately, the result there were not sufficiently strong to imply rapid mixing of Glauber dynamics. Their analytic tools for Spectral Independence (and others) seems to not be able to handle all that well vertices with unbounded degree. Here we derive stronger results for Spectral independence than those in [3] in the sense that they are more *general* and more *accurate*. Specifically, in our analysis we are able to accommodate vertices of *all degrees*, while we use a more elaborate matrix norm to establish spectral independence, reminiscent of those introduced in [12]. Furthermore, we utilise results from [8] that allow us deal with the unbounded degrees of the graph in order to establish our rapid mixing results.

2 Results

Consider the fixed graph $G = (V, E)$ on n vertices. Given the parameter $\lambda > 0$, which we call *fugacity*, we define the *Hard-Core* model $\mu = \mu_{G,\lambda}$ to be a distribution on the independent sets of the graph G, Specifically, every independent set σ is assigned probability measure $\mu(\sigma)$ defined by

$$\mu(\sigma) \propto \lambda^{|\sigma|} \ , \tag{1}$$

where $|\sigma|$ is equal to the size of the independent set σ.

We use $\{\pm 1\}^V$ to encode the configurations of the Hard-Core model, i.e., the independent sets of G. Particularly, the assignment $+1$ implies that the vertex is in the independent set, while -1 implies the opposite. We often use physics' terminology where the vertices with assignment $+1$ are called "occupied", whereas the vertices with -1 are "unoccupied".

We use the discrete time, (single site) *Glauber dynamics* to approximately sample from the aforementioned distributions. Glauber dynamics is a Markov chain with state space the support of the distribution μ. Typically, we assume that the chain starts from an arbitrary configuration $X_0 \in \{\pm 1\}^V$. For $t \geq 0$, the transition from the state X_t to X_{t+1} is according to the following steps:

1. Choose uniformly at random a vertex v.
2. For every vertex w different than v, set $X_{t+1}(w) = X_t(w)$.
3. Set $X_{t+1}(v)$ according to the marginal of μ at v, conditional on the neighbours of v having the configuration specified by X_{t+1}.

It is standard that when a Markov chain satisfies a set of technical conditions called *ergodicity*, then it converges to a unique stationary distribution. For the cases we consider here, Glauber dynamics is trivially ergodic, while the stationary distribution is the corresponding Hard-Core model μ.

Let P be the transition matrix of an ergodic Markov chain $\{X_t\}$ with a finite state space Ω and equilibrium distribution μ. For $t \geq 0$ and $\sigma \in \Omega$, let $P^t(\sigma, \cdot)$ denote the distribution of X_t when the initial state of the chain satisfies $X_0 = \sigma$. The *mixing time* of the Markov chain $\{X_t\}_{t\geq 0}$ is defined by

$$T_{\text{mix}} = \max_{\sigma\in\Omega} \min\left\{t > 0 \mid \|P^t(\sigma,\cdot) - \mu\|_{\text{TV}} \leq \frac{1}{2\text{e}}\right\} \ .$$

Our focus is on the mixing time of Glauber dynamics for the Hard-Core model for the case where the underlying graph is a typical instance of $G(n, d/n)$, where the expected degree $d > 0$ is a assumed to be a fixed number.

2.1 Mixing Time for Hard-Core Model

For $z > 1$, we let the function $\lambda_c(z) = \frac{z^z}{(z-1)^{(z+1)}}$. It is a well-known result from [24] that the uniqueness region of the Hard-Core model on the k-ary tree, where $k \geq 2$, holds for any λ such that

$$\lambda < \lambda_c(k) \ .$$

The following theorem is the main result of this work.

▶ **Theorem 1.** *For fixed $d > 1$ and any $\lambda < \lambda_c(d)$, there is a constant $C > 0$ such that the following is true:*

Let $\mu_{\boldsymbol{G}}$ be the Hard-Core model with fugacity λ on the graph $\boldsymbol{G} \sim G(n, d/n)$. With probability $1 - o(1)$ over the instances of $\boldsymbol{G}$, Glauber dynamics on $\mu_{\boldsymbol{G}}$ exhibits mixing time

$$T_{\text{mix}} \leq n^{\left(1+\frac{C}{\log\log n}\right)} \ .$$

2.2 Extensions to Monomer-Dimer Model

Utilising the techniques we develop in order to prove Theorem 1, we get mixing time bounds for the Glauber dynamics on the Monomer-Dimer model on $G(n, d/n)$.

Given a fixed graph $G = (V, E)$ and a parameter $\lambda > 0$, which we call *edge weight*, we define the Monomer-Dimer model $\mu = \mu_{G,\lambda}$ to be a distribution on the *matchings* of the graph G such that every matching σ is assigned probability measure $\mu(\sigma)$ defined by

$$\mu(\sigma) \propto \lambda^{|\sigma|} \ , \tag{2}$$

where $|\sigma|$ is equal to the number of edges in the matching σ.

Note that the Hard-Core model considers configurations on the vertices of G, while the Monomer-Dimer model considers configurations on the edges. Similarly to the independent sets, we use $\{\pm 1\}^E$ to encode the matchings of G. Specifically, the assignment $+1$ on the edge e implies that the edge is in matching, while -1 implies the opposite.

For the Monomer-Dimer model the definition of Glauber dynamics $\{X_t\}_{t\geq 0}$ extends in the natural way. That is, assume that the chain starts from an arbitrary configuration $X_0 \in]\pm 1^E$. For $t \geq 0$, the transition from the state X_t to X_{t+1} is according to the following steps:

1. Choose uniformly at random an edge e.
2. For every edge f different than e, set $X_{t+1}(f) = X_t(f)$.
3. Set $X_{t+1}(e)$ according to the marginal of μ at e, conditional on the neighbours of e having the configuration specified by X_{t+1}.

We consider the case of the Monomer-Dimer distribution where the underlying graph is an instance of $G(n, d/n)$. We prove the following result.

▶ **Theorem 2.** *For fixed $d > 1$ and any $\lambda > 0$, there is a constant $C > 0$ such that the following is true:*

Let $\mu_{\boldsymbol{G}}$ be the Monomer-Dimer model with edge weight λ on the graph $\boldsymbol{G} \sim G(n, d/n)$. With probability $1 - o(1)$ over the instances of $\boldsymbol{G}$, Glauber dynamics on $\mu_{\boldsymbol{G}}$ exhibits mixing time

$$T_{\text{mix}} \leq n^{\left(1+C\sqrt{\frac{\log\log n}{\log n}}\right)} .$$

The proof of Theorem 2 can be found in the full version of this paper.

For the Monomer-Dimer model on general graphs, the best-known result is the $\tilde{O}(n^2 m)$ mixing time of the Jerrum-Sinclair chain [23], where $m = |E|$ is the number of edges. For graphs with bounded maximum degree $\Delta = O(1)$, the spectral independence technique proved the $O(n \log n)$ mixing time of Glauber dynamics [9]. However, this result cannot be applied directly to the random graph $G(n, d/n)$, because the maximum degree of a random graph is typically unbounded. For the Monomer-Dimer model on $G(n, d/n)$, [3] gave a sampling algorithm with running time $n^{1+\theta}$, where $\theta > 0$ is an arbitrarily small constant, and [22] also proved the $n^{2+o(1)}$ mixing time of Glauber dynamics in a special case $\lambda = 1$. Our result in Theorem 2 proves the $n^{1+o(1)}$ mixing time of Glauber dynamics, which improves all the previous results for the Monomer-Dimer model on the random graph $G(n, d/n)$ with constant λ. It is an open problem to improve the mixing time in Theorem 2. Moreover, for general graphs, the tight mixing time of Glauber dynamics for the Monomer-Dimer model is also a challenging open problem.

We remark that for the Monomer-Dimer model, we actually proved the $n^{1+o(1)}$ mixing time of Glauber dynamics on *all* graphs satisfying $\Delta \log^2 \Delta = o(\log^2 n)$. See the full version of this paper for a more general result.

This version of the paper focuses on the Hard-Core model, i.e., proving Theorem 1. The proofs for the Monomer-Dimer model is in the full version.

Notation

Suppose that we are given a Gibbs distribution μ on the graph $G = (V, E)$. We denote with Ω the support of μ.

Suppose that Ω is a set of configurations at the vertices of G. Then, for any $\Lambda \subseteq V$ and any $\tau \in \{\pm 1\}^{\Lambda}$, we let $\mu^{\Lambda,\tau}$ (or μ^{τ} if Λ is clear from the context) denote the distribution μ conditional on that the configuration at Λ is τ. Alternatively, we use the notation $\mu(\cdot \mid (\Lambda, \tau))$ for the same conditional distribution. We let $\Omega^{\tau} \subseteq \Omega$ be the support of $\mu^{\Lambda,\tau}$. We call τ *feasible* if Ω^{τ} is nonempty.

For any subset $S \subseteq V$, let μ_S denote the marginal of μ at S, while let Ω_S denote the support of μ_S. In a natural way, we define the conditional marginal. That is, for $\Lambda \subseteq V \setminus S$ and $\sigma \in \{\pm 1\}^{\Lambda}$, we let $\mu_S^{\Lambda,\sigma}$ (or μ_S^{σ} if Λ is clear from the context) denote the marginal at S conditional on the configuration at Λ being σ. Alternatively we use $\mu_S(\cdot \mid (\Lambda, \sigma))$ for μ_S^{σ}. We let Ω_S^{σ} denote the support of μ_S^{σ}.

All the above notation for configurations on the vertices of G can be extended naturally for configurations on the edges of the graph G. We omit presenting it, because it is very similar to the above.

2.3 Hard-Core Model – Entropy Tensorisation for Rapid Mixing

We prove Theorem 1 by exploiting the notion of *approximate tensorisation of the entropy*.

Let μ be a distribution with support $\Omega \subseteq \{\pm 1\}^V$. For any function $f : \Omega \to \mathbb{R}_{\geq 0}$, we let $\mu(f) = \sum_{x\in\Omega} \mu(x)f(x)$, i.e., $\mu(f)$ is the expected value of f with respect to μ. Define the entropy of f with respect to μ by

$$\mathrm{Ent}_\mu(f) = \mu\left(f \log \tfrac{f}{\mu(f)}\right) \ ,$$

where we use the convention that $0 \log 0 = 0$.

Let $\tau \in \Omega_{V\setminus S}$ for some $S \subset V$. Define the function $f_\tau : \Omega_S^\tau \to \mathbb{R}_{\geq 0}$ by having $f_\tau(\sigma) = f(\tau \cup \sigma)$ for all $\sigma \in \Omega_S^\tau$ [1]. Let $\mathrm{Ent}_S^\tau(f_\tau)$ denote the entropy of f_τ with respect to the conditional distribution μ_S^τ. Furthermore, we let

$$\mu(\mathrm{Ent}_S(f)) = \sum_{\tau\in\Omega_{V\setminus S}} \mu_{V\setminus S}(\tau)\mathrm{Ent}_S^\tau(f_\tau) \ ,$$

i.e., $\mu(\mathrm{Ent}_S(f))$ is the average of the entropy $\mathrm{Ent}_S^\tau(f_\tau)$ with respect to the measure $\mu_{V\setminus S}(\cdot)$. When $S = \{v\}$, i.e., the set S is a singleton, we abbreviate $\mu(\mathrm{Ent}_{\{v\}}(f))$ to $\mu(\mathrm{Ent}_v(f))$.

▶ **Definition 3** (Approximate Tensorisation of Entropy). *A distribution μ with support $\Omega \subseteq \{\pm 1\}^V$ satisfies the approximate tensorisation of entropy with constant $C > 0$ if for all $f : \Omega \to \mathbb{R}_{\geq 0}$ we have that*

$$\mathrm{Ent}_\mu(f) \leq C \cdot \sum_{v\in V} \mu\left(\mathrm{Ent}_v(f)\right) \ .$$

On can establish bounds on the mixing time of Glauber dynamics by means of the approximate tensorisation of entropy of the equilibrium distribution μ. Specifically, if μ satisfies the approximate tensorisation of entropy with constant C, then after every transition of Glauber dynamics, the Kullback–Leibler divergence[2] between the current distribution and the stationary distribution decays by a factor which is at least $(1 - C/n)$, where $n = |V|$ is the number of variables.

As far as the mixing time of Glauber dynamics is concerned, if a distribution μ satisfies the approximate tensorisation of entropy with parameter C then we have following well known relation (e.g. see [9, Fact 3.5]),

$$T_{\mathrm{mix}} \leq \left\lceil Cn\left(\log\log\frac{1}{\mu_{\min}} + \log(2) + 2\right)\right\rceil, \qquad \text{where } \mu_{\min} = \min_{x\in\Omega}\mu(x) \ . \tag{3}$$

In light of the above, Theorem 1 follows as a corollary from the following result.

---

[1] With a slight abuse of notation we use $\tau \cup \sigma$ to indicate the configuration what agrees with τ at S and with σ at $V \setminus S$.

[2] For discrete probability distributions P and Q on a discrete space $\mathcal{X}$, the Kullback–Leibler divergence is defined by $D_{\mathrm{KL}}(P||Q) = \sum_{x\in\mathcal{X}} P(x) \log \frac{P(x)}{Q(x)}$.

▶ **Theorem 4** (Hard-Core Model Tensorisation). *For any fixed $d > 1$ and any $\lambda < \lambda_c(d)$, there is a constant $A > 0$ that depends only on d and λ such that the following is true:*

Let $\mu_{\boldsymbol{G}}$ be the Hard-Core model with fugacity λ on the graph $\boldsymbol{G} \sim G(n, d/n)$. With probability $1 - o(1)$ over the instances of $\boldsymbol{G}$, $\mu_{\boldsymbol{G}}$ satisfies the approximate tensorisation of entropy with parameter $n^{A/\log\log n}$.

Proof of Theorem 1. Theorem 1 follows from Theorem 4 and (3).

Specifically, plugging the result from Theorem 4 into (3) we get the following: with probability $1 - o(1)$ over the instances of $\boldsymbol{G}$ we have that

$$\begin{aligned} T_{\text{mix}} &\leq n^{1+\frac{A}{\log\log n}} \left(\log\log \frac{1}{\mu_{\min}} + \log(2) + 2 \right) \\ &\leq n^{1+\frac{A}{\log\log n}} \left(\log\log \left(1 + \lambda + \lambda^{-1}\right)^n + \log(2) + 2 \right) \\ &= n^{1+\frac{A}{\log\log n}} \left(\log n + \log\log(1 + \lambda + \lambda^{-1}) \right) \leq n^{1+\frac{2A}{\log\log n}} \quad . \end{aligned}$$

For the second derivation, we note that for the Hard-Core distribution $\mu = \mu_{\boldsymbol{G}}$, we have that $\mu_{\min}$ is at least $\min\{1, \lambda^n\}/(1+\lambda)^n$, which implies that $\mu_{\min} \geq (1 + \lambda + \lambda^{-1})^{-n}$.

Note that Theorem 1 follows from the above, by setting $C = 2A$. ◀

3 Our Approach & Contributions

In this section we describe our approach towards establishing our results. Our focus is on the Hard-Core model.

3.1 Tensorisation and Block-Factorisation of Entropy

We establish the tensorisation of the entropy, described in Theorem 4, by exploiting the recently introduced notion of *block factorisation of entropy* in [5]. Specifically, we build on the framework introduced in [9] to relate the tensorisation and the block factorisation of the entropy.

The framework in [9] relies on the assumption that the maximum degree of the underlying graph is bounded. Otherwise, the results it implies are not strong. In our setting here, a vanilla application of this approach would not be sufficient to give the desirable bounds on the tensorisation constant due to the fact that the typical instances of $G(n, d/n)$ have unbounded maximum degree. To this end, we employ techniques from [8].

Given the graph $G = (V, E)$, and the integer $\ell \geq 0$, we let $\binom{V}{\ell}$ denote all subsets $S \subseteq V$ with $|S| = \ell$.

▶ **Definition 5** (ℓ-block Factorisation of Entropy). *Let μ be a distribution over $\{\pm 1\}^V$ and $1 \leq \ell \leq |V| = n$ be an integer. The distribution μ satisfies the ℓ block factorisation of entropy with parameter C if for all $f : \Omega \to \mathbb{R}_{\geq 0}$ we have that*

$$\text{Ent}_\mu(f) \leq \frac{C}{\binom{n}{\ell}} \sum_{S \in \binom{V}{\ell}} \mu\left(\text{Ent}_S(f)\right) \quad . \tag{4}$$

The notion of the ℓ block factorisation of entropy generalises that of the approximate tensorisation of entropy. Specifically, a distribution that satisfies the $\ell = 1$ block factorisation of entropy with parameter C, also satisfies the approximate tensorisation of entropy with parameter C/n.

As far as the Hard-Core model on $G(n, d/n)$ is concerned, we show the following theorem via the spectral independence technique, which is one of the main technical results in our paper.

▶ **Theorem 6.** *For fixed $d > 1$ and any $0 < \lambda < \lambda_c(d)$, consider $\boldsymbol{G} \sim G(n, d/n)$ and let $\mu_{\boldsymbol{G}}$ be the Hard-Core model on $\boldsymbol{G}$ with fugacity λ. With probability $1 - o(1)$ over the instances of $\boldsymbol{G}$ the following is true: There is a constant $K = K(d, \lambda) > 0$, such that for*

$$\frac{1}{\alpha} = K \frac{\log n}{\log \log n} \ ,$$

for any $1/\alpha \leq \ell < n$, $\mu_{\boldsymbol{G}}$ satisfies the ℓ-block factorisation of entropy with parameter $C = (\frac{en}{\ell})^{1+1/\alpha}$.

Let us have a high level overview of how we use the ℓ-block factorisation and particularly Theorem 6 to establish our entropy tensorisation result in Theorem 4.

Note that Theorem 6 essentially implies the following: Suppose that $G = (V, E)$ is a *typical instance* of $G(n, d/n)$. Then, the Hard-Core model μ on G, with fugacity $\lambda < \lambda_c(d)$, is such that for any $f : \Omega \to \mathbb{R}_{>0}$ we have

$$\mathrm{Ent}_{\mu}(f) \leq \left(\frac{\mathrm{e}}{\theta}\right)^{1+1/\alpha} \frac{1}{\binom{n}{\ell}} \sum_{S \in \binom{V}{\ell}} \mu\left(\mathrm{Ent}_S(f)\right) \ , \tag{5}$$

where $\ell = \lceil \theta n \rceil$ and $\theta \in (0, 1)$ is a constant satisfying $\lceil \theta n \rceil \geq 1/\alpha = \Omega(\log n / \log \log n)$.

Let $G[S]$ be the subgraph of G that is induced by the vertices in the set S. On the RHS of (5), the entropy is evaluated with respect to conditional distributions μ_S^τ, which is the Hard-Core model on the subgraph $G[S]$ given the boundary condition τ on $V \setminus S$.

We let $C(S)$ denote the set of connected components in $G[S]$. With a slight abuse of notation, we use $U \in C(S)$ to denote the set of vertices in the component U, as well. It is not hard to see that the Hard-Core model μ_S^τ, for $\tau \in \Omega_{V \setminus S}$, factorises as a product distribution over Gibbs marginals at the components $U \in C(S)$, i.e.,

$$\mu_S^\tau = \bigotimes_{U \in C(S)} \mu_U^\tau \ .$$

We use the following result for the factorisation of entropy on product distributions [6, 4, 9].

▶ **Lemma 7** ([9, Lemma 4.1])**.** *For any $S \subseteq V$, any $\tau \in \Omega_{V \setminus S}$, any $f : \Omega_S^\tau \to \mathbb{R}_{\geq 0}$,*

$$\mathrm{Ent}_S^\tau(f) \leq \sum_{U \in C(S)} \mu_S^\tau[\mathrm{Ent}_U(f)] \ .$$

Combining Lemma 7 and (5) we get that

$$\mathrm{Ent}_{\mu}(f) \leq \left(\frac{\mathrm{e}}{\theta}\right)^{1+1/\alpha} \mathbb{E}_{\boldsymbol{S} \sim \binom{V}{\ell}} \left[\textstyle\sum_{U \in C(\boldsymbol{S})} \mu\left(\mathrm{Ent}_U(f)\right)\right] \ , \tag{6}$$

where $\boldsymbol{S} \sim \binom{V}{\ell}$ denotes that $\boldsymbol{S}$ is a uniformly random element from $\binom{V}{\ell}$.

The above step allows us to reduce the proof of approximate tensorisation to that of the components in $C(\boldsymbol{S})$. We choose the parameter $\ell = \lceil \theta n \rceil$ so that the connected components in $C(\boldsymbol{S})$ are typically small.

In light of the above, Theorem 4 follows by establishing two results: The first one is to derive a bound on the constant of the approximate tensorisation of entropy for the components of size k in $C(\boldsymbol{S})$, for each $k > 0$. The second result is to derive tail bounds on the size of the components in $C(\boldsymbol{S})$ for $\boldsymbol{S} \sim \binom{V}{\ell}$. Since the components are small with high probability, the following crude bound on the approximate tensorisation of entropy is enough for our analysis.

▶ **Lemma 8.** *For any fixed $d > 0$, for any $\lambda < \lambda_c(d)$, consider $\boldsymbol{G} \sim G(n, d/n)$. With probability $1 - o(1)$ over the instances of $\boldsymbol{G}$, the following is true:*

For any $k \geq 1$ and $H \subseteq V$ such that $|H| = k$, the Hard-Core model μ_H on $\boldsymbol{G}[H]$ with fugacity λ satisfies the approximate tensorisation of entropy with constant

$$\mathrm{AT}(k) \leq \min\left\{2k^2\left(1+\lambda+1/\lambda\right)^{2k+2},\ 3\log\left(1+\lambda+1/\lambda\right)\cdot\left((1+\lambda)k\right)^{2+2\eta}\right\}\ , \tag{7}$$

where $\eta = B(\log n)^{1/r}$, while $B = B(d,\lambda)$ and $r = r(d) \in (1,2)$ are constants that depend on d, λ.

As far as size of the components in $C(\boldsymbol{S})$ is concerned, we use the following result from [3].

▶ **Lemma 9** ([3])**.** *Let $d > 1$ be a constant. There is a constant $L = L(d)$ such that the following holds with probability at least $1 - o(1)$ over the $\boldsymbol{G} \sim G(n, d/n)$. Let $\boldsymbol{S} \sim \binom{V}{\ell}$, while let $C_v \subseteq \boldsymbol{S}$ be the set of vertices that are in the same component as vertex v in $\boldsymbol{G}[\boldsymbol{S}]$. For any integer $k \geq \log n$, it holds that*

$$\Pr[|C_v| = k] \leq (2\mathrm{e})^{\mathrm{e}Lk}\left(\frac{2\ell}{n}\right)^k \leq (2\mathrm{e})^{\mathrm{e}Lk}\,(2\theta)^k\ .$$

Theorem 4 follows by combining Theorem 6, with Lemmas 9 and 8. For a full proof of Theorem 4, see Section 5.

3.2 Spectral Independence with Branching Values

An important component in our proof of Theorem 6 is to establish Spectral Independence bounds for the Hard-Core model on typical instances of $G(n, d/n)$.

For worst-case graph instances (i.e., non random), typically, we establish Spectral Independence for a region of the parameters of the Gibbs distribution which is expressed in terms of the maximum degree Δ of the underlying graph G. As far as $G(n, d/n)$ is concerned, the maximum degree does not seem to be the appropriate graph parameter to consider for this problem.

Here, we utilise the notion of branching value. The notion of the branching value as well as its use for establishing Spectral Independence was introduced in [3]. Unfortunately, the result there were not sufficiently strong to imply rapid mixing of Glauber dynamics. Here we derive stronger results for Spectral independence than those in [3] in the sense that they are more *general* and more *accurate*. Specifically, in our analysis we are able to accommodate vertices of *all degrees*, while we use a more elaborate matrix norm to establish spectral independence, reminiscent of those introduced in [12]. Furthermore, we utilise results from [8] that allow us deal with the unbounded degrees of the graph in order to establish our rapid mixing results.

Before getting to further details in our discussion, let us first introduce some basic notions. We start with the *pairwise influence matrix* $\mathcal{I}_G^{\Lambda,\tau}$ and the related notion of Spectral Independence. These notions were first introduced in [1]. In this paper, we use the absolute version introduced in [15].

Consider a *fixed* graph $G = (V, E)$. Assume that we are given a Gibbs distribution μ on the configuration space $\{\pm 1\}^V$. We define the pairwise influence matrix $\mathcal{I}_G^{\Lambda,\tau}$ as follows: for a set of vertices $\Lambda \subset V$ and a configuration τ at Λ, the matrix $\mathcal{I}_G^{\Lambda,\tau}$ is indexed by the vertices in $V \setminus \Lambda$, while for any two vertices, different with each other $u, w \in V \setminus \Lambda$, if w can take both values ± 1 given τ, we have that

$$\mathcal{I}_G^{\Lambda,\tau}(w,u) = ||\mu_u(\cdot \mid (\Lambda,\tau),(\{w\},+)) - \mu_u(\cdot \mid (\Lambda,\tau),(\{w\},-))||_{\text{TV}} \ ; \tag{8}$$

if w can only take one value in ± 1 given τ, we have $\mathcal{I}_G^{\Lambda,\tau}(w,u) = 0$. Also, we have that $\mathcal{I}_G^{\Lambda,\tau}(w,w) = 0$ for all $w \in V \setminus \Lambda$. That is, the diagonal of $\mathcal{I}_G^{\Lambda,\tau}$ is always zero.

Recall that, above, $\mu_u(\cdot \mid (\Lambda,\tau),(\{w\},1))$ is the Gibbs marginal that vertex u, conditional that the configuration at Λ is τ and the configuration at w is 1. We have the analogous for $\mu_u(\cdot \mid (\Lambda,\tau),(\{w\},-1))$.

▶ **Definition 10** (Spectral Independence). *For a real number $\eta > 0$, the Gibbs distribution μ_G on $G = (V,E)$ is η-spectrally independent, if for every $0 \le k \le |V| - 2$, $\Lambda \subseteq V$ of size k and $\tau \in \{\pm 1\}^\Lambda$ the spectral radius of $\mathcal{I}_G^{\Lambda,\tau}$ satisfies that $\rho(\mathcal{I}_G^{\Lambda,\tau}) \le \eta$.*

We bound the spectral radius of $\mathcal{I}_G^{\Lambda,\tau}$ by means of matrix norms. Specifically, we use the following norm of $\mathcal{I}_G^{\Lambda,\tau}$

$$\left|\left| D^{-1} \cdot \mathcal{I}_G^{\Lambda,\tau} \cdot D \right|\right|_\infty , \tag{9}$$

where D is the diagonal matrix indexed by the vertices in $V \setminus \Lambda$ such that

$$D(u,u) = \begin{cases} \deg_G(v)^{1/\chi} & \text{if } \deg_G(v) \ge 1 \\ 1 & \text{if } \deg_G(v) = 0 \ , \end{cases} \tag{10}$$

where the parameter χ is being specified later.

Let $G = (V,E)$ be a fixed graph. For any vertex $v \in V$ and integer $\ell \ge 0$, we use $N_{v,\ell}$ to denote the number of simple paths with $\ell + 1$ vertices that start from v in graph G. By definition, we have that $N_{v,0} = 1$.

▶ **Definition 11** (d-branching value). *Let $d \ge 1$ be a real number and $G = (V,E)$ be a graph. For any vertex $v \in V$, the d-branching value S_v is defined by $\sum_{\ell \ge 0} N_{v,\ell}/d^\ell$.*

We establish spectral independence results that utilise the notion of d-branching value that was introduced in [3]. The following theorem is an example of the Spectral Independence results we derive here. In our proof, we actually use the stronger result in Theorem 19 . This analysis of spectral independence is of independent interest.

▶ **Theorem 12.** *Let $d > 1$ be a real number and $G = (V,E)$ be a graph. Let μ_G be the Hard-Core model with fugacity $\lambda < \lambda_c(d)$. For any $\alpha > 0$ such that the d-branching value $S_v \le \alpha$ for all $v \in V$ the following is true: μ_G is η-spectrally independent for*

$$\eta \le C_0 \cdot \alpha^{1/r} \ ,$$

where $C_0 = C_0(d,\lambda)$ and $r = r(d) \in (1,2)$ are constants.

There are a couple of interesting point about Theorem 12 to make. The first one is that the bound on η does not have any dependence on the degrees of the graph G. This is because we utilise the matrix norm $\|D^{-1} \cdot \mathcal{I}_G^{\Lambda,\tau} \cdot D\|_\infty$ instead of $\|\mathcal{I}_G^{\Lambda,\tau}\|_\infty$ that is typically used to establish the bound on the spectral independence. Furthermore, note that Theorem 12 is *not* necessarily about $G(n,d/n)$, i.e., it applies to an arbitrary graph. As a matter of fact in order to use the above result for $G(n,d/n)$ we need to establish bounds on its branching value. To this end, we use the following result from [3] so that we can take $\alpha = \log n$ in Theorem 12.

▶ **Lemma 13** ([3, Lemma 9]). *Let $d \geq 1$. For any fixed $d' > d$, with probability $1 - o(1)$ over $\boldsymbol{G} \sim G(n, d/n)$, the d'-branching factor of every vertex in G is at most $\log n$.*

It is worth mentioning that Lemma 13, here, is a *weaker* version of Lemma 9 in [3], i.e., we do not really need the the full strength of the result there.

In light of the above results, an interesting open problem is to turn the branching-value based spectral independence result in Theorem 12 into rapid mixing bound one for Glauber dynamics on a general graphs with bounded branching value. Note that this is not possible with the techniques we develop here.

Concluding this short introductory section about Spectral Independence, let us remark that for our results we work with the so-called *Complete Spectral Independence* for the Hard-Core model, introduced in [7, 8]. This is more general a notion compared to the (standard) Spectral Independence. For further discussion see Section 4.2.

4 Entropy Factorisation from Stability and Spectral Independence

In this section we establish the ℓ-block factorisation of entropy for the Hard-Core model on $G(n, d/n)$ as it is described in Theorem 6. To this end, we employ techniques from [8]. This means that we study the Hard-Core model on $G(n, d/n)$ in terms of the stability of ratios of the marginals and the so-called Complete Spectral Independence.

4.1 Ratios of Gibbs Marginals & Stability

Consider the *fixed* graph $G = (V, E)$ and a Gibbs distribution μ on this graph. For a vertex $w \in V$, the region $K \subseteq V \setminus \{w\}$ and $\tau \in \{\pm 1\}^K$, we consider the *ratio of marginals* at w denoted as $R^{K,\tau}(w)$ such that

$$R_G^{K,\tau}(w) = \frac{\mu_w(+1 \mid K, \tau)}{\mu_w(-1 \mid K, \tau)} \ . \tag{11}$$

Recall that $\mu_w(\cdot \mid K, \tau)$ denotes the marginal of the Gibbs distribution $\mu(\cdot \mid K, \tau)$ at vertex w. Also, note that the above allows for $R^{K,\tau}(w) = \infty$, e.g., when $\mu_w(-1 \mid K, \tau) = 0$ and $\mu_w(+1 \mid K, \tau) \neq 0$.

▶ **Definition 14** (Marginal stability). *Let $\zeta > 0$ be a real number. The Gibbs distribution μ_G on $G = (V, E)$ is called ζ-marginally stable if for any $\Lambda \subset V$, any $w \in V \setminus \Lambda$, for any configuration τ at Λ and any $S \subseteq \Lambda$ we have that*

$$R_G^{\Lambda,\tau}(w) \leq \zeta \qquad \text{and} \qquad R_G^{\Lambda,\tau}(w) \leq \zeta \cdot R_G^{S,\tau_S}(w) \ . \tag{12}$$

As far as the stability of the Hard-Core marginals at $G(n, d/n)$ is concerned, we prove the following result.

▶ **Theorem 15** (Stability Hard-Core Model). *For any fixed $d > 0$, for any $\lambda < \lambda_c(d)$, consider $\boldsymbol{G} \sim G(n, d/n)$ and let $\mu_{\boldsymbol{G}}$ be the Hard-Core model on $\boldsymbol{G}$ with fugacity λ. With probability $1 - o(1)$ over the instances $\boldsymbol{G}$, $\mu_{\boldsymbol{G}}$ is $2(1+\lambda)^{\frac{2\log n}{\log\log n}}$-marginally stable.*

Proof. Let $\zeta = 2(1+\lambda)^{2\frac{\log n}{\log\log n}}$. Also, let $N(w)$ be the set of the neighbours of w.

For any $\Lambda \subseteq V$ and any $\tau \in \{\pm\}^\Lambda$, we have that $\mu_w(+1 \mid \Lambda, \tau) \leq \frac{\lambda}{1+\lambda}$. One can see that the equality holds if $N(w) \subseteq \Lambda$ and for every $u \in N(w)$ we have that $\tau(w) = -1$. Noting that $R_{\boldsymbol{G}}^{\Lambda,\tau}(w)$ is increasing in the value of the Gibbs marginal $\mu_w(+1 \mid \Lambda, \tau)$, it is immediate that

$$\Pr\left[R_{\boldsymbol{G}}^{\Lambda,\tau}(w) \leq \lambda < \zeta \quad \forall \Lambda \subseteq V,\ \forall w \in V \setminus \Lambda\right] = 1 \ . \tag{13}$$

It remains to show that

$$\Pr\left[R_{\boldsymbol{G}}^{\Lambda,\tau}(w) \leq \zeta \cdot R_{\boldsymbol{G}}^{S,\tau_S}(w) \quad \forall \Lambda \subset V,\ \forall S \subset \Lambda,\ \forall w \in V \setminus \Lambda\right] = 1 - o(1) \ . \tag{14}$$

In light of (13), (14) follows by showing that

$$\Pr\left[R_{\boldsymbol{G}}^{S,\tau_S}(2) > 2\lambda\,(1+\lambda)^{-2\frac{\log n}{\log\log n}} \quad \forall \Lambda \subset V,\ \forall S \subset \Lambda,\ \forall w \in V \setminus \Lambda\right] = 1 - o(1) \ . \tag{15}$$

If there is $u \in N(w)$ such that $\tau(u) = +1$, then $R_{\boldsymbol{G}}^{\Lambda,\tau}(w) = 0$ and (14) holds trivially since $R_{\boldsymbol{G}}^{S,\tau_S}(w) \geq 0$. We focus on the case that all vertices $u \in N(w) \cap \Lambda$ satisfy $\tau(u) = -1$.

Let $\mathcal{E}$ be the event that none of the vertices in $N(w)$ is occupied, while let γ_S be the probability of the event $\mathcal{E}$ under the Gibbs distribution $\mu(\cdot \mid S, \tau_S)$. It is standard to show that

$$R_{\boldsymbol{G}}^{S,\tau_S}(w) = \frac{\frac{\lambda}{1+\lambda}\gamma_S}{1 - \frac{\lambda}{1+\lambda}\gamma_S} \ .$$

Noting that the function $f(x) = \frac{x}{1-x}$ is increasing in $x \in (0,1)$, while $\gamma_S \geq (\frac{1}{1+\lambda})^{\deg_{\boldsymbol{G}}(w)}$, we have that

$$R_{\boldsymbol{G}}^{S,\tau_S}(w) \geq \frac{\frac{\lambda}{1+\lambda}(\frac{1}{1+\lambda})^{\deg_{\boldsymbol{G}}(w)}}{1 - \frac{\lambda}{1+\lambda}(\frac{1}{1+\lambda})^{\deg_{\boldsymbol{G}}(w)}} = \frac{\lambda}{(1+\lambda)^{\deg_{\boldsymbol{G}}(w)+1} - \lambda} \ .$$

From the above, it is immediate to get (15). Specifically, it follows from the above inequality and a standard bound on the maximum degree of random graph which implies that for any fixed number $\epsilon > 0$, the maximum degree in $\boldsymbol{G}$ is less than $(1+\epsilon)\frac{\log n}{\log\log n}$ with probability $1 - o(1)$.

This concludes the proof of Theorem 15. ◀

4.2 (Complete) Spectral Independence

The notions of the pairwise influence matrix $\mathcal{I}_G^{\Lambda,\tau}$ and the Spectral Independence, as we introduce them in Section 3.2, are typically used to establish bounds on the spectral gap for Glauber dynamics and hence derive bounds on the mixing time of the chain.

The authors in [9], make a further use of Spectral Independence to obtain the approximate tensorisation of entropy. Unfortunately, a vanilla application of their technique is not sufficient to prove our tensorisation results, mainly, because of the unbounded degrees we typically have in $G(n, d/n)$.

In this work, we exploit ideas from [9] together with the related notion of the *Complete Spectral Independence*, in order to establish our factorisation results for the entropy in Theorem 6. Specifically, we utilise the connection between complete spectral independence and the ℓ block factorisation of entropy that was established in [8] (see further details in the following section).

Since the notions of the pairwise influence matrix $\mathcal{I}_G^{\Lambda,\tau}$ and the Spectral Independence are so important, let us recall them once more, even though they have already been defined in Section 3.2. Consider a *fixed* graph $G = (V, E)$. Assume that we are given a Gibbs distribution μ on the configuration space $\{\pm 1\}^V$.

We define the pairwise influence matrix $\mathcal{I}_G^{\Lambda,\tau}$ as follows: for a set of vertices $\Lambda \subset V$ and a configuration τ at Λ, the matrix $\mathcal{I}_G^{\Lambda,\tau}$ is indexed by the vertices in $V \setminus \Lambda$, while for any two vertices $v, w \in V \setminus \Lambda$, different with each other, if w can take both values ± 1 given τ, we have that

$$\mathcal{I}_G^{\Lambda,\tau}(w,u) = ||\mu_u(\cdot \mid (\Lambda,\tau),(\{w\},+)) - \mu_u(\cdot \mid (\Lambda,\tau),(\{w\},-))||_{\text{TV}} \quad ; \tag{16}$$

if w can only take one value in ± 1 given τ, we have $\mathcal{I}_G^{\Lambda,\tau}(w,u) = 0$. Also, we have that $\mathcal{I}_G^{\Lambda,\tau}(w,w) = 0$ for all $w \in V \setminus \Lambda$. That is, the diagonal of $\mathcal{I}_G^{\Lambda,\tau}$ is always zero.

Recall that, above, $\mu_u(\cdot \mid (\Lambda,\tau),(\{w\},1))$ is the Gibbs marginal that vertex u, conditional that the configuration at Λ is τ and the configuration at w is 1. We have the analogous for $\mu_u(\cdot \mid (\Lambda,\tau),(\{w\},-1))$.

▶ **Definition 16** (Spectral Independence). *For a real number $\eta > 0$, the Gibbs distribution μ_G on $G = (V,E)$ is η-spectrally independent, if for every $0 \leq k \leq |V| - 2$, $\Lambda \subseteq V$ of size k and $\tau \in \{\pm 1\}^\Lambda$ the spectral radius of $\mathcal{I}_G^{\Lambda,\tau}$ satisfies that $\rho(\mathcal{I}_G^{\Lambda,\tau}) \leq \eta$.*

We proceed to introduce the Complete Spectral Independence. First, consider the notion of the Magnetising operation.

▶ **Definition 17** (Magnetising operation). *Let μ_G be a Gibbs distribution on the graph $G = (V,E)$. For any local fields $\vec{\phi} \in \mathbb{R}_{>0}^V$, the magnetised distribution $\vec{\phi} * \mu$ satisfies*

$$\forall \sigma \in \{\pm 1\}^V, \quad (\vec{\phi} * \mu)(\sigma) \propto \mu(\sigma) \prod_{v \in V : \sigma_v = +1} \phi_v \ .$$

We denote $\vec{\phi} * \mu$ by $\phi * \mu$ if $\vec{\phi}$ is a constant vector with value ϕ.

Suppose that μ is the Hard-Core model on G with fugacity λ. It is immediate that the magnetisied distribution $\vec{\phi} * \mu$ can be viewed as the *non-homogenious* Hard-Core model such that each vertex v has its own fugacity $\lambda_v = \lambda \cdot \phi_v$.

▶ **Definition 18** (Complete Spectral Independence). *For two reals $\eta > 0$ and $s > 0$, the Gibbs distribution μ_G on $G = (V,E)$ is (η, s)-completely spectrally independent, if the magnetised distribution $\vec{\phi} * \mu$ is η-spectrally independent for all $\vec{\phi} \in (0, 1+s]^V$.*

As far as the Hard-Core model on the random graph $G(n, d/n)$ is concerned, we prove the following result.

▶ **Theorem 19.** *For any fixed $d > 1$ and $\lambda < \lambda_c(d)$, there exist bounded constants $r = r(d,\lambda) \in (1,2)$, $B = B(d,\lambda) > 0$ and $s = s(d,\lambda) > 0$ such that the following holds:*

Consider $\boldsymbol{G} \sim G(n, d/n)$ and let $\mu_{\boldsymbol{G}}$ be the Hard-Core model on $\boldsymbol{G}$ with fugacity λ. With probability $1 - o(1)$ over the instances of $\boldsymbol{G}$, $\mu_{\boldsymbol{G}}$ is $(B \cdot (\log n)^{1/r}, s)$-completely spectrally independent.

The proof of Theorem 19 appears in the full version of this paper, where we first relate the influence matrix on the graph to the influence matrix on the self-avoiding walk tree [31, 27] and then use the potential function in [28] to analysis the *weighted* total influence on the self-avoiding walk tree.

4.3 Entropy Block Factorisation - Proof of Theorem 6

The following theorem, from [8], allows us to derive a bound on the ℓ- block factorisation parameter of the entropy by using the result in Theorem 15 for the stability of Gibbs marginals and the result in Theorem 19 for Complete Spectral Independence.

▶ **Theorem 20** ([8, Lemma 2.3]). *Let $\eta > 0, \xi > 0$ and $\zeta > 0$ be parameters. Let μ_G be a Gibbs distribution on $G = (V, E)$. If μ_G is (η, ξ)-completely spectrally independent and ζ-marginally stable, then for any $1/\alpha \leq \ell < n$, μ_G satisfies the ℓ block factorisation of entropy with parameter $C = (\frac{en}{\ell})^{1+1/\alpha}$, where*

$$\alpha = \min\left\{\frac{1}{2\eta}, \frac{\log(1+\xi)}{\log(1+\xi)+\log 2\zeta}\right\} .$$

Proof of Theorem 6. From Theorem 19 we have the following: with probability $1 - o(1)$ over the instances of $\boldsymbol{G}$ we have that $\mu_{\boldsymbol{G}}$ is (η, s)-completely spectrally independent where $s = s(d, \lambda)$ is *constant*, while

$$\eta = B \cdot (\log n)^{1/r} = o\left(\frac{\log n}{\log\log n}\right),$$

where $B = B(d, \lambda)$ and $r = r(d, \lambda) \in (1, 2)$ are constants specified in the statement of Theorem 19. The second equality above follows by noting that $1/r < 1$, bounded away from 1.

Furthermore, from Theorem 15 we have the following: With probability $1 - o(1)$ over the instances of $\boldsymbol{G}$, the distribution $\mu_{\boldsymbol{G}}$ is ζ-marginally stable, where

$$\zeta \leq 2(1+\lambda)^{2\frac{\log n}{\log\log n}} .$$

In light of all the above, the theorem follows by plugging the above values into Theorem 20. ◀

5 Approximate Tensorisation of Entropy

In this section we prove our results related to the approximate tensorisation of the entropy. These are Theorem 4 and Lemma 8.

5.1 Proof of Theorem 4

In this section we give the full proof of Theorem 4. Recall the high level description of the steps we follow towards this endeavour in Section 3.1.

Proof of Theorem 4. From Theorem 6 we have the following: For $d > 1$ and $\lambda < \lambda_c(d)$, consider $\boldsymbol{G} \sim G(n, d/n)$, while let $\mu = \mu_{\boldsymbol{G}}$ be the Hard-Core model on $\boldsymbol{G}$ with fugacity λ. Let the number $\theta = \theta(d, \lambda)$ in the interval $(0, 1)$ be a parameter whose value is going to be specified later. Then, with probability $1 - o(1)$ over the instances of $\boldsymbol{G}$, for $\ell = \lceil \theta n \rceil$ and for any $f : \Omega \to \mathbb{R}_{>0}$ we have that

$$\mathrm{Ent}_\mu(f) \leq \left(\frac{\mathrm{e}}{\theta}\right)^{1+1/\alpha} \frac{1}{\binom{n}{\ell}} \sum_{S \in \binom{V}{\ell}} \mu\left(\mathrm{Ent}_S(f)\right). \tag{17}$$

Recall that $C(S)$ denotes the set of connected components in $\boldsymbol{G}[S]$, the subgraph that is induced by vertices in S. With a slight abuse of notation, we use $U \in C(S)$ to denote the set of vertices in the component U. By the conditional independence property of the Gibbs distribution and Lemma 7, we have

$$\begin{aligned}
\mathrm{Ent}_\mu(f) &\le \left(\frac{\mathrm{e}}{\theta}\right)^{1+1/\alpha} \frac{1}{\binom{n}{\ell}} \sum_{S\in\binom{V}{\ell}} \sum_{U\in C(S)} \mu\left(\mathrm{Ent}_U(f)\right) \\
\text{(by Lemma 8)} \quad &\le \left(\frac{\mathrm{e}}{\theta}\right)^{1+1/\alpha} \frac{1}{\binom{n}{\ell}} \sum_{S\in\binom{V}{\ell}} \sum_{U\in C(S)} \mathrm{AT}(|U|) \sum_{v\in U} \mu[\mathrm{Ent}_v(f)] \\
&\le \left(\frac{\mathrm{e}}{\theta}\right)^{1+1/\alpha} \sum_{v\in V} \mu[\mathrm{Ent}_v(f)] \sum_{k\ge 1} \mathrm{AT}(k)\Pr[|C_v|=k] \ , \qquad (18)
\end{aligned}$$

where C_v is the connected component in $\boldsymbol{G}[S]$, where S is sampled from $\binom{V}{\ell}$ uniformly at random. In order to bound the innermost summation on the R.H.S. of (18) we distinguish two cases for k. For $1 \le k \le \log n$, we use the trivial bound $\Pr[|C_v| = k] \le 1$, while Lemma 8 implies that

$$\begin{aligned}
\sum_{k=1}^{\log n} \mathrm{AT}(k)\Pr[|C_v|=k] \le \sum_{k=1}^{\log n} \mathrm{AT}(k) &= \sum_{k=1}^{\log n} 3\log\left(1+\lambda+\lambda^{-1}\right)\cdot((1+\lambda)k)^{2+2\eta} \\
&\le 3\log\left(1+\lambda+\lambda^{-1}\right)\cdot\log n\cdot((1+\lambda)\log n)^{2+2\eta} \\
&\le 3\log\left(1+\lambda+\lambda^{-1}\right)\cdot((1+\lambda)\log n)^{3+2\eta} \ ,
\end{aligned}$$

where $\eta = B(\log n)^{1/r}$, for constants $B = B(d,\lambda)$ and $r = r(d) \in (1,2)$. Elementary calculations imply that

$$\sum_{k=1}^{\log n} \mathrm{AT}(k)\Pr[|C_v|=k] \le 3\log\left(1+\lambda+\lambda^{-1}\right)\cdot((1+\lambda)\log n)^{3+2\eta} \le n^x \ , \qquad (19)$$

for $x = o\left(\frac{1}{\log\log n}\right)$.

For $k \ge \log n$, we use the bound in Lemma 9 for $\Pr[|C_v| = k]$, while from Lemma 8 we have

$$\sum_{k\ge\log n} \mathrm{AT}(k)\Pr[|C_v|=k] \le 2k^2\left(1+\lambda+\lambda^{-1}\right)^{2k+2}(2\mathrm{e})^{\mathrm{e}Lk}(2\theta)^k \ ,$$

where $L = L(d)$ is the parameter in Lemma 9. We choose sufficiently small $\theta = \theta(d,\lambda)$ such that

$$\forall k \ge 1, \quad 2k^2\left(1+\lambda+\lambda^{-1}\right)^{2k+2}(2\mathrm{e})^{\mathrm{e}Lk}(2\theta)^k \le (1/2)^k \ .$$

This implies that

$$\sum_{k\ge\log n} \mathrm{AT}(k)\Pr[|C_v|=k] \le \sum_{k\ge\log n}\left(\frac{1}{2}\right)^k \le 1 \ . \qquad (20)$$

Plugging (19), (20) into (18), we get the following: With probability $1-o(1)$ over the instances of $\boldsymbol{G}$ we have that

$$\mathrm{Ent}_\mu(f) \le \left(\frac{\mathrm{e}}{\theta}\right)^{1+1/\alpha}\left(n^{\left(\frac{1}{\log\log n}\right)}+1\right)\sum_{v\in V}\mu[\mathrm{Ent}_v(f)] \ .$$

Since, by Theorem 6 we have that $\frac{1}{\alpha} = K(\frac{\log n}{\log\log n})$, for a constant $K = K(d,\lambda)$, and $\theta = \theta(d,\lambda)$ is also a constant, the above inequality can be written as follows: there is a constant $A = A(d,\lambda)$ such that

$$\mathrm{Ent}_\mu(f) \leq n^{\left(\frac{A}{\log\log n}\right)} \sum_{v\in V} \mu[\mathrm{Ent}_v(f)] \ .$$

The above concludes the proof of Theorem 4. ◀

Abstract

Motivated by the theory of *spin-glasses* in physics, we study the so-called *reconstruction problem* on the tree, and on the sparse random graph $\boldsymbol{G}(n, d/n)$. Both cases reduce naturally to analysing broadcasting models, where each edge has its own broadcasting matrix, and this matrix is drawn independently from a predefined distribution.

We establish the *reconstruction threshold* for the cases where the broadcasting matrices give rise to symmetric, 2-spin Gibbs distributions. This threshold seems to be a natural extension of the well-known *Kesten-Stigum bound* that manifests in the classic version of the reconstruction problem. Our results determine, as a special case, the reconstruction threshold for the prominent *Edwards–Anderson model* of spin-glasses, on the tree.

Also, we extend our analysis to the setting of the Galton-Watson random tree, and the (sparse) random graph $\boldsymbol{G}(n, d/n)$, where we establish the corresponding thresholds. Interestingly, for the Edwards–Anderson model on the random graph, we show that the *replica symmetry breaking* phase transition, established by Guerra and and Toninelli in [21], coincides with the reconstruction threshold.

Compared to classical Gibbs distributions, spin-glasses have several unique features. In that respect, their study calls for new ideas, e.g. we introduce novel estimators for the reconstruction problem. The main technical challenge in the analysis of such systems, is the presence of (too) many levels of randomness, which we manage to circumvent by utilising recently proposed tools coming from the analysis of Markov chains.

1 Introduction

Motivated by the theory of *spin-glasses* in physics, we study the so-called *reconstruction problem* with respect to the related distributions, on the tree, and on the sparse random graph $\boldsymbol{G}(n, d/n)$.

Spin-glasses are *disordered* magnetic materials that are studied by physicists (not necessarily the theoretical ones). It has been noted that even though they are a type of magnet, actually, "they are not very good at being magnets". Metallic spin-glasses are "unremarkable conductors", and the insulating spin-glasses are "fairly useless as practical insulators ... ", e.g. see [30].

However, the research on spin-glasses has provided tools to analyse some exciting, and extremely challenging, problems in mathematics, physics, but also *real world* ones. Through their study, we have garnered a deep understanding of the nature of complex systems. A case in point is the pioneering work of Giorgio Parisi in '70s on the so-called *Sherrington-Kirkpatrick* spin-glass, which introduces the formulation of the renowned *replica symmetry breaking* [27]. Parisi's ideas were highly influential in physics community, and later, in mathematics, and computer science. The theory of replica symmetry breaking was among the groundbreaking ideas which got Parisi the Nobel Prise in Physics in 2021.

Perhaps one of the most successful, and extensively studied, spin-glass models, is the famous *Edwards-Anderson* model (EA-model for short), introduced back in '70s by Sam Edwards and Philip Anderson in [16]. Few months after the work of Edwards and Anderson, David Sherrington and Scott Kirkpatrick, in [28], introduced their own model of spin-glasses, the well-known in computer science literature, *Sherrington-Kirkpatrick* model (or SK-model for short). As it turns out, the SK-model corresponds to the *mean field* version of the EA-model.

Given a fixed graph $G = (V, E)$, the Edwards-Anderson model with *inverse* temperature $\beta > 0$, is the *random* Gibbs distribution $\boldsymbol{\mu}$ on the configuration space $\{\pm 1\}^V$ defined as follows: let $\{\boldsymbol{J}_e : e \in E\}$ be independent identically distributed (i.i.d.) *standard Gaussians*. Then each configuration $\sigma \in \{\pm 1\}^V$ receives probability mass $\boldsymbol{\mu}(\sigma)$, defined by

$$\boldsymbol{\mu}(\sigma) \propto \exp\left(\beta \cdot \sum_{\{u,w\}\in E} \mathbf{1}\{\sigma(u) = \sigma(w)\} \cdot \boldsymbol{J}_{\{u,w\}}\right) \ , \tag{1}$$

where $\propto$ stands for "proportional to". We usually refer to $\{\boldsymbol{J}_e\}_{e\in E}$ as the *coupling parameters*. Let us comment here that, traditionally, the Gibbs distribution is defined by replacing the indicator $\mathbf{1}\{\sigma(u) = \sigma(w)\}$ in (1), with the product $\sigma(u)\sigma(w)$, in the physics literature. However, the two formulations are equivalent, as a simple transformation converts one to the other (see the full version). We also note that there is a simpler version of the Edwards-Anderson model, in which coupling parameters take independently ± 1 values, uniformly at random.

Apart from its mathematical elegance, and theoretical importance, the Edwards-Anderson model, and the related spin-glass distributions, arise also in applications such as neural networks (e.g. the so-called Hopfield model), protein folding, and conformational dynamics. We refer the interested reader to [30], and references therein.

In this work, we largely study the Edwards-Anderson model on trees, and the (locally tree-like) *random graph* $\boldsymbol{G}(n, d/n)$ with constant expected degree d. This is the random graph on n vertices, such that each edge appears independently with probability d/n.

Since the Edwards-Anderson model on $\boldsymbol{G}(n, d/n)$ shares essential features with random *Constraint Satisfaction Problems* (r-CSPs for short), it is not surprising that has been studied extensively in terms of phase transitions, in physics, e.g. [19, 25], mathematics, e.g. [21, 12], but also in computer science, e.g. for sampling algorithms [17, 2].

In contrast to the standard Gibbs distributions on trees, e.g. the Ising model, the Hard-core model, and the Potts model, the Edwards-Anderson model, despite being the most basic distribution for spin-glasses, has not been sufficiently studied. As a result, several fundamental questions about it still remain open. Here, we consider the tree *reconstruction problem* for the Edwards-Anderson model (and some natural extensions).

The reconstruction problem studies the effect of the configuration at a vertex, r, on that of the vertices at distance h from r, as $h \to \infty$. Specifically, we want to distinguish the region of parameters where the effect is vanishing, from that where the effect is non-vanishing. Typically, the two regions are specified in terms of a *sharp threshold*, i.e., we have an abrupt transition from one region to the other as we vary the parameters of the model. We usually call this phenomenon *reconstruction threshold*, and it has been the subject of intense study, e.g. [26, 1, 22, 7, 29, 10]. In the context of r-CSPs, the onset of reconstruction has been linked to an abrupt deterioration of the performance of algorithms (both searching and counting), e.g. see [1].

In this work, among other results, we establish precisely the reconstruction threshold for the Edwards-Anderson model on the Δ-ary tree, the Galton-Watson tree with general offspring distribution, and the random graph $\boldsymbol{G}(n, d/n)$. Furthermore, as far as the Edwards-Anderson model on $\boldsymbol{G}(n, d/n)$ is concerned, we combine our results with [21, 12], to conclude that the reconstruction threshold coincides with the so-called *Replica Symmetry Breaking* phase transition.

Interestingly, for the Δ-ary tree, we establish the reconstruction threshold, not only for the Edwards-Anderson model, but also for the general version of the Gibbs distribution $\boldsymbol{\mu}$ defined in (1). That is, the coupling parameters are i.i.d. following a *general distribution*, not necessary the standard Normal.

It turns out that the corresponding reconstruction problems on the Galton-Watson tree with Poisson(d) offspring, and on the sparse random graph $\boldsymbol{G}(n, d/n)$, are not too different from each other. Connections have been established between these two Gibbs distributions, e.g. see [4, 15, 11, 14]. We relate the two reconstruction results, i.e., for the tree and the graph, by exploiting the idea of planted-model (Teacher-Student model [31]) and the notion of mutual *contiguity* [12]. In that respect, our basic analysis involves the complete Δ-tree, and the Galton-Watson tree, while, subsequently, we extend these results to the random graph $\boldsymbol{G}(n, d/n)$.

We study the reconstruction problem on trees by means of the broadcasting models. These are abstractions of *noisy transmission* of information over the edges of the tree, i.e., the edges act as noisy channels. To our knowledge, the study of the broadcasting models, and the closely related reconstruction problem, dates back to '60s with the seminal work of Kesten and Stigum [24].

Establishing the reconstruction threshold for the Edwards-Anderson model on the Δ-ary tree, as well as the generalisation of this distribution, turns out to be a challenging problem. The difficulty of these models stems from the manifestation of local *frustration phenomena*, i.e., mixed ferromagnetic and antiferromagnetic interaction in the same neighbourhood, but also from the "many levels of randomness" we need to deal with in their analysis.

To this end, we make an extensive use of various potentials in order to simplify the analysis. To establish non-reconstruction, we employ some newly introduced techniques in the area of Markov chains and Spectral Independence [3, 9], that combine potential functions to analyse tree recursions. To establish reconstruction, we use a carefully crafted potential as an estimator for the root configuration. We call this estimator *flip-majority vote*.

1.1 Broadcasting, Reconstruction and the Kesten-Stigum bound

Consider the Δ-ary tree $T = (V, E)$, of height $h > 0$. Let r be the root of the tree T. Broadcasting on T, is a stochastic process which abstracts noisy transmission of information over the edges of the tree.

There is a finite set of spins $\mathcal{A}$, and an $\mathcal{A} \times \mathcal{A}$ stochastic matrix M, which we call the *broadcasting matrix*, or *transition matrix*. With the broadcasting we obtain a configuration $\boldsymbol{\sigma} \in \mathcal{A}^V$ by working recursively as follows: assume that the configuration at the root r is obtained according to some predefined distribution over $\mathcal{A}$. If for the non-leaf vertex u in T we have $\boldsymbol{\sigma}(u) = i$, then for each vertex w, child of u, we have $\boldsymbol{\sigma}(w) = j$ with probability $M(i, j)$, independently of the other children, i.e.,

$$\Pr[\boldsymbol{\sigma}(w) = j \mid \boldsymbol{\sigma}(u) = i] = M(i, j) \ .$$

Here we assume that $\boldsymbol{\sigma}(r)$ is distributed uniformly at random in $\mathcal{A}$.

A natural problem to study in this setting is the so-called *reconstruction problem*. Suppose that μ_h is the marginal distribution of the configuration of the vertices at distance h from the root. The reconstruction problem amounts to studying the influence of the configuration at the root of the tree to the marginal μ_h. Specifically, we want to compare the two distributions $\mu_h(\cdot \mid \boldsymbol{\sigma}(r) = i)$, and $\mu_h(\cdot \mid \boldsymbol{\sigma}(r) = j)$ for different $i, j \in \mathcal{A}$, i.e., μ_h conditional on the configuration at the root being i and j, respectively. The comparison is by means of the total variation distance, i.e.,

$$||\mu_h(\cdot \mid \boldsymbol{\sigma}(r) = i) - \mu_h(\cdot \mid \boldsymbol{\sigma}(r) = j)||_{\mathrm{TV}} \ .$$

Typically, we focus on the behaviour of the quantity above, as h grows.

▶ **Definition 1.** *We say that the distribution μ exhibits* reconstruction *if there exist spins $i, j \in \mathcal{A}$ such that*

$$\limsup_{h \to \infty} ||\mu_h(\cdot \mid \boldsymbol{\sigma}(r) = i) - \mu_h(\cdot \mid \boldsymbol{\sigma}(r) = j)||_{\mathrm{TV}} > 0 \ .$$

On the other hand, if for all $i, j \in \mathcal{A}$ the above limit is zero, then we have non-reconstruction.

The broadcasting process we describe above gives rise to well-known Gibbs distributions on T such as the *Ising model*, the *Potts model* etc. In terms of the Gibbs distributions on the tree, the reconstruction problem can be formulated as to whether the free-measure on the tree is *extremal*, or not. The extremality here is considered with respect to whether the Gibbs distribution can be expressed as a convex combination of two, or more measures, e.g. see [20]. It is interesting to compare the extremality condition with various spatial mixing conditions of the Gibbs distribution. Perhaps the most interesting case is to compare it with the Gibbs tree *uniqueness*. Then, it is standard to show that the extremality is a *weaker* condition than uniqueness.

The reconstruction problem has been studied since 1960s. Perhaps the most general result in the area is the so-called *Kesten-Stigum bound* [24], or KS-bound (for short). Let $\Delta_{\mathrm{KS}} = \Delta_{\mathrm{KS}}(M)$ be such that

$$\Delta_{\mathrm{KS}} = \lambda_2^{-2}(M) \ , \tag{2}$$

where $\lambda_2(M)$ is the second largest, in magnitude, eigenvalue of the transition matrix M. The result of [24] implies that if $\Delta > \Delta_{\mathrm{KS}}$, then we have reconstruction.

In light of the above, a natural question is whether the condition $\Delta < \Delta_{\mathrm{KS}}$ implies that we have non-reconstruction. In general, the answer to this question is no, e.g. see [5, 29]. However, for several important distributions, including the Ising model, the KS-bound is tight, in the sense that the condition $\Delta < \Delta_{\mathrm{KS}}$ indeed implies non-reconstruction, see [7, 18, 22].

1.2 Broadcasting with random matrices

Here, we consider the natural problem of broadcasting on a tree, where the transition matrix is *random*. In this setting, as before, we consider the Δ-ary tree $T = (V, E)$, of height $h > 0$, rooted at r. Also, we have a finite set of spins $\mathcal{A}$. Rather than using the same matrix for every edge of the tree, each edge has its own matrix, which is an independent sample from a predefined distribution ψ.

More formally, every $\mathcal{A} \times \mathcal{A}$ stochastic matrix can be viewed as a point in the $|\mathcal{A}|^2$ Euclidean space. We endow the set of all $\mathcal{A} \times \mathcal{A}$ stochastic matrices with the σ-algebra induced by the Borel algebra. Then, ψ is a distribution over the set of these matrices.

Once we have a matrix for each edge of T, the broadcasting proceeds with the same rules as in the deterministic case. If for the non-leaf vertex u in T we have $\boldsymbol{\sigma}(u) = i$, then the vertex w, child of u, gets $\boldsymbol{\sigma}(w) = j$ with probability $\boldsymbol{M}_e(i, j)$, independently of the other children of u, i.e.,

$$\Pr[\boldsymbol{\sigma}(w) = j \mid \boldsymbol{\sigma}(u) = i] = \boldsymbol{M}_e(i, j) \ ,$$

where $e = \{u, w\}$.

The above setting gives rise to a *random* probability measure on the set of configurations $\mathcal{A}^V$ which we denote as $\boldsymbol{\mu} = \boldsymbol{\mu}_{T,\psi}$. Hence, the configuration $\boldsymbol{\sigma} \in \mathcal{A}^V$ we get from the broadcasting, consists of *two-levels of randomness*. The first level is due to the fact that the measure $\boldsymbol{\mu}$ is induced by the random instances of the broadcasting matrices $\{\boldsymbol{M}_e\}_{e\in E}$. Once these matrices have been fixed, the second level of randomness emerges from the random choices of the broadcasting process. The above formulation gives rise to well-studied Gibbs distributions, such as the Edwards–Anderson model of spin-glasses, by choosing appropriately the distribution ψ.

In this new setting, we study the reconstruction problem. Here, the definition of reconstruction differs slightly from Definition 1 above. Denote with $\boldsymbol{\mu}_h$ the marginal of $\boldsymbol{\mu}$ on the vertices at distance h from the root of the tree T. Then, the reconstruction problem is defined as follows:

▶ **Definition 2.** *For a distribution ψ on $\mathcal{A} \times \mathcal{A}$ stochastic matrices , we say that the random measure $\boldsymbol{\mu} = \boldsymbol{\mu}_{T,\psi}$ exhibits* reconstruction *if there exist spins $i, j \in \mathcal{A}$ such that*

$$\limsup_{h\to\infty} \mathbb{E}\left[||\boldsymbol{\mu}_h(\cdot \mid \boldsymbol{\sigma}(r) = i) - \boldsymbol{\mu}_h(\cdot \mid \boldsymbol{\sigma}(r) = j)||_{\mathrm{TV}}\right] > 0 \ ,$$

where the expectation is with respect to the randomness of $\boldsymbol{\mu}$.

On the other hand, if for all $i, j \in \mathcal{A}$ the above limit is zero, then we have non-reconstruction*.*

We consider the reconstruction problem in terms of the KS-bound, i.e., we examine whether it is tight, or not. Before addressing this question, we need to specify what the parameter Δ_{KS} might be in this setting.

It turns out that a natural candidate for Δ_{KS} can be defined as follows:

Let $\boldsymbol{M}$ be a matrix sampled from the distribution ψ, and define

$$\Xi = \mathbb{E}\left[\boldsymbol{M} \otimes \boldsymbol{M}\right] \ , \tag{3}$$

i.e., the matrix Ξ is the expectation of the tensor product of the matrix $\boldsymbol{M}$ with itself. Let $\mathbf{1} \in \mathbb{R}^{\mathcal{A}}$ denote the vector whose entries are all equal to one. Also, write

$$\mathcal{E} = \left\{z \in \mathbb{R}^{\mathcal{A}} \otimes \mathbb{R}^{\mathcal{A}} : \forall y \in \mathbb{R}^{\mathcal{A}} \langle z, \mathbf{1} \otimes y\rangle = \langle z, y \otimes \mathbf{1}\rangle = 0\right\} \ ,$$

where $\langle \cdot, \cdot \rangle$ is the standard inner product operation. Then, we define $\Delta_{\mathrm{KS}}(\psi)$ to be such that

$$\Delta_{\mathrm{KS}}(\psi) = \left(\max_{x \in \mathcal{E}^{\cdot} : ||x||=1} \langle \Xi x, x \rangle \right)^{-1} \quad . \tag{4}$$

The above quantity, Δ_{KS}, arises in the study of phases transitions in random CSPs [12]. Specifically, it signifies an *upper bound* on the density of the so-called *Replica Symmetric* phase, of symmetric Gibbs distributions. The value Δ_{KS} is derived in [12] by means of a stability analysis of the so-called *free-energy* functional. Note that the above definition for $\Delta_{\mathrm{KS}}(\psi)$ applies to any set of spins $\mathcal{A}$, and any distribution ψ on $\mathcal{A} \times \mathcal{A}$ matrices.

Here, we prove that the above is indeed the analogue of KS-bound for *symmetric*, 2-spin distributions $\boldsymbol{\mu}$. That is, for any value of the parameter $\beta > 0$, and for any distribution ψ over the broadcasting matrices whose support is comprised of symmetric 2×2 matrices, we prove that the Δ-ary tree T exhibits reconstruction when $\Delta > \Delta_{\mathrm{KS}}(\psi)$, while we have non-reconstruction when $\Delta < \Delta_{\mathrm{KS}}(\psi)$.

Furthermore, we go beyond the basic case of the Δ-ary tree. Firstly, we extend our results to the cases where the underlying graph is the *Galton-Watson* random tree with general offspring distribution. Secondly, we exploit the notion of contiguity of measures to derive non-reconstruction results for the Edwards-Anderson model on the random graph $\boldsymbol{G}(n, d/n)$.

2 Results

We start the presentation of our results on the 2-spin, symmetric distributions, by considering the Δ-ary tree. Specifically, for integers $\Delta > 0$ and $h > 0$, let $T = (V, E)$ be the Δ-ary tree of height h, rooted at vertex r. We let $\mathcal{A} = \{\pm 1\}$ be the set of spins.

Assume that each edge of the tree is equipped with its own broadcasting matrix, each matrix drawn *independently* from the distribution induced by the following experiment: We have two parameters, a real number $\beta > 0$, and a distribution ϕ on the real numbers $\mathbb{R}$, i.e., we have the probability space $(\mathbb{R}, \mathcal{F}, \phi)$ where $\mathcal{F}$ is the σ-algebra induced by the Borel algebra. We generate a matrix $\boldsymbol{M}$ following the two steps below:

Step 1 Draw $\boldsymbol{J} \in \mathbb{R}$ from the distribution ϕ.

Step 2 Generate the $\mathcal{A} \times \mathcal{A}$ matrix $\boldsymbol{M}$ such that

$$\boldsymbol{M} = \frac{1}{\exp(\beta \boldsymbol{J}) + 1} \begin{bmatrix} \exp(\beta \boldsymbol{J}) & 1 \\ 1 & \exp(\beta \boldsymbol{J}) \end{bmatrix} \quad . \tag{5}$$

Note that our broadcasting matrices are always *symmetric*.

The above broadcasting process gives rise to configurations in $\mathcal{A}^V$ following the Gibbs distribution $\boldsymbol{\mu}_{\beta,\phi}$ specified as follows: Let $\{\boldsymbol{J}_e\}_{e \in E}$ be independent, identically distributed (i.i.d.) random variables such that each one of them is distributed as in ϕ (this is the same distribution used to generate matrix $\boldsymbol{M}$). Each $\sigma \in \mathcal{A}^V$ is assigned probability mass $\boldsymbol{\mu}_{\beta,\phi}(\sigma)$ defined by

$$\boldsymbol{\mu}_{\beta,\phi}(\sigma) \propto \exp\left(\beta \textstyle\sum_{\{w,u\} \in E} \mathbf{1}\{\sigma(u) = \sigma(w)\} \cdot \boldsymbol{J}_{\{u,w\}} \right) \quad , \tag{6}$$

where $\propto$ stands for "proportional to".

At this point, it is immediate that by choosing ϕ to be the *standard Gaussian* distribution, we retrieve the Edwards-Anderson model in (1). Note however, that (6) above generates a whole family of "spin-glass" distributions with the EA-model being a special case.

The definition of the distribution of the broadcasting matrix in (5) allows us to derive an explicit formula for the quantity Δ_{KS} in (4). Specifically, for $\boldsymbol{J}$ distributed according to ϕ, it is not hard to prove (see the full version) that

$$\Delta_{\mathrm{KS}}(\beta,\phi)=\left(\mathbb{E}\left[\left(\frac{1-\exp(\beta\boldsymbol{J})}{1+\exp(\beta\boldsymbol{J})}\right)^2\right]\right)^{-1}\ , \tag{7}$$

where the expectation is with respect to the random variable $\boldsymbol{J}$. In light of the above, we prove the following result for the general Gibbs distribution.

▶ **Theorem 3.** *For a real number $\beta>q0$, and a distribution ϕ on the real numbers $\mathbb{R}$ let $\Delta_{\mathrm{KS}}=\Delta_{\mathrm{KS}}(\beta,\phi)$ be defined as in* (7)*.*

For any integer $\Delta>\Delta_{\mathrm{KS}}$, the Gibbs distribution $\boldsymbol{\mu}_{\beta,\phi}$, defined as in (6)*, on the Δ-ary tree exhibits reconstruction. On the other hand, if $\Delta<\Delta_{\mathrm{KS}}$ the distribution $\boldsymbol{\mu}_{\beta,\phi}$ exhibits non-reconstruction.*

The proof of Theorem 3 appears in the full version. Let us state the implications of Theorem 3 for the Edwards-Anderson model on the Δ-ary tree.

▶ **Corollary 4.** *For $\beta>0$ and the standard Gaussian $\boldsymbol{J}$, let*

$$\Delta_{\mathrm{EA}}(\beta)=\left(\mathbb{E}\left[\left(\frac{1-\exp(\beta\boldsymbol{J})}{1+\exp(\beta\boldsymbol{J})}\right)^2\right]\right)^{-1}\ ,$$

where the expectation is with respect to $\boldsymbol{J}$.

For any integer $\Delta>\Delta_{\mathrm{EA}}(\beta)$, the distribution $\boldsymbol{\mu}_{\beta}$, the Edwards-Anderson model with inverse temperature β on the Δ-ary tree, exhibits reconstruction. On the other hand, if $\Delta<\Delta_{\mathrm{EA}}(\beta)$ the distribution $\boldsymbol{\mu}_{\beta}$ exhibits non-reconstruction.

2.1 The case of the Galton-Watson tree

As a further step, we study the reconstruction problem on the Galton-Watson tree. Even though this is a very interesting problem on its own, we make use of our results for the Galton-Watson tree to derive subsequent results for $\boldsymbol{G}(n,d/n)$, see Section 2.2.

Let $\zeta:\mathbb{Z}_{\geq 0}\to[0,1]$ be a distribution over the non-negative integers. Then, the rooted tree $\boldsymbol{T}$ is a Galton-Watson tree with offspring distribution ζ, if the number of children for each vertex in $\boldsymbol{T}$ is distributed according to ζ, *independently* from the other vertices.

Note that broadcasting with random matrices over the Galton-Watson tree $\boldsymbol{T}$, gives rise to configurations that consist of *three* levels of randomness. One of the challenges we circumvent with our analysis, is to disentangle all of three levels of randomness, and make clear the contribution of each one of them. Before getting there, we need to clarify what we mean by (non-)reconstruction in the current setting.

▶ **Definition 5.** *Consider the distributions ϕ over $\mathbb{R}$ and ζ over $\mathbb{Z}_{\geq 0}$, and a real number $\beta\geq 0$. Let the Galton-Watson tree $\boldsymbol{T}$ with offspring distribution ζ, while let the measure $\boldsymbol{\mu}=\boldsymbol{\mu}_{\beta,\phi}$ be defined as in* (6)*, on the tree $\boldsymbol{T}$. We say that $\boldsymbol{\mu}$ exhibits* reconstruction *if*

$$\limsup_{h\to\infty}\mathbb{E}_{\boldsymbol{T}}\left[\ \mathbb{E}_{\boldsymbol{\mu}}\left[||\boldsymbol{\mu}_h(\cdot\mid\boldsymbol{\sigma}(r)=+1)-\boldsymbol{\mu}_h(\cdot\mid\boldsymbol{\sigma}(r)=-1)||_{\mathrm{TV}}\ \mid\boldsymbol{T}\right]\ \right]>0\ .$$

On the other hand, if the above limit is zero, then we have non-reconstruction*.*

For the above, recall that $\boldsymbol{\mu}_h$ is the marginal of $\boldsymbol{\mu}$ on the set of vertices at distance h from the root. Note that if $\boldsymbol{T}$ has no vertex at level h, then the total variation distance above is, degenerately, equal to zero. We use the double expectation in Definition 5 for the sake of clarity: we can just replace it by a single expectation with respect to both the random tree $\boldsymbol{T}$, and the random measure $\boldsymbol{\mu}$.

As far as the reconstruction problem on the Galton-Watson trees is concerned, we have the following result.

▶ **Theorem 6.** *For any real numbers $d > 0, \beta > 0$, for any distribution ϕ on $\mathbb{R}$, for any distribution ζ on $\mathbb{Z}_{\geq 0}$ with expectation d, and* bounded second moment*, let $\boldsymbol{T}$ be the Galton-Watson tree with offspring distribution ζ. Let also $\boldsymbol{\mu}_{\beta,\phi}$ be the Gibbs distribution defined as in* (6)*, on the tree $\boldsymbol{T}$. Finally, let $\Delta_{\mathrm{KS}} = \Delta_{\mathrm{KS}}(\beta, \phi)$ be defined as in* (7)*.*

The distribution $\boldsymbol{\mu}_{\beta,\phi}$ exhibits reconstruction if $d > \Delta_{\mathrm{KS}}$. On the other hand, if $d < \Delta_{\mathrm{KS}}$, the distribution $\boldsymbol{\mu}_{\beta,\phi}$ exhibits non-reconstruction.

Let us now state the implications of Theorem 6 for the Edwards-Anderson model on the Galton-Watson tree.

▶ **Corollary 7.** *For $\beta > 0$, consider the quantity $\Delta_{\mathrm{EA}}(\beta)$ defined in Corollary 4. For any real number $d > 0$, and any distribution $\zeta : \mathbb{Z}_{\geq 0} \to [0, 1]$ with expectation d, and* bounded second moment*, let $\boldsymbol{T}$ be the Galton-Watson tree with offspring distribution ζ.*

Then, for $\boldsymbol{\mu}_\beta$ the Edwards-Anderson model with inverse temperature β, on the tree $\boldsymbol{T}$, the following is true. The distribution $\boldsymbol{\mu}_\beta$ exhibits reconstruction if $d > \Delta_{\mathrm{EA}}(\beta)$. On the other hand, if $d < \Delta_{\mathrm{EA}}(\beta)$, the distribution $\boldsymbol{\mu}_\beta$ exhibits non-reconstruction.

2.2 The Edwards-Anderson model on $G(n, d/n)$

For integer $n \geq 1$, and real $p \in [0, 1]$, let $\boldsymbol{G} = \boldsymbol{G}(n, p)$ be the random graph on $V_n = \{x_1, \ldots, x_n\}$, whose edge set $E(\boldsymbol{G})$ is obtained by including each edge with probability, p *independently*.

The *Edwards-Anderson model* on $\boldsymbol{G}$ at inverse temperature $\beta > 0$, is defined as follows: for $\boldsymbol{J} = \{\boldsymbol{J}_e\}_{e \in E(\boldsymbol{G})}$ a family of independent *standard Gaussians*, we let

$$\mu_{\boldsymbol{G},\boldsymbol{J},\beta}(\sigma) = \tfrac{1}{Z_\beta(\boldsymbol{G},\boldsymbol{J})} \exp\left(\beta \textstyle\sum_{x \sim y} \mathbf{1}\{\sigma(y) = \sigma(x)\} \cdot \boldsymbol{J}_{\{x,y\}}\right) \ , \tag{8}$$

where

$$Z_\beta(\boldsymbol{G}, \boldsymbol{J}) = \textstyle\sum_{\tau \in \{\pm 1\}^{V_n}} \exp\left(\beta \sum_{x \sim y} \mathbf{1}\{\tau(y) = \tau(x)\} \cdot \boldsymbol{J}_{\{x,y\}}\right) \ .$$

Here we assume that $p = \frac{d}{n}$, where $d > 0$ is a fixed number. Typically, we study this distribution as $n \to \infty$. The natural question we ask here is how does the model change as we vary d. According to the physics predictions, for any β there exists a *condensation threshold*, denoted as $d_{\mathrm{cond}}(\beta)$, where the function

$$d \mapsto \lim_{n \to \infty} \frac{1}{n} \mathbb{E}[\ln Z_\beta(\boldsymbol{G}, \boldsymbol{J})]$$

is non-analytic [19]. This conjecture was proved by Guerra and Toninelli [21]. The regime $d < d_{\mathrm{cond}}(\beta)$ is called the *replica symmetric phase*. This region has several interesting properties; here we consider one that seems to be most relevant to our discussion. For any $d < d_{\mathrm{cond}}(\beta)$ the distribution $\mu_{\boldsymbol{G},\boldsymbol{J},\beta}$ satisfies the following property: for $\boldsymbol{\sigma}$ distributed as

in $\mu_{\boldsymbol{G},\boldsymbol{J},\beta}$, for two randomly chosen vertices $\mathbf{x}$ and $\mathbf{y}$, the configurations $\boldsymbol{\sigma}(\mathbf{x})$ and $\boldsymbol{\sigma}(\mathbf{y})$ are asymptotically independent. Formally, the above can be expressed as follows: for $d < d_{\text{cond}}(\beta)$ and any $i, j \in \{\pm 1\}$, we have that

$$\limsup_{n\to\infty} \frac{1}{n^2} \sum_{x,y\in V_n} \mathbb{E}\left[\langle \mathbf{1}\{\boldsymbol{\sigma}(x) = i\} \times \mathbf{1}\{\boldsymbol{\sigma}(y) = j\}\rangle - \langle \mathbf{1}\{\boldsymbol{\sigma}(x) = i\}\rangle \times \langle \mathbf{1}\{\boldsymbol{\sigma}(y) = j\}\rangle\right] = 0 \ ,$$

where $\langle\cdot\rangle$ denotes expectation with respect to the Gibbs distribution $\mu_{\boldsymbol{G},\boldsymbol{J},\beta}$. Note that the above holds not only for pairs of vertices, but also for sets of k vertices, for any fixed integer $k > 0$. Using our notation, the work by Guerra and Toninelli [21] implies the following result.

▶ **Theorem 8** ([21]). *For any $\beta > 0$, for the distribution $\mu_{\boldsymbol{G},\boldsymbol{J},\beta}$ defined as in* (8)*, we have that*

$$d_{\text{cond}}(\beta) = \left(\mathbb{E}\left[\left(\frac{1-\exp(\beta\boldsymbol{J})}{1+\exp(\beta\boldsymbol{J})}\right)^2\right]\right)^{-1} \ ,$$

where $\boldsymbol{J}$ is a standard Gaussian random variable.

Interestingly, one obtains the above by combining our Theorem 6 and using results from [12, 13]. Our main focus is on the reconstruction threshold for the Edwards-Anderson model on $\boldsymbol{G}$. The reconstruction for $\mu_{\boldsymbol{G},\boldsymbol{J},\beta}(\cdot)$ is defined in a slightly different way than what we have for the random tree.

▶ **Definition 9.** *For $d > 0$, for $\beta > 0$, consider the Gibbs distribution $\mu_{\boldsymbol{G},\boldsymbol{J},\beta}$ as this is defined in* (8)*. We say that the measure $\mu = \mu_{\boldsymbol{G},\boldsymbol{J},\beta}$ exhibits* reconstruction *if*

$$\limsup_{h\to\infty} \lim_{n\to\infty} \frac{1}{n} \sum_{x\in V_n} \mathbb{E}\left[||\mu_{x,h}(\cdot \mid \boldsymbol{\sigma}(x) = +1) - \mu_{x,h}(\cdot \mid \boldsymbol{\sigma}(x) = -1)||_{\text{TV}}\right] > 0 \ ,$$

where $\mu_{x,h}$ denote the Gibbs marginal at the vertices at distance h from vertex x. On the other hand, if the above limit is zero, then we have non-reconstruction*.*

Perhaps, it is interesting to notice the order with which we take the double limit in the above definition. We let the reconstruction threshold, denoted as d_{recon}, to be the infimum over $d > 0$ such that

$$\limsup_{h\to\infty} \lim_{n\to\infty} \frac{1}{n} \sum_{x\in V_n} \mathbb{E}\left[||\mu_h(\cdot \mid \boldsymbol{\sigma}(x) = +1) - \mu_h(\cdot \mid \boldsymbol{\sigma}(x) = -1)||_{\text{TV}}\right] > 0 \ .$$

The region of values of d such that $d < d_{\text{recon}}$ is called the *non-reconstruction phase*. It is immediate from Definition 9 that, for any $d < d_{\text{recon}}$, we have that non-reconstruction.

In the following result, we prove that the replica symmetric phase coincides with the non-reconstruction phase of the Edwards-Anderson model on $\boldsymbol{G}$.

▶ **Theorem 10.** *For any $\beta > 0$, for the distribution $\mu_{\boldsymbol{G},\boldsymbol{J},\beta}$ defined as in* (8)*, we have that $d_{\text{recon}}(\beta) = d_{\text{cond}}(\beta)$.*

The above follows from Theorems 8, 7 and [12, Corollary 1.5].

Notation

For the graph $G = (V, E)$ and the Gibbs distribution μ on the set of configurations $\{\pm 1\}^V$. For a configuration σ, we let $\sigma(\Lambda)$ denote the configuration that σ specifies on the set of vertices Λ. We let μ_Λ denote the marginal of μ at the set Λ. We let $\mu(\cdot \mid \Lambda, \sigma)$, denote the distribution μ conditional on the configuration at Λ being σ. Also, we interpret the conditional marginal $\mu_\Lambda(\cdot \mid \Lambda', \sigma)$, for $\Lambda' \subseteq V$, in the natural way.

3 Approach

A major challenge in our setting is that we have to deal with multiple levels of randomness, i.e., we have two levels of randomness in the case of the Δ-ary tree, while the levels increase with the Galton-Watson trees. To circumvent this problem, we follow an analysis that allows us to disentangle the different sources of randomness in our models. In this section, we provide a high-level description of our approach. We restrict our discussion on the Δ-ary tree.

Non-reconstruction

Consider the Δ-ary tree $T = (V, E)$ rooted at r. Suppose that we have a distribution μ as in (6) on T, while assume that each edge $e \in E$ has its own coupling parameter J_e. Assume, for the moment, that the coupling parameters at the edges are fixed, e.g. the reader may assume that are arbitrary real numbers. That is, each J_e can be either positive, or negative. Hence, one might consider the aforementioned distribution as a *non-homogenous* Ising model which involves both ferromagnetic and anti-ferromagnetic interactions. Let us focus on non-reconstruction. We derive an upper bound on

$$||\mu_h(\cdot \mid \boldsymbol{\sigma}(r) = +1) - \mu_h(\cdot \mid \boldsymbol{\sigma}(r) = -1)||_{\text{TV}} \quad ,$$

which is expressed in terms of the *influence* between neighbouring vertices. The notion of influence between vertices is the same as the one developed in the context of *Spectral Independence* technique for establishing rapid mixing of Glauber dynamics [3, 9]. These influences are used in the context of the so-called *down-up* coupling to establish non-reconstruction. This is a coupling approach from [6], which also relies on ideas in [29].

Let us be more specific. For the probability measure μ we consider, let R_r be the *ratio of Gibbs marginals* at the root r defined by

$$R_r = \frac{\mu_r(+1)}{\mu_r(-1)} \quad . \tag{9}$$

Recall that $\mu_r(\cdot)$ denotes the marginal of the Gibbs distribution $\mu(\cdot)$ at the root r. For a vertex $u \in V$, we let T_u be the subtree of T that includes u, and all its descendants. Also, we let R_u be the ratio of marginals at vertex u, where the Gibbs distribution is, now, with respect to the subtree T_u.

Suppose that the vertices $w_1, \ldots, w_\Delta$ are the children of the root r. Our focus is on expressing $\log R_r$ recursively, as a function of $\log R_{w_1}, \ldots, \log R_{w_\Delta}$. Note that we study the logarithm of the ratios involved, which can be viewed as applying the potential function $\log(\cdot)$ to the tree recursions. We have that $\log(R_r) = H(\log R_{w_1}, \ldots, \log R_{w_\Delta})$ where

$$H(x_1, x_2, \ldots, x_\Delta) = \sum_{i=1}^{\Delta} \log\left(\frac{\exp\left(x_i + \beta J_{\{r,w_i\}}\right) + 1}{\exp(x_i) + \exp\left(\beta J_{\{r,w_i\}}\right)}\right) \quad . \tag{10}$$

Note that $J_{\{r,w_i\}}$ is the coupling parameter that corresponds to the edge between the root r with its child w_i. All the above extends naturally in the case where we impose boundary conditions. That is, for a region $K \subseteq V$, and $\tau \in \{\pm 1\}^K$, we define the ratio of marginals $R_r^{K,\tau}$ at the root, where now the ratio is between the conditional marginals $\mu_r(+1 \mid K, \tau)$ and $\mu_r(-1 \mid K, \tau)$. The recursive function H for the conditional ratios is exactly the same as the one above.

Our interest is on the *gradient* of the function H. Specifically, for every $i \in [\Delta]$, we let

$$\Gamma_{\{r,w_i\}} = \sup_{x_1,\ldots,x_\Delta} \left| \frac{\partial}{\partial x_i} H(x_1, x_2, \ldots, x_\Delta) \right| \ . \tag{11}$$

It turns out that, in our case, $\Gamma_{\{r,w_i\}}$ has a simple form

$$\Gamma_{\{r,w_i\}} = \frac{\left|1 - \exp\left(\beta J_{\{r,w\}}\right)\right|}{1 + \exp\left(\beta J_{\{r,w_i\}}\right)} \ .$$

Utilising the idea of down-up coupling from [6], we prove the following:

$$||\mu_h(\cdot \mid \boldsymbol{\sigma}(r) = +1) - \mu_h(\cdot \mid \boldsymbol{\sigma}(r) = -1)||_{TV} \leq \sqrt{\sum_{v \in \Lambda} \prod_{e \in \text{path}(r,v)} \Gamma_e^2} \ , \tag{12}$$

where $\Lambda = \Lambda(h)$ denotes the set of vertices at distance h from the root r. Note that the above provides a bound for the total variation distance of the the marginals for fixed, i.e., non-random, couplings $\{J_e\}_{e \in E}$. Inequality (12), extends naturally when we study reconstruction for the distribution $\boldsymbol{\mu}$ defined in (6), i.e., when the coupling parameters $\boldsymbol{J}_e$ are i.i.d. samples from a distribution ϕ. Indeed, averaging yields

$$\mathbb{E}\left[\left(||\boldsymbol{\mu}_h(\cdot \mid \boldsymbol{\sigma}(r) = +1) - \boldsymbol{\mu}_h(\cdot \mid \boldsymbol{\sigma}(r) = -1)||_{TV}\right)^2\right] \leq \sum_{v \in \Lambda} \prod_{e \in \text{path}(r,v)} \mathbb{E}\left[\boldsymbol{\Gamma}_e^2\right] \ , \tag{13}$$

where we have $\boldsymbol{\Gamma}_e = \frac{|1-\exp(\beta \boldsymbol{J}_e)|}{1+\exp(\beta \boldsymbol{J}_e)}$, for each $e \in E$. Note that the above holds, since each $\boldsymbol{\Gamma}_e$ depends only on $\boldsymbol{J}_e$, while the coupling parameters $\boldsymbol{J}_e$ are assumed to be independent with each other.

At this point, and since the $\boldsymbol{J}_e$'s are identically distributed, we further observe that for any $e \in E$, we have that

$$\Delta_{\text{KS}}(\beta, \phi) = \left(\mathbb{E}\left[\boldsymbol{\Gamma}_e^2\right]\right)^{-1} \ .$$

Since the underlying tree T is Δ-ary, it is immediate to see that for $\Delta < \Delta_{\text{KS}}(\beta, \phi)$, the r.h.s. of (13) tends to zero as $h \to \infty$. From this point on, it is standard to prove non-reconstruction.

Our analysis allows to deal with the randomness of the spin-glass measure $\boldsymbol{\mu}$ by utilising the bound in (12). That is, the upper bound on the total variation distance has a nice *product* form of the quantities Γ_e, which, in turn, expresses the dependence of the total variation distance on the edge couplings $\{J_e\}_{e \in E}$. This product form of the bound, behaves rather nicely when we need to take averages over the randomness of the coupling parameters $\{\boldsymbol{J}_e\}_{e \in E}$ of the the spin-glass measure $\boldsymbol{\mu}$.

Reconstruction

In the reconstruction regime, the configuration at the root has a non-vanishing effect on the configuration of the vertices at distance h, regardless of the height h. Specifically, the corresponding leaf configurations from the measure conditioned on root's spin being $+1$, and -1, are so different with each other, that discrepancies cannot be attributed to random fluctuations. Therefore, a question that naturally arises is how can we take advantage of the discrepancies so that we infer the spin of the root.

For the standard ferromagnetic Ising, several approaches have been developed to establish reconstruction (see [18], [8], [23]). Here, we build on an elegant argument in [18]. The authors in this work, show that a simple *majority vote* of the leaf spins, conveys information sufficient to reconstruct root's spin, The majority vote on the leaves is defined by

$$M_h = \sum_{u \in \Lambda} \sigma(u) \ . \tag{14}$$

The estimation rule is to infer that the spin at the root is $\mathrm{sgn}\{M_h\}$, i.e., the sign of M_h. Impressively, it turns out that this estimator is optimal, i.e., it coincides with the *maximum likelihood* one. For the Δ-ary tree, one establishes reconstruction for the ferromagnetic Ising model by employing a second moment argument on the estimator M_h.

For the distributions we consider here, the above estimator is far from sufficient. This is due to various facts. Firstly, we allow for mixed couplings on the edges, i.e., certain edges can be ferromagnetic, and others can be anti-ferromagnetic. Secondly, the strength of the interaction, i.e., the magnitude of $\boldsymbol{J}_e$'s, is expected to vary from one edge to the other. To this end, we introduce a new estimator, and we establish reconstruction by building on the second moment argument from [18]. The starting point towards deriving this estimator, comes from just considering the standard anti-antiferromagnetic Ising. The statistic from (14), clearly does not work for this distribution. However, there is an easy remedy, by taking into account the parity of the height h, i.e., if h is an even, or an odd number. We infer that the spin at the root is equal to $\mathrm{sgn}\left\{\widehat{M}_h\right\}$, where

$$\widehat{M}_h = (-1)^h \sum_{u\in\Lambda} \sigma(u) \ .$$

For the spin-glass distributions we consider here, we need to get the above idea even further. Firstly, in order to accommodate the *mixed* ferromagnetic and anti-ferromagnetic couplings on the edges of the tree. It seems meaningful to use the estimator $\mathrm{sgn}\left\{\widetilde{M}_h\right\}$ for the root configuration, where

$$\widetilde{M}_h = \sum_{u\in\Lambda} \sigma(u) \prod_{e\in\mathrm{path}(r,u)} \mathrm{sign}\{\boldsymbol{J}_e\} \ ,$$

with $\mathrm{path}(r,u)$ denoting the set of edges along the unique path connecting r to u. So that in $\widetilde{M}_h$, for each leaf we essentially examine the parity of the number of antiferromagnetic couplings along the path that connects it to the root. Unfortunately, for the above estimator, our second moment argument does not seem to work all that well.

The estimator we end up using, is a *reweighted* version of $\widetilde{M}_h$, which we call the "flip majority" vote, and is defined by

$$F_h = \sum_{u\in\Lambda} \sigma(u) \prod_{e\in\mathrm{path}(r,u)} \tfrac{1-\exp(\beta\boldsymbol{J}_e)}{1+\exp(\beta\boldsymbol{J}_e)} \ .$$

Note that the absolute value of the weight for the edge e, above, coincides with the quantity $\boldsymbol{\Gamma}_e$ in (13). Naturally, the estimation rule is to infer that the root spin is $\mathrm{sgn}\{F_h\}$.

Improved Mixing for the Convex Polygon Triangulation Flip Walk

David Eppstein
Department of Computer Science, University of California, Irvine, CA, USA

Daniel Frishberg
Department of Computer Science, University of California, Irvine, CA, USA

Abstract

We prove that the well-studied *triangulation flip walk* on a convex point set mixes in time $O(n^3 \log^3 n)$, the first progress since McShine and Tetali's $O(n^5 \log n)$ bound in 1997. In the process we give lower and upper bounds of respectively $\Omega(1/(\sqrt{n} \log n))$ and $O(1/\sqrt{n})$ – asymptotically tight up to an $O(\log n)$ factor – for the *expansion* of the *associahedron* graph K_n. The upper bound recovers Molloy, Reed, and Steiger's $\Omega(n^{3/2})$ bound on the mixing time of the walk. To obtain these results, we introduce a framework consisting of a set of sufficient conditions under which a given Markov chain mixes rapidly. This framework is a purely combinatorial analogue that in some circumstances gives better results than the *projection-restriction* technique of Jerrum, Son, Tetali, and Vigoda. In particular, in addition to the result for triangulations, we show quasipolynomial mixing for the *k-angulation* flip walk on a convex point set, for fixed $k \geq 4$.

1 Introduction and background

The study of *mixing times* – the art and science of proving upper and lower bounds on the efficiency of Markov chain Monte Carlo sampling methods – is a well-established area of research, of interest for combinatorial sampling problems, spin systems in statistical physics, probability, and the study of subset systems. Work in this area brings together techniques from spectral graph theory, combinatorics, and probability, and dates back decades; for a comprehensive survey of classic methods, results, and open questions see the canonical text by Levin, Wilmer, and Peres [27]. Recent breakthroughs [1, 2, 3, 8, 9, 10, 24, 26] – incorporating techniques from the theory of abstract simplicial complexes – have led to a recent slew of results for the mixing times of combinatorial chains for sampling independent sets, matchings, Ising model configurations, and a number of other structures in graphs, injecting renewed energy into an already active area.

We focus on a class of *geometric* sampling problems that has received considerable attention from the counting and sampling [4, 22] and mixing time [29, 31, 35, 6] research communities over the last few decades, but for which tight bounds have been elusive: sampling *triangulations*. A triangulation is a maximal set of non-crossing edges connecting pairs of points (see Figure 1) in a given n-point set. Every pair of triangles sharing an edge forms a

quadrilateral. A triangulation *flip* consists of removing such an edge, and replacing it with the only other possible diagonal within the same quadrilateral. Flips give a natural Markov chain (the *flip walk*): one selects a uniformly random diagonal from a given triangulation and (if possible) flips the diagonal.

McShine and Tetali gave a classic result in a 1997 paper [29], showing that in the special case of a convex two-dimensional point set (a convex n-gon), the flip walk *mixes* (converges to approximately uniform) in time $O(n^5 \log n)$, improving on the best-known prior (and first polynomial) upper bound, $O(n^{25})$, by Molloy, Reed, and Steiger [31]. McShine and Tetali applied a Markov chain comparison technique due to Diaconis and Saloff-Coste [12] and to Randall and Tetali [32] to obtain their bound, using a bijection between triangulations and a structure known as *Dyck paths*. They noted that they could not improve on this bound using this bijection. Furthermore, they believed that an earlier *lower* bound of $\Omega(n^{3/2})$, also by Molloy, Reed, and Steiger [31], should be tight. We show the following result (see Section 3 for the precise definition of mixing time):

▶ **Theorem 1.** *The triangulation flip walk on the convex $n+2$-point set mixes in time $O(n^3 \log^3 n)$.*

Prior to the present paper, no progress had been made either on upper or lower bounds for this chain in 25 years – even as new polynomial upper bounds and exponential lower bounds were given for other geometric chains, from lattice point set triangulations [35, 6] to quadrangulations of planar maps [7], and despite many breakthroughs using the newer techniques for other problems.

In addition to this specific result, we give a general decomposition theorem – which we will state as Theorem 13 once we have built up enough preliminaries, for bounding mixing times by recursively decomposing the state space of a Markov chain. This theorem is a purely combinatorial alternative to the spectral result of Jerrum, Son, Tetali, and Vigoda [21].

1.1 Decomposition framework

To prove our result, we develop a general decomposition framework that applies to a broad class of Markov chains, as an alternative to prior work by Jerrum, Son, Tetali, and Vigoda [21] that used spectral methods. We obtain our new mixing result for triangulations, then generalize our technique to obtain the first nontrivial mixing result for k-angulations. In a companion paper [15] we further generalize this work to obtain the first rapid mixing bounds for Markov chains for sampling independent sets, dominating sets, and *b-edge covers* (generalizing edge covers) in graphs of bounded treewidth, and for maximal independent sets, b-matchings, and *maximal b-matchings* in graphs of bounded treewidth and degree. In that work we also strengthen existing results [18, 14] for proper q-colorings in graphs of bounded treewidth and degree.

The key observation that unifies these chains is that, when viewing their state spaces as graphs (exponentially large graphs relative to the input), they all admit a recursive decomposition satisfying key properties. First, each such graph, called a "flip graph," can be partitioned into a small number of induced subgraphs, where each subgraph is a *Cartesian product* of smaller graphs that are structurally similar to the original graph – and thus can be partitioned again into even smaller product graphs. Second, at each level of recursion, pairs of subgraphs are connected by large matchings. Intuitively, we can "slice" a flip graph into subgraphs that are well connected to each other, then "peel" apart the subgraphs using their Cartesian product structure, and repeat the process recursively. Each recursive level of slicing cuts through many edges (the large matchings), and indeed the peeling also

disconnects many mutually well-connected subgraphs from one another. Prior work exists applying this "slicing" and "peeling" paradigm – albeit with spectral methods instead of purely combinatorial methods – using Jerrum, Son, Tetali, and Vigoda's decomposition theorem (Theorem 14) for combinatorial chains [21, 18, 14]. One of our contributions is to unify these applications, along with the geometric chains, into a sufficient set of conditions under which one can apply the existing decomposition theorem: Lemma 15.

A more substantial technical contribution is our Theorem 13, a combinatorial analogue to Jerrum, Son, Tetali, and Vigoda's Theorem 14. One can use our theorem in place of theirs and, in some cases, obtain better mixing bounds. In particular, in the case of triangulations, we obtain polynomial mixing via an adaptation of our (combinatorial) technique (Lemma 19) – and it is not clear how to adapt the existing spectral methods to get even a polynomial bound. In the case of k-angulations, our theorem gives a bound that has better dependence on the parameter k.

1.2 Paper organization

In the remainder of this section we will define the Markov chains we are analyzing and summarize our main results. Then, in Section 2, we will give intuition for the decomposition by describing its application to triangulations. In Section 4 we will present our general decomposition meta-theorems, and compare our contribution to prior work by Jerrum, Son, Tetali, and Vigoda [21]. In particular, we will discuss why our purely combinatorial machinery is needed for obtaining new bounds in the case of triangulations. In the full version of our paper [16] we will prove a general result that gives a coarse bound on triangulation mixing; we will then improve this bound to near tightness in the full paper version, and give a matching upper bound (up to logarithmic factors) in the full version. Also in the full version, we show that general k-angulations admit a decomposition satisfying a relaxation (Lemma 18) of our general theorem that implies quasipolynomial-time mixing. We analyze the particular quasipolynomial bound we obtain, and show that our combinatorial technique (Theorem 13) gives a better dependence on k than one would obtain with the prior decomposition theorem. In the full version of the paper we prove our general combinatorial decomposition theorem, Theorem 13. In the full version we prove a theorem about lattice triangulations, and fill in a few remaining proof details.

1.3 Triangulations of convex point sets and lattice point sets

Let P_n be the regular polygon with n vertices. Every triangulation t of P_{n+2} has $n-1$ diagonals, and every diagonal can be *flipped*: every diagonal D belongs to two triangles forming a convex quadrilateral, so D can be removed and replaced with the diagonal D' lying in the same quadrilateral and crossing D. The set of all triangulations of P_{n+2}, for $n \geq 1$, is the vertex set of a graph that we denote K_n (this notation is standard), whose edges are the flips between adjacent triangulations. The graph K_n is known to be realizable as the 1-skeleton of an $n-1$-dimensional polytope [28] called the *associahedron* (we also use this name for the graph itself). It is also known to be isomorphic to the rotation graph on the set of all binary plane trees with $n+1$ leaves [34], and equivalently the set of all parenthesizations of an algebraic expression with $n+1$ terms, with "flips" defined as applications of the associative property of multiplication.

The structure of this graph depends only on the convexity and the number of vertices of the polygon, and not on its precise geometry. That is, P_{n+2} need not be regular for K_n to be well defined.

McShine and Tetali [29] showed that the *mixing time* (see Section 3) of the uniform random walk on $K_{3,n+2}$ is $O(n^5 \log n)$, following Molloy, Reed, and Steiger's [31] lower bound of $\Omega(n^{3/2})$. These bounds together can be shown, using standard inequalities [33], to imply that the *expansion* of $K_{3,n+2}$ is $\Omega(1/(n^4 \log n))$ and $O(n^{1/4})$. It is easy to generalize triangulations to *k-angulations* of a convex polygon $P_{(k-2)n+2}$, and to generalize the definition of a flip between triangulations to a flip between k-angulations: a k-angulation is a maximal division of the polygon into k-gons, and a flip consists of taking a pair of k-gons that share a diagonal, removing that diagonal, and replacing it with one of the other diagonals in the resulting $2k-2$-gon. One can then define the *k-angulation flip walk* on the k-angulations of $P_{(k-2)n+2}$. An analogous graph to the associahedron is defined over the triangulations of the integer lattice (grid) point set with n rows of points and n columns. Substantial prior work has been done on bounds for the number of triangulations in this graph ([4, 22]), as well as characterizing the mixing time of random walks on the graph, when the walks are weighted by a function of the lengths of the edges in a triangulation ([6, 5]).

1.4 Convex triangulation flip walk and mixing time

Consider the following random walk on the triangulations of the convex $n+2$-gon:

for $t = 1, 2, \ldots$ **do**
  Begin with an arbitrary triangulation t.
  Flip a fair coin.
  If the result is tails, do nothing.
  Else, select a diagonal in t uniformly at random, and flip the diagonal.
end for

(The "do nothing" step is a standard MCMC step that enforces a technical condition known as *laziness*, required for the arguments that bound mixing time.) At any given time step, this walk induces a probability distribution π over the triangulations of the $n+2$-gon. Standard spectral graph theory shows that π converges to the uniform distribution in the limit. Formally, what McShine and Tetali showed [29] is that the number of steps before π is within *total variation distance* $1/4$ of the uniform distribution is bounded by $O(n^5 \log n)$ – in other words, that the *mixing time* is $O(n^5 \log n)$. Any polynomial bound means the walk *mixes rapidly*. We formally define total variation distance:

The *total variation distance* between two probability distributions μ and ν over the same set Ω is defined as

$$d(\mu, \nu) = \frac{1}{2} \sum_{S \in \Omega} |\pi(S) - \pi^*(S)|.$$

Consider a Markov chain with state space Ω. Given a starting state $S \in \Omega$, the chain induces a probability distribution π_t at each time step t. Under certain mild conditions, all of which are satisfied by the k-angulation flip walk, this distribution is known to converge in the limit to a *stationary* distribution π^*, which for the k-angulation flip walk is the uniform distribution on the k-angulations of the convex polygon. The *mixing time* is defined as follows: Given an arbitrary $\varepsilon > 0$, the *mixing time*, $\tau(\varepsilon)$, of a Markov chain with state space Ω and stationary distribution π^* is the minimum time t such that, regardless of starting state, we always have

$$d(\pi_t, \pi^*) < \varepsilon.$$

Suppose that the chain belongs to a family of chains, whose size is parameterized by a value n. (It may be that Ω is exponential in n.) If $\tau(\varepsilon)$ is upper bounded by a function that is polynomial in $\log(1/\varepsilon)$ and in n, say that the chain is *rapidly mixing*. It is common to omit the parameter ε, assuming its value to be the arbitrary constant $1/4$.

1.5 Main results

We show the following result for the expansion of the associahedron:

▶ **Theorem 2.** *The expansion of the associahedron $K_{3,n+2}$ is $\Omega(1/(\sqrt{n}\log n))$ and $O(1/\sqrt{n})$.*

We will prove the lower bound in the full paper version [16] using the *multicommodity flow*-based machinery we introduce in Section 4, after giving intuition in Section 2. Combining this result with the connection between flows and mixing [33] – with some additional effort in the full version – gives our new $O(n^3 \log^3 n)$ bound (Theorem 1) for triangulation mixing.

Although the expansion lower bound is more interesting for the sake of rapid mixing, the upper bound in Theorem 2 – which we prove in the full version – recovers Molloy, Reed, and Steiger's $\Omega(n^{3/2})$ mixing lower bound [31]. It is also the first result showing that the associahedron has combinatorial expansion $o(1)$. By contrast, Anari, Liu, Oveis Gharan, and Vinzant recently proved [3, 2], settling a conjecture of Mihail and Vazirani [30], that matroids have expansion one. (Mihail and Vazirani in fact conjectured that all graphs realizable as the 1-skeleton of a *0-1 polytope* have expansion one.) Although the set of convex n-gon triangulations is not a matroid, it is an important subset system – and this work shows that it does not have expansion one. More generally, we give the following quasipolynomial bound for k-angulations:

▶ **Theorem 3.** *For every fixed $k \geq 3$, the k-angulation flip walk on the convex $(k-2)n+2$-point set mixes in time $n^{O(k \log n)}$.*

In the full version of the paper [16], we give a lower bound on the *treewidth* of the $n \times n$ integer lattice point set triangulation flip graph:

▶ **Theorem 4.** *The treewidth of the triangulation flip graph F_n on the $n \times n$ integer lattice point set is $\Omega(N^{1-o(1)})$, where $N = |V(F_n)|$.*

2 Decomposing the convex point set triangulation flip graph

2.1 Bounding mixing via expansion

We have a Markov chain that is in fact a random walk on the associahedron K_n. We wish to bound the mixing time of this walk. It turns out that one way to do this is by lower-bounding the *expansion* of the same graph K_n. Intuitively, expansion concerns the extent to which "bottlenecks" exist in a graph. More precisely, it measures the "sparsest" cut – the minimum ratio of the number of edges in a cut divided by the number of vertices on the smaller side of the cut:

The *edge expansion* (or simply *expansion*), $h(G)$, of a graph $G = (V, E)$ is the quantity

$$\min_{S \subseteq V : |S| \leq |V|/2} |\partial S|/|S|,$$

where $\partial S = \{(s,t) | s \in S, t \notin S\}$ is the set of edges across the $(S, V \setminus S)$ cut. It is known [20, 33] that a lower bound on edge expansion leads to an upper bound on mixing:

▶ **Lemma 5.** *The mixing time of the Markov chain whose transition matrix is the normalized adjacency matrix of a Δ-regular graph G is*

$$O\left(\frac{\Delta^2 \log(|V(G)|)}{(h(G))^2}\right).$$

One can do better [13, 33] if the paths in a *multicommodity flow* are not too long (Section 3).

2.2 "Slicing and peeling"

We would like to show that there are many edges in every cut, relative to the number of vertices on one side of the cut. We partition the triangulations $V(K_n)$ into n equivalence classes, each inducing a subgraph of K_n. We show that many edges exist between each pair of the subgraphs. Thus the partitioning "slices" through many edges. After the partitioning, we show that each of the induced subgraphs has large expansion. To do so, we show that each such subgraph decomposes into many copies of a smaller flip graph K_i, $i < n$. This inductive structure lets us assume that K_i has large expansion – then show that the copies of the smaller flip graph are all well connected to one another. We call this "peeling," because one must peel the many K_i copies from one another – removing many edges – to isolate each copy. Molloy, Reed, and Steiger [31] obtained their $O(n^{25})$ mixing *upper* bound via a different decomposition, namely using the *central* triangle, via a non-flow-based method. That decomposition is the one we use for our quasipolynomial bound for general k-angulations in the full paper version. However, we use a different decomposition here, one with a structure that lets us obtain a nearly tight bound, via a multicommodity flow construction. We formalize the slicing step now:

Fix a "special" edge e^* of the convex $n+2$-gon P_{n+2}. For each triangle T having e^* as one of its edges, define the *oriented class* $\mathcal{C}^*(T)$ to be the set of triangulations of P_{n+2} that include T as one of their triangles. Let $\mathcal{T}_n$ be the set of all such triangles; let $\mathcal{S}_n$ be the set of all classes $\{\mathcal{C}^*(T)|T \in \mathcal{T}_n\}$.

Orient P_{n+2} so that e^* is on the bottom. Then say that T (respectively $\mathcal{C}^*(T)$) is to the *left* of T' (respectively $\mathcal{C}^*(T')$) if the topmost vertex of T lies counterclockwise around P_{n+2} from the topmost vertex of T'. Say that T' lies to the *right* of T. Write $T < T'$ and $T' > T$.

See Figure 1.

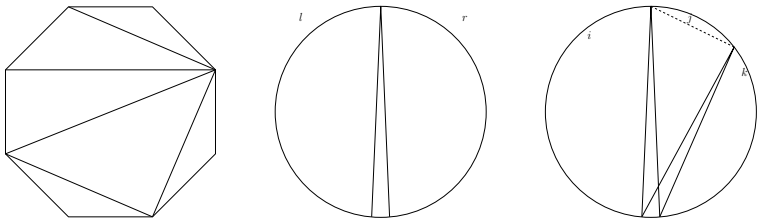

Figure 1 Left: A triangulation of the regular octagon. Center: a class $\mathcal{C}^*(T) \in \mathcal{S}_n$, represented schematically by the triangle T that induces it. We depict the regular $n+2$-gon as a circle (which it approximates as $n \to \infty$), for ease of illustration. Each triangulation $t \in \mathcal{C}^*(T)$ consists of T (the triangle shown), and an arbitrary triangulation of the two polygons on either side of T. Notice that $\mathcal{C}^*(T) \cong K_l \square K_r$, where T partitions the $n+2$-gon into an l-gon and an r-gon. Right: the matching $\mathcal{E}^*(T, T')$ between classes $\mathcal{C}^*(T) \cong K_i \square K_{j+k}$ and $\mathcal{C}^*(T') \cong K_{i+j} \square K_k$, is in bijection with the triangulations in $K_i \square K_j \square K_k$ (induced by the quadrilateral containing T and T'). Therefore, $|\mathcal{E}^*(T, T')| = C_i C_j C_k$.

We make observations about the structure of each class as an induced subgraph of K_n.

The *Cartesian product* graph $G \square H$ of graphs G and H has vertices $V(G) \times V(H)$ and edges

$$\{((u,v),(u',v))|(u,u') \in E(G), v \in V(H)\}$$

$$\cup\{((u,v),(u,v'))|(v,v') \in E(H), u \in V(G)\}.$$

Given a vertex $w = (u,v) \in V(G) \times V(H)$, call u the *projection* of w onto G, and similarly call v the projection of w onto H. (Applying the obvious associativity of the Cartesian product operator, one can naturally define the product $G_1 \square G_2 \square \cdots \square G_k = \square_{i=1}^{k} G_i$.)

We can now characterize the structure of each class as an induced subgraph of K_n:

▶ **Lemma 6.** *Each class $\mathcal{C}^*(T)$ is isomorphic to a Cartesian product of two associahedron graphs K_l and K_r, with $l + r = n - 1$.*

Proof. Each triangle T partitions the $n + 2$-gon into two smaller convex polygons with side lengths $l + 1$ and $r + 1$, such that $l + r = n - 1$. Thus each triangulation in $\mathcal{C}^*(T)$ can be identified with a tuple of triangulations of these smaller polygons. The Cartesian product structure then follows from the fact that every flip between two triangulations in $\mathcal{C}^*(T)$ can be identified with a flip in one of the smaller polygons. ◀

Lemma 6 will be central to the peeling step. For the slicing step, building on the idea in Lemma 6 will help us characterize the edge sets between classes:

Given classes $\mathcal{C}^*(T), \mathcal{C}^*(T') \in \mathcal{S}_n$, denote by $\mathcal{E}^*(T, T')$ the set of edges (flips) between $\mathcal{C}^*(T)$ and $\mathcal{C}^*(T')$. Let $\mathcal{B}^*_{n,T'}(T)$ and $\mathcal{B}^*_{n,T}(T')$ be the *boundary sets* – the sets of endpoints of edges in $\mathcal{E}^*(T, T')$ – that lie respectively in $\mathcal{C}^*(T)$ and $\mathcal{C}^*(T')$.

▶ **Lemma 7.** *For each pair of classes $\mathcal{C}^*(T)$ and $\mathcal{C}^*(T')$, the boundary set $\mathcal{B}^*_{n,T'}(T)$ induces a subgraph of $\mathcal{C}^*(T)$ isomorphic to a Cartesian product of the form $K_i \square K_j \square K_k$, for some $i + j + k = n - 2$.*

Proof. Each flip between triangulations in adjacent classes $\mathcal{C}^*(T)$ involves flipping a diagonal of T to transform the triangulation $t \in \mathcal{C}^*(T)$ into triangulation $t' \in \mathcal{C}^*(T')$. Whenever this is possible, there must exist a quadrilateral Q, sharing two sides with T (the sides that are not flipped), such that both t and t' contain Q. Furthermore, every $t \in \mathcal{C}^*(T)$ containing Q has a flip to a distinct $t' \in \mathcal{C}^*(T')$. The set of all such boundary vertices $t \in \mathcal{C}^*(T)$ can be identified with the Cartesian product described because Q partitions P_{n+2} into three smaller polygons, so that each triangulation in $\mathcal{B}^*_{n,T'}(T)$ consists of a tuple of triangulations in each of these smaller polygons, and such that every flip between triangulations in $\mathcal{B}^*_{n,T'}(T)$ consists of a flip in one of these smaller polygons. ◀

▶ **Lemma 8.** *The set $\mathcal{E}^*(T, T')$ of edges between each pair of classes $\mathcal{C}^*(T)$ and $\mathcal{C}^*(T')$ is a nonempty matching. Furthermore, this edge set is in bijection with the vertices of a Cartesian product $K_i \square K_j \square K_k, i + j + k = n - 2$.*

Proof. The claim follows from the reasoning in Lemma 7 and from the observation that each triangulation in $\mathcal{B}^*_{n,T'}(T)$ has exactly one flip (namely, flipping a side of the triangle T) to a neighbor in $\mathcal{B}^*_{n,T}(T')$. ◀

Lemma 8 characterizes the structure of the edge sets (namely matchings) between classes; we would also like to know the sizes of the matchings. We will use the following formula:

Let C_n be the nth *Catalan number*, defined as $C_n = \frac{1}{n+1}\binom{2n}{n}$.

▶ **Lemma 9** ([25, 19])**.** *The number of vertices in the associahedron K_n is C_n, and this number grows as $\frac{1}{\sqrt{\pi} \cdot n^{3/2}} \cdot 2^{2n}$.*

We will prove the following in the full version of our paper [16]:

▶ **Lemma 10.** *For every $T, T' \in \mathcal{T}_n$,*

$$|\mathcal{E}^*(T, T')| \geq \frac{|\mathcal{C}^*(T)||\mathcal{C}^*(T')|}{C_n}.$$

Lemma 10 – which states that the number of edges between a pair of classes is at least equal to the product of the cardinalities of the classes, divided by the total number of vertices in the graph $|V(K_n)| = C_n$ – is crucial to this paper. To explain why this is, we will need to present our multicommodity flow construction (in the full version of the paper [16]). We will give intuition in Section 4. For now, it suffices to say that Lemma 10 implies that there are many edges between a given pair of classes, justifying (intuitively) the slicing step. For the peeling step, we need the fact that Cartesian graph products preserve the well-connectedness of the graphs in the product [17]:

▶ **Lemma 11.** *Given graphs $G_1, G_2, \ldots, G_k$, Cartesian product $G_1 \square G_2 \square \cdots \square G_k$ satisfies*

$$h(G_1 \square G_2 \square \cdots \square G_k) \geq \frac{1}{2} \min_i h(G_i).$$

Lemma 6 says that each of the classes $\mathcal{C}^*(T) \in \mathcal{S}_n$ is a Cartesian graph product of associahedron graphs K_l, K_r, $l < n, r < n$, allowing us to "peel" (decompose) $\mathcal{C}^*(T)$ into graphs that can then be recursively sliced into classes and peeled. Lemma 11 implies that the peeling must disconnect many edges, as it involves splitting a Cartesian product graph into many subgraphs (copies of K_l).

We will make all of this intuition rigorous in the full paper version by constructing our flow. The choice of paths through which to route flow will closely trace the edges in this recursive "slicing and peeling" decomposition. We will then show that, with this choice of paths, the resulting *congestion* – the maximum amount of flow carried along an edge – is bounded by a suitable polynomial factor. This will provide a lower bound on the expansion.

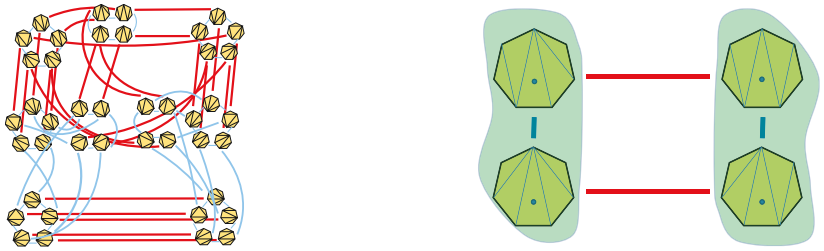

Figure 2 Left: The associahedron graph K_5, with each vertex representing a triangulation of the regular heptagon. Flips are shown with edges (in blue and red). The vertex set $V(K_n)$ is partitioned into a set $\mathcal{S}_n$ of five equivalence classes (of varying sizes). Within each class, all triangulations share the same triangle containing the bottom edge e^*. Flips (edges) between triangulations in the same class are shown in blue. Flips between triangulations in different classes are shown in red. To "slice" K_5 into its subgraphs, one must cut through these red matchings. **Right**: A class $\mathcal{C}^*(T)$ from the graph K_5 on the left-hand side, viewed as an induced subgraph of K_5. The identifying triangle T is marked with a blue dot. This subgraph is isomorphic to a Cartesian product of two K_2 graphs; each copy of K_2 induced by fixing the rightmost diagonal is outlined in green. "Peeling" apart this product requires disconnecting the two red edges connecting the K_2 copies.

3 Bounding expansion via multicommodity flows

The way we will lower-bound expansion is by using *multicommodity flows* [33, 23]. A *multicommodity flow* ϕ in a graph $G = (V, E)$ is a collection of functions $\{f_{st} : A \to \mathbb{R} \mid s, t \in V\}$, where $A = \bigcup_{\{u,v\} \in E} \{(u, v), (v, u)\}$, combined with a *demand function* $D : V \times V \to \mathbb{R}$.

Each f_{st} is a flow sending $D(s,t)$ units of a commodity from vertex s to vertex t through the edges of G. We consider the capacities of all edges to be infinite. Let $f_{st}(u,v)$ be the amount of flow sent by f_{st} across the arc (u,v). (It may be that $f_{st}(u,v) \neq f_{st}(v,u)$.) Let

$$f(u,v) = \frac{1}{|V|} \sum_{s,t \in V \times V} f_{st}(u,v),$$

and let $\rho = \max_{(u,v)\in A} f(u,v)$. Call ρ the *congestion*. Unless we specify otherwise, we will mean by "multicommodity flow" a *uniform multicommodity flow*, i.e. one in which $D(s,t) = 1$ for all s,t. The following is well established and enables the use of multicommodity flows as a powerful lower-bounding technique for expansion:

▶ **Lemma 12.** *Given a uniform multicommodity flow f in a graph $G = (V,E)$ with congestion ρ, the expansion $h(G)$ is at least $1/(2\rho)$.*

Lemma 12, combined with Lemma 5, gives an automatic upper bound on mixing time given a multicommodity flow with an upper bound on congestion – but with a quadratic loss. As we will discuss in the full paper version, one can do better if the paths used in the flow are short [13, 33].

4 Our framework

In addition to the new mixing bounds for triangulations and for general k-angulations, we make general technical contributions, in the form of three meta-theorems, which we present in this section. Our first general technical contribution, Theorem 13, provides a recursive mechanism for analyzing the expansion of a flip graph in terms of the expansion of its subgraphs. Equivalently, viewing the random walk on such a flip graph as a Markov chain, this theorem provides a mechanism for analyzing the mixing time of a chain, in terms of the mixing times of smaller *restriction* chains into which one decomposes the original chain – and analyzing a *projection* chain over these smaller chains. We obtain, in certain circumstances such as the k-angulation walk, better mixing time bounds than one obtains applying similar prior decomposition theorems – which used a different underlying machinery.

The second theorem, Lemma 15, observes and formalizes a set of conditions satisfied by a number of chains (equivalently, flip graphs) under which one can apply either our Theorem 13, or prior decomposition techniques, to obtain rapid mixing reuslts. Depending on the chain, one may then obtain better results either by applying Theorem 13, or by applying the prior techniques. Lemma 15 does not require using our Theorem 13; instead, one can use the spectral gap or log-Sobolev constant as the underlying techincal machinery using Jerrum, Son, Tetali, and Vigoda's Theorem 14. Prior work exists applying these techniques (using Theorem 14) to sampling q-colorings [18] in bounded-treewidth graphs and independent sets in regular trees [21], as well as probabilistic graphical models in machine learning [11] satisfying certain conditions. Lemma 15 amounts to an observation unifying these applications. We apply this observation to general k-angulations, noting that they satisfy a relaxation of this theorem (Lemma 18), giving a quasipolynomial bound. This bound will come from incurring a polynomial loss over logarithmic recursion depth.

The third theorem, Lemma 19, adapts the machinery in Theorem 13 to eliminate this multiplicative loss altogether, assuming that a chain satisfies certain properties. One such key property is the existence large matchings in Lemma 10 in Section 2. Another property, which we will discuss further after presenting Lemma 19, is that the *boundary sets* – the vertices in one class (equivalently, states in a restriction chain) having neighbors in another class –

are well connected to the rest of the first class. When these properties are satisfied, one can apply our flow machinery to overcome the multiplicative loss and obtain a polynomial bound. However, the improvement relies on observations about congestion that do not obviously translate to the spectral setting.

4.1 Markov chain decomposition via multicommodity flow

In this section we state our first general theorem. To place our contribution in context with prior work, we cast our flip graphs in the language of Markov chains. As we discussed in Section 1.4, any Markov chain satisfying certain mild conditions has a *stationary* distribution π^* (which in the case of our triangulation walks is uniform). We can view such a chain as a random walk on a graph $\mathcal{M}$ (an unweighted graph in the case of the chains we consider, which have uniform distributions and regular transition probabilities). In the case of convex polygon triangulations, we have $\mathcal{M} = K_n$.

The flip graph $\mathcal{M}$ has vertex set Ω and (up to normalization by degree) adjacency matrix P – and we abuse notation, identifying the Markov chain $\mathcal{M}$ with this graph. When π^* is not uniform, it is easy to generalize the flip graph to a *weighted* graph, with each vertex (state) t assigned weight $\pi(t)$, and each transition (edge) (t, t') assigned weight $\pi(t)P(t, t') = \pi(t')P(t', t)$. We assume here that this latter equality holds, a condition on the chain $\mathcal{M}$ known as *reversibility*. We then replace a uniform multicommodity flow with one where $D(t, t') = \pi(t)\pi(t')$ (up to normalization factors).

Consider a Markov chain $\mathcal{M}$ with finite state space Ω and probability transition matrix P, and stationary distribution π. Consider a partition of the states of Ω into classes $\Omega_1, \Omega_2, \ldots, \Omega_k$. Let the *restriction* chain, for $i = 1, \ldots, k$, be the chain with state space Ω_i, probability distribution π_i, with $\pi_i(x) = \pi(x)/(\sum_{y\in\Omega_i} \pi(y))$, for $x \in \Omega_i$, and transition probabilities $P_i(x, y) = P(x, y)/(\sum_{z\in\Omega_i} P(x, z))$. Let the *projection* chain be the chain with state space $\bar{\Omega} = \{1, 2, \ldots, k\}$, stationary distribution $\bar{\pi}$, with $\bar{\pi}(i) = \sum_{x\in\Omega_i} \pi(i)$, and transition probabilities $\bar{P}(i, j) = \sum_{x\in\Omega_i, y\in\Omega_j} P(x, y)$.

▶ **Theorem 13.** *Let $\mathcal{M}$ be a reversible Markov chain with finite state space Ω probability transition matrix P, and stationary distribution π^*. Suppose $\mathcal{M}$ is connected (irreducible). Suppose $\mathcal{M}$ can be decomposed into a collection of restriction chains $(\Omega_1, P_1), (\Omega_2, P_2), \ldots, (\Omega_k, P_k)$, and a projection chain $(\bar{\Omega}, \bar{P})$. Suppose each restriction chain admits a multicommodity flow (or canonical paths) construction with congestion at most $\rho_{\max}$. Suppose also that there exists a multicommodity flow construction in the projection chain with congestion at most $\bar{\rho}$. Then there exists a multicommodity flow construction in $\mathcal{M}$ (viewed as a weighted graph in the natural way) with congestion*

$$(1 + 2\bar{\rho}\gamma\Delta)\rho_{\max},$$

where $\gamma = \max_{i\in[k]} \max_{x\in\Omega_i} \sum_{y\notin\Omega_i} P(x, y)$, and Δ is the degree of $\mathcal{M}$.

We give a full proof in the full version of the paper. Jerrum, Son, Tetali, and Vigoda [21] presented an analogous (and classic) decomposition theorem, which we restate below as Theorem 14, and which has become a standard tool in mixing time analysis. The key difference between our theorem and theirs is that our theorem uses multicommodity flows, while their theorem uses the so-called *spectral gap* – another parameter that can use to bound the mixing time of a chain. Often, the spectral gap gives tighter mixing bounds than combinatorial methods. Their Theorem 14 gave bounds analogous to our Theorem 13, but with the multicommodity flow congestion replaced with the *spectral gap* of a chain

– and with a 3γ term in place of our 2γ. (They also gave an analogous version for the *log-Sobolev* constant – yet another parameter for bounding mixing times.) The spectral gap of a chain $\mathcal{M} = (\Omega, P)$, which we denote λ, is the difference between the two largest eigenvalues of the transition matrix P (which we can view as the normalized adjacency matrix of the corresponding weighted graph). The key point is that while on the one hand the mixing time τ satisfies $\tau \leq \lambda^{-1} \log |\Omega|$, the bound on mixing using expansion in Lemma 5 comes from passing through the spectral gap: $\lambda \geq \frac{(h(\mathcal{M}))^2}{2\Delta^2}$, where Δ is the degree of the flip graph and $h(\mathcal{M})$ is the expansion of $\mathcal{M}$. The quadratic loss in passing from expansion to mixing is not incurred when bounding the spectral gap directly, so one can obtain better bounds via the spectral gap. Jerrum, Son, Tetali, and Vigoda gave a mechanism for doing precisely this:

▶ **Theorem 14** ([21]). *Let $\mathcal{M}$ be a reversible Markov chain with finite state space Ω probability transition matrix P, and stationary distribution π^*. Suppose $\mathcal{M}$ is connected (irreducible). Suppose $\mathcal{M}$ can be decomposed into a collection of restriction chains $(\Omega_1, P_1), (\Omega_2, P_2), \ldots, (\Omega_k, P_k)$, and a projection chain $(\bar{\Omega}, \bar{P})$. Suppose each restriction chain has spectral gap at least $\lambda_{\min}$. Suppose also that the projection chain has spectral gap at least $\bar{\lambda}$. Then $\mathcal{M}$ has gap at least*

$$\min\left\{\frac{\lambda_{\min}}{3}, \frac{\bar{\lambda}\lambda_{\min}}{3\gamma + \bar{\lambda}}\right\},$$

where γ is as in Theorem 13.

Our Theorem 13 has a simple, purely combinatorial proof (in the full paper version), and fills a gap in the literature by showing that such a construction can be used in place of the spectral machinery from the earlier technique. We also obtain a tighter bound on expansion than would result from a black-box application of Theorem 14. The cost to our improvement is in passing from expansion to mixing via the spectral gap. Nonetheless, we will show that in the case of triangulations, our Theorem 13 can be adapted to give a new mixing bound whereas, by contrast, it is not clear how to obtain even a polynomial bound adapting Jerrum, Son, Tetali, and Vigoda's spectral machinery. We will also show that for general k-angulations, one can, with our technique, use a combinatorial insight to eliminate the γ factor in our decomposition in favor of a Δ^{-1} factor (for k-angulations we have $\gamma = k/\Delta$) – whereas it is not clear how to do so with the spectral decomposition.

4.2 General pattern for bounding projection chain congestion

Our second decomposition theorem, which we will apply to general k-angulations, states that if one can recursively decompose a chain into restriction chains in a particular fashion, and if the projection chain is well connected, then Theorem 13 gives an expansion bound:

▶ **Lemma 15.** *Let $\mathcal{F} = \{\mathcal{M}_1, \mathcal{M}_2, \ldots\}$ be a family of connected graphs, parameterized by a value n. Suppose that every graph $\mathcal{M}_n = (\mathcal{V}_n, \mathcal{E}_n) \in \mathcal{F}$, for $n \geq 2$, can be partitioned into a set $\mathcal{S}_n$ of classes satisfying the following conditions:*

1. *Each class in $\mathcal{S}_n$ is isomorphic to a Cartesian product of one or more graphs $\mathcal{C}(T) \cong \mathcal{M}_{i_1} \square \cdots \mathcal{M}_{i_k}$, where for each such graph $\mathcal{M}_{i_j} \in \mathcal{F}$, $i_j \leq n/2$.*
2. *The number of classes is $O(1)$.*
3. *For every pair of classes $\mathcal{C}(T), \mathcal{C}(T') \in \mathcal{S}_n$ that share an edge, the number of edges between the two classes is $\Omega(1)$ times the size of each of the two classes.*
4. *The ratio of the sizes of any two classes is $\Theta(1)$.*

Suppose further that $|\mathcal{V}_1| = 1$. Then the expansion of $\mathcal{M}_n$ is $\Omega(n^{-O(1)})$.

Lemma 15 is easy to prove given Theorem 13. An analogue in terms of spectral gap is easy to prove given Theorem 14. Furthermore, as we will prove in the full paper version, a precise statement of the bounds given by Lemma 15 is as follows:

▶ **Lemma 16.** *Suppose a flip graph $\mathcal{M}_n = (\mathcal{V}_n, \mathcal{E}_n)$ belongs to a family $\mathcal{F}$ of graphs satisfying the conditions of Lemma 15. Suppose further that every graph $\mathcal{M}_k = (\mathcal{V}_k, \mathcal{E}_k) \in \mathcal{F}$, $k < n$, satisfies*

$$|\mathcal{V}_k|/|\mathcal{E}_{k,\min}| \leq f(k),$$

for some function $f(k)$, where $\mathcal{E}_{k,\min}$ is the smallest edge set between adjacent classes $\mathcal{C}(T), \mathcal{C}(T') \in \mathcal{S}_k$, where $\mathcal{S}_k$ is as in Lemma 15. Then the expansion of $\mathcal{M}_n$ is

$$\Omega(1/(2f(n))^{\log n})),$$

where γ is as in Theorem 13, and Δ is the degree of $\mathcal{M}_n$.

Proof. Constructing an arbitrary multicommodity flow (or set of canonical paths) in the projection graph at each inductive step gives the result claimed. The term $|\mathcal{V}_k|/|\mathcal{E}_{k,\min}|$ bounds the (normalized) congestion in any such flow because the total amount of flow exchanged by all pairs of vertices (states) combined is $|\mathcal{V}_k|^2$, and the minimum weight of an edge in the projection graph is $|\mathcal{E}_{k,\min}|$.

Notice that we do not incur a $\gamma\Delta$ term here, because even if a state (vertex) in $\Omega_i \subseteq \mathcal{V}_k$ has neighbors $x \in \Omega_j, y \in \Omega_l$, z still only receives no more than $|\mathcal{V}_k|^2/\mathcal{E}_{k,\min}\}$ flow across the edges (z, x) and (z, y) combined. ◀

▶ Remark 17. The $\gamma\Delta$ factor in Theorem 13, which does not appear in Lemma 16, does appear in a straightforward appliation of Jerrum, Son, Tetali, and Vigoda's Theorem 14.

We will show that k-angulations (with fixed $k \geq 4$) satisfy a relaxation of Lemma 15:

▶ **Lemma 18.** *Suppose a family $\mathcal{F}$ of graphs satisfies the conditions of Lemma 15, with the $\Omega(1)$, $O(1)$, and $\Theta(1)$ factors in Conditions 3, 2, and 4 respectively replaced by $\Omega(n^{-O(1)})$, $O(n^{O(1)})$, and $\Theta(n^{O(1)})$. Then for every $\mathcal{M}_n \in \mathcal{F}$, the expansion of $\mathcal{M}_n$ is $\Omega(n^{-O(\log n)})$.*

Lemma 15 enables us to relate a number of chains admitting a certain decomposition process in a black-box fashion, unifying prior work applying Theorem 14 separately to individual chains. Marc Heinrich [18] presented a similar but less general construction for the Glauber dynamics on q-colorings in bounded-treewidth graphs; other precursors exist, including for the hardcore model on certain trees [21] and a general argument for a class of graphical models [11]. In the companion paper [15] we mentioned in Section 1, we apply Lemma 15 to chains for sampling independent sets and dominating sets in bounded-treewidth graphs, as well as chains on q-colorings, maximal independent sets, and several other structures, in graphs whose treewidth and degree are bounded.

4.3 Eliminating inductive loss: nearly tight conductance for triangulations

We now give the meta-theorem that we will apply to triangulations. Lemma 15 – using either Theorem 13 or Theorem 14 – gives a merely quasipolynomial bound when applied straightforwardly to k-angulations, including the case of triangulations – simply because the $f(n)$ term in Lemma 16 is $\omega(1)$ and thus the overall congestion is $\omega(1)^{\log n}$ (not polynomial). However, it turns out that the large matchings given by Lemma 10 between pairs of classes

in the case of triangulations (but not general k-angulations), combined with some additional structure in the triangulation flip walk, satisfy an alternative set of conditions that suffice for rapid mixing. The conditions are:

▶ **Lemma 19.** *Let $\mathcal{F} = \{\mathcal{M}_1, \mathcal{M}_2, \dots\}$ be an infinite family of connected graphs, parameterized by a value n. Suppose that for every graph $\mathcal{M}_n = (\mathcal{V}_n, \mathcal{E}_n) \in \mathcal{F}$, for $n \geq 2$, the vertex set $\mathcal{V}_n$ can be partitioned into a set $\mathcal{S}_n$ of classes inducing subgraphs of $\mathcal{M}_n$ that satisfy the following conditions:*

1. *Each subgraph is isomorphic to a Cartesian product of one or more graphs $\mathcal{C}(T) \cong \mathcal{M}_{i_1} \square \cdots \mathcal{M}_{i_k}$, where for each such graph $\mathcal{M}_{i_j} \in \mathcal{F}$, $i_j < n$.*
2. *The number of classes is $n^{O(1)}$.*
3. *For every pair of classes $\mathcal{C}(T), \mathcal{C}(T') \in \mathcal{S}_n$, the set of edges between the subgraphs induced by the two classes is a matching of size at least $\frac{|\mathcal{C}(T)||\mathcal{C}(T')|}{|\mathcal{V}_n|}$.*
4. *Given a pair of classes $\mathcal{C}(T), \mathcal{C}(T') \in \mathcal{S}_n$, there exists a graph $\mathcal{M}_i$ in the Cartesian product $\mathcal{C}(T)$, and a class $\mathcal{C}(U) \in \mathcal{S}_i$ within the graph $\mathcal{M}_i$, such that the set of vertices in $\mathcal{C}(T)$ having a neighbor in $\mathcal{C}(T')$ is precisely the set of vertices in $\mathcal{C}(T)$ whose projection onto $\mathcal{M}_i$ lies in $\mathcal{C}(U)$. Furthermore, no class $\mathcal{C}(U)$ within $\mathcal{M}_i$ is the projection of more than one such boundary.*

Suppose further that $|\mathcal{V}_1| = 1$. Then the expansion of $\mathcal{M}_n$ is $\Omega(1/(\kappa(n)n))$, where $\kappa(n) = \max_{1 \leq i \leq n} |\mathcal{C}(S_i)|$ is the maximum number of classes in any $\mathcal{M}_i, i \leq n$.

Unlike Lemma 15, this lemma requires a purely combinatorial construction; it is not clear how to apply spectral methods to obtain even a polynomial bound. Condition 4 is crucial. To give more intuition for this condition, we state and prove the following fact about the triangulation flip graph (visualized in Figure 3):

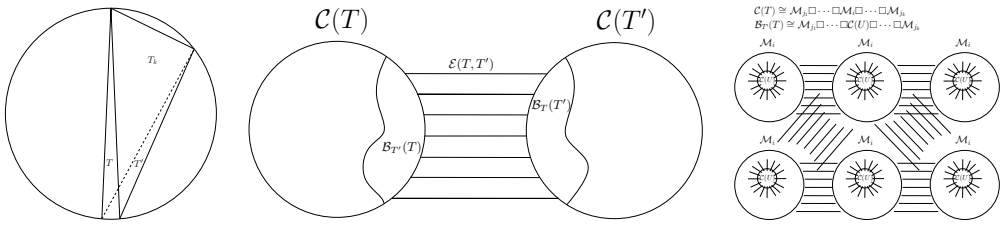

Figure 3 Left: (Lemma 20) The set of edges $\mathcal{E}^*(T, T')$ has $K_i \square \mathcal{C}^*(T_k)$ as its set of boundary vertices in $\mathcal{C}^*(T)$. **Center**: An illustration of Condition 3 in Lemma 19, showing a large matching $\mathcal{E}(T, T')$ between two classes (subgraphs) $\mathcal{C}(T)$ and $\mathcal{C}(T')$. **Right**: An illustration of Conditions 1 and 4 in Lemma 19: $\mathcal{C}(T)$ as a Cartesian product of smaller graphs $\mathcal{M}_{j_1}, \dots, \mathcal{M}_i, \dots, \mathcal{M}_{j_k}$ in the family $\mathcal{F}$. The schematic view shows this Cartesian product as a collection of copies of $\mathcal{M}_i$, connected via perfect matchings between pairs of the copies – with the pairs to connect determined by the structure of the Cartesian product. The boundary $\mathcal{B}_{T'}(T)$ (center) is isomorphic to a class $\mathcal{C}(U)$ (right) within $\mathcal{M}_i$, a graph in the product. Within each copy of $\mathcal{M}_i$, many edges connect $\mathcal{C}(U)$ to the rest of $\mathcal{M}_i$.

▶ **Lemma 20.** *Given $T, T' \in \mathcal{T}_n$, suppose T' lies to the right of T. Then the subgraph of $\mathcal{C}^*(T)$ induced by $\mathcal{B}^*_{n,T'}(T)$ is isomorphic to a Cartesian product $K_l \square \mathcal{C}^*(T_k)$, where $l + r = n - 1$, and where T_k has as an edge the right diagonal of T, and as the vertex opposite this edge the topmost vertex of T'. A symmetric fact holds for $\mathcal{B}^*_{n,T}(T')$.*

Proof. Every triangulation in $\mathcal{B}^*_{n,T'}(T)$ (i) includes the triangle T and (ii) is a single flip away from including the triangle T'. As we observed in the proof of Lemma 7, this implies that $\mathcal{B}^*_{n,T'}(T)$ consists of the set of triangulations in $\mathcal{C}^*(T)$ containing a quadrilateral Q.

Specifically, Q shares two sides with T: one of these is e^*, and the other is the left side of T. One of the other two sides of Q is the right side of $\mathcal{C}^*(T')$. Combining this side with the "top" side of Q and with the right side of T, one obtains the triangle T_k, proving the claim. ◀

Lemma 20 implies that there are many edges between the boundary set $\mathcal{B}^*_{n,T'}(T)$ and the rest of $\mathcal{C}^*(T)$: $\mathcal{C}^*(T) \cong K_l \square K_r$, where K_l and K_r are smaller associahedron graphs, so $\mathcal{C}^*(T)$ is a collection of copies of K_r, with pairs of copies connected by perfect matchings. Each K_r copy can itself be decomposed into a set $\mathcal{S}_r$ of classes, one of which, namely $\mathcal{C}^*(T_k)$, is the intersection of $\mathcal{B}^*_{n,T'}(T)$ with the K_r copy. Applying Condition 3 to the K_r copy implies that there are many edges between boundary vertices in $\mathcal{C}^*(T_k)$ to other subgraphs (classes) in the K_r copy. That is, the boundary set $\mathcal{B}^*_{n,T'}(T)$ is well connected to the rest of $\mathcal{C}^*(T)$.

Figure 3 visualizes this situation in general terms for the framework. We have now proven:

▶ **Lemma 21.** *The associahedron graph K_n, along with the oriented partition we have defined, satisfies the conditions of Lemma 19.*

Proof. The connectedness of K_n is known [29]. Conditions 1 and 3 follow from Lemma 6, Lemma 8, and Lemma 10. Concerning the boundary sets, Condition 4 follows from Lemma 20 and from the discussion leading to this lemma. ◀

Together with Lemma 5 and the easy fact that K_n is a $\Theta(n)$-regular graph, Lemma 21 implies rapid mixing, pending the proof of Lemma 19 – which we prove in the full paper version [16].

4.4 Intuition for the flow construction for triangulations

We will prove Lemma 19 in the full paper version, from which a coarse expansion lower bound for triangulations – and a corresponding coarse (but polynomial) upper bound for mixing – will be immediate by Lemma 21. We give some intuition now for the flow construction we will give in the proof of Lemma 19, and in particular for the centrality of Condition 3 and Condition 4 (corresponding respectively to Lemma 10 and Lemma 20 for triangulations). Consider the case of triangulations, for concreteness. Every $t \in \mathcal{C}^*(T), t' \in \mathcal{C}^*(T')$ must exchange a unit of flow. This means that a total of $|\mathcal{C}^*(T)||\mathcal{C}^*(T')|$ flow must be sent across the matching $\mathcal{E}^*(T,T')$. To minimize congestion, it will be optimal to equally distribute this flow across all of the boundary matching edges. We can decompose the overall problem of routing flow from each $t \in \mathcal{C}^*(T)$ to each $t' \in \mathcal{C}^*(T')$ into three subproblems: (i) *concentrating* flow from every triangulation in $\mathcal{C}^*(T)$ within the boundary set $\mathcal{B}^*_{n,T'}(T)$, (ii) routing flow across the matching edges $\mathcal{E}^*(T,T')$, i.e. from $\mathcal{B}^*_{n,T'}(T) \subseteq \mathcal{C}^*(T)$ to $\mathcal{B}^*_{n,T}(T') \subseteq \mathcal{C}^*(T')$, and (iii) *distributing* flow from the boundary $\mathcal{B}^*_{n,T}(T')$ to each $t' \in \mathcal{C}^*(T')$. Now, the amount of flow that must be concentrated from $\mathcal{C}^*(T)$ at *each* boundary triangulation $u \in \mathcal{B}^*_{n,T'}(T)$ (and symmetrically distributed from *each* $v \in \mathcal{B}^*_{n,T}(T')$ throughout $\mathcal{C}^*(T')$) is equal to

$$\frac{|\mathcal{C}^*(T)||\mathcal{C}^*(T')|}{|\mathcal{B}^*_{n,T'}(T)|} = \frac{|\mathcal{C}^*(T)||\mathcal{C}^*(T')|}{|\mathcal{B}^*_{n,T}(T')|} = \frac{|\mathcal{C}^*(T)||\mathcal{C}^*(T')|}{|\mathcal{E}^*(T,T')|} \leq C_n,$$

where we have used the equality $|\mathcal{B}^*_{n,T'}(T)| = |\mathcal{B}^*_{n,T}(T')| = |\mathcal{E}^*(T,T')|$ by Lemma 7 and Lemma 8, and where the inequality follows from Lemma 10. As a result, in the "concentration" and "distribution" subproblems (i) and (iii), at most C_n flow is concentrated at or distributed from any given triangulation (Figure 4). This bound yields a recursive structure: the concentration (respectively distribution) subproblem decomposes into a flow problem

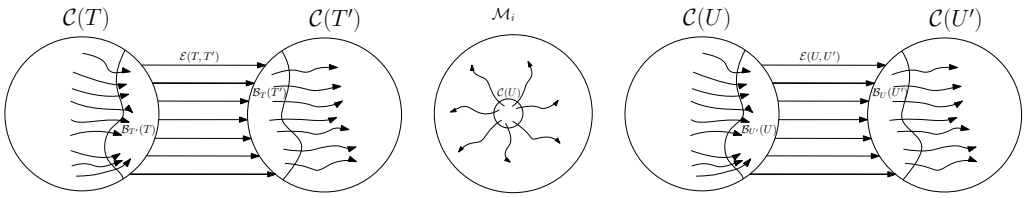

Figure 4 Left: The problem of sending flow from each $t \in \mathcal{C}^*(T)$ to each $t' \in \mathcal{C}^*(T')$, decomposed into subproblems: (i) *concentrating* flow within $\mathcal{B}^*_{n,T'}(T)$, (ii) *transmitting* the flow across the boundary matching $\mathcal{E}^*(T,T')$, and (iii) *distributing* the flow from $\mathcal{B}^*_{n,T}(T')$ throughout $\mathcal{C}^*(T')$. **Center**: Within each copy of $\mathcal{M}_i$ in the product $\mathcal{C}^*(T') \cong \mathcal{M}_{j_1} \square \cdots \square \mathcal{M}_i \square \cdots \square \mathcal{M}_{j_k}$, the distribution problem in Figure 4 induces the problem of distributing flow from a class $\mathcal{C}^*(U)$ – namely the projection of $\mathcal{B}^*_{n,T}(T')$ onto $\mathcal{M}_i$ – throughout the rest of $\mathcal{M}_i$. **Right**: The problem in the center figure induces subproblems in which $\mathcal{C}^*(U) \subseteq \mathcal{M}_i$ must send flow to each $\mathcal{C}^*(U') \subseteq \mathcal{M}_i$. These subproblems are of the same form as the original $\mathcal{C}^*(T), \mathcal{C}^*(T')$ problem (left), and can be solved recursively. The large matchings $\mathcal{E}^*(T,T'), \mathcal{E}^*(U,U')$ guaranteed by Condition 3 prevent any recursive congestion increase.

within $\mathcal{C}^*(T)$ (respectively $\mathcal{C}^*(T')$), in which, by the inequality, each triangulation has C_n total units of flow it must receive (or send). We will then apply Condition 4, observing (see Figure 4) that the concentration (symmetrically) distribution of this flow can be done entirely between pairs of classes $\mathcal{C}^*(U), \mathcal{C}^*(U')$ within copies of a smaller flip graph $\mathcal{M}_i$ in the Cartesian product $\mathcal{C}^*(T') \cong \mathcal{M}_{j_1} \square \cdots \square \mathcal{M}_i \square \cdots \square \mathcal{M}_{j_k}$.

The $\mathcal{C}^*(U), \mathcal{C}^*(U')$ subproblem is of the same form as the original $\mathcal{C}^*(T), \mathcal{C}^*(T')$ problem (Figure 4), and we will show that the C_n bound on the flow (normalizing to congestion one) across the $\mathcal{E}^*(T,T')$ edges will induce the same C_n bound across the $\mathcal{E}^*(U,U')$ edges in the induced subproblem. We further decompose the $\mathcal{C}^*(U), \mathcal{C}^*(U')$ problem into concentration, transmission, and distribution subproblems without any gain in overall congestion. To see this, view the initial flow problem in K_n as though every triangulation $t \in V(K_n)$ is initially "charged" with $|V(K_n)| = C_n$ total units of flow to distribute throughout K_n. Similarly, in the induced distribution subproblem within each copy of $\mathcal{M}_i = K_i$ in the product $\mathcal{C}^*(T')$, each vertex on the boundary $\mathcal{B}^*_{n,T'}(T)$ is initially "charged" with C_n total units to distribute throughout K_i. Just as the original problem in K_n results in each $\mathcal{E}^*(T,T')$ carrying at most C_n flow across each edge, similarly (we will show in the full paper version) the induced problem in K_i results in each $\mathcal{E}^*(U,U')$ carrying at most C_n flow across each edge. This preservation of the bound C_n under the recursion avoids any congestion increase.

One must be cautious, due to the linear recursion depth, not to accrue even a constant-factor loss in the recursive step (the coefficient 2 in Theorem 13). In Theorem 13, it turns out that this loss comes from routing *outbound* flow within a class $\mathcal{C}^*(T)$ – flow that must be sent to other classes – and then also routing *inbound* flow. The combination of these steps involves two "recursive invocations" of a uniform multicommodity flow that is inductively assumed to exist within $\mathcal{C}^*(T)$. We will show in the full paper version that one can avoid the second "invocation" with an initial "shuffling" step: a uniform flow within $\mathcal{C}^*(T)$ in which each triangulation $t \in \mathcal{C}^*(T)$ distributes all of its outbound flow evenly throughout $\mathcal{C}^*(T)$.

It is here that Jerrum, Son, Tetali, and Vigoda's spectral Theorem 14 breaks down, giving a 3-factor loss at each recursion level, due to applying the Cauchy-Schwarz inequality to a *Dirichlet form* that is decomposed into expressions over the restriction chains. Although Jerrum, Son, Tetali, and Vigoda gave circumstances for mitigating or eliminating their multiplicative loss, this chain does not satisfy those conditions in an obvious way.

Optimal Adjacency Labels for Subgraphs of Cartesian Products

Louis Esperet

Viktor Zamaraev
University of Liverpool, UK

Abstract

For any hereditary graph class $\mathcal{F}$, we construct optimal adjacency labeling schemes for the classes of subgraphs and induced subgraphs of Cartesian products of graphs in $\mathcal{F}$. As a consequence, we show that, if $\mathcal{F}$ admits efficient adjacency labels (or, equivalently, small induced-universal graphs) meeting the information-theoretic minimum, then the classes of subgraphs and induced subgraphs of Cartesian products of graphs in $\mathcal{F}$ do too. Our proof uses ideas from randomized communication complexity and hashing, and improves upon recent results of Chepoi, Labourel, and Ratel [Journal of Graph Theory, 2020].

Acknowledgements We are very grateful to Sebastian Wild, who prevented us trying to reinvent perfect hashing.

1 Introduction

In this paper, we present optimal adjacency labeling schemes (equivalently, induced-universal graph constructions) for subgraphs of Cartesian products, which essentially closes a recent line of work studying these objects [1, 2, 3, 4, 8, 10].

Adjacency labeling

A *class* of graphs is a set $\mathcal{F}$ of graphs closed under isomorphism, where the set $\mathcal{F}_n \subseteq \mathcal{F}$ of graphs on n vertices has vertex set $[n]$. It is *hereditary* if it is also closed under taking induced subgraphs, and *monotone* if it is also closed under taking subgraphs. An *adjacency labeling scheme* for a class $\mathcal{F}$ consists of a *decoder* $D : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}$ such that for every $G \in \mathcal{F}$ there exists a *labeling* $\ell : V(G) \to \{0,1\}^*$ satisfying

$$\forall x, y \in V(G) : \qquad D(\ell(x), \ell(y)) = 1 \iff xy \in E(G)\,.$$

The *size* of the adjacency labeling scheme (or *labeling scheme* for short) is the function $n \mapsto \max_{G \in \mathcal{F}_n} \max_{x \in V(G)} |\ell(x)|$, where $|\ell(x)|$ is the number of bits of $\ell(x)$. Labeling schemes have been studied extensively since their introduction by Kannan, Naor, & Rudich [13] and Muller [15]. If $\mathcal{F}$ admits a labeling scheme of size $s(n)$, then a graph $G \in \mathcal{F}_n$ can be recovered from the $n \cdot s(n)$ total bits in the adjacency labels of its vertices, so a labeling scheme is an encoding of the graph, distributed among its vertices. The information-theoretic lower bound on any encoding is $\log |\mathcal{F}_n|$, so the question is, when can the distributed adjacency labeling scheme approach this bound? In other words, which classes of graphs admit labeling schemes of size $O(\frac{1}{n} \log |\mathcal{F}_n|)$? We will say that a graph class has an *efficient* labeling scheme if it either has a labeling scheme of size $O(1)$ (i.e. it satisfies $\log |\mathcal{F}_n| = o(n \log n)$ [16]), or $O(\frac{1}{n} \log |\mathcal{F}_n|)$.

Cartesian products

Write $G \square H$ for the Cartesian product of G and H, write G^d for the d-wise Cartesian product of G, and for any class $\mathcal{F}$ write $\mathcal{F}^\square = \{G_1 \square G_2 \square \cdots \square G_d : d \in \mathbb{N}, G_i \in \mathcal{F}\}$ for the class of Cartesian products of graphs in $\mathcal{F}$. A vertex x of $G_1 \square \cdots \square G_d$ can be written $x = (x_1, \ldots, x_d)$ where $x_i \in V(G_i)$ and two vertices x, y are adjacent if and only if they differ on exactly one coordinate $i \in [d]$, and on this coordinate $x_i y_i \in E(G_i)$. Write $\mathsf{mon}(\mathcal{F}^\square)$ and $\mathsf{her}(\mathcal{F}^\square)$, respectively, for the monotone and hereditary closures of this class, which are the sets of all graphs G that are a subgraph (respectively, induced subgraph) of some $H \in \mathcal{F}^\square$.

We will construct optimal labeling schemes for $\mathsf{mon}(\mathcal{F}^\square)$ and $\mathsf{her}(\mathcal{F}^\square)$ from an optimal labeling scheme for $\mathcal{F}$. Cartesian products appear several times independently in the recent literature on labeling schemes [3, 8, 2] (and later in [10, 1, 4]), and are extremely natural for the problem of adjacency labeling for a few reasons.

First, for example, if $\mathcal{F}$ is the class of complete graphs, a labeling scheme for $\mathsf{her}(\mathcal{F}^\square)$ is equivalent to an encoding $\ell : T \to \{0,1\}^*$ of strings $T \subseteq \Sigma^*$, with Σ being an arbitrarily large finite alphabet, such that a decoder who doesn't know T can decide whether $x, y \in T$ have Hamming distance 1, using only the encodings $\ell(x)$ and $\ell(y)$. Replacing complete graphs with, say, paths, one obtains induced subgraphs of grids in arbitrary dimension. Switching to $\mathsf{mon}(\mathcal{F}^\square)$ allows arbitrary edges of these products to be deleted.

Second, Cartesian product graphs admit, by definition, a natural but inefficient "implicit representation", meaning (informally) that the adjacency between two vertices x and y can be verified by examining their representation (in this case, the tuples $x = (x_1, \ldots, x_d)$ and $y = (y_1, \ldots, y_d)$). Formalizing and quantifying this general notion was the motivation for labeling schemes in [13], who also observed that adjacency labeling schemes are equivalent to *induced-universal graphs* (or simply *universal graphs*). A sequence of graphs $(U_n)_{n \in \mathbb{N}}$ are universal graphs of size $n \mapsto |U_n|$ for a class $\mathcal{F}$ if each n-vertex graph $G \in \mathcal{F}$ is an induced subgraph of U_n. A labeling scheme of size $s(n)$ is equivalent to a universal graph of size $2^{s(n)}$, and Cartesian product graphs admit natural but inefficient universal graphs: if $(U_n)_{n \in \mathbb{N}}$ are universal graphs for $\mathcal{F}$ then for large enough $d = d(n)$, the graphs $(U_n^d)_{n \in \mathbb{N}}$ are universal for $\mathsf{her}(\mathcal{F}^\square)$. In general, this construction has exponential size: the hypercubes K_2^d are themselves universal for $\mathsf{her}(\{K_2\}^\square)$, but a star with $n-1$ leaves cannot be embedded in K_2^d for $d < n-1$, so these universal graphs are of size at least 2^{n-1}. It is not clear *a priori* whether it is possible to use the universal graphs for the base class $\mathcal{F}$ to obtain more efficient universal graphs for $\mathsf{her}(\mathcal{F}^\square)$, and even less clear for $\mathsf{mon}(\mathcal{F}^\square)$, but we will show in this paper how to do so.

Finally, there was the possibility that *subgraphs* of Cartesian products could provide the first explicit counterexample to the Implicit Graph Conjecture (IGC) of [13, 17], which suggested that the condition $\log |\mathcal{F}_n| = O(n \log n)$ was *sufficient* for $\mathcal{F}$ to admit a labeling

scheme of size $O(\log n)$; this was refuted by a non-constructive counting argument in a recent breakthrough of Hatami & Hatami [11]. There is a labeling scheme of size $O(\log^2 n)$ for the subgraphs of hypercubes, due to a folklore bound of $\log n$ on the degeneracy of this class (see [5]) and a general $O(k \log n)$ labeling scheme for classes of degeneracy k [13]. Designing an efficient labeling scheme for *induced* subgraphs of hypercubes (rather, the weaker question of proving bounds on $|\mathcal{F}_n|$ for this family) was an open problem of Alecu, Atminas, & Lozin [2], resolved concurrently and independently in [8]; this also gave an example of a class with an efficient labeling scheme but unbounded *functionality*, answering another open question of [2]. Also independently, Chepoi, Labourel, & Ratel [3] studied the structure of general Cartesian products, motivated by the problem of designing labeling schemes for the classes $\mathsf{mon}(\mathcal{F}^{\square})$. They give upper bounds (via bounds on the degeneracy) for a number of special cases but do not improve on the $O(\log^2 n)$ bound for hypercubes. The following 3 observations then suggested that subgraphs of Cartesian products could give the first explicit counterexample to the IGC (and this was posed as an open problem in [4]):

1. It is shown in [4] that, while *induced* subgraphs of hypercubes have a constant-size *adjacency sketch* (a probabilistic version of a labeling scheme), the *subgraphs* of hypercubes do not, so, with respect to *randomized* labels, subgraphs are more complex than induced subgraphs.
2. The above result shows that the class of subgraphs of hypercubes is a counterexample to a conjecture of [10]. That conjecture was refuted earlier by a construction of [7] that, with some extension, refuted the IGC itself [11].
3. The previous work considering Cartesian products [3, 8, 10, 2, 1] had not improved on the $O(\log^2 n)$ bound for subgraphs.

Alas, a consequence of our main result is that subgraphs of Cartesian products are *not* counterexamples to the IGC.

Results and techniques

We improve the best-known $O(\log^2 n)$ bound for subgraphs of hypercubes to the optimal $O(\log n)$, and in general show how to construct optimal labels for all subgraphs and induced subgraphs of Cartesian products. Our proof is short, and departs significantly from standard techniques in the field of labeling schemes: we do not rely on any structural results, graph width parameters, or decompositions, and instead use communication complexity (as in [8, 10]), encoding, and hashing arguments, which may be useful for future work on labeling schemes. We prove:

▶ **Theorem 1.** *Let $\mathcal{F}$ be a hereditary class with an adjacency labeling scheme of size $s(n)$. Then:*

1. $\mathsf{her}(\mathcal{F}^{\square})$ *has a labeling scheme of size at most* $4s(n) + O(\log n)$.
2. $\mathsf{mon}(\mathcal{F}^{\square})$ *has a labeling scheme where each* $G \in \mathsf{mon}(\mathcal{F}^{\square})$ *on n vertices is given labels of size at most* $4s(n) + O(k(G) + \log n)$*, where $k(G)$ is the degeneracy of G.*

We allow $\mathcal{F}$ to be finite, in which case $s(n) = O(1)$; in particular, setting $\mathcal{F} = \{K_2, K_1\}$, we get the result for hypercubes:

▶ **Corollary 2.** *Let $\mathcal{H}$ be the class of hypercube graphs. Then* $\mathsf{mon}(\mathcal{H})$ *has a labeling scheme of size* $O(\log n)$.

All of the labeling schemes of Chepoi, Labourel, & Ratel [3] are obtained by bounding $k(G)$ and applying the black-box $O(k(G) \cdot \log n)$ bound of [13]. For example, they get labels of size $O(d \log^2 n)$ when the base class $\mathcal{F}$ has degeneracy d, by showing that $\mathsf{mon}(\mathcal{F}^{\square})$ has degeneracy $O(d \log n)$. Our result can be substituted for that black-box, replacing the

multiplicative $O(\log n)$ with an *additive* $O(\log n)$, thereby improving all of the results of [3] when combined with their bounds on $k(G)$; for example, achieving $O(d \log n)$ when $\mathcal{F}$ has degeneracy d.

For subgraphs of hypercubes, [3] observed that a bound of $O(\mathsf{vc}(G) \log n)$ follows from the inequality $k(G) \leq \mathsf{vc}(G)$ due to Haussler [12], where $\mathsf{vc}(G)$ is the VC dimension[1], which can be as large as $\log n$ but is often much smaller; they generalize this inequality in various ways to other Cartesian products. Our result supercedes the VC dimension result for hypercubes.

Theorem 1 is optimal up to constant factors (which we have not tried to optimize), and yields the following corollary (see Section 3 for proofs).

▶ **Corollary 3.** *If a hereditary class $\mathcal{F}$ has an efficient labeling scheme, then so do* $\mathsf{her}(\mathcal{F}^{\square})$ *and* $\mathsf{mon}(\mathcal{F}^{\square})$.

One of our main motivations was to find explicit counterexamples to the IGC; a consequence of the above corollary is that, counterexamples to the IGC cannot be obtained by taking the monotone closure of Cartesian products of some hereditary class $\mathcal{F}$, unless $\mathcal{F}$ itself is already a counterexample. This leaves open the problem of finding an explicit counterexample to the IGC, which would require developing the first lower-bound technique for adjacency labeling schemes.

2 Adjacency Labeling Scheme

Notation

For two binary strings x, y, we write $x \oplus y$ for the bitwise XOR. For two graphs G and H, we will write $G \subset H$ if G is a subgraph of H, and $G \subset_I H$ if G is an *induced* subgraph of H. We will write $V(G)$ and $E(G)$ as the vertex and edge set of a graph G, respectively. All graphs in this paper are simple and undirected. A graph G has *degeneracy* k if all subgraphs of G have a vertex of degree at most k.

Strategy

Suppose $G \subset G_1 \square \cdots \square G_d$ is a subgraph of a Cartesian product. Then $V(G) \subseteq V(G_1) \times \cdots \times V(G_d)$. Let $H \subset_I G_1 \square \cdots \square G_d$ be the subgraph induced by $V(G)$, so that $E(G) \subseteq E(H)$. One may think of G as being obtained from the induced subgraph H by deleting some edges. Then two vertices $x, y \in V(G)$ are adjacent if and only if:

1. There exists exactly one coordinate $i \in [d]$ where $x_i \neq y_i$;
2. On this coordinate, $x_i y_i \in E(G_i)$; and,
3. The edge $xy \in E(H)$ has not been deleted in $E(G)$.

We construct the labels for vertices in G in three phases, which check these conditions in sequence.

2.1 Phase 1: Exactly One Difference

We give two proofs for Phase 1. The first is a reduction to the k-Hamming Distance communication protocol. The second proof is direct and self-contained; it is an extension of the proof of the labeling scheme for induced subgraphs of hypercubes, in the unpublished note [9] (adapted from [8, 10]). In both cases the labels are obtained by the probabilistic method, and are efficiently computable by a randomized algorithm.

[1] See [3] for the definition of VC dimension

For any alphabet Σ and any two strings $x, y \in \Sigma^d$ where $d \in \mathbb{N}$, write $\mathsf{dist}(x, y)$ for the Hamming distance between x and y, i.e. $\mathsf{dist}(x, y) = |\{i \in [d] : x_i \neq y_i\}|$.

For the first proof, we require a result in communication complexity (which we translate into our terminology). A version with two-sided error appears in [18], the one-sided error version below is implicit in [10] (and may appear elsewhere in the literature, which we did not find).

▶ **Theorem 4** ([18, 10]). *There exists a constant $c > 0$ satisfying the following. For any $k \in \mathbb{N}$, there exists a function $D : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}$ such that, for any $d \in \mathbb{N}$ and set $S \subseteq \{0,1\}^d$ of size $|S| = n$, there exists a probability distribution L over functions $\ell : S \to \{0,1\}^{ck^2}$, where for all $x, y \in S$,*

1. *If $\mathsf{dist}(x, y) \leq k$ then $\mathbb{P}_{\ell \sim L}[D(\ell(x), \ell(y)) = 1] = 1$; and,*
2. *If $\mathsf{dist}(x, y) > k$ then $\mathbb{P}_{\ell \sim L}[D(\ell(x), \ell(y)) = 0] \geq 2/3$.*

We transform these randomized labels into deterministic labels using standard arguments:

▶ **Proposition 5.** *There exists a constant $c > 0$ satisfying the following. For any $k \in \mathbb{N}$, there exists a function $D : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}$ such that, for any $d \in \mathbb{N}$ and set $S \subseteq \{0,1\}^d$ of size $|S| = n$, there exists a function $\ell : S \to \{0,1\}^{ck^2 \log n}$ where for all $x, y \in S$, $D(\ell(x), \ell(y)) = 1$ if and only if $\mathsf{dist}(x, y) \leq k$.*

Proof. Let $D' : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}$, $c > 0$, and L be the function, the constant, and the probability distribution given for S by Theorem 4. Let $q = \lceil 2 \log_3 n \rceil$, and let L' be the distribution over functions defined by choosing $\ell_1, \ldots, \ell_q \sim L$ independently at random, and setting $\ell(x) = (\ell_1(x), \ell_2(x), \ldots, \ell_q(x))$ for each $x \in S$. Define $D : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}$ such that

$$D(\ell(x), \ell(y)) = \bigwedge_{i=1}^{q} D'(\ell_i(x), \ell_i(y)) \,.$$

Observe that, if $x, y \in S$ have $\mathsf{dist}(x, y) \leq k$ then $\mathbb{P}[D(\ell(x), \ell(y)) = 1] = 1$ since for each $i \in [q]$ we have $\mathbb{P}[D'(\ell_i(x), \ell_i(y)) = 1] = 1$. On the other hand, if $x, y \in S$ have $\mathsf{dist}(x, y) > k$, then

$$\mathbb{P}[D(\ell(x), \ell(y)) = 1] < (1/3)^q \leq 1/n^2 \,.$$

By the union bound, the probability that there exist $x, y \in S$ such that $D(\ell(x), \ell(y))$ takes the incorrect value is strictly less than 1. Therefore there exists a fixed function $\ell : S \to \{0,1\}^{ck^2 q}$ satisfying the required conditions, where $ck^2 q = Ck^2 \log n$ for an appropriate constant C. ◀

We reduce the problem for alphabets Σ to the 2-Hamming Distance labeling problem above.

▶ **Lemma 6.** *There exists a function $D : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}$ and a constant $c > 0$ such that, for any countable alphabet Σ, any $d \in \mathbb{N}$, and any set $S \subseteq \Sigma^d$ of size $|S| = n$, there exists a function $\ell : S \to \{0,1\}^k$ for $k \leq c \log n$, where $D(\ell(x), \ell(y)) = 1$ if and only if $\mathsf{dist}(x, y) = 1$.*

Proof. Since $\lceil \log n \rceil$ bits can be added to any $\ell(x)$ to ensure that $\ell(x)$ is unique, it suffices to construct functions D, ℓ where $D(\ell(x), \ell(y)) = 1$ if and only if $\mathsf{dist}(x, y) \leq 1$, instead of $\mathsf{dist}(x, y) = 1$ exactly.

Since S has at most n elements, we may assume that Σ has a finite number N of elements, since we may reduce to the set of elements which appear in the strings S. We may then identify Σ with $[N]$ and define an encoding $\mathsf{enc} : [N] \to \{0,1\}^N$ where for any $\sigma \in [N]$, $\mathsf{enc}(\sigma)$ is the string that takes value 1 on coordinate σ, and all other coordinates take value 0.

Abusing notation, for any $x \in \Sigma^d$, we may now define the concatenated encoding $\mathsf{enc}(x) = \mathsf{enc}(x_1) \circ \mathsf{enc}(x_2) \circ \cdots \circ \mathsf{enc}(x_d)$, where $\circ$ denotes concatenation. It is easy to verify that for any $x, y \in \Sigma^d$, $\mathsf{dist}(\mathsf{enc}(x), \mathsf{enc}(y)) = 2 \cdot \mathsf{dist}(x, y)$. We may therefore apply Proposition 5 with $k = 2$ on the set $S' = \{\mathsf{enc}(x) : x \in S\}$ to obtain a function $D : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}$, a constant $C > 0$, and a function $\ell' : S' \to \{0,1\}^{C \log n}$ such that for all $x, y \in S$,

$$D(\ell'(\mathsf{enc}(x)), \ell'(\mathsf{enc}(y))) = 1 \iff \mathsf{dist}(\mathsf{enc}(x), \mathsf{enc}(y)) \leq 2 \iff \mathsf{dist}(x, y) \leq 1\,.$$

We may then conclude the proof by setting $\ell(x) = \ell'(\mathsf{enc}(x))$ for each $x \in S$. ◀

Below, we give an alternative, direct proof that does not reduce to k-Hamming Distance.

▶ **Proposition 7.** *For any set $S \subseteq \{0,1\}^d$, there exists a random function $\ell : S \to \{0,1\}^4$ such that, for all $x, y \in S$,*

1. *If $\mathsf{dist}(x, y) \leq 1$ then $\mathop{\mathbb{P}}_{\ell}[\mathsf{dist}(\ell(x), \ell(y)) \leq 1] = 1$, and*
2. *If $\mathsf{dist}(x, y) > 1$ then $\mathop{\mathbb{P}}_{\ell}[\mathsf{dist}(\ell(x), \ell(y)) \leq 1] \leq 3/4$.*

Proof. Choose a uniformly random map $p : [d] \to [4]$ and partition $[d]$ into four sets $P_j = p^{-1}(j)$. For each $i \in [4]$, define $\ell(x)_i := \bigoplus_{j \in P_i} x_j$.

Let $x, y \in S$ and write $w = \ell(x) \oplus \ell(y)$. Note that $\mathsf{dist}(\ell(x), \ell(y)) = |w|$, which is the number of 1s in w. If $\mathsf{dist}(x, y) = 0$ then $\mathsf{dist}(\ell(x), \ell(y)) = 0 \leq 1$. Now suppose $\mathsf{dist}(x, y) = 1$. For any choice of $p : [d] \to [4]$, one of the sets P_i contains the differing coordinate and will have $w_i = 1$, while the other three sets P_j will have $w_j = 0$, so $\mathop{\mathbb{P}}_{\ell}[\mathsf{dist}(\ell(x), \ell(y)) \leq 1] = 1$.

Now suppose $\mathsf{dist}(x, y) = t \geq 2$. We will show that $|w| \leq 1$ with probability at most $3/4$. Note that w is obtained by the random process where $\vec{0} = w^{(0)}, w = w^{(t)}$, and $w^{(i)}$ is obtained from $w^{(i-1)}$ by flipping a uniformly random coordinate.

Observe that, for $i \geq 1$, $\mathbb{P}\left[w^{(i)} = \vec{0}\right] \leq 1/4$. This is because $w^{(i)} = \vec{0}$ can occur only if $|w^{(i-1)}| = 1$, so the probability of flipping the 1-valued coordinate is $1/4$. If $|w^{(i-1)}| \geq 1$ then $\mathbb{P}\left[|w^{(i)}| \leq 1 \;\middle|\; |w^{(i-1)}| \geq 1\right] \leq 1/2$ since either $|w^{(i-1)}| = 1$ and then $|w^{(i)}| = 0 \leq 1$ with probability $1/4$, or $|w^{(i-1)}| \geq 2$ and $|w^{(i)}| = 1$ with probability at most $1/2$. Then, for $t \geq 2$,

$$\begin{aligned}\mathbb{P}\left[|w^{(t)}| \leq 1\right] &= \mathbb{P}\left[w^{(t-1)} = \vec{0}\right] + \mathbb{P}\left[|w^{(t-1)}| \geq 1\right] \cdot \mathbb{P}\left[|w^{(t)}| = 1 \;\middle|\; |w^{(t-1)}| \geq 1\right] \\ &\leq \frac{1}{4} + \frac{1}{2} = \frac{3}{4}\,.\end{aligned}$$

◀

▶ **Proposition 8.** *There exists a function $D : \{0,1\}^4 \times \{0,1\}^4 \to \{0,1\}$ such that, for any countable alphabet, Σ, any $d \in \mathbb{N}$, and any $S \subseteq \Sigma^d$ of size $n = |S|$, there exists a random function $\ell : S \to \{0,1\}^4$ such that, for all $x, y \in S$,*

1. *If $\mathsf{dist}(x, y) \leq 1$, then $\mathop{\mathbb{P}}_{\ell}[D(\ell(x), \ell(y)) = 1] = 1$, and*
2. *If $\mathsf{dist}(x, y) > 1$, then $\mathop{\mathbb{P}}_{\ell}[D(\ell(x), \ell(y)) = 1] \leq 15/16$.*

Proof. For each $\sigma \in \Sigma$ and $i \in [d]$, generate an independently and uniformly random bit $q_i(\sigma) \sim \{0,1\}$. Then for each $x \in S$ define $p(x) = (q_1(x_1), \ldots, q_d(x_d)) \in \{0,1\}^d$ and $S' = \{p(x) : x \in S\}$, and let ℓ' be the random function $S' \to \{0,1\}^4$ guaranteed to exist by Proposition 7. We define the random function $\ell : S \to \{0,1\}^4$ as $\ell(x) = \ell'(p(x))$. We define $D(\ell(x), \ell(y)) = 1$ if and only if $\mathsf{dist}(\ell'(p(x)), \ell'(p(y))) \leq 1$.

Let $x, y \in S$. If $\mathsf{dist}(x,y) \le 1$, so there is a unique $i \in [d]$ with $x_i \neq y_i$, then

$$\mathbb{P}\left[\mathsf{dist}(p(x),p(y)) = 1\right] = \mathbb{P}\left[q_i(x_i) \neq q_i(y_i)\right] = \mathbb{P}\left[\mathsf{dist}(p(x),p(y)) = 0\right] = 1/2\,,$$

so $\mathbb{P}\left[\mathsf{dist}(p(x),p(y)) \le 1\right] = 1$. Then by Proposition 7,

$$\mathbb{P}\left[D(\ell(x),\ell(y)) = 1\right] = \mathbb{P}\left[\mathsf{dist}(\ell'(p(x)),\ell'(p(y))) \le 1\right] = 1\,.$$

If $\mathsf{dist}(x,y) > 1$ so that there are distinct $i, i' \in [d]$ such that $x_i \neq y_i$ and $x_{i'} \neq y_{i'}$, then

$$\mathbb{P}\left[\mathsf{dist}(p(x),p(y)) \ge 2\right] \ge \mathbb{P}\left[q_i(x_i) \neq q_i(y_i) \wedge q_{i'}(x_{i'}) \neq q_{i'}(y_{i'})\right] = 1/4\,.$$

Then by Proposition 7,

$$\begin{aligned}\mathbb{P}\left[D(\ell(x),\ell(y)) = 1\right] &= \mathbb{P}\left[\mathsf{dist}(\ell'(p(x)),\ell'(p(y))) \le 1\right] \\ &= \mathbb{P}\left[\mathsf{dist}(p(x),p(y)) \le 1 \vee \mathsf{dist}(\ell'(p(x)),\ell'(p(y))) \le 1\right] \\ &\le 3/4 + (1-3/4)(3/4) = 15/16\,.\end{aligned}$$

◀

The alternative proof of Lemma 6 now concludes by using Proposition 8 with a nearly identical derandomization argument as in Proposition 5.

2.2 Phase 2: Induced Subgraphs

After the first phase, we are guaranteed that there is a unique coordinate $i \in [d]$ where $x_i \neq y_i$. In the second phase we wish to determine whether $x_i y_i \in E(G_i)$. It is convenient to have labeling schemes for the factors $G_1, \dots, G_d$ where we can XOR the labels together while retaining the ability to compute adjacency. Define an *XOR-labeling scheme* the same as an adjacency labeling scheme, with the restriction that for each $s \in \mathbb{N}$ there is some function $g_s : \{0,1\}^s \to \{0,1\}$ such that on any two labels $\ell(x), \ell(y)$ of size s, the decoder outputs $D(\ell(x),\ell(y)) = g_s(\ell(x) \oplus \ell(y))$. Any labeling scheme can be transformed into an XOR-labeling scheme with at most a constant-factor loss:

▶ **Lemma 9.** *Let $\mathcal{F}$ be any class of graphs with an adjacency labeling scheme of size $s(n)$. Then $\mathcal{F}$ admits an XOR-labeling scheme of size at most $4s(n)$.*

Proof. Let $D : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}$ be the decoder of the adjacency labeling scheme for $\mathcal{F}$, fix any $n \in \mathbb{N}$, and write $s = s(n)$. Note that D must be symmetric, so $D(a,b) = D(b,a)$ for any $a, b \in \{0,1\}^s$. Let $\phi : \{0,1\}^s \to \{0,1\}^{4s}$ be uniformly randomly chosen, so that for every $z \in \{0,1\}^s$, $\phi(z) \sim \{0,1\}^{4s}$ is a uniform and independently random variable. For any two distinct pairs $\{z_1, z_2\}, \{z_1', z_2'\} \in \binom{\{0,1\}^s}{2}$ where $z_1 \neq z_2$, $z_1' \neq z_2'$, and $\{z_1, z_2\} \neq \{z_1', z_2'\}$, the probability that $\phi(z_1) \oplus \phi(z_2) = \phi(z_1') \oplus \phi(z_2')$ is at most 2^{-4s}, since at least one of the variables $\phi(z_1), \phi(z_2), \phi(z_1'), \phi(z_2')$ is independent of the other ones. Therefore, by the union bound,

$$\mathbb{P}\left[\exists \{z_1,z_2\},\{z_1',z_2'\} : \phi(z_1) \oplus \phi(z_2) = \phi(z_1') \oplus \phi(z_2')\right] \le \binom{2^s}{2}^2 2^{-4s} \le \frac{1}{4}\,.$$

Then there is $\phi : \{0,1\}^s \to \{0,1\}^{4s}$ such that each distinct pair $\{z_1, z_2\} \in \binom{\{0,1\}^s}{2}$ is assigned has a distinct unique value $\phi(z_1) \oplus \phi(z_2)$. So the function $\Phi(\{z_1, z_2\}) := \phi(z_1) \oplus \phi(z_2)$ is a one-to-one map $\binom{\{0,1\}^s}{2} \to \{0,1\}^{4s}$. Then for any graph $G \in \mathcal{F}$ on n vertices, with labeling $\ell : V(G) \to \{0,1\}^s$, we may assign the new label $\phi(\ell(x))$ to each vertex x. On labels $\phi(\ell(x)), \phi(\ell(y)) \in \{0,1\}^s$, the decoder for the XOR-labeling scheme simply computes $\{\ell(x), \ell(y)\} = \Phi^{-1}(\phi(\ell(x)) \oplus \phi(\ell(y)))$ and outputs $D(\ell(x),\ell(y))$, where we are using the fact that $D(\ell(x),\ell(y)) = D(\ell(y),\ell(x))$, so that the ordering of the pair $\{\ell(x),\ell(y)\}$ does not matter. ◀

We can now prove the first part of Theorem 1.

▶ **Lemma 10.** *Let $\mathcal{F}$ be a hereditary class of graphs that admits an adjacency labeling scheme of size $s(n)$. Then $\mathsf{her}(\mathcal{F}^{\square})$ admits an adjacency labeling scheme of size $4s(n) + O(\log n)$.*

Proof. By Lemma 9, there is an XOR-labeling scheme for $\mathcal{F}$ with labels of size $4s(n)$. Let $D : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}$ be the decoder for this scheme, with $D(a,b) = g(a \oplus b)$ for some function g. Design the labels for $\mathsf{her}(\mathcal{F}^{\square})$ as follows. Consider a graph $G \in \mathsf{her}(\mathcal{F}^{\square})$, so that $G \subset_I G_1 \square G_2 \square \cdots \square G_d$ for some $d \in \mathbb{N}$ and $G_i \in \mathcal{F}$ for each $i \in [d]$. Since $\mathcal{F}$ is hereditary, we may assume that each G_i has at most n vertices; otherwise we could simply replace it with the subgraph of G_i induced by the vertices $\{x_i : x \in V(G)\}$. For each $x = (x_1, \ldots, x_d) \in V(G)$, construct the label as follows:

1. Treating the vertices in each G_i as characters of the alphabet $[n]$, use $O(\log n)$ bits to assign the label given to $x = (x_1, \ldots, x_d) \in [n]^d$ by Lemma 6.
2. Using $4s(n)$ bits, append the vector $\bigoplus_{i \in [d]} \ell_i(x_i)$, where $\ell_i(x_i)$ is the label of $x_i \in V(G_i)$ in graph G_i, according to the XOR-labeling scheme for $\mathcal{F}$.

The decoder operates as follows. Given the labels for $x, y \in V(G)$:

1. If x and y differ on exactly one coordinate, as determined by the first part of the label, continue to the next step. Otherwise output "not adjacent."
2. Now guaranteed that there is a unique $i \in [d]$ such that $x_i \neq y_i$, output "adjacent" if and only if the following is 1:

$$\begin{aligned} D\left(\bigoplus_{j\in[d]} \ell_j(x_j), \bigoplus_{j\in[d]} \ell_j(y_j)\right) &= g\left(\bigoplus_{j\in[d]} \ell_j(x_j) \oplus \bigoplus \ell_j(y_j)\right) \\ &= g\left(\ell_i(x_i) \oplus \ell_i(y_i) \oplus \bigoplus_{j\neq i} \ell_j(x_j) \oplus \ell_j(y_j)\right) \\ &= g(\ell_i(x_i) \oplus \ell_i(y_i)), \end{aligned}$$

   where the final equality holds because $x_j = y_j$ for all $j \neq i$, so $\ell_j(x_j) = \ell_j(y_j)$. Then the output value is 1 if and only $x_i y_i$ is an edge of G_i; equivalently, xy is an edge of G.

This concludes the proof. ◀

The XOR-labeling trick can also be used to simplify the proof of [10] for adjacency *sketches* of Cartesian products. That proof is similar to the one above, except it uses a two-level hashing scheme and some other tricks to avoid destroying the labels of x_i and y_i with the XOR (with sufficiently large probability of success). This two-level hashing approach does not succeed in our current setting, and we avoid it with XOR-labeling.

2.3 Phase 3: Subgraphs

Finally, we must check whether the edge $xy \in E(H)$ in the *induced* subgraph $H \subset_I G_1 \square \cdots \square G_d$ has been deleted in $E(G)$. There is a minimal and perfect tool for this task:

▶ **Theorem 11** (Minimal Perfect Hashing)**.** *For every $m, k \in \mathbb{N}$, there is a family $\mathcal{P}_{m,k}$ of hash functions $[m] \to [k]$ such that, for any $S \subseteq [m]$ of size k, there exists $h \in \mathcal{P}_{m,k}$ where the image of S under h is $[k]$ and for every distinct $i, j \in S$ we have $h(i) \neq h(j)$. The function h can be stored in $k \ln e + \log\log m + o(k + \log\log m)$ bits of space and it can be computed by a randomized algorithm in expected time $O(k + \log\log m)$.*

Minimal perfect hashing has been well-studied. A proof of the space bound appears in [14] and significant effort has been applied to improving the construction and evaluation time. We take the above statement from [6]. We now conclude the proof of Theorem 1 by applying the next lemma to the class $\mathcal{G} = \mathsf{her}(\mathcal{F}^{\square})$, using the labeling scheme for $\mathsf{her}(\mathcal{F}^{\square})$ obtained in Lemma 10 (note that $\mathsf{mon}(\mathsf{her}(\mathcal{F}^{\square})) = \mathsf{mon}(\mathcal{F}^{\square})$).

▶ **Lemma 12.** *Let $\mathcal{G}$ be any graph class which admits an adjacency labeling scheme of size $s(n)$. Then $\mathsf{mon}(\mathcal{G})$ admits an adjacency labeling scheme where each $G \in \mathsf{mon}(\mathcal{G})$ on n vertices has labels of size $s(n) + O(k(G) + \log n)$, where $k(G)$ is the degeneracy of G.*

Proof. Let $G \in \mathsf{mon}(\mathcal{G})$ have n vertices, so that it is a subgraph of $H \in \mathcal{G}$ on n vertices. The labeling scheme is as follows.

1. Fix a total order $\prec$ on $V(H)$ such that each vertex x has at most $k = k(G)$ neighbors y in H such that $x \prec y$; this exists by definition. We will identify each vertex x with its position in the order.
2. For each vertex x, assign the label as follows:
   a. Use $s(n)$ bits for the adjacency label of x in H.
   b. Use $\log n$ bits to indicate x (the position in the order).
   c. Let $N^+(x)$ be the set of neighbors $x \prec y$. Construct a perfect hash function $h_x : N^+(x) \to [k]$ and store it, using $O(k + \log\log n)$ bits.
   d. Use k bits to write the function $\mathsf{edge}_x : [k] \to \{0,1\}$ which takes value 1 on $i \in [k]$ if and only if xy is an edge of G, where y is the unique vertex in $N^+(x)$ satisfying $h_x(y) = i$.

Given the labels for x and y, the decoder performs the following:

1. If xy are not adjacent in H, output "not adjacent".
2. Otherwise xy are adjacent. If $x \prec y$, we are guaranteed that y is in the domain of h_x, so output "adjacent" if and only if $\mathsf{edge}_x(h_x(y)) = 1$. If $y \prec x$, output "adjacent" if and only if $\mathsf{edge}_y(h_y(x)) = 1$.

This concludes the proof. ◀

3 Optimality

We now prove the optimality of our labeling schemes, and Corollary 3. We require:

▶ **Proposition 13.** *For any hereditary class $\mathcal{F}$, let $k(n)$ be the maximum degeneracy of an n-vertex graph $G \in \mathsf{her}(\mathcal{F}^{\square})$. Then $\mathsf{her}(\mathcal{F}^{\square})$ contains a graph H on n vertices with at least $n \cdot k(n)/4$ edges, so $\mathsf{mon}(\mathcal{F}^{\square})$ contains all $2^{n \cdot k(n)/4}$ spanning subgraphs of H.*

Proof. Since G has degeneracy $k = k(n)$, it contains an induced subgraph $G' \subset_I G$ with minimum degree k and $n_1 \leq n$ vertices. If $n_1 \geq n/2$ then G itself has at least $kn_1/2 \geq kn/4$ edges, and we are done. Now assume $n_1 < n/2$. Since $G \in \mathsf{her}(\mathcal{F}^{\square})$, $G \subset_I H_1 \square \cdots \square H_t$ for some $t \in \mathbb{N}$ and $H_i \in \mathcal{F}$. So for any $d \in \mathbb{N}$, the graph $(G')^d \subset_I (H_1 \square \cdots \square H_t)^d$ belongs to $\mathsf{her}(\mathcal{F}^{\square})$. Consider the graph $H \subset_I (G')^d$ defined as follows. Choose any $w \in V(G')$, and for each $i \in [d]$ let

$$V_i = \{(v_1, v_2, \ldots, v_d) : v_i \in V(G') \text{ and } \forall j \neq i, v_j = w\},$$

and let H be the graph induced by vertices $V_1 \cup \cdots \cup V_d$. Then H has dn_1 vertices, each of degree at least k, since each $v \in V_i$ is adjacent to k other vertices in V_i. Set $d = \lceil n/n_1 \rceil$, so that H has at least n vertices, and let $m = dn_1 - n$, which satisfies $m < n_1$. Remove any m vertices of V_1. The remaining graph H' has n vertices, and at least $(d-1)n_1 \geq n - n_1 > n/2$ vertices of degree k. Then H' has at least $kn/4$ edges. ◀

The next proposition shows that Theorem 1 is optimal up to constant factors. It is straightforward to check that this proposition implies Corollary 3.

▶ **Proposition 14.** *Let $\mathcal{F}$ be a hereditary class whose optimal adjacency labeling scheme has size $s(n)$ and which contains a graph with at least one edge. Then any adjacency labeling scheme for $\mathsf{her}(\mathcal{F}^{\square})$ has size at least $\Omega(s(n) + \log n)$, and any adjacency labeling scheme for $\mathsf{mon}(\mathcal{F}^{\square})$ has size at least $\Omega(s(n) + k(n) + \log n)$, where $k(n)$ is the maximum degeneracy of any n-vertex graph in $\mathsf{mon}(\mathcal{F}^{\square})$.*

Proof. Since $\mathcal{F} \subseteq \mathsf{her}(\mathcal{F}^{\square})$ and $\mathcal{F} \subseteq \mathsf{mon}(\mathcal{F}^{\square})$, we have a lower bound of $s(n)$ for the labeling schemes for both of these classes. Since $\mathcal{F}$ contains a graph G with at least one edge, the Cartesian products contain the class of hypercubes: $\mathsf{her}(\{K_2\}^{\square}) \subseteq \mathsf{her}(\mathcal{F}^{\square}) \subseteq \mathsf{mon}(\mathcal{F}^{\square})$. A labeling scheme for $\mathsf{her}(\{K_2\}^{\square})$ must have size $\Omega(\log n)$ (which can be seen since each vertex of K_2^d has a unique neighborhood and thus requires a unique label). This establishes the lower bound for $\mathsf{her}(\mathcal{F}^{\square})$, since the labels must have size $\max\{s(n), \Omega(\log n)\} = \Omega(s(n) + \log n)$. Finally, by Proposition 13, the number of n-vertex graphs in $\mathsf{mon}(\mathcal{F}^{\square})$ is at least $2^{\Omega(nk(n))}$, so there is a lower bound on the label size of $\Omega(k(n))$, which implies a lower bound of $\max\{s(n), \Omega(\log n), \Omega(k(n))\} = \Omega(s(n) + k(n) + \log n)$ for $\mathsf{mon}(\mathcal{F}^{\square})$. ◀

Abstract

We study truthful mechanisms for welfare maximization in online bipartite matching. In our (multi-parameter) setting, every buyer is associated with a (possibly private) desired set of items, and has a private value for being assigned an item in her desired set. Unlike most online matching settings, where agents arrive online, in our setting the items arrive online in an adversarial order while the buyers are present for the entire duration of the process. This poses a significant challenge to the design of truthful mechanisms, due to the ability of buyers to strategize over future rounds. We provide an almost full picture of the competitive ratios in different scenarios, including myopic vs. non-myopic agents, tardy vs. prompt payments, and private vs. public desired sets. Among other results, we identify the frontier up to which the celebrated $e/(e-1)$ competitive ratio for the vertex-weighted online matching of Karp, Vazirani and Vazirani extends to truthful agents and online items.

1 Introduction

Matching in bipartite graphs is a fundamental model that has gained massive importance in numerous applications with the growth of the Internet. Some examples include items and buyers in e-commerce, drivers and passengers in ride-sharing platforms, ad slots and

advertisers in online ad auctions, and jobs and workers in online labor markets. In these applications, it is common that vertices on one side are known from the outset, while vertices from the other side arrive one-by-one in an online fashion. Upon the arrival of an online vertex, its information is revealed (containing, e.g., its set of adjacent edges, and their weights), and the algorithm has to immediately and irrevocably decide either to match it with an available offline partner or leave it unmatched forever. The goal is to maximize the sum of the weights along the matched edges.

A celebrated result in online matching by Karp, Vazirani, and Vazirani [18] shows that, in the unweighted setting, a simple randomized strategy called RANKING achieves a competitive ratio of $e/(e-1)$, and this is optimal. This result extends to the setting where the vertices on the offline side are weighted and the objective is to maximize the sum of the weights of the matched vertices. Although the original algorithm for this problem, PERTURBED-GREEDY [1], was designed for non-strategic settings, online matching problems have also been studied in the presence of *strategic* agents e.g., [21, 25, 11, 7]. This is not a mere theoretical exercise: in many applications of online matching the parties involved are interested in misreporting their true valuations to obtain a better outcome, e.g., combinatorial and ad-auctions, kidney exchange, school-student matching, and house allocation. In the presence of strategic agents, an agent's value is her private information, and is not directly available to the mechanism designer. The main challenge here is to design *incentive-compatible* or *truthful* mechanisms which, besides finding a good matching, also ensure that it is in the agents' best interest to report their true values. In addition to making decisions regarding the matching itself, such mechanisms can also charge some payment from the agents in order to incentivize them to truthfully report their values. Here, each agent strives to maximize her *quasi-linear utility*, i.e. the value she obtains from her assigned item, minus the payment she has to make.

In almost all previous studies, the agents are represented by the vertices on the online side, while the items they are competing over are available offline. In many natural internet applications, e.g. selling advertising opportunities via repeated auctions, the agents are fixed and observe a stream of items arriving online. This motivates the study of a *reversed* online matching problem, where each vertex on the offline side is strategic on her value, and her set of desired items that arrive online. This variant has been considered thus far only in very restricted settings [8, 9]. This is not a coincidence: when agents are present throughout the entire matching process, many new manipulation opportunities arise, and incentivizing truthful behavior is significantly more challenging. Indeed, the online nature of the problem forces any mechanism to repeatedly make irrevocable decisions upon the arrival of goods, lacking knowledge about future opportunities that might arise to the participating agents. The agents – possibly aware of those future opportunities – may strategize to gain benefits in the future, defying standard tools applicable when agents arrive online.

Our work provides a systematic analysis of this scenario, and gives (almost) tight competitive ratios under a rich variation of natural assumptions. We study the problem along different dimensions, as follows. First, we consider two types of agents – myopic and non-myopic – that are characterized by the different information they have on the instance. Myopic agents make strategic considerations that are limited to the current time step, without looking forward into the future (see, e.g., Deng, Panigrahi and Zhang [9]), whereas non-myopic agents optimize across multiple time steps, using the up-front knowledge of the underlying (online) graph. The assumption of myopic agents clearly eradicates some of the difficulties of designing (almost tight) online mechanisms with offline strategic agents, thus allowing us to derive efficient mechanisms from known online matching algorithms, e.g., from Aggarwal et al. [1]. Second, we consider two types of private information. In the first scenario we consider, an

Table 1 Summary of our results, with $\nu = \min(m, n)$, where n is the number of agents and m the number of items.

	deterministic	randomized
prompt	2 (Theorem 12)	$e/(e-1)$ (Theorem 13)

(a) Myopic agents.

	deterministic	randomized
tardy	2 (Theorem 14)	$e/(e-1)$ (Theorem 14)
prompt	$\geq \nu$ (Theorem 3)	$\Omega(\log \nu / \log\log \nu)$ (Theorem 4)

(b) Non-myopic agents with *public* graph edges.

	deterministic	randomized
tardy	equiv. to prompt	equiv. to prompt
prompt	$\leq \nu$ (Theorem 9)	$\mathcal{O}(\log \nu)$ (Theorem 10)

(c) Non-myopic agents with *private* graph edges.

agent's private information consists only of her private value for her desired items, but the set of desired items is publicly known. In the second scenario, both the value and the set of desired items are private information. Notably, in both cases the graph structure is revealed to the mechanism step-by-step, upon the arrival of every item. Finally, we distinguish between *prompt* and *tardy* mechanisms. Both types of mechanisms make allocation decisions immediately. However, they differ in the time at which they make payment decisions. Prompt mechanisms make payment decisions immediately upon allocation, while tardy mechanisms may delay payment decisions to the end of the entire process.

1.1 Our Results and Techniques

We conduct a systematic study of online bipartite matching with online items and offline agents, in a variety of scenarios and we provide (almost) tight bounds for the settings of interest, as summarized in Table 1.

Myopic agents. The simpler setting we investigate is that of myopic agents. These agents care only about their instantaneous utility, and do not strategize over the future. As such, we only consider prompt mechanisms for this type of agents. By exploiting the myopic nature of the agents, it is not difficult to turn the best (non-truthful) algorithms into (truthful) mechanisms. In particular, we construct a deterministic prompt mechanism based on the greedy matching algorithm that is guaranteed to achieve at least a half of the optimal welfare. We also give a randomized prompt mechanism based on the algorithm for weighted online matching [1], which is $e/(e-1)$-competitive. This shows that the transition from non-strategic agents to strategic myopic agents does not lead to a deterioration in efficiency guarantees. Notably, for the special case we study, our bounds for myopic online matching improve vastly over those obtained by Deng, Panigrahi and Zhang [9] for general XOS valuations. The results for myopic agents are reported in Appendix A.

Non-myopic agents with public graph edges. In a more general setting, we consider non-myopic agents who can strategize about their values, but not about their desired items: upon the arrival of an item, the set of agents interested in it is revealed (no strategizing involved), but the agent values are reported by the agents themselves. This variant is single-parameter, for which Myerson's lemma applies [24]. We prove that, if the mechanism is allowed to wait until the end of the online phase to set prices (i.e., tardy mechanism), it is possible to

achieve the same bounds as in the myopic case – by showing that our algorithms Greedy and Perturbed-Greedy maintain a certain form of *global monotonicity*. In contrast, when prices have to be fixed upon item arrival, an agent might hope to receive an item, i.e. one over which there is not as much competition, for a better price later if she waits instead of truthfully reporting her interest in the current item. To avoid this, prompt prices need to be non-decreasing throughout the mechanism, which allows us to show a sharp deterioration from tardy to prompt mechanisms: for deterministic mechanisms, we prove a $\nu = \min(m, n)$ competitive lower bound, where n and m denote the number of agents and items, respectively. For *randomized* prompt mechanisms obtaining such a lower bound is much more challenging, but as a central result we manage to establish an $\Omega(\log \nu / \log \log \nu)$ lower bound, using Yao's minimax principle. Starting from a carefully designed distribution of problem instances with exponentially increasing agent valuations, we employ a primal-dual approach together with our previous observations on the behavior of *deterministic* truthful mechanisms to bound the achievable competitive ratio. Almost matching deterministic and randomized upper bounds for prompt mechanisms are inherited from non-myopic prompt mechanisms with private graph edges. See Section 3 for our results for public graph edges.

Non-myopic agents with private graph edges. We finally consider non-myopic agents when both valuations and the set of desired items are private information. For deterministic prompt mechanisms, the ν lower bound from the case of public graph edges applies. Moreover, we show that in the case of private edges, every deterministic truthful mechanism is essentially prompt. Thus, tardy mechanisms for this case retain the ν lower bound, exhibiting a large gap between tardy mechanisms for public vs. private edges. We then provide a prompt truthful deterministic mechanism that is ν-competitive, matching the lower bound. For randomized prompt truthful mechanisms, the $\Omega(\log \nu / \log \log \nu)$ lower bound from the case of public edges applies to tardy randomized mechanisms as well, since these are probability distributions over deterministic mechanisms and, as stated above, all deterministic truthful mechanisms for private edges are prompt. On the positive side, we provide a randomized prompt truthful mechanism that gives an almost matching competitive ratio of $O(\log \nu)$. This algorithm is based on a tailored explore-exploit approach. Our results for private graph edges are reported in Section 4.

Ex-post vs. ex-ante truthfulness. Finally, we explore the notion of *ex-ante* truthfulness, as opposed to *ex-post* truthfulness, where agents' true declarations maximize their expected utility instead of their utility in *any realization* of the random choices of the mechanism. Clearly, ex-post truthfulness implies ex-ante truthfulness. In the setting with myopic buyers, we only need to consider ex-post truthfulness as we obtain tight approximation in this stronger model that closes the problem also for the ex-ante analogue. In the setting of non-myopic buyers, we show that the additional hardness introduced by truthfulness cannot be fully attributed to the fact that we require ex-post truthfulness. Specifically, we establish a lower bound of 2 for the competitive ratio of ex-ante truthful mechanisms for this setting (even with respect to randomized tardy ones), exhibiting a gap to the corresponding $e/(e-1)$ upper bound for myopic buyers. Our proof utilizes an instance for which we establish lower bounds on the expected utility of various types of agents. We then employ these to show a contradiction to the mechanism's correctness. Our results for ex-ante truthfulness are reported in Section 6.

Remark. Throughout the paper, we assume that weights are assigned to vertices (agents) rather than edges; note, it is well known that for the more general case of edge weights even the algorithmic problem is hopeless (see, e.g., Appendix G of [1]). One may also wonder why we do not study non-myopic agents with public valuations but private edges. The reason is that in the case of public valuations, it is easy to see that agents cannot benefit from misreporting their edges, implying that Greedy and Perturbed-Greedy are truthful.

1.2 Further Related Work

Karp, Vazirani and Vazirani [18] introduce the online matching problem, and study it under one-sided bipartite arrivals. They observe that the trivial 1/2-competitive greedy algorithm (which matches any arriving vertex to an arbitrary unmatched neighbor, if one exists) is optimal among deterministic algorithms for this problem. They also provide a groundbreaking and elegant randomized algorithm for this problem, called Ranking, which achieves an optimal $e/(e-1)$ competitive ratio. The work of Karp, Vazirani and Vazirani [18] was extended to vertex weighted settings by Aggarwal et al. [1], who give an optimal $e/(e-1)$-competitive, randomized algorithm using *random perturbations* of weights by appropriate multiplicative factors. The same bound has been re-proven over the years [6, 10, 14, 12]. Various extensions of one sided online matching and its economic applications (e.g., display ads) have been widely studied, see e.g. the excellent survey of Mehta [22] for further reference. Online matching has also been studied under edge and general vertex arrivals, as well as in different stochastic settings (see e.g., [19, 20, 13, 17, 15, 16]).

An important generalization of assignment problems in the form of matchings are combinatorial auctions, where buyers can obtain a *subset* of the available items, instead of just one. Combinatorial auctions with offline strategic buyers and online items have been recently studied by [9] for submodular and XOS valuations in the case of myopic buyers – considered also in this work – and in the less constrained setting of items that must not be irrevocably assigned at time of arrival. Deng, Panigrahi and Zhang [9] show (for myopic buyers) a sharp separation between submodular valuations, which admit a logarithmic competitive ratio, and XOS valuations, for which a polynomial lower bound is proven. In our work, we prove tight constant bounds for myopic buyers in the important special case of a unit-demand matching.

Cole, Dobzinski and Fleischer [8] formally introduced the notions of *prompt* and *tardy* for mechanisms, after observing the severe negative aspects of many existing (tardy) methods. They study prompt truthful mechanisms for an online problem that is related to ours, but with some restrictions: while agents are still on the offline side of the graph, their items of interest are restricted to form an interval over the online steps (which corresponds to the interval buyers are present). Further, agents report their departure time (which can be public/private) once they arrive, and their arrival time is public knowledge. Babaioff, Blumrosen and Roth [4] later investigated truthful prompt mechanisms for allocating an unknown number of identical items arriving online, which can be phrased in our model as having all desired sets equal to the same prefix of the sequence of items. Both of these works [8, 4] are close to ours in spirit. They present logarithmic-competitive prompt mechanisms in restricted settings, and prove lower bounds using Yao's pinciple (≥ 2 in [8], and $\Omega(\log\log n)$ in [4]). The notions of tardy and prompt mechanisms have since been adopted in the literature, see e.g. [3, 28]. The model of offline agents and online items has been the subject of extensive investigation in economic theory in dynamic mechanism design. Despite this obvious relation to our setting, there are fundamental differences (see for example [23, 2, 5]). In dynamic mechanism design, a strategic buyer learns her valuations at time of arrival of each item. Opposed to our setting, priors on agents' valuations for each online item are usually known beforehand. Finally,

in our matching setting the agents' valuations can assume only two values, v_i and 0, and we consider unit demand buyers instead of additive valuation agents as it is customary in dynamic mechanism design.

2 Preliminaries

We are given a bipartite graph $G = (B, I; E)$, where B is a set of n vertices, corresponding to buyers, I is a set of m vertices, corresponding to items, and $E \subseteq B \times I$ is the set of edges. We denote by ν the smallest between the number of buyers n and the items m. The set of buyers is known beforehand, while the items arrive one by one in some unknown, possibly adversarial, order. Without loss of generality we assume that item j arrives at time j. Each buyer i has two pieces of private information: the set of items she is interested in, and her value v_i if she gets at least one of them (the value for other items is 0). Upon the arrival of a new item, every buyer declares if she is interested in the current item and, if yes, her value. Let $b_{i,j}$ denote the bid of buyer i for item j (with the convention that $b_{i,j} = 0$ if buyer i is not interested in item j). Without loss of generality, we may assume that buyers cannot change their declared valuation after they have declared it once[1], i.e. every nonzero bid of the same buyer is the same value b_i, and that every buyer is assigned at most one item.

A mechanism $\mathcal{M}$ is composed of an *allocation* scheme and a *payment* scheme. Upon the arrival of every item, and based on buyer bids, the mechanism decides immediately and irrevocably to either assign the new item to some buyer who has not been assigned an item yet, or leave it unassigned forever. Thus, the resulting allocation is a matching in G: every buyer receives at most one item, and every item is allocated to at most one buyer. We denote by μ the induced matching, so that μ_j denotes the buyer to whom item j is assigned (we assume that an item j can only be assigned to a buyer who declares interest in j). If j is unassigned, we write $\mu_j = \emptyset$. We also write μ_i^{-1} to denote the item assigned to buyer i, with the convention that $\mu_i^{-1} = \emptyset$ if i is left unassigned. The *allocation* is computed online; i.e., μ_j is determined using only the bids on items up to j. In addition to the allocation, the mechanism decides how much each buyer should pay. A payment scheme is denoted by p, where p_i denotes the non-negative payment of buyer i. We distinguish between two types of *payment* schemes, according to the time at which the mechanism determines the payment. A *tardy* mechanism is one where the payment vector p is computed in the end of the process. A *prompt* mechanism is one where the payment p_i of every buyer i is determined upon the assignment of buyer i (i.e., upon the arrival of item μ_i^{-1}). The mechanism's objective is to maximize the *social welfare* of the allocation μ, which is the sum of the buyer values for their assigned items. The social welfare is given by $\mathrm{SW}(\mu) = \sum_{i \in B} v_i \cdot \mathbb{1}_{\{(i,\mu_i^{-1}) \in E\}}$. Note that a mechanism can also be randomized, so that its allocation is a distribution over matchings. In case of a randomized mechanism, we measure its efficiency by the expected social welfare. We say that a mechanism gives an α approximation, or is α-competitive (where $\alpha \geq 1$), if its (expected) social welfare is at least an $1/\alpha$ fraction of the welfare of a maximum weight matching. That is, μ is α-competitive if $\mathrm{OPT} = \mathrm{SW}(\mu^\star) \leq \alpha \cdot \mathbb{E}\left[\mathrm{SW}(\mu)\right]$, where $\mu^\star$ is the maximum weight matching in G.

A *bidding strategy* $\mathcal{B}_i$ for buyer i is a sequence of bids $b_{i,j}$ that specifies, every time a new item j arrives, whether to declare interest in it and which value to report. The bid $\mathcal{B}_i$ might depend on the bids of the other agents, the actions of the mechanism, and the knowledge the buyers have on the sequence of items. Recall that once an agent declares a positive valuation

[1] Mechanisms can "punish" such behavior by discarding the buyer from further consideration

$b_{i,j} = b_i > 0$ for some item j, she cannot change her value thereafter; namely, all bids for future items j' can take the value of either b_i or 0. Let $\mathcal{B}$ denote the profile of buyer bidding strategies, and $\mathcal{B}_{-i}$ denote the profile of all buyer strategies excluding buyer i. We assume that every buyer has a quasi-linear utility function: $u_i(\mathcal{M}, \mathcal{B}_i, \mathcal{B}_{-i}) = v_i \cdot \mathbb{1}_{\{(i,\mu_i^{-1})\in E\}} - p_i$.

A buyer is called *myopic* if upon the arrival of every item j, she cares only about maximizing her utility in that round, without considering its effect on future rounds. I.e., upon the arrival of item j, she maximizes the utility function $u_{i,j} = v_i \cdot \mathbb{1}_{\{\mu_j=i,\,(i,j)\in E\}} - p_i$. We consider myopic agents only in the context of prompt mechanisms, where the price p_i is determined immediately. We study the following ex-post notion of truthfulness: (i) A mechanism for myopic agents is *truthful* if it is always in the best interest of a myopic buyer to declare her value truthfully. (ii) A mechanism for non-myopic agents is *truthful* if an agent maximizes her utility for every realization of the mechanism by declaring her value truthfully. Finally, we only consider mechanisms that are *ex-post individually rational*, meaning that all agents (myopic or not) have non-negative utility, for every realization of the mechanism.

3 Prompt mechanisms with public graph edges

We start with the setting where agents are assumed to know, and strategize about, the whole sequence of items arriving. Note that this is a strong information asymmetry between agents and mechanism, as the latter only discovers the items as they are revealed online and has no information on the future. As a first step in this challenging model, in this section we study the case where agents may only lie on their valuations. Our main focus here is on establishing lower bounds, which will naturally extend to the case where the edges of the graph are private information.

3.1 Deterministic truthful mechanisms

When mechanisms are required to be prompt, the problem becomes much harder despite the fact that each agent's private information is just a single value. This is due to the online nature of the problem versus the possibly universal knowledge of the buyers, as outlined before. We first concentrate on deterministic prompt truthful mechanisms, and prove that the scope of these is quite limited. The critical item property is also used in [4] to prove a lower bound analogous to Theorem 3.

▶ **Definition 1** (critical item property). *We say that a deterministic mechanism satisfies the* critical item property *if and only if for every buyer i, there exists some $j \in I$ such that for any reported value b_i of i, the mechanism assigns i with item j, or none at all. Note that j may depend on the edges of the graph, and on the values of other buyers.*

▶ **Lemma 2.** *Prompt deterministic truthful mechanisms for the problem with public graph edges satisfy the critical item property.*

Proof. For the sake of contradiction, assume that there is a buyer i who gets item j_1 at price p_1 if she reports a value β_1 and gets item j_2 at price p_2 if she reports a value β_2. Without loss of generality, let $j_1 < j_2$. By truthfulness, the mechanism must give item j_1 to buyer i if she reports a value $\geq p_1$ (as far as the mechanism knows, i might not like items after j_1, and she would have incentive to lie and report β_1 if she is not given j_1). Thus, we have $p_2 \leq \beta_2 < p_1$, where the first inequality comes from individual rationality. But now, buyer i has incentive to report β_2, in order to get j_2 and pay p_2 which is less than p_1. ◀

▶ **Theorem 3.** *Any prompt deterministic truthful mechanism for the problem with public graph edges has competitive ratio of at most* $\nu = \min(m, n)$.

Proof. Consider an instance with n buyers with value 1 that are all interested in the first item. If there is a buyer i who will never get item 1 no matter what she reports, then we change the instance so that i has an arbitrary large value and is only interested in item 1, in which case i will get nothing and the mechanism does not even approximate the optimal social welfare. Conversely, if there is no such buyer, then the critical item property states that no other item can be allocated, which gives an approximation ratio of $\min(m, n)$. ◀

3.2 Randomized truthful mechanisms

Somewhat surprisingly, the previous result has revealed a large gap between tardy and prompt deterministic mechanisms, when the topology of the graph is public knowledge: while tardy mechanisms can be implemented *for free*, i.e., maintaining the efficiency guarantees of (non-strategic) combinatorial algorithms, for prompt mechanisms the story is different. After showing that deterministic mechanisms cannot achieve anything better than ν, we turn our focus towards impossibility results for randomized mechanisms. We utilize a well-known property of randomized truthful mechanisms, which (by definition) make truthful reports utility-maximizing for any outcome of a mechanism's random decisions, even in hindsight: this implies that they are lotteries over deterministic truthful mechanisms, which satisfy the properties shown in the previous section. By Yao's minimax principle [29], it is then enough to construct a distribution over instances, such that the optimal solutions have welfare $\Omega(\log n)$, and a best-possible deterministic mechanism $\mathcal{M}$, since it satisfies the critical item property, outputs solutions with expected value $\mathcal{O}(\log \log n)$.

▶ **Theorem 4.** *Any prompt randomized truthful mechanism for the problem with public graph edges has competitive ratio of at least* $\Omega(\log \nu / \log \log \nu)$.

Proof. Fix any prompt randomized ex-post truthful mechanism for public graph edges. We argue by Yao's principle [29] that its competitive ratio is at least $\Omega(\log \nu / \log \log \nu)$. This holds due to the upcoming Lemma 5, which shows that there exists a distribution over instances, such that the optimal solutions have welfare at least $n \log(n)/2$ with high probability, and such that any deterministic mechanism (since it satisfies the critical item property) outputs solutions with expected value $\mathcal{O}(n \log \log n)$. More precisely, given a random instance r and a mechanism $\mathcal{M}_s$ with random coin flips s, recall that Yao's principle states that:

$$\min_r \left[\frac{\mathbb{E}_s[\mathcal{M}_s(r)]}{\mathrm{OPT}(r)}\right] \leq \mathbb{E}_r \left[\frac{\mathbb{E}_s[\mathcal{M}_s(r)]}{\mathrm{OPT}(r)}\right] = \mathbb{E}_s \left[\mathbb{E}_r \left[\frac{\mathcal{M}_s(r)}{\mathrm{OPT}(r)}\right]\right] \leq \max_s \left[\mathbb{E}_r \left[\frac{\mathcal{M}_s(r)}{\mathrm{OPT}(r)}\right]\right]$$

In particular, fixing the coin flips s, the mechanism $\mathcal{M}_s$ is deterministic and truthful. Hence, Lemma 5 bounds its expected approximation ratio over the random instance r, with

$$\mathbb{E}_r \left[\frac{\mathcal{M}_s(r)}{\mathrm{OPT}(r)}\right] \leq \mathbb{E}_r \left[\frac{\mathcal{M}_s(r)}{\log(n)/2} + \mathbb{1}_{\{\mathrm{OPT}(r) \leq \log(n)/2\}}\right] \leq \frac{\mathcal{O}(\log \log n)}{\log(n)/2} + \mathcal{O}(1/\log^2 n),$$

where the first inequality holds by the disjunction of whether or not $\mathrm{OPT}(r) \leq \log(n)/2$ for a given r. Combining the two inequalities concludes the proof. ◀

▶ **Lemma 5.** *There is a distribution over instances with n buyers and n items, for which any deterministic mechanism satisfying the critical item property outputs solutions with expected value $\mathcal{O}(n \log \log n)$, and such that the optimal solution has value $\geq n \log(n)/2$ with probability at least $1 - O(1/\log^2 n)$.*

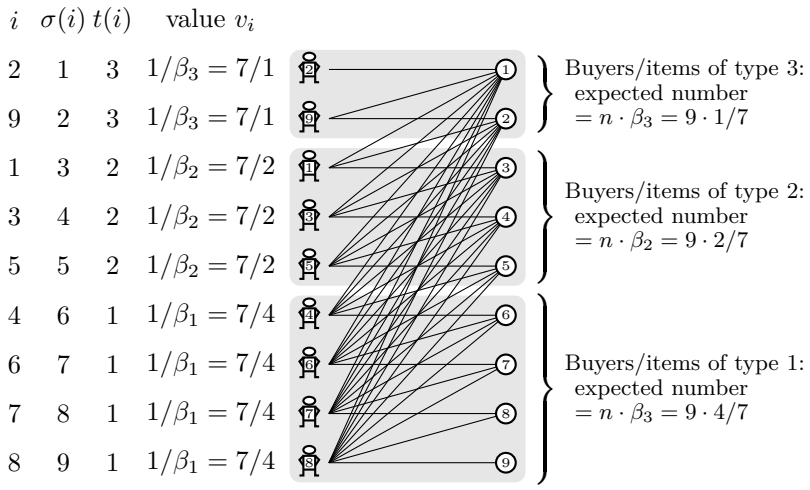

Figure 1 The instance from Lemma 5 with $k = 3$ and $n = 9$. Items are ordered (from top to bottom) according to their arrival times, and buyers are ordered (from top to bottom) according to σ (sort by decreasing types, breaking ties with indices). Preferences of buyers are given by the edges of the graph.

Proof. Let $k \geq 1$ be a parameter, which corresponds to the number of types of buyers, and let $\beta_1 > \cdots > \beta_k > 0$ be the probabilities of each type ($\beta_1 + \cdots + \beta_k = 1$). We choose $\beta_t = 2^{-t}/(1 - 2^{-k})$ for all t, and we set $n = 1 + 2^k$. Consider the following distribution over instances, with n buyers and n items. Each buyer i draws independently a type $t(i) \in \{1, \ldots, k\}$ with probability $\beta_{t(i)}$, and we set her value to $v_i = 1/\beta_{t(i)}$. Then, we sort buyers by decreasing $t(i)$, breaking ties using indices, and call $\sigma(i) \in \{1, \ldots, n\}$ the rank of buyer i in this ordering. We decide that buyer i is interested in all items up to the $\sigma(i)$-th one. To visualize this procedure, we refer to Figure 1. It is easy to find the optimal allocation: it consists in assigning each buyer of rank $\sigma(i)$ the $\sigma(i)$-th item, in a perfect matching. Thus the expected optimal social welfare is equal to

$$\mathbb{E}\left[\mathrm{OPT}\right] = \sum_{i=1}^{n} \sum_{t=1}^{k} \beta_t \cdot 1/\beta_t = n \cdot k.$$

Moreover, because each type is drawn independently the variance of OPTis

$$\mathrm{Var}(\mathrm{OPT}) = \sum_{i=1}^{n} \mathrm{Var}(v_i) \leq \sum_{i=1}^{n} \mathbb{E}[v_i^2] = n \cdot \sum_{t=1}^{k} \frac{1}{\beta_t} \leq 2n^2.$$

In particular, if we apply Chebyshev's inequality, we obtain

$$\mathbb{P}\left[\mathrm{OPT} \leq \frac{nk}{2}\right] \leq \mathbb{P}\left[|\mathrm{OPT} - nk| \geq \frac{nk}{2}\right] \leq \frac{\mathrm{Var}(\mathrm{OPT})}{(nk/2)^2} \leq \frac{8}{k^2}.$$

We now define the type $s(j) = t(\sigma^{-1}(j))$ of an item j as the type of the j-th buyer in the ordering σ, which corresponds to the type of its buyer in the abovementioned optimal matching. Observe that of each type, there are as many items as buyers, and that buyer i cannot be allocated an item j of type $s(j) < t(i)$. For each buyer i and for all types $t \leq s$, let $x^i_{s,t}$ be the probability (over the randomness of the types of all buyers except i) that i gets an item of type s, conditioning on the fact that i has type t. Let $x_{s,t} = \sum_i x^i_{s,t}/n$, that is, the average probability that a type t buyer will be assigned a type s item. The expected social welfare of our deterministic mechanism is equal to

$$\mathbb{E}\left[\mathrm{SW}(\mu)\right] = \sum_{i=1}^{n}\sum_{t=1}^{k} \beta_t \cdot 1/\beta_t \cdot \sum_{s=t}^{k} x_{s,t}^i = n\sum_{t=1}^{k}\sum_{s=t}^{k} x_{s,t}.$$

In expectation, the mechanism sells $\sum_i \sum_{t=1}^{s} \beta_t \cdot x_{s,t}^i$ items of type s. Because there are equally many items and buyers of each type, the expected number of items of type s is $\beta_s \cdot n$. Thus, we have the linear constraint

$$\forall 1 \leq s \leq k, \qquad \sum_{t=1}^{s} \beta_t \cdot x_{s,t} \leq \beta_s.$$

We are now going to use the critical item property. Fix a buyer i, and condition on the types of all buyers except her. We show that there exists an item $j(i) \in \{1, \ldots, n\}$, such that for every type $t(i)$, either i gets item $j(i)$, or she gets nothing. Denote as I_t the instance given by the fixed types of all buyers except i, together with buyer i who has type t. Using the critical item property with instance I_1, where i instead is of type 1 (meaning that i is interested in maximally many items), there is an item $j(i)$ such that buyer i either gets $j(i)$ or nothing. From the perspective of the mechanism, any other instance I_t (defined analogously) is identical to instance I_1 up to the point when i stops being interested in items. At this point, if buyer i has already been allocated an item, then it must be $j(i)$. Otherwise, she will not get anything.

Now that $j(i)$ is well-defined (and only depends on types of other buyers), let y_s^i be the probability (over the randomness of the types of all buyers except i) that there exists some type t such that if t is the type of i, then item $j(i)$ has type s. Let $y_s = \sum_i y_s^i/n$. Because buyer i can only get item $j(i)$, and because $j(i)$ is independent from $t(i)$, we have $x_{s,t}^i \leq y_s^i$. Thus, summing over all buyers, we have the linear constraint $x_{s,t} \leq y_s$, for all $1 \leq t \leq s \leq k$. Finally, conditioning on the types of all buyers except i, we show that there is only a small number of types that $j(i)$ can take. Recall that $s(j(i)) = t(\sigma^{-1}(j(i)))$, that is, the type of item $j(i)$ is by definition the type of the $j(i)$-th buyer in the ordering σ, where σ was obtained by sorting buyers in decreasing order of type. Consider the ordering induced by σ after excluding buyer i, and denote i_1 and i_2 the buyers of rank $j(i) - 1$ and $j(i)$. In the original ordering σ, either i comes before i_1 (in which case $s(j(i)) = t(i_1)$), or i comes after i_2 (in which case $s(j(i)) = t(i_2)$), or i comes between i_1 and i_2 (in which case $s(j(i)) = t(i)$). In any case, $t(i_1) \geq s(j(i)) \geq t(i_2)$. This shows that there are at most $2+z$ possible values for $s(j(i))$, where z denotes the number of types not seen among other buyers. By a standard computation, the expected value of z is smaller than $\sum_{t=1}^{k}(1-\beta_t)^{n-1}$. Recall that y_s denotes the average probability over i that there exists a type for i which can make $j(i)$ have type s, where the randomness is over the instance without i. Since for every *fixed* such instance, $j(i)$ can only possibly take two of the types seen in buyers except i, for any fixed i, it holds that $\sum_{s=1}^{k} y_s^i \leq \alpha$, where $\alpha = 2 + \sum_{t=1}^{k}(1-\beta_t)^{n-1}$, and therefore, the same holds also on average, i.e. for the y_s. Thus, averaging over possible types for the other buyers, and summing over i, we have the linear constraint $\sum_{s=1}^{k} y_s \leq \alpha$. If we choose $n = 1 + 2^k$ and $\beta_t = 2^{-t}/(1-2^{-k})$, we have

$$\sum_{t=1}^{k}(1-\beta_t)^{n-1} \leq \sum_{t=1}^{k} e^{-2^{k-t}/(1-2^{-k})} \leq \sum_{t=0}^{+\infty} e^{-2^t} \leq 1,$$

and thus $\alpha \leq 3$. To conclude the proof, we use the linear constraints obtained to define a linear program (P) whose objective function is the expected value of the social welfare

$$\begin{aligned}
\max \sum_{t=1}^{k}\sum_{s=t}^{k} x_{s,t} \qquad & \text{(P)} \\
\text{s.t. } & x_{s,t} \le y_s \\
& \textstyle\sum_{t=1}^{s} \beta_t \cdot x_{s,t} \le \beta_s \\
& \textstyle\sum_{s=1}^{k} y_s \le \alpha \\
& x_{s,t}, y_s \ge 0
\end{aligned}
\qquad\qquad
\begin{aligned}
\min\ \alpha \cdot w + \sum_{s=1}^{k} \beta_s \cdot v_s \qquad & \text{(D)} \\
\text{s.t. } & u_{s,t} + \beta_t \cdot v_s \ge 1 \\
& w \ge \textstyle\sum_{t=1}^{s} u_{s,t} \\
& u_{s,t}, v_s, w \ge 0
\end{aligned}$$

obtained by a deterministic truthful mechanism. We want to show that the objective function of our linear program is at most $\mathcal{O}(n \log k)$. To this end, Lemma 6 builds a solution for the dual linear program (D), whose value is an upper bound on the value of the primal linear program (for convenience, the objective function is divided by n). ◀

▶ **Lemma 6.** *Consider the linear program (P), parameterized by $\alpha > 0$ and $\beta_1 > \cdots > \beta_k > 0$. If $\beta_t = 2^{-t}/(1-2^{-k})$ for all $1 \le t \le k$, then the dual (D) has a feasible solution of value $\mathcal{O}(\alpha \log k)$.*

Proof. Set $\delta = \lceil \log_2 k \rceil$, then following solution of the dual is feasible and yields the desired objective value: $w = \delta$, $v_s = 0$ if $s < \delta$ and $2^{s-\delta}$ otherwise, while the $u_{s,t}$ are defined as:

$$\forall 1 \le t \le s \le k, \quad u_{s,t} = \begin{cases} 1 & \text{if } s < \delta \\ 1 - 2^{s-\delta-t} & \text{if } 0 \le s - \delta \le t \\ 0 & \text{otherwise} \end{cases}$$ ◀

4 Mechanisms with private graph edges

We move to the (harder) case where the graph edges are private information of the agents. The additional hardness, interestingly, severely affects the competitive guarantees for tardy truthful mechanisms. We begin by characterizing deterministic mechanisms, and then move on to results for randomized mechanisms.

4.1 Deterministic truthful mechanisms

In the previous section we assumed that the agents could not misreport their interest in items, thus reducing the problem to a single-parameter one. We now lift this assumption, and investigate the effect on the competitive ratio of deterministic truthful mechanisms. We show that deterministic truthful mechanisms can always be implemented in a prompt manner. Then, we give matching upper and lower bounds on the best approximation ratio for the social welfare.

▶ **Lemma 7.** *Tardy deterministic truthful mechanisms for the problem with private graph edges satisfy the critical item property (see Definition 1).*

Proof. For the sake of contradiction, assume that there is a buyer i who gets item j_1 at price p_1 if she reports a value β_1, and gets item j_2 at price p_2 if she reports a value β_2. Without loss of generality, we assume that $j_1 < j_2$. First, we argue that $p_1 = p_2$. Indeed, if $p_1 > p_2$ then i with value β_1 has incentive to lie and report β_2; whereas if $p_1 < p_2$ then i with value β_2 has incentive to lie and report β_1. Second, we slightly change the instance,

such that buyer i has value β_2 and is not interested in items after j_1. When allocating j_1, the mechanism has not seen any difference to the original instance, hence i has incentive to lie and report β_1 to get j_1, then lie and pretend she was interested in subsequent items to make sure she is charged p_1. ◀

▶ **Lemma 8.** *Tardy deterministic truthful mechanisms for the problem with private graph edges are prompt.*

Proof. Assume that our mechanism assigns an item j to buyer i, who reports value b_i. By Lemma 7, the mechanism satisfies the critical item property, and j is the only item which can be assigned to i. Let π be the minimum value that i could have reported and still be assigned j. By truthfulness, i must be charged exactly π. Indeed, if she is charged $p > \pi$ then i with value b_i has incentive to lie and report π; whereas if she is charged $p < \pi$ then i with value p would have incentives to lie and report b_i. Now, when the mechanism assigns j to i, it can retrospectively compute π, which proves that the mechanism is prompt. ◀

▶ **Theorem 9.** *There exists a deterministic truthful mechanism that achieves an $\nu = \min(m, n)$ approximation of the offline optimum. This result is tight in the class of deterministic truthful mechanisms, when graph edges are private.*

Proof. Consider the simple mechanism which only assigns an item to a buyer if she has the highest value seen so far (breaking ties arbitrarily), charging her the second highest value seen so far. This is a ν-competitive deterministic truthful mechanism. For the tightness, Lemma 8 shows that deterministic tardy mechanisms are in fact prompt, thus the lower bound from Theorem 4 (public graph edges) applies to this setting. ◀

5 Randomized truthful mechanisms

Recall that randomized (ex-post) truthful mechanisms are lotteries over deterministic truthful mechanisms, which in turn satisfy the characterizing properties we obtain for the deterministic case. The proof of our lower bound in Theorem 4 was based on this fact. This same argument also applies to mechanisms for private edges, even when they are tardy. On the positive side, we construct a prompt randomized truthful mechanism, the Explore-Exploit Mechanism, that yields a logarithmic approximation. The Explore-Exploit Mechanism divides the buyers into two types: "explore" buyers will not receive any item but are used to set the price for the "exploit" buyers. To guarantee truthfulness, we enforce monotonicity of the prices proposed by the seller during the routine: with prices always increasing, there is no way a buyer can benefit from withholding information in previous stages of the process to get something at a cheaper price later.

▶ **Theorem 10.** *The Explore-Exploit Mechanism is truthful, and computes a $O(\log n)$ approximation to the optimal social welfare. This result is nearly tight (up to $\log \log n$) in the class of randomized truthful mechanisms when the edges are private information, even for tardy mechanisms.*

Proof. Buyers of type *Explore* will not get any item, and thus have no incentive to lie. Buyers of type *Exploit* only need to say if they are interested to buy an item at a given price. Because prices are non-decreasing, they have no incentive to misreport their value or their interest in an item. For each item j, we define x_j as the maximum value seen among buyers interested in items up to j.

$$\forall j \in I, \qquad x_j = \max\{v_i \text{ with } i \in B \text{ such that } \exists j' \leq j, (i, j') \in E\}$$

Algorithm 1 Explore-Exploit Mechanism.

Initialization:
  Set $p \leftarrow 0$ and draw $k \leftarrow \text{Unif}(\{0, 1, \ldots, \lceil \log_2 n \rceil\})$
  For each buyer i, draw type $t_i \leftarrow \text{Unif}(\{Explore, Exploit\})$.
When an item arrives:
  Buyers report if they are interested in the item.
  For each buyer i of type $t_i = Explore$ who is interested in the item**, do**
    Set $p \leftarrow \max(p, v_i/2^k)$
  Sell the item at price p to a buyer i of type $t_i = Exploit$, who is interested
  in the item and does not yet have an item, chosen arbitrarily (e.g. lowest index).

For the sake of analysis, we look at a maximum weight matching $\mu \subseteq E$, having a total value of OPT. Each edge $(i, j) \in \mu$ from the optimal solution is assigned to a bucket $\ell_{(i,j)} = \lceil \log_2(x_j/v_i) \rceil \in \mathbb{N}$. Then for each $\ell \in \mathbb{N}$ we define OPT_ℓ as the total weight of the restriction of the optimal solution to bucket ℓ.

$$\text{OPT} = \sum_{\ell \geq 0} \text{OPT}_\ell \qquad \text{where } \forall \ell \geq 0, \quad \text{OPT}_\ell = \sum_{(i,j) \in \mu} v_i \cdot \mathbb{1}_{\{\ell_{(i,j)} = \ell\}}$$

Let V be maximum value among buyers who are interested in at least one item. By optimality of μ, the corresponding buyer must be given an item, and thus $\text{OPT}_0 \geq V$. Now observe that for each $(i, j) \in \mu$ such that $\ell_{(i,j)} > \lceil \log_2 n \rceil$, we have $v_i < x_j/n \leq V/n \leq \text{OPT}_0/n$. Thus, the sum of OPT_ℓ for $\ell > \lceil \log_2 n \rceil$ is smaller than OPT_0. Therefore, buckets $0, 1, \ldots, \lceil \log_2 n \rceil$ contain at least half of OPT, that is

$$\frac{\text{OPT}}{2} \leq \sum_{\ell=0}^{\lceil \log_2 n \rceil} \text{OPT}_\ell$$

For all $\ell \in \{0, 1 \ldots, \lceil \log_2 n \rceil\}$, we will now show that if $k = \ell$ then the Explore-Exploit Mechanism gives a solution of expected cost at least $\Omega(\text{OPT}_\ell)$. Then we will conclude the proof using the law of total probability: summing over k shows that the Explore-Exploit Mechanism computes a solution of expected cost at least $\Omega(\text{OPT}/\log n)$. First, assume that $k = 0$. For each edge $(i, j) \in \mu$ in bucket $\ell_{(i,j)} = 0$, then i is the best buyer seen by the time j arrives. With probability $1/4$, buyer i has type *Exploit* and the second best buyer has type *Explore*. In that case, the Explore-Exploit Mechanism gives buyer i an item (either j or one of the previous items). Using linearity of expectation, the Explore-Exploit Mechanism outputs a solution of expected value at least $\text{OPT}_0/4$. Second, assume that $k = \ell$ with $\ell \in \{1, \ldots, \lceil \log_2 n \rceil\}$. This case requires an amortized analysis: for each buyer i, denote X_i the random variable equal to v_i if i gets an item and 0 otherwise; and for each item j, denote Y_j the random variable equal to the value of the buyer to whom j is assigned, and 0 if j is unassigned. Notice that the Explore-Exploit Mechanism outputs a solution of value $= \sum_{i \in B} X_i = \sum_{j \in I} Y_j$. Let $(i, j) \in \mu$ be an edge from bucket $\ell_{(i,j)} = \ell$. We are going to show that

$$\mathbb{E}\left[X_i + 4Y_j \mid k = \ell \text{ and } t_i = Exploit\right] \geq v_i.$$

We condition on the fact that $k = \ell$ and $t_i = Exploit$. If buyer i already has an item when item j arrives, then $X_i = v_i$. Otherwise, the best buyer seen so far has type *Explore* with probability $1/2$, in which case the Explore-Exploit Mechanism gives item j to a

buyer of value $\geq x_j/2^\ell \geq v_i/2$. Buyer i has type $t_i = \textit{Exploit}$ with probability 1/2, thus $v_i \leq E[2X_i + 8Y_j \mid k = \ell]$. Summing this last inequality over edges from bucket ℓ shows that the Explore-Exploit Mechanism outputs a solution of expected value at least $\mathrm{OPT}_\ell/10$.

Let's move our attention to the lower bound . Fix all random decisions of an ex-post truthful randomized mechanism. This yields a deterministic algorithm, that together with the original mechanism's payment scheme yields a (tardy) mechanism. This mechanism is deterministic, and truthful due to the definition of truthfulness. Also, such a mechanism fulfills the critical item property (Lemma 7), and can even be made prompt (Lemma 8). With this, we can follow the original proof of the lower bound. ◀

6 Ex-ante truthfulness

One might wonder if the hardness of truthful mechanisms for our problem is mainly due to the very restrictive notion of ex-post truthfulness. We state here that also for the much looser ex-ante truthfulness, the setting of non-myopic buyers separates clearly from the myopic case. The proof is via a nontrivial construction allowing bounds on agents' expected utilities.

▶ **Theorem 11.** *There exists no randomized ex-ante truthful mechanism that yields an α-approximation to the optimal social welfare, for the problem with private edges and any $\alpha < 2$. This is true even for tardy mechanisms.*

Proof. Fix $\alpha < 2$ and assume mechanism M guarantees an expected approximation ratio of α. Consider the following problem instance: there are n' buyers and $m = n' + 1$ items. Every item j has exactly one interested buyer, i_j, and all i_j have some small value $v_{i_j} = \epsilon > 0$. There exist some additional buyers $B_1 \subseteq B$ with different values who are interested only in item 1, and one buyer, i, whom we fix for our considerations. Note that $|B| = n' + n_1$, with $n_1 = |B_1|$. For n' large enough, clearly, $n'\epsilon > \max_{i' \in B_1} v_{i'}$ and the contribution of item 1 to the optimum becomes negligible with growing n'. Therefore, for M to guarantee an α-approximation, there must exist $j \in \{2, \ldots, n' + 1\}$ such that i_j is assigned the according item with probability at least $\frac{1}{\alpha}$, or in case item 1 is worth more than ϵ, at least probability $\frac{1}{\alpha} - \Delta_1$, where Δ_1 arbitrarily small for large n'.

Now, if we choose $i = i_j$, then M will assign item j to i_j w.pr. $\geq \frac{1}{\alpha} - \Delta_1$, and charge an expected price of at most ϵ. The latter is because the price cannot depend on i's bid due to incentive compatibility, and it needs to be below i's value. Assume we replace i's valuation by some $v > \epsilon$, and call this new buyer $i^{(1)}$. Since M is ex-ante truthful, still, the exp. utility $u_{i^{(1)}}$ achieved with a truthful report must be at least as large as when reporting ϵ instead of v, i.e. at least $(v - \epsilon)(\frac{1}{\alpha} - \Delta_1) > \frac{1}{2}v$, which is at least half of v because α is < 2 and ϵ, Δ_1 can be chosen arbitrarily small. We replace $i^{(1)}$ again by a different buyer $i = i^{(2)}$. She still has valuation v, however, she is now interested in items 1 *and* j. We consider the first step of M, i.e. the assignment decision made for item 1. Assuming that v is the largest value bid on item 1, and given the fact that M has no idea if any additional value will present itself in the later steps, the probability that M assigns item 1 to $i^{(2)}$ is at least $\frac{1}{\alpha} - \Delta_2$, where Δ_2 approaches 0 since the other bids on item 1 might be, in comparison, too small to matter. Note again that the assignment decision cannot depend on v itself, but only on the fact that it is the largest value bid on item 1.

We know that $i^{(2)}$ can get utility larger than $\frac{v}{2}$ by simply reporting type $i^{(1)}$ instead. We also know that since she is assigned item 1 w.pr. $> \frac{1}{2}$, she is assigned item j w.pr. $< \frac{1}{2}$. This, intuitively, means that not all of the guaranteed utility is generated by item j, not even if the price of j is always 0 – but some must be generated because her expected price paid when

item 1 is assigned is bounded away from v, i.e. $p_{i^{(2)}}(1) = v - \Delta_3$. In fact, the exp. price M charges from $i^{(2)}$ when assigning item 1 cannot be smaller if $i^{(2)}$ later reports interest in item j, since this would give a buyer of type $i^{(1)}$ incentive to also report interest in j. Also, the price charged from $i^{(2)}$ when assigning item j cannot be less than 0, and when there is no item assigned, $i^{(2)}$ is not charged anything (see preliminaries). This implies that, for $P_k(i)$ denoting the assignment probability of item k to buyer i,

$$\begin{aligned} u_{i^{(2)}} &= (v - p_{i^{(2)}}(1)) \cdot P_1(i^{(2)}) + (v - p_{i^{(2)}}(j)) \cdot P_j(i^{(2)}) \\ &= \Delta_3 \cdot P_1(i^{(2)}) + (v - p_{i^{(2)}}(j)) \cdot P_j(i^{(2)}) > \frac{v}{2} \end{aligned}$$

Otherwise, we would have a contradiction on the utility being larger than $\frac{v}{2}$, i.e. it would be beneficial for $i^{(2)}$ to only report interest in item j. In consequence, it also holds

$$u_{i^{(2)}} = \Delta_3 \cdot P_1(i^{(2)}) + (v - p_{i^{(2)}}(j)) \cdot P_j(i^{(2)}) \geq \Delta_3 \cdot P_1(i^{(2)}) + (v - v) \cdot P_j(i^{(2)}) > 0.$$

This is true because the exp. price when receiving item j can be no more than v, and $P_j(i^{(2)}) < \frac{1}{2}$. Therefore, there exists some $v^- < v$ for which it holds that

$$u_{i^-}(1) = u_{i^{(2)}}(1) - P_1(i^{(2)})(v - v^-) = (\Delta_3 - (v - v^-))P_1(i^{(2)})$$

Here, $u_{i^-}(1)$ denotes the utility obtained from being assigned item 1 of some buyer with valuation v^- for item 1, and 0 otherwise, when she reports $i^{(2)}$ as her type. Note that if buyer i^- reports value v for item 1 and 0 for all others, she will also obtain $u_{i^-}(1)$ from being assigned the first item: the assignment decision is made before the algorithm can know the difference, and the expected price paid cannot depend on the buyer's later reports due to truthfulness.

We use this to show a contradiction to the approximation ratio of M. Assume there exists, in absence of $i^{(2)}$, such a buyer i^- with smaller value v^- and utility of $u^-(1) > 0$ when reporting to have value v, who is interested in purchasing item 1, i.e. $i^- \in B_1$. Since M is ex-ante truthful, a truthful report for her will also result in positive expected utility of at least $u^-(1)$. As a direct consequence, it holds also that the probability $P_1(i^-)$ for assigning item 1 to i^- (when she reports truthfully) is lower bounded, in order to achieve above expected utility, as follows: $P_1(i^-) \geq \frac{u_{i^-}(1)}{v^-}$. Finally, we copy buyer i^- at least $\frac{v^-}{u_{i^-}(1)} + 1$ times. If necessary for tie-breaking, we distort their values a bit. Our conclusions about $i^{(2)}$'s utility hold once $i^{(2)}$ reports the largest value for item 1, regardless of other values. This means, if either of our copied v^- should decide to deviate and report to be valued like $i^{(2)}$ instead, they can recover utility $u_{i^-}(1)$. As a result, each one of the copies, when reporting truthfully, has at least the same utility, and therefore an assignment probability of at least $P_1(i^-)$. This, in sum, results in a probability of more than 1 for assigning item 1, i.e., a contradiction. ◀

7 Conclusions

We have studied vertex-weighted bipartite online matching with offline agents in various settings, obtaining an almost-complete picture of the competitive ratios achievable by mechanisms under different truthfulness notions. Our results encompass that for myopic truthfulness, the best algorithmic results [18, 1] transfer to the online agents setting. This showcases that the very general myopic bounds of [9] are far from tight for restricted settings like ours. On the other hand, we also show that equally near-optimal approximations are impossible under the assumption of classic truthfulness, even ex-ante; and for ex-post

truthfulness our seemingly simple problem already exhibits lower bounds almost matching the myopic, logarithmic competitive ratio for submodular combinatorial auctions in [9]. We leave open to what extent this additional hardness (moving from a tight $e/(e-1)$ myopic to $\Omega(\log n/\log\log n)$ truthful) already happens when imposing ex-ante truthfulness. This is an interesting subject of investigation, also for different scenarios than the one of our ≥ 2 lower bound (private edges).

A Mechanisms for Myopic Buyers

In this section we study myopic buyers. We show that for this class of agents, one can obtain strategy proof versions of the best (non-truthful) algorithms [18]. Formally, we construct a deterministic prompt mechanism that achieves at least half of the welfare of the best offline matching, and a randomized prompt mechanism that is (in expectation) $e/(e-1)$-competitive with the best offline matching. We start describing our deterministic mechanism HonestGreedy, which mimics the classical Greedy algorithm for online weighted matching in a way that is robust to strategic bidding. Every time a new item arrives, HonestGreedy runs a second price auction [27] to allocate it between the remaining (interested) buyers. Since the buyers are myopic, every time a new item arrives, they behave like if it was the last: clearly there is no point in lying about being interested in an item. Moreover, the truthfulness in each step (as well as the individual rationality) is guaranteed by the well-known properties of the second price auction. Note that the mechanism sets the price for item i immediately, so it is prompt. The analysis of the approximation guarantee is also quite simple: the allocation output by HonestGreedy is the same one that the standard Greedy algorithm would have computed on the same input. It is well known that Greedy is 2-competitive with respect to the best offline matching (see, e.g., Appendix B of [1]), and that this approximation is tight in the class of deterministic algorithms [18]. We summarize these observations.

▶ **Theorem 12.** *The deterministic prompt mechanism HonestGreedy is truthful for myopic agents and guarantees a 2 approximation to the best offline matching. The approximation is tight even for (non-truthful) deterministic algorithms.*

We complement this deterministic 2-competitive, simple mechanism with an optimal, randomized $e/(e-1)$−competitive alternative, HonestPerturbedGreedy, based on Perturbed-Greedy of Aggarwal et al. [1]. There, each offline vertex is associated with a random multiplier; then, every time one of the online vertices arrives, it is matched to the

Algorithm 2 HonestPerturbedGreedy.

1: **For** each buyer i**, do**
2: Draw x_i uniformly at random from $[0, 1]$
3: Let $y_i = 1 - e^{x_i - 1}$
4: Reveal publicly all x_i and y_i
5: **For** item j arriving online**, do**
6: Receive bids for j and let $N(j)$ be the set of agents interested in j
7: Allocate j to $i^\star \in \arg\max\{b_i \cdot y_i \mid i \in N(j)\}$ ▷ Allocation Rule
8: Charge $i^\star$ with $p_{i^\star} = \max\left\{\frac{y_i}{y_{i^\star}} b_i \mid i \in N(j) \setminus \{i^\star\}\right\}$ ▷ Payment Rule
9: Discard for further consideration $i^\star$

free neighbor with largest multiplier-value product. To protect from the strategic behavior of agents, HonestPerturbedGreedy declares – before the beginning of the online phase – publicly all random multipliers, and then implements Myerson's payment rule [24] for every round. For a formal description we refer to the pseudocode of HonestPerturbedGreedy, where we maintain the convention that the max of an empty set is 0 and thus if $N(j)$ is empty in line 7, then j is discarded and the mechanism passes to the next item. The properties of HonestPerturbedGreedy are summarized in the following Theorem, whose formal proof is deferred to Appendix C.

▶ **Theorem 13.** *The randomized prompt mechanism HonestPerturbedGreedy is truthful for myopic agents and achieves (in expectation) a $e/(e-1)$ approximation to the best offline matching. The approximation is tight even for (non-truthful) randomized algorithms.*

B Tardy mechanisms with public graph edges

When the graph edges are public knowledge, we can turn once again to using the algorithmic approaches outlined in the previous Section, i.e. Greedy and Perturbed-Greedy. Now that agents cannot strategically withhold or misreport the existence of edges, a tardy truthful mechanism can use the whole graph structure (but of course still not the reported value b_i) when computing the price charged from any buyer i. The prompt, round-wise payment rules we designed for myopic buyers, however, do not guarantee non-myopic truthfulness. What remains to prove therefore is that these algorithms can be augmented by a different (tardy) payment rule to be made truthful. This is formally done in two steps: first, it is established that the allocations produced are monotone, and then Myerson's Lemma is employed to enforce truthfulness. All in all, we have the following.

▶ **Theorem 14.** *There exists a deterministic, respectively randomized, tardy mechanism that is truthful for non-myopic agents with public graph edges and guarantees a 2, resp. $e/(e-1)$, approximation to the best offline matching. The approximation is tight even for (non-truthful) deterministic, resp. randomized, algorithms.*

Note that the allocation computed by the mechanisms we just described are analogous to the ones computed by HonestGreedy and HonestPerturbedGreedy, but the payments are different! We are still using Myerson's Lemma, but the critical prices[2] are clearly different, as they are computed considering the whole run of the algorithm. To see this, consider the following example. There are two buyers, b_1 and b_2, and two items i_1 and i_2. b_1 is interested

[2] The critical price is the smallest bid that would have still resulted in the item being allocated to the agent. See the Appendix C for a formal definition

in both the items and has a value of 1, while b_2 only cares about i_1, with a value of 0.9. Assume also for the sake of simplicy that the perturbations y_1 and y_2 of PERTURBED-GREEDY are both 1. Both versions of PERTURBED-GREEDY would only allocate i_1 to b_1, but at two different prices: the mechanism for myopic agents would charge 0.9, while the tardy one for non-myopic agents would wait until the end of the second round and charge 0.

C Proofs of Theorems 13 and 14

In this section we prove the properties of HONESTPERTURBEDGREEDY and of the tardy versions of GREEDY and PERTURBED-GREEDY presented in Appendices A and B. Starting from the guarantees of their non-strategic counterparts it is immediate to see that the approximation factor claimed are indeed correct. The only property to show is incentive compatibility. A crucial ingredient to prove incentive compatibility is Myerson's Lemma, that we recall here for the sake of completeness. The Lemma has been proved in Myerson's seminal paper [24]; here we follow the more modern approach by Roughgarden [26]. Since in this paper we study unit-demand agents, we restrict to consider only this type of agents.

We start introducing the notion of single-parameter environments. In such environments, there are n agents and a set X of feasible allocations of items to agents. Each agents is characterized by a private valuation to get an item and strives to maximize her quasi-linear utility. To familiarize with this notion consider the model of non-myopic buyers with public graph edges studied in the paper: those agents are indeed single-parameters, as their valuations is their only private information. At the same time, note that the "edge compatibility" is implicitly modeled by the following set of feasible allocations of items to agents: an allocation $\mathbf{x} \in \{0,1\}^n$ is feasible if and only if it is corresponds with a matching in the underlying buyers-items bipartite graph. As already mentioned in the main body, a mechanism $\mathcal{M}$ is characterized by two features: an allocation $\mathbf{x} \in X$ and a payment rule $\mathbf{p}$. While the allocation specifies who gets what, the payment rule defines how much each agent pays. Allocation and payments are functions of the bids; in particular, we use the notation $x_i(b_i, b_{-i}) \in \{0,1\}$ to specify whether the i^{th} agent is allocated an item, given her bid b_i and the $n-1$ bids b_{-i} of the other agents. We are ready for the following crucial definitions.

▶ **Definition 15** (Monotone allocation). *An allocation rule* $\mathbf{x}$ *for a single-parameter environment is monotone if for every bidder* i *and bids* b_{-i} *by the other bidders, the allocation* $x_i(z, b_{-i})$ *to* i *is nondecreasing in its bid* z*.*

▶ **Definition 16** (critical prices). *Fix and agent* i *and bids* b_{-i} *of the other agents. Then the critical price for* i *is defined as the smallest bid* z_i *such that* i *is allocated an item, if any. Formally, if we use the convention that the* inf *of an empty set is* 0*, we have* $z_i = \inf\{z \mid x_i(z, b_{-i}) = 1\}$

Clearly, the critical prices enforce ex-post individual rationality. Myerson showed that they also induce (ex-post) truthfulness; we report here a version of Lemma 2 of Myerson [24] that is tailored to our problem and then show the two Theorems.

▶ **Theorem 17** (Myerson's Lemma). *Fix a single-parameter mechanism. Given any monotone allocation* $\mathbf{x}$*, it is possible to compute a payment scheme* $\mathbf{p}$ *such that the resulting mechanism is truthful and individually rational. In particular, in* $\mathbf{p}$*, each agents that receives an item pays its critical price and* 0 *otherwise.*

▶ **Theorem 13.** *The randomized prompt mechanism* HONESTPERTURBEDGREEDY *is truthful for myopic agents and achieves (in expectation) a* $e/(e-1)$ *approximation to the best offline matching. The approximation is tight even for (non-truthful) randomized algorithms.*

Proof. We start the proof by arguing that HonestPerturbedGreedy is truthful and individually rational for myopic agents. First, note that when any item j arrives, there is no point for the buyers still unallocated to lie about their interest for it: if they are not interested and they bid, they would risk to get j and lose future opportunity to get allocated to something they are interested in, while if they are interested they do not want to lose the opportunity (since they have no information on the future, and the prices charged never exceed their valuations). If we restrict to consider the buyers $N(j)$ interested in item j, we see that the problem reduces to a single-parameter auction: the agents are myopic and just want to maximize their utility by getting j at a small price. All y_i are public knowledge and non-negative, so our allocation rule (line 7 of HonestPerturbedGreedy), fixing these values, is clearly monotone (the more an agent i bids, the more likely she is to exhibit the largest $y_i \cdot b_i$). The allocation is therefore implementable using the Myerson payment rule (line 8 of HonestPerturbedGreedy). We can conclude, by Myerson's Lemma, that our mechanism is truthful for myopic buyers. Moreover, it is easy to verify that the payment rule enforces individual rationality. Once we have settled the truthfulness, we can assume that all buyers declare their true bids and thus the allocation output by HonestPerturbedGreedy is the same as Perturbed-Greedy *for any realization* of the perturbations x_i and inherits the same approximation: HonestPerturbedGreedy is $e/(e-1)$-competitive in expectation. ◀

▶ **Theorem 14.** *There exists a deterministic, respectively randomized, tardy mechanism that is truthful for non-myopic agents with public graph edges and guarantees a* 2*, resp.* $e/(e-1)$*, approximation to the best offline matching. The approximation is tight even for (non-truthful) deterministic, resp. randomized, algorithms.*

Proof. It is easy to see how the two mechanisms are monotone, thus it is possible to employ directly Myerson's Lemma, as the problem is single-parameter (i.e., the only private information of buyer i is the single value v_i). Therefore, Greedy or Perturbed-Greedy (with fixed perturbation factors) together with the critical payments defined in Myerson's Lemma result in a truthful mechanism. Note that the greedy algorithm clearly respects our ex-post notion of truthfulness, since no randomization is involved. For the Perturbed-Greedy algorithm, this is also true since we fix all random decisions (perturbation) up front, and choose the payment rule accordingly. ◀

Completely Reachable Automata: A Polynomial Algorithm and Quadratic Upper Bounds

Robert Ferens
University of Wrocław, Poland

Marek Szykuła
University of Wrocław, Poland

Abstract

A complete deterministic finite (semi)automaton (DFA) with a set of states Q is *completely reachable* if every non-empty subset of Q can be obtained as the image of the action of some word applied to Q. The concept of completely reachable automata appeared several times, in particular, in connection with synchronizing automata; the class contains the Černý automata and covers a few separately investigated subclasses. The notion was introduced by Bondar and Volkov (2016), who also raised the question about the complexity of deciding if an automaton is completely reachable. We develop a polynomial-time algorithm for this problem, which is based on a new complement-intersecting technique for finding an extending word for a subset of states. The algorithm works in $\mathcal{O}(|\Sigma| \cdot n^3)$ time, where $n = |Q|$ is the number of states and $|\Sigma|$ is the size of the input alphabet. Finally, we prove a weak Don's conjecture for this class of automata: a subset of size k is reachable with a word of length smaller than $2n(n-k)$. This implies a quadratic upper bound in n on the length of the shortest synchronizing words (reset threshold) for the class of completely reachable automata and generalizes earlier upper bounds derived for its subclasses.

1 Introduction

The concept of completely reachable automata origins from the theory of synchronizing automata. A deterministic finite automaton is *synchronizing* if starting from the set of all states, after reading a suitable *reset* word, we can narrow (reach) the set of possible states to a singleton. On the other hand, an automaton is *completely reachable* if starting from the set of all states, we can reach every non-empty subset of states. Thus, every completely reachable automaton is synchronizing, and the class of completely reachable automata forms a remarkable subclass of (synchronizing) automata.

Synchronizing automata are most famous due to a longstanding open problem: the Černý conjecture, which states that every synchronizing n-state automaton admits a reset word of length at most $(n-1)^2$. Applications of synchronizing automata include testing of reactive systems [20] and synchronization of codes [2, 4]. The currently best upper bound for the Černý problem is cubic in n [18, 21, 22]. Finding better bounds for particular cases was a topic of extensive study. Some of the related computational problems such as checking if an automaton is synchronizing are solved in polynomial time [11]. Other ones, such as finding a reset word of the smallest length, are hard, but practical (heuristic and optimizing) methods are developed [23]. Most of the research on the topic of synchronizing automata was collected and comprehensively described in the recent survey [25]; we also refer to older ones [16, 24].

Other studies where completely reachable automata appear include the descriptional complexity of formal languages. Here, the complete reachability of an automaton is often juxtaposed with the maximality of the state complexity or the syntactic complexity of languages recognized by automata [5, 15, 17].

The notion of completely reachable automata was first introduced in 2016 by Bondar and Volkov [6], who also asked about the complexity of the computational problem of deciding whether a given automaton is completely reachable. The analogous decision problem for synchronizing automata is easily solvable in quadratic time in the number of states. Later studies revealed a connection to the so-called Rystsov graph, whose generalization can be used to characterize completely reachable automata [5, 7]. However, this does not yet lead to an effective algorithm, as it is unknown how to compute these graphs. Recently, the case of binary automata was solved with a quasilinear-time algorithm [8], which strongly relies on the specificity of both letters when they ensure the complete reachability of the automaton.

The class of completely reachable automata contains several previously studied cases. It contains the Černý automata [9], which meet the conjectured bound $(n-1)^2$ for the Černý problem, and some of the so-called *slowly synchronizing series* [1]. The class of automata with the full transition monoid [13], synchronizing automata with simple idempotents [19] and aperiodically 1-contracting automata [10] are proper subclasses of completely reachable automata. For the first two subclasses and a special case of the third one quadratic upper bounds on the length of the shortest reset words instead of a cubic one were established for the Černý problem. However, for the whole class of completely reachable automata, only cubic bounds were known (though better than in the general case) [5].

In connection to the bounds, a remarkable conjecture and a generalization of the Černý one is Don's conjecture [10, Conjecture 18]. It states that for an n-state automaton, for every $1 \leq k < n$, if a subset of states of size k is reachable, then it can be reached with a word of length at most $n(n-k)$. This conjecture was disproved in general [14] but weaker versions were proposed: one restricting to completely reachable automata [14, Problem 4] and another general one, in relation to avoiding words [12, Conjecture 15].

1.1 Contribution

We design a polynomial-time algorithm for the problem of deciding whether an automaton is completely reachable, thus solving the 7-year-old open question [6]. For this solution, we develop a complement-intersecting technique, which allows finding a short extending word for a given subset of states (i.e., that gives a larger preimage). We optimize the complexity of the algorithm to work in $\mathcal{O}(|\Sigma| \cdot n^3)$ time.

Based on the discovered properties, we prove that every non-empty subset of $k < n$ states in a completely reachable n-state automaton is reachable with a word of length smaller than $2n(n-k)$. This is a weaker version (by the factor of 2) of Don's conjecture stated for completely reachable automata [14, Problem 4].

It follows that a completely reachable n-state automaton has a reset word of length at most $2n^2 - n\ln n - 4n + 2$ (for $n \geq 3$). This generalizes and improves the previous bounds obtained with different techniques for known proper subclasses of completely reachable automata: automata with a full transition monoid (with the previous upper bound $2n^2 - 6n + 5$) [13], synchronizing automata with simple idempotents (with the previous upper bound $2n^2 - 4n + 2$) [19], and 1-contracting automata (only a special case was solved) [10].

2 Solving Complete Reachability in Polynomial Time

2.1 Reachability

A *complete deterministic finite semiautomaton* (called simply *automaton*) is a 3-tuple (Q, Σ, δ), where Q is a finite set of *states*, Σ is an *input alphabet*, and $\delta\colon Q \times \Sigma \to Q$ is the *transition function*, which is extended to a function $Q \times \Sigma^* \to Q$ in the usual way. Throughout the paper, by n we always denote the number of states in Q.

Given a subset $S \subseteq Q$, the *image* of S under the action of a word $w \in \Sigma^*$ is $\delta(S, w) = \{\delta(q, w) \mid q \in S\}$. The *preimage* of S under the action of w is $\delta^{-1}(S, w) = \{q \in Q \mid \delta(q, w) \in S\}$. For a state q, we also simplify $\delta^{-1}(q, w) = \delta^{-1}(\{q\}, w)$. Note that $q \in \delta(Q, w)$ if and only if $\delta^{-1}(q, w) \neq \emptyset$. For a subset $S \subseteq Q$, by $\overline{S}$ we denote its complement $Q \setminus S$.

For two subsets $S, T \subseteq Q$, if there exists a word $w \in \Sigma^*$ such that $\delta(T, w) = S$, then we say that S is *reachable from* T *with* the word w. Then we also say that T is a *w-predecessor* of S. It is simply a *predecessor* of S if it is a w-predecessor for some word w. One set can have many w-predecessors, but there is at most one maximal with respect to inclusion (and size).

▶ Remark 1. For $S \subseteq Q$ and $w \in \Sigma^*$, the preimage $\delta^{-1}(S, w)$ is a w-predecessor of S if and only if $\delta^{-1}(q, w) \neq \emptyset$ for every state $q \in S$. Equivalently, we have $\delta(\delta^{-1}(S, w)) = S$.

▶ Remark 2. For $S \subseteq Q$ and $w \in \Sigma^*$, if $\delta^{-1}(S, w)$ is a w-predecessor of S, then all w-predecessors of S are contained in it, thus $\delta^{-1}(S, w)$ is maximal in terms of inclusion and size. If $\delta^{-1}(S, w)$ is not a w-predecessor of S, then S does not have any w-predecessors.

A word w is called *extending* for a subset S, or w *extends* S, if $|\delta^{-1}(S, w)| > |S|$. It is called *properly extending* if additionally $\delta^{-1}(S, w)$ is a w-predecessor of S, i.e., $\delta^{-1}(q, w) \neq \emptyset$ for all $q \in S$.

A subset $S \subseteq Q$ is *reachable* in the automaton if S is reachable from Q with any word. An automaton is *completely reachable* if all non-empty subsets $S \subseteq Q$ are reachable. Equivalently, Q is a predecessor of all its non-empty subsets. The latter leads to an alternative characterization of completely reachable automata:

▶ Remark 3. An automaton (Q, Σ, δ) is completely reachable if and only if for every non-empty proper subset of Q, there is a properly extending word.

The decision problem Completely Reachable is the following: Given an automaton (Q, Σ, δ), is it completely reachable?

2.2 Witnesses

For an automaton (Q, Σ, δ), we consider unreachable sets that have the maximal size among all unreachable subsets of Q. They play the role of witnesses for the non-complete reachability of the automaton (or counterexamples for its complete reachability).

▶ **Definition 4** (Witness). *A non-empty set $S \subsetneq Q$ is a* witness *if it is unreachable and has the maximal size of all unreachable subsets of Q.*

Since Q is trivially reachable, the maximal size of unreachable subsets of Q is in $\{0, \ldots, n-1\}$. It equals 0 (i.e., there is no witness) if and only if the automaton is completely reachable.

Although any non-empty unreachable set is evidence that the automaton is not completely reachable, it turns out that verifying if a set is a witness is computationally easier – later we show that we can verify the complete reachability and also find a witness if it exists in polynomial time. Verifying whether a given set is reachable (or unreachable) in general is PSPACE-complete [6] and it remains hard in many variations of the problem [3].

We start with a simpler solution in co-NP, where we just guess a candidate for a witness and verify it. A witness obviously cannot have a larger predecessor, as this predecessor or maybe some other larger set would be unreachable and so a witness instead. Still, a set can have exponentially many predecessors of the same size. The following observation allows us to infer the existence of a larger predecessor indirectly.

▶ **Lemma 5.** *Let $S, T \subseteq Q$ be distinct. If a word $u \in \Sigma^*$ is properly extending $S \cup T$, then u is also properly extending S or T.*

Proof. Let u be a properly extending word for $U = S \cup T \subsetneq Q$, thus there is a larger maximal u-predecessor U' of U, i.e., $\delta(U', u) = U$, $\delta^{-1}(U, u) = U'$, and $|U'| > |U|$. By Remark 1, we have $|\delta^{-1}(q, u)| \geq 1$ for all $q \in U$. As this holds for all the states of S and T, they also have their u-predecessors $\delta^{-1}(S, u)$ and $\delta^{-1}(T, u)$, respectively. Suppose that $|\delta^{-1}(S, u)| = |S|$ and $|\delta^{-1}(T, u)| = |T|$. Then $|\delta^{-1}(q, u)| = 1$ for all $q \in U$, which gives a contradiction with $|U'| > |U|$. ◀

▶ **Corollary 6.** *Let $S, T \subsetneq Q$ be two distinct witnesses. Then $S \cup T = Q$.*

Proof. Since $S \neq T$, the union $S \cup T$ is larger than the witness size $|S| = |T|$, thus it must be reachable. If $S \cup T \neq Q$, then $S \cup T$ has a larger predecessor. By Lemma 5, either S or T also has a larger predecessor, which contradicts that they both are witnesses. ◀

Now, we focus on detecting sets that are potential witnesses. We relax the required property for being a witness and introduce an auxiliary definition:

▶ **Definition 7** (Witness candidate)**.** *A non-empty set $S \subsetneq Q$ is a* witness candidate *if it does not have a larger predecessor and all its predecessors (which are of the same size) have pairwise disjoint complements.*

▶ Remark 8. For two sets $T, T' \subseteq Q$, the condition of disjoint complements $\overline{T} \cap \overline{T'} = \emptyset$ is equivalent to $T \cup T' = Q$.

▶ **Lemma 9.** *A witness is a witness candidate.*

Proof. Let S be a witness and let T and T' be two distinct predecessors of S. As they are of the same size $|T| = |T'| = |S|$ and S is reachable from both T and T', they also must be witnesses. By Corollary 6, $T \cup T' = Q$. Therefore, S meets the definition of a witness candidate. ◀

Thus, every witness is a witness candidate and clearly, every witness candidate is unreachable (moreover, it is unreachable from every larger set). However, both converses do not necessarily hold.

▶ **Example 10.** The automaton from Figure 1 (left) is not completely reachable, and:

- All sets of size 5 are witnesses.
- The sets $Q \setminus \{q_i, q_{(i+1) \bmod 6}\}$ for $i \in \{0, \ldots, 5\}$ are reachable.

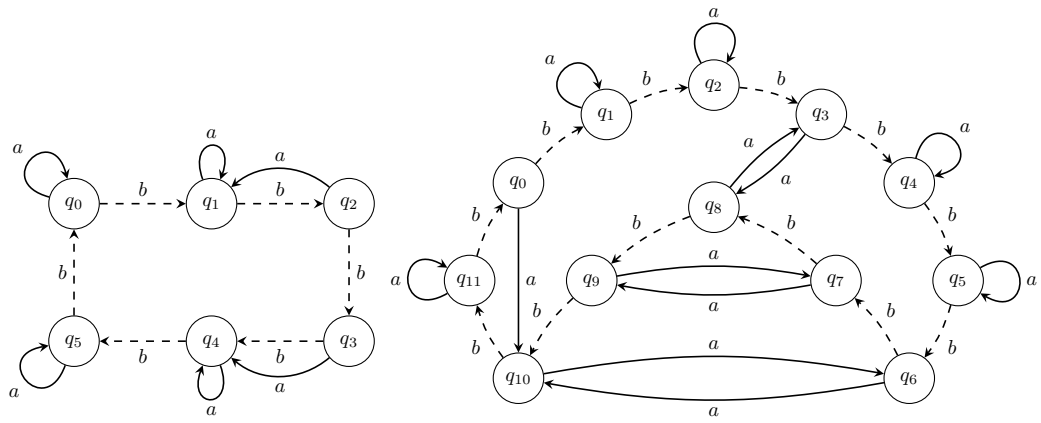

Figure 1 Left: an example of an automaton that is not completely reachable. **Right:** an example of a completely reachable automaton [8, Fig. 3]. (a's transitions are solid, b's transitions are dashed.)

- The sets $Q \setminus \{q_i, q_{(i+2) \bmod 6}\}$ for $i \in \{0, \ldots, 5\}$ are unreachable (only the action of b yields a predecessor). They do not admit a properly extending word but they are not witness candidates, since their complements are not disjoint.
- The set $\{q_0, q_2, q_4\}$ and its complement $\{q_1, q_3, q_5\}$ are witness candidates but not witnesses, as they have size 3.
- All non-empty proper subsets of Q are extensible, e.g., $\delta^{-1}(q_1, (ab)^3, a) = Q$, but not necessarily properly extensible.

The following remark will be useful for efficient checking if a set is a witness candidate:

▶ Remark 11. A witness candidate S has at most $\lfloor n/(n - |S|) \rfloor$ predecessors.

Proof. The complements of the predecessors of S are pairwise disjoint, so each state is contained in at most one complement of size $n - |S|$. ◀

2.3 An Algorithm in co-NP

We build a polynomial procedure that checks whether a given set S is a witness candidate. It is shown in Algorithm 1. Starting from S, we process all its predecessors in a breath-first search manner; for this, a FIFO queue *Process* is used. A next set T is taken in line 6. Then, we verify whether $\overline{T} \cap \overline{T'} \neq \emptyset$, for some previously processed set T'. For this, we maintain *Absent* array, which for every state q indicates whether q occurred in the complement of some previously processed set, and if so, this set is stored as $Absent[q]$. We additionally use this array to check whether the same set T has been processed previously (line 9); if so, then it is ignored. Otherwise, S is not a witness candidate as the complements of its two predecessors have a non-empty intersection. We update this array in lines 12–13. Finally, in lines 14–19, we add one-letter predecessors of T to the queue. If one of the predecessors is larger than T, then this immediately implies that S is not a witness candidate. Since predecessors are never smaller, this means that all processed sets that are put into the queue are of the same size $|S|$. When all predecessors of S have been considered and neither of the two conditions occurred, the function reports that S is a witness candidate.

The function is a base for our next algorithms. Hence, even though we do not need to optimize it here, in the next lemma, we describe the technical details for achieving optimal time complexity. In particular, an important optimization that lowers the time complexity

Algorithm 1 Verifying whether a given subset is a witness candidate from Definition 7.

Input: An n-state automaton $\mathscr{A} = (Q, \Sigma, \delta)$ and a non-empty $S \subsetneq Q$.
Output: **true** if S is a witness candidate; **false** otherwise.

```
1:  function IsWitnessCandidate(𝒜, S)
2:      Process ← EmptyFifoQueue()        ▷ It contains predecessors of S to be processed
3:      Process.Push(S)
4:      Absent ← Array indexed by q ∈ Q initialized with none
5:      while not Process.Empty() do
6:          T ← Process.Pop()
7:          if Absent[q] ≠ none for some q ∈ T̄ then          ▷ Then T ∪ T′ ≠ Q
8:              T′ ← Absent[q]
9:              if T = T′ then
10:                 continue                    ▷ T has been processed previously
11:             return false    ▷ T and T′ are predecessors with non-disjoint complements
12:         for all q ∈ T̄ do
13:             Absent[q] ← T
14:         for all a ∈ Σ do
15:             if T has a-predecessor then
16:                 T′ = δ^{-1}(T, a)
17:                 if |T′| > |S| then
18:                     return false
19:                 Process.Push(T′)
20:     return true                          ▷ All predecessors of S were checked
```

is storing each processed set T as a list of states in its complement. Then we can perform all operations on a set T in $\mathcal{O}(n - |S|)$ time, which compensates the number of iterations, which is at most $\mathcal{O}(n/(n - |S|))$.

▶ **Lemma 12.** *Function* IsWitnessCandidate *from Algorithm 1 is correct and can be implemented to work in* $\mathcal{O}(|\Sigma| \cdot n)$ *time.*

Proof. *Correctness:* The function can end in line 11, 18, or 20. The first case means that S has two distinct predecessors, T and T' such that $\overline{T} \cap \overline{T'} \neq \emptyset$, which implies that S is not a witness candidate. The second case (line 18) means that we have found a larger predecessor of S, thus S is not a witness candidate. The last possibility (line 20), where the function ends with a positive answer, occurs when there are no more predecessors of S to consider (*Process* becomes empty), so all predecessors of S have been checked and the two previous cases have not occurred. Thus, S satisfies the conditions from Definition 7.
Running time: We separately consider the time complexity of two types of iterations of the main loop: *full* and *extra* iterations. An extra iteration is where the case from line 7 holds; then the iteration ends either in line 10 or 11. Otherwise, we count it as a full iteration.

In each iteration, T has size $|S|$, because a predecessor cannot be smaller than the set and we check in line 18 if it is larger. The number of distinct processed predecessors (including S itself) of the same size $|S| < n$ with pairwise disjoint complements is at most $\lfloor n/(n - |S|) \rfloor$. This bounds the number of full iterations. In extra iterations, the same sets can be repeated. As these sets are added in full iterations, and one full iteration adds at most $|\Sigma|$ sets to the queue, the number of extra iterations is at most $|\Sigma| \cdot (\lfloor n/(n - |S|) \rfloor)$.

If we store T (and all sets in *Process*) as a list of states in its complement, then full one iteration takes $\mathcal{O}(|\Sigma| \cdot (n - |S|))$ time: Lines 6–11 trivially take $\mathcal{O}(n - |S|)$ time. Updating *Absent* in lines 12–13 also takes $\mathcal{O}(n-|S|)$ time, if we store a pointer/reference to T (line 14 in $\mathcal{O}(1)$) instead of copying. Computing one-letter predecessors in lines 15–19 can be performed in $\mathcal{O}(|\Sigma| \cdot (n - |S|))$ time as follows. At the beginning of the function, we additionally do some preprocessing of the automaton. For each $a \in \Sigma$ and $q \in Q$, we compute the list of states $\delta^{-1}(q, a)$; note that for the same a, these lists are always disjoint. For each $a \in \Sigma$, we also count the states $q \in Q$ such that $|\delta^{-1}(q, a)| = 0$; let z_a be their number. Then in line 15, we check if $\delta^{-1}(T, a)$ is a-predecessor by counting the states $p \in \overline{T}$ such that $|\delta^{-1}(p, a)| = 0$. The set $\delta^{-1}(T, a)$ is a-predecessor if and only if the number of such states p equals z_a, because if it is smaller, then some state $q \in T$ has an empty preimage under the action of a. Next, we compute $\delta^{-1}(\overline{T}, a)$ by joining the preprocessed lists for a for each $q \in \overline{T}$, and $T' = Q \setminus \delta^{-1}(\overline{T}, a)$ is also stored in the form of a list of states in the complement. Since a predecessor is never smaller than the set, we have $|T'| \geq |T| = |S|$, thus the length of this list is at most $|S|$, so we do this computation in $\mathcal{O}(n - |S|)$ time.

Also, the running time of an extra iteration (lines 6 up to 11) is easily bounded by $\mathcal{O}(n - |S|)$ time.

Summarizing, full iterations take $\mathcal{O}(n/(n - |S|) \cdot |\Sigma| \cdot (n - |S|))$ time and extra iterations take $\mathcal{O}(|\Sigma| \cdot n/(n - |S|) \cdot (n - |S|))$ time, which gives the same upper bound on the total. The aforementioned preprocessing can be done in $\mathcal{O}(|\Sigma| \cdot n)$ time as well. ◀

▶ Remark 13. The asymptotic running time of IsWitnessCandidate in terms of $|\Sigma|$ and n is the best possible because $|\Sigma| \cdot n$ is the number of automaton's transitions that we have to read in the worst case.

▶ **Theorem 14.** *Problem Completely Reachable can be solved in co-NP.*

Proof. To certify that a given automaton $\mathscr{A}$ is not completely reachable, we can guess a witness candidate $S \subsetneq Q$ and call IsWitnessCandidate$(\mathscr{A}, S)$ to verify it. If the automaton is not completely reachable, then there exists some witness, which is a witness candidate. Otherwise, there are no unreachable non-empty sets, thus no witness candidates. ◀

2.4 A Polynomial-Time Algorithm

The overall idea to make the algorithm work in deterministic polynomial time is as follows. We replace guessing a witness with a constructive procedure. We extend the function from Algorithm 1 so that instead of a Boolean answer, it finds a properly extending word for S. This works under a certain assumption that S is not a witness candidate and there are no witness candidates of size larger than $|S|$. When S is a witness candidate, the function returns **none**.

Then, we use this function to hunt for a witness. We iteratively reduce each set of size $n - 1$ to smaller sets S in the way that if some witness is a subset of the initial set, then this witness is also a subset of set S. As we process the sets from the largest size, we keep the assumption that there are no witness candidates larger than the currently processed set. Hence, the first found witness candidate will be a witness.

2.4.1 Finding Properly Extending Words

The function for finding properly extending words is shown in Algorithm 2. Here, together with predecessor sets T of S, we also keep track of the words w such that $\delta(T, w) = S$. The main difference with IsWitnessCandidate is the case in line 7. For the union $T \cup T'$,

Algorithm 2 An algorithm finding a properly extending word (a larger predecessor) for a given set (recursive version).

Input: An n-state automaton $\mathscr{A} = (Q, \Sigma, \delta)$ and a non-empty $S \subsetneq Q$.
Output: A properly extending word for S or **none** . If S is a witness candidate, then always returns **none** . If S is not a witness candidate and there are no witness candidates of size $> |S|$, then always returns a word.

```
1:  function FindProperlyExtendingWord(𝒜, S)
2:      Process ← EmptyFifoQueue()      ▷ It contains pairs (T, w) such that δ(T, w) = S
3:      Process.Push((S, ε))
4:      Absent ← Array indexed by q ∈ Q initialized with none
5:      while not Process.Empty() do
6:          (T, w) ← Process.Pop()
7:          if Absent[q] ≠ none for some q ∈ T̄ then          ▷ Then T ∪ T′ ≠ Q
8:              (T′, w′) ← Absent[q]
9:              if T′ = T then
10:                 continue                                  ▷ T′ has been processed previously
11:             u ← FindProperlyExtendingWord(𝒜, T ∪ T′)
12:             if u = none then
13:                 return none
14:             else                          ▷ u is a properly extending word for T ∪ T′
15:                 if |δ⁻¹(T, u)| > |T| then                 ▷ u properly extends T
16:                     return uw
17:                 else                                      ▷ u properly extends T′
18:                     return uw′
19:         for all q ∈ T̄ do
20:             Absent[q] ← (T, w)
21:         for all a ∈ Σ do
22:             if T has a-predecessor then
23:                 T′ = δ⁻¹(T, a)
24:                 if |T′| > |S| then
25:                     return aw
26:                 Process.Push((T′, aw))
27:     return none                                           ▷ S is a witness candidate
```

we aim at finding a properly extending word for it, which then turns out to be properly extending either for T or T' by Lemma 5; this is done by a recursive call in line 11. This call can return **none** instead, which means that a witness candidate larger than S was found.

▶ **Example 15.** For the automaton from Figure 1 (left) and $S = \{q_0, q_2, q_4, q_5\}$ (this is an unreachable and not properly extensible set, but not a witness candidate), FindProperlyExtendingWord returns **none** using one recursive call.

Proof. Since letter a cannot be applied, the second iteration is with $T = \delta^{-1}(S, b) = \{q_5, q_1, q_3, q_4\}$, and similarly, the third one is with $T = \delta^{-1}(S, b^2) = \{q_4, q_0, q_2, q_3\}$. Now, since the complements of $\{q_4, q_0, q_2, q_3\}$ and S contain the common state q_1, we recursively call the function for the union $Q \setminus \{q_1\}$. This union set is a witness and has 6 predecessors (including itself). After processing all these predecessors, the function returns **none**. ◀

▶ **Example 16.** For the automaton from Figure 1 (right) and let $S = \{q_0, q_{10}\}$, FindProperlyExtendingWord returns the word ab^2 using 8 recursive calls.

▶ **Lemma 17.** *Function FindProperlyExtendingWord is correct and works in at most $\mathcal{O}(|\Sigma| \cdot n^2 \log n)$ time. Moreover, if a word is returned, then it has length at most $\mathcal{O}(n \log n)$.*

Proof sketch. The correctness can be proved by descending induction on the set size, using similar arguments as for Lemma 12 and Lemma 5

Without counting the recursive call, the running time is $\mathcal{O}(|\Sigma| \cdot n^2/(n - |S|))$; for this, to avoid higher complexity by copying potentially long words, we need to concatenate words by storing pointers to both parts and maintain the induced transformations $Q \to Q$ along them. If we consider the recursive calls, in the worst case $n - |S|$ we call the function on sets of sizes $n - |S|, n - |S| + 1, \ldots, n - 1$; in the calculation we get the harmonic series what is bounded by the logarithm, giving the final running time and word length bounds. ◀

2.4.2 Set Reduction for Witness Containment

Suppose that given a subset $S \subsetneq Q$, we search for a witness that is contained within it. Having a properly extending word w for S, we can reduce S to its proper subset by excluding some states which surely cannot be in any witness contained in S. The next lemma shows the criterion.

▶ **Lemma 18.** *Let $S \subseteq Q$ and $\delta^{-1}(S, w)$ be a w-predecessor of S for some w. Then for every witness candidate $S' \subseteq S$, every state $q \in S'$ is such that $|\delta^{-1}(q, w)| = 1$.*

Proof. Since $\delta^{-1}(S, w)$ is a w-predecessor of S, by Remark 1, we have $\delta^{-1}(q, w) \neq \emptyset$ for every state $q \in S$. Suppose for a contradiction that there exists $S' \subseteq S$ that is a witness candidate and contains a state $p \in S'$ such that $|\delta^{-1}(p, w)| > 1$. Note that the set $\delta^{-1}(S', w)$ is a w-predecessor of S', since its superset S has a w-predecessor, and:

$$|\delta^{-1}(S', w)| = |\delta^{-1}(p, w)| + \sum_{s \in S \setminus \{p\}} |\delta^{-1}(s, w)| > 1 + (|S| - 1) = |S|.$$

Thus, S' cannot be a witness candidate, since it has a larger predecessor. ◀

As a witness is also a witness candidate, the lemma also applies to witnesses. From the lemma, we know that by having a properly extending word for S, we can remove at least one state from S and all the witnesses will still be contained in the resulting set. Function Reduce$(\mathscr{A}, S, w)$ in Algorithm 3 realizes this reduction and returns a set of states that can be removed. If w is given as a transformation, the function trivially works in $\mathcal{O}(n)$ time.

Algorithm 3 Reducing a set for possible witness containment.

Input: An n-state automaton $\mathscr{A} = (Q, \Sigma, \delta)$, a non-empty $S \subsetneq Q$, and a properly extending word w for S.

Output: A non-empty subset $R \subseteq S$ such that all the witnesses contained in S are also contained in $S \setminus R$.

```
1: function Reduce(𝒜, S, w)
2:     return {p ∈ S : |δ⁻¹(p, w)| > 1}
```

2.4.3 Finding a Witness

We have all ingredients to build a polynomial algorithm that solves the decision problem Completely Reachable. It is shown in Algorithm 4. If the automaton is not completely reachable, the algorithm also finds a witness. Starting from all sets of size $n-1$, we process sets in descending order by size. Processing a set consists of finding a properly extending word for it and reducing the set for a witness containment by this word.

Algorithm 4 A polynomial-time algorithm verifying the complete reachability of an automaton or finding a witness.

Input: An n-state automaton $\mathscr{A} = (Q, \Sigma, \delta)$.
Output: **none** if $\mathscr{A}$ is completely reachable; a witness otherwise.

```
1:  function FindWitness(𝒜)
2:      Queue ← EmptyPriorityQueue()   ▷ Ordered by set size; the largest sets go first
3:      for all q ∈ Q do
4:          Queue.Push(Q \ {q})                ▷ Initialize with sets of size n − 1
5:      while not Queue.Empty() do
6:          S ← Queue.Pop()                    ▷ Get a set of the largest size
7:          w ← FindProperlyExtendingWord(𝒜, S)
8:          if w = none then
9:              return S                       ▷ Found witness
10:         R ← Reduce(𝒜, S, w)                ▷ R is non-empty
11:         S′ ← S \ R                         ▷ S′ ⊊ S
12:         if S′ ≠ ∅ then
13:             Queue.Push(S′)
14:     return none                            ▷ No witnesses
```

▶ **Lemma 19.** *Function FindWitness is correct and works in $\mathcal{O}(|\Sigma| \cdot n^4 \log n)$ time.*

▶ Remark 20. The number of witnesses of size k is at most $\lfloor n/k \rfloor$, as their complements must be pairwise disjoint – otherwise, we could properly extend at least one of them by Lemma 5. Function FindWitness can be easily modified to find all the witnesses: after finding the first witness of size k, we can continue the main loop until all sets of size k are processed.

2.5 Improving Running Time

The main idea for the improvement is to use already computed reductions instead of finding a properly extending word recursively (Algorithm 2, line 13), which is required when we encounter the case of non-disjoint complements. For lowering the time complexity by this optimization, using adequate set representations is also crucial.

2.5.1 Reduction History

A *reduction history* RED is an array of size n of lists of states. For a state $q \in Q$, $RED[q]$ denotes the list of states assigned to q. Let $|RED[q]|$ denote the length of this list, and let $RED[q][i]$ denote the i-th state for $1 \leq i \leq |RED[q]|$. The states in the list must be pairwise different and distinct from q.

A reduction history represents our current knowledge about possible witness containment and will be progressively filled out in the algorithm, starting from the empty lists. For each $q \in Q$, the reduction history defines a *reduction chain* that is a sequence of reduced sets

$R^q_0, R^q_1, \ldots, R^q_{|RED[q]|}$. The first set $R^q_0 = Q \setminus \{q\}$, and each next set is obtained from the previous set by removing the corresponding state in the list: for $1 \leq i \leq |RED[q]|$, we define $R^q_i = R^q_{i-1} \setminus \{RED[q][i]\}$ (equivalently, $R^q_i = Q \setminus (\{q\} \cup \bigcup_{i \in \{1,\ldots,|RED[q]|\}} \{RED[q][i]\})$).

A reduction history RED is *valid* (for an automaton) if for each $q \in Q$ and each $1 \leq i \leq |RED[q]|$, there exists a properly extending word w for R^q_{i-1} such that $|\delta^{-1}(RED[q][i], w)| > 1$. This means that the reduction for witness containment of R^q_{i-1} to R^q_i by removing the state $RED[q][i]$ is justified by Lemma 18, i.e., all witnesses contained in R^q_{i-1} are also contained in R^q_i. However, note that the reduction can be not exhaustive with respect to w, i.e., there may exist other states $p \in R^q_{i-1} \setminus \{RED[q][i]\}$ such that $|\delta^{-1}(p, w)| > 1$, which also could be removed by Lemma 18. In our algorithm, this situation will be possible because we do not always compute properly extending words directly but infer their existence based on the reductions computed for other sets, tracing only one state to remove.

Besides being valid, we need that our reduction history is sufficiently filled out. For $q \in Q$, the *deficiency* of $RED[q]$ is the length $|RED[q]|$ thus equals the number of states to be removed from $Q \setminus \{q\}$. The *deficiency* of the whole reduction history RED is its minimum deficiency over $q \in Q$. Hence, a valid history reduction of deficiency d stores information for reducing every set of size $n-1$ to a set of size at most $n-1-d$.

Algorithm 5 A fast reduction retrieval for witness containment for a given set from the past stored reductions.

Input: An n-state automaton $\mathscr{A} = (Q, \Sigma, \delta)$, a non-empty set $S \subsetneq Q$, and a reduction history RED.
Require: RED is a valid reduction history of deficiency at least $n - |S|$.
Output: A state $p \in S$ such that there exists a properly extending word w for S such that $|\delta^{-1}(p, w)| > 1$.

```
1: function GetStoredReduction(𝒜, S, RED)
2:     q ← any state from S̄
3:     for i ← 1, 2, ... do
4:         assert(i ≤ |RED[q]|)
5:         p ← RED[q][i]
6:         if p ∈ S then
7:             return p
```

Function GetStoredReduction from Algorithm 5 quickly finds a reduction of a given set S, provided that a valid reduction history with a large enough deficiency is available. The function starts from picking any q outside of S, and it repeats the reduction chain starting from $Q \setminus \{q\} \supseteq S$. It seeks the first removed state that belongs to S. In this way, since the same reduction was applied previously to a superset of S, it can be correctly applied to S as well, i.e., the same word is properly extending word for both the superset and S. We note that this may not hold for the states removed later, since then a properly extending word inferred from the reduction history may not be properly extending for S (may not give a predecessor of S).

Since the found state $p \in S$ has the property that there exists a properly extending word w for S such that $|\delta^{-1}(p, w)| > 1$, we can apply Lemma 18 and get a smaller $S' = S \setminus \{p\} \subsetneq S$ such that every witness in S is also contained in S'.

▶ **Lemma 21.** *Function* GetStoredReduction *is correct and can be implemented to work in* $\mathcal{O}(n)$ *time.*

2.5.2 Finding a Reduction

We redesign earlier Algorithm 2 for finding a properly extending word so that we return a reduction (here, one state to remove) directly for the given S. GetStoredReduction can be used for computing the reduction fast, but only if our reduction history has a large enough deficiency, i.e., in each of the reduction chains, $Q \setminus \{q\}$ is reduced to a set smaller than the set that we want to reduce. We cannot ensure this for S, but if in the main algorithm, we reduce the sets in descending order by their size, then we can fulfil the weaker requirement that the reduction chains end with sets of size at most $|S|$. Then, to reduce S, we perform as the previous algorithm until encountering the case of a non-empty complements intersection. Then we can use GetStoredReduction for the obtained set of size at least $|S| + 1$.

Function FindReduction from Algorithm 6 for a given S finds a state to remove or **none** if S is a witness candidate. The most important difference with previous FindProperlyExtendingWord is the use of GetStoredReduction in line 11 and processing its result p.

To keep the time complexity low, as before, we need to store the sets T in the form of a list of states in the complement. This time, we do not maintain the induced transformations for words (they are too costly here). Instead, we compute $\delta(p, w)$ applying the letters one by one, but only for this state, which is doable in $\mathcal{O}(n/(n - |S|))$ time, avoiding quadratic time complexity.

▶ **Lemma 22.** *Function FindReduction is correct and can be implemented to work in $\mathcal{O}(|\Sigma| \cdot n)$ time.*

2.5.3 The Optimized Algorithm

The optimized algorithm FindWitnessFaster is shown in Algorithm 7. For reducing sets, it relies on FindReduction, which returns a state p such that there exists a properly extending word w for S and $|\delta^{-1}(p, w)| > 1$. We can remove p from S by Lemma 18, i.e., every witness contained in S must be also contained in $S' = S \setminus \{p\}$.

Additionally, the sets in *Queue* are stored together with their initially removed state q, to know where to store their reductions in the reduction history. Note that in an iteration, the set S taken from the queue is the currently last set $R^q_{|RED[q]|}$ from the reduction chain for q, and S' will be a next set in this chain. Updating the reduction history with state p keeps it valid, which also follows from the guaranteed existence of a properly extending word by FindReduction. As we process the sets in descending order by size, our reduction history always has the required deficiency when used in line 8.

▶ **Lemma 23.** *Function FindWitnessFaster is correct and works in $\mathcal{O}(|\Sigma| \cdot n^3)$ time.*

3 An Upper Bound on Reset Threshold

3.1 Synchronization

A *reset word* is a word w such that $|\delta(Q, w)| = 1$. Equivalently, we have $\delta^{-1}(q, w) = Q$ for some $q \in Q$. If an automaton admits a reset word, then it is called *synchronizing* and its *reset threshold* is the length of the shortest reset words.

The central problem in the theory of synchronizing automata is the famous Černý conjecture, which states that every synchronizing n-state automaton has its reset threshold at most $(n - 1)^2$. For the subclass of completely reachable automata, the previously known upper bound on the reset threshold was $7/48n^3 + \mathcal{O}(n^2)$ [5], which has been obtained through the technique of avoiding [22], that is, it follows in particular from the fact that every set of size $n - 1$ is reachable with a word of length at most n.

Algorithm 6 An algorithm finding a reduction for witness containment using a reduction history.

Input: An n-state automaton $\mathscr{A} = (Q, \Sigma, \delta)$, a non-empty $S \subsetneq Q$, and a reduction history *RED*.
Require: *RED* is a valid reduction history of deficiency at least $n - |S| - 1$.
Output: If S is not a witness candidate: a state $p \in S$ such that there exists a properly extending word w for S such that $|\delta^{-1}(p, w)| > 1$. Otherwise: **none**.

```
1:  function FindReduction(𝒜, S, RED)
2:      Process ← EmptyFifoQueue()
3:      Process.Push((S, ε))
4:      Absent ← Array indexed by q ∈ Q initialized with none
5:      while not Process.Empty() do
6:          (T, w) ← Process.Pop()
7:          if Absent[q] ≠ none for some q ∈ T̄ then          ▷ Then T ∪ T′ ≠ Q
8:              (T′, w′) ← Absent[q]
9:              if T′ = T then
10:                 continue                                  ▷ T′ has been processed previously
11:             p ← GetStoredReduction(𝒜, T ∪ T′, RED)
12:             if p ∈ T then
13:                 return δ(p, w)
14:             else                                          ▷ Then p ∈ T′
15:                 return δ(p, w′)
16:         for all q ∈ T̄ do
17:             Absent[q] ← (T, w)
18:         for all a ∈ Σ do
19:             if T has a-predecessor then
20:                 T′ = δ^{-1}(T, a)
21:                 if |T′| > |S| then
22:                     p ← any state such that |δ^{-1}(T, a)| > 1
23:                     return δ(p, w)
24:                 Process.Push((T′, aw))
25:     return none                                           ▷ S is a witness candidate
```

3.2 Finding Short Properly Extending Words

For a completely reachable automaton, function FindProperlyExtendingWord from Algorithm 8 always finds a properly extending word. Therefore, using the well-known *extension* method (e.g., [24]), we can construct a synchronizing word starting from some singleton $\{q\}$ and iteratively increasing the set by at least one in at most $n - 1$ iterations, finally obtaining Q. This is an easy way to get the upper bound of order $\mathcal{O}(n^2 \log n)$ by Lemma 17. However, it is not enough to prove a quadratic upper bound, so we are going to further adapt the algorithm for that.

The idea is to keep track of all subsets for an intersection of complements, instead of starting an independent search for a properly extending word recursively. This modification is shown in Algorithm 8.

The function keeps *Trace* map, which stores for a given predecessor set, by the application of what letter it has been obtained or, in the second case, of what two sets it is a union. It also stores S' as the current origin set, which is the set for which we are going to find a larger predecessor currently.

Algorithm 7 A faster algorithm for finding a witness.

Input: An n-state automaton $\mathscr{A} = (Q, \Sigma, \delta)$.
Output: **none** if $\mathscr{A}$ is completely reachable; a witness otherwise.

```
 1: function FindWitnessFaster(𝒜)
 2:     RED[q] ← EmptyList  for all q ∈ Q          ▷ Empty reduction history
 3:     Queue ← EmptyPriorityQueue()               ▷ Contains pairs (S, q); ordered by |S|
 4:     for all q ∈ Q do
 5:         Queue.Push((Q \ {q}, q))
 6:     while not Queue.Empty() do
 7:         (S, q) ← Queue.Pop()                   ▷ Get a set of the largest size
 8:         p ← FindReduction(𝒜, S, RED)
 9:         if p = none then
10:             return S                           ▷ Found witness
11:         RED[q].append(p)                       ▷ Store the removed state
12:         S' ← S \ {p}
13:         if S' ≠ ∅ then
14:             Queue.Push((S', q))
15:     return none                                ▷ No witnesses
```

The function has two phases. First, it searches for a larger predecessor or a non-empty complement intersection as the previous variants. In the second case, it only changes the origin set S' (line 15), notes this in the map *Trace* and initiates a fresh search for S'. In the second phase (from line 25), a properly extending word is reconstructed (like in FindProperlyExtendingWord after a recursive call) until we reach our original S.

▶ **Lemma 24.** *Function FindShortProperlyExtendingWord is correct.*

The remaining effort is to prove an upper bound on the length of the returned word.

3.2.1 Nested Boxes

To bound the length of the found word, we consider an auxiliary combinatorial problem. Consider an n-element universe Q. Two subsets $S, T \subseteq Q$ are *colliding* if $S \cap T \notin \{\emptyset, S, T\}$. Thus, colliding sets have a non-trivial intersection. A family of non-empty subsets of Q is called *non-colliding* if all the subsets are pairwise non-colliding.

▶ **Definition 25.** *For an $n \geq 1$, the number $MaxNestedBoxes(n)$ is the maximum size of a non-colliding family for an n-element universe.*

The problem is equivalent to, e.g., the maximum number of boxes for n items, such that a box must contain either an item or at least two boxes.

▶ **Lemma 26.** $MaxNestedBoxes(n) = 2n - 1$.

The generalized version of the problem limits the maximum size of the subsets:

▶ **Definition 27.** *For an $n \geq 1$, the number $MaxNestedBoxes(n, k)$ is the maximum size of a non-colliding family for an n-element universe where each subset from the family has size at most k.*

▶ **Lemma 28.** $MaxNestedBoxes(n, k) = 2n - \lceil n/k \rceil$.

Algorithm 8 An algorithm finding a short properly extending word.

Input: An n-state automaton $\mathscr{A} = (Q, \Sigma, \delta)$ and a non-empty $S \subsetneq Q$.
Require: $\mathscr{A}$ is completely reachable.
Output: A properly extending word w of S.

1: **function** FindShortProperlyExtendingWord($\mathscr{A}, S$)
2: $Trace \leftarrow$ EmptyMap() ▷ For a processed set, it stores how this set was obtained; for not yet processed sets, it gives **none**
3: $Process \leftarrow$ EmptyFifoQueue()
4: $S' \leftarrow S$ ▷ Current origin set
5: $Trace[S'] \leftarrow \varepsilon$
6: $Process$.Push(S')
7: **while true do**
8: **assert**(**not** $Process$.IsEmpty()) ▷ Otherwise S' is a witness candidate
9: $T \leftarrow Process$.Pop()
10: **if** $|T| > |S'|$ **then** ▷ Found a properly extending word for S'
11: $S' \leftarrow T$
12: **break**
13: **if** there is T' such that $Trace[T'] \neq$ **none** and $T \subsetneq T \cup T' \subsetneq Q$ **then**
14: $S' \leftarrow T \cup T'$ ▷ New origin set; $|S'| > |S|$
15: $Trace[S'] \leftarrow (T, T')$
16: $Process$.Clear() ▷ Continue only for the new origin
17: $Process$.Push(S')
18: **else**
19: **for all** $a \in \Sigma$ **do**
20: **if** a is properly extending T **then**
21: $T' \leftarrow \delta^{-1}(T, a)$
22: **if** $Trace[T'] =$ **none then** ▷ A not yet processed set
23: $Trace[T'] \leftarrow a$ ▷ $\delta(T', a) = T$
24: $Process$.Push(T')
25: $w \leftarrow \varepsilon$ ▷ Word reconstruction starts with the empty word
26: **while** $S' \neq S$ **do**
27: **assert**($Trace[S'] \neq$ **none**)
28: **if** $Trace[S']$ is a letter **then**
29: $a \leftarrow Trace[S']$
30: $S' \leftarrow \delta(S', a)$
31: $w \leftarrow wa$
32: **else**
33: $(T, T') \leftarrow Trace[S']$ ▷ w properly extends $T \cup T'$
34: **if** $|\delta^{-1}(T, w)| > |T|$ **then** ▷ w properly extends T
35: $S' \leftarrow T$
36: **else** ▷ w properly extends T'
37: $S' \leftarrow T'$
38: **return** w

3.2.2 Final Bounding

We apply the above combinatorial problem to derive an upper bound on the length of a word found by FindShortProperlyExtendingWord. The crucial property is that the family of the complements of all subsets T that are processed in the block of lines 19–24 is

non-colliding, since for these subsets T, the condition in line 13 does not hold. The upper bound follows since all the letters in the final word are added in line 31, where S' is always the complement of one of the sets from the family.

▶ **Lemma 29.** *For a completely reachable automaton and a non-empty proper subset $S \subsetneq Q$, the word returned by* FindShortProperlyExtendingWord *from Algorithm 8 has length at most $MaxNestedBoxes(n, n - |S|) = 2n - \lceil n/(n - |S|) \rceil$.*

Finally, using the standard extension method (starting from a subset S and iteratively extending it to Q) and some calculations, we obtain a weaker Don's conjecture (cf. [14, Problem 4]):

▶ **Theorem 30.** *For a completely reachable n-state automaton (Q, Σ, δ), every non-empty proper subset $S \subseteq Q$ is reachable with a word of length at most*

$$(n - |S|)2n - n\ln(n - |S|) - n/(n - |S|) < 2n(n - |S|).$$

▶ **Corollary 31.** *The reset threshold of a completely reachable automaton with $n \geq 3$ states is at most*

$$(n - 2)2n - n\ln(n - 2) - n/(n - 2) < 2n^2 - n\ln n - 4n + 2.$$

Abstract

Parameterization above (or below) a guarantee is a successful concept in parameterized algorithms. The idea is that many computational problems admit "natural" guarantees bringing to algorithmic questions whether a better solution (above the guarantee) could be obtained efficiently. For example, for every boolean CNF formula on m clauses, there is an assignment that satisfies at least $m/2$ clauses. How difficult is it to decide whether there is an assignment satisfying more than $m/2 + k$ clauses? Or, if an n-vertex graph has a perfect matching, then its vertex cover is at least $n/2$. Is there a vertex cover of size at least $n/2 + k$ for some $k \geq 1$ and how difficult is it to find such a vertex cover?

The above guarantee paradigm has led to several exciting discoveries in the areas of parameterized algorithms and kernelization. We argue that this paradigm could bring forth fresh perspectives on well-studied problems in approximation algorithms. Our example is the longest cycle problem. One of the oldest results in extremal combinatorics is the celebrated Dirac's theorem from 1952. Dirac's theorem provides the following guarantee on the length of the longest cycle: for every 2-connected n-vertex graph G with minimum degree $\delta(G) \leq n/2$, the length of the longest cycle L is at least $2\delta(G)$. Thus the "essential" part of finding the longest cycle is in approximating the "offset" $k = L - 2\delta(G)$. The main result of this paper is the above-guarantee approximation theorem for k. Informally, the theorem says that approximating the offset k is not harder than approximating the total length L of a cycle. In other words, for any (reasonably well-behaved) function f, a polynomial time algorithm constructing a cycle of length $f(L)$ in an undirected graph with a cycle of length L, yields a polynomial time algorithm constructing a cycle of length $2\delta(G) + \Omega(f(k))$.

1 Introduction

One of the concepts that had a strong impact on the development of parameterized algorithms and kernelization is the idea of the above guarantee parameterization. Above guarantee parameterization grounds on the following observation: *the natural parameterization of a maximization/minimization problem by the solution size is not satisfactory if there is a lower bound for the solution size that is sufficiently large* [23]. To make this discussion concrete, consider the example of the classical NP-complete problem Max Cut. Observe that in any graph with m edges there is always a cut containing at least $m/2$ edges. (Actually, slightly better bounds are known in the literature [18, 10].) Thus Max Cut is trivially fixed-parameter tractable (FPT) parameterized by the size of the max-cut. Indeed, the following simple algorithm shows that the problem is FPT: If $k \leq m/2$, then return yes; else $m \leq 2k$ and any brute-force algorithm will do the job. However, the question about Max Cut becomes much more meaningful and interesting, when one seeks a cut above the "guaranteed" lower bound $m/2$.

The above guarantee approach was introduced by Mahajan and Raman [46] and it was successfully applied in the study of several fundamental problems in parameterized complexity and kernelization. For illustrative examples, we refer to [1, 4, 14, 23, 25, 33, 34, 35, 37, 38, 45], see also the recent survey of Gutin and Mnich [36]. Quite surprisingly, the theory of the above (or below) guarantee *approximation* remains unexplored. (Notable exceptions are the works of Mishra et al. [47] on approximating the minimum vertex cover beyond the size of a maximum matching and of Bollobás and Scott on approximating max-cut beyond the $m/2 + \sqrt{m/8}$ bound [10].)

In this paper, we bring the philosophy of the above guarantee parameterization into the realm of approximation algorithms. In particular,

> The goal of this paper is to study the approximability of the classical problems of finding a longest cycle and a longest (s,t)-path in a graph from the viewpoint of the above guarantee parameterization.

Our results. Approximating the length of a longest cycle in a graph enjoys a lengthy and rich history [6, 8, 21, 20, 29, 30, 49]. There are several fundamental results in extremal combinatorics providing lower bounds on the length of a longest cycle in a graph. The oldest of these bounds is given by Dirac's Theorem from 1952 [17]. Dirac's Theorem states that a 2-connected graph G with the minimum vertex degree $\delta(G)$ contains a cycle of length $L \geq \min\{2\delta(G), |V(G)|\}$. Since every longest cycle in a graph G with $\delta(G) < \frac{1}{2}|V(G)|$ (otherwise, G is Hamiltonian and a longest cycle can be found in polynomial time) always has a "complementary" part of length $2\delta(G)$, the essence of the problem is in computing the "offset" $k = L - 2\delta(G)$. Informally, the first main finding of our paper is that Dirac's theorem is well-compatible with approximation. We prove that approximating the offset k is essentially not more difficult than approximating the length L.

More precisely. Recall that f is subadditive if for all x, y it holds that $f(x+y) \leq f(x)+f(y)$. Our main result is the following theorem.

▶ **Theorem 1.** *Let $f : \mathbb{R}_+ \to \mathbb{R}_+$ be a non-decreasing subadditive function and suppose that we are given a polynomial-time algorithm finding a cycle of length at least $f(L)$ in graphs with the longest cycle length L. Then there exists a polynomial time algorithm that finds a cycle of length at least $2\delta(G) + \Omega(f(L - 2\delta(G)))$ in a 2-connected graph G with $\delta(G) \leq \frac{1}{2}|V(G)|$ and the longest cycle length L.*

The 2-connectivity condition is important. As was noted in [24], deciding whether a connected graph G contains a cycle of length at least $2\delta(G)$ is NP-complete. Theorem 1 trivially extends to approximating the longest path problem above $2\delta(G)$. For the longest path, the requirement on 2-connectivity of a graph can be relaxed to connectivity. This can be done by a standard reduction of adding an apex vertex v to the connected graph G, see e.g. [24]. The minimum vertex degree in the new graph $G+v$, which is 2-connected, is equal to $\delta(G)+1$, and G has a path of length at least L if and only if $G+v$ has a cycle of length at least $L+2$. Thus approximation of the longest cycle (by making use of Theorem 1) in $G+v$, is also the approximation of the longest path in G.

Related work. The first approximation algorithms for longest paths and cycles followed the development of exact parameterized algorithms. Monien [48] and Bodlaender [9] gave parameterized algorithms computing a path of length L in times $\mathcal{O}(L!2^L n)$ and $\mathcal{O}(L!nm)$ respectively. These algorithms imply also approximation algorithms constructing in polynomial time a path of length $\Omega(\log L/\log\log L)$, where L is the longest path length in graph G. In their celebrated work on color coding, Alon, Yuster, and, Zwick [2] obtained an algorithm that in time $\mathcal{O}(5.44^L n)$ finds a path/cycle of length L. The algorithm of Alon et al. implies constructing in polynomial time a path of length $\Omega(\log L)$. A significant amount of the consecutive work targets to improve the base of the exponent c^L in the running times of the parameterized algorithms for longest paths and cycles [43, 50, 28, 5, 7]. The surveys [27, 44], and [15, Chapter 10] provide an overview of ideas and methods in this research direction. The exponential dependence in L in the running times of these algorithms is asymptotically optimal: An algorithm finding a path (or cycle) of length L in time $2^{o(L)}n^{\mathcal{O}(1)}$ would fail the Exponential Time Hypothesis (ETH) of Impagliazzo, Paturi, and Zane [39]. Thus none of the further improvements in the running times of parameterized algorithms for longest cycle or path, would lead to a better than $\Omega(\log L)$ approximation bound.

Björklund and Husfeldt [6] made the first step "beyond color-coding" in approximating the longest path. They gave a polynomial-time algorithm that finds a path of length $\Omega(\log L/\log\log L)^2$ in a graph with the longest path length L. Gabow in [30] enhanced and extended this result to approximating the longest cycle. His algorithm computes a cycle of length $2^{\Omega(\sqrt{\log L/\log\log L})}$ in a graph with a cycle of length L. Gabow and Nie [32] observed that a refinement of Gabow's algorithm leads to a polynomial-time algorithm constructing cycles of length $2^{\Omega(\sqrt{\log L})}$. This is better than $(\log(L))^{\mathcal{O}(1)}$ but worse than L^{ε}. Pipelining the algorithm of Gabow and Nie with Theorem 1 yields a polynomial time algorithm constructing in a 2-connected graph G a cycle of length $2\delta(G)+\Omega(c^{\sqrt{\log k}})$. For graphs of bounded vertex degrees, better approximation algorithms are known [13, 21].

The gap between the upper and lower bounds for the longest path approximation is still big. Karger, Motwani, and Ramkumar [41] proved that the longest path problem does not belong to APX unless P = NP. They also show that for any $\varepsilon>0$, it cannot be approximated within $2^{\log^{1-\varepsilon} n}$ unless NP $\subseteq$ DTIME$(2^{O(\log^{1/\varepsilon} n)})$. Bazgan, Santha, and Tuza [3] extended these lower bounds to cubic Hamiltonian graphs. For directed graphs the gap between the upper and lower bounds is narrower [8, 31].

Our approximation algorithms are inspired by the recent work Fomin, Golovach, Sagunov, and Simonov [24] on the parameterized complexity of the longest cycle beyond Dirac's bound. Fomin et al. were interested in computing the "offset" beyond $2\delta(G)$ exactly. Their parameterizes algorithm decides whether G contains a cycle of length at least $2\delta(G)+k$ in time $2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$, and thus in polynomial time computes a cycle of length $2\delta(G)+\Omega(\log k)$. However, the tools developed in [24] are not sufficient to go beyond $\Omega(\log k)$-bound on the

offset. The main combinatorial tools from [24] are Erdős-Gallai decomposition and Dirac decomposition of graphs. For the needs of approximation, we have to develop novel ("nested") variants or prove additional structural properties of these decompositions.

Dirac's theorem is one of the central pillars of Extremal Graph Theory. The excellent surveys [12] and [11] provide an introduction to this fundamental subarea of graph theory. Besides [24], the algorithmic applications of Dirac's theorem from the perspective of parameterized complexity were studied by Jansen, Kozma, and Nederlof in [40].

Paper structure. Section 2 provides an overview of the techniques employed to achieve our results. Then, Section 3 introduces notations and lists auxiliary results. Section 4 guides through the proof of the approximation result for (s,t)-paths, which is the key ingredient required for Theorem 1. Finally, we conclude with a summary and some open questions in Section 5. Note that the proofs of technical statements are omitted from this extended abstract due to space constraints. Detailed proofs of all results can be found in the full version of the paper [26].

2 Overview of the proofs

In this section, we provide a high-level strategy of the proof of Theorem 1, as well as key technical ideas needed along the way. The central concept of our work is an approximation algorithm for the Longest Cycle problem. Formally, such an algorithm should run in polynomial time for a given graph G and should output a cycle of length at least $f(L)$, where L is the length of the longest cycle in G. The function f here is the *approximation guarantee* of the algorithm. In our work, we allow it to be an arbitrary non-decreasing function $f : \mathbb{R}_+ \to \mathbb{R}_+$ that is also subadditive (i.e., $f(x) + f(y) \geq f(x+y)$ for arbitrary x, y). We also note that an $f(L)$-approximation algorithm for Longest Cycle immediately gives a $\frac{1}{2}f(2L)$-approximation algorithm for Long (s,t)-Path in 2-connected graphs (by Menger's theorem, see Lemma 4 for details).

Our two main contributions assume that we are given such an f-approximation algorithm as a black box. In fact, we only require to run this algorithm on an arbitrary graph as an oracle and receive its output. We do not need to modify or know the algorithm routine.

While the basis of our algorithm comes from the structural results of Fomin et al. [24], in the first part of this section we do not provide the details on how it is used.

The first of our contributions is a polynomial-time algorithm that finds a long (s,t)-path in a given 2-connected graph G with two vertices $s, t \in V(G)$. The longest (s,t)-path in G always has length $\delta(G - \{s,t\}) + k$ for $k \geq 0$ by Erdős-Gallai theorem, and the goal of the algorithm is to find an (s,t)-path of length at least $\delta(G - \{s,t\}) + \Omega(f(k))$ in G. To find such a path, this algorithm first recursively decomposes the graph G in a specific technical way. As a result, it outputs several triples (H_i, s_i, t_i) in polynomial time, where H_i is a 2-connected minor of G and $s_i, t_i \in V(H_i)$. For each triple, the algorithm runs the black box to find a f-approximation of the longest (s_i, t_i)-path in H_i. In the second round, our algorithm cleverly uses constructed approximations to construct a path of length at least $\delta(G - \{s,t\}) + \Omega(f(k))$ in the initial graph G. This is summarized as the following theorem.

▶ **Theorem 2.** *Let $f : \mathbb{R}_+ \to \mathbb{R}_+$ be a non-decreasing subadditive function and suppose that we are given a polynomial-time algorithm computing an (s,t)-path of length at least $f(L)$ in graphs with given two vertices s and t having the longest (s,t)-path of length L. Then there is a polynomial-time algorithm that outputs an (s,t)-path of length at least $\delta(G - \{s,t\}) + \Omega(f(L - \delta(G - \{s,t\})))$ in a 2-connected graph G with two given vertices s and t having the longest (s,t)-path length L.*

The second (and main) contribution of this paper is the polynomial-time algorithm that approximates the longest cycle in a given 2-connected graph G such that $2\delta(G) \leq |V(G)|$. It employs the black-box f-approximation algorithm for Longest Cycle to find a cycle of length $2\delta(G) + \Omega(f(k))$, where $2\delta(G) + k$ is the length of the longest cycle in G. By Dirac's theorem applied to G, k is always at least 0.

To achieve that, our algorithm first tries to decompose the graph G. However, in contrast to the first contributed algorithm, here the decomposition process is much simpler. In fact, the decomposition routine is never applied recursively, as the decomposition itself needs not to be used: its existence is sufficient to apply another, simple, procedure.

Similarly to the first contribution, the algorithm then outputs a series of triples (H_i, s_i, t_i), where H_i is a 2-connected minor of G and $s_i, t_i \in V(H_i)$. The difference here is that for each triple the algorithm runs not the initial black-box f-approximation algorithm, but the algorithm of the first contribution, i.e. the algorithm of Theorem 2. Thus, the output of each run is an (s_i, t_i)-path of length $\delta(H_i - \{s_i, t_i\}) + \Omega(f(k_i))$ in H_i, where $\delta(H_i - \{s_i, t_i\}) + k_i$ is the length of the longest (s_i, t_i)-path in H_i.

Finally, from each approximation, our algorithm constructs a cycle of length at least $2\delta(G) + \Omega(f(k_i))$. It is guaranteed that $k_i = \Omega(k)$ for at least one i, so the longest of all constructed cycles is of length at least $2\delta(G) + \Omega(f(k))$. The following theorem is in order.

▶ **Theorem 1.** *Let $f : \mathbb{R}_+ \to \mathbb{R}_+$ be a non-decreasing subadditive function and suppose that we are given a polynomial-time algorithm finding a cycle of length at least $f(L)$ in graphs with the longest cycle length L. Then there exists a polynomial time algorithm that finds a cycle of length at least $2\delta(G) + \Omega(f(L - 2\delta(G)))$ in a 2-connected graph G with $\delta(G) \leq \frac{1}{2}|V(G)|$ and the longest cycle length L.*

One may note that Theorem 2 actually follows from Theorem 1 (again, by Menger's theorem, see Lemma 4). However, as described above, the algorithm in Theorem 1 employs the algorithm of Theorem 2, so we have to prove the latter before the former.

In the remaining part of this section, we provide more detailed proof overviews of both theorems, in particular, we explain how the algorithms employ the structural results of [24]. In both proofs, we complement these results by showing useful properties of specific graph decompositions. For clarity, we start with Theorem 1, as its proof is less involved.

2.1 Approximating long cycles

The basis of our algorithm is the structural result due to Fomin et al. [24]. In that work, the authors show the following: There is an algorithm that, given a cycle in a 2-connected graph, either finds a longer cycle or finds that G is of a "particular structure". This algorithm can be applied to any cycle of length less than $(2 + \sigma_1) \cdot \delta(G)$ (to be specific, we use $\sigma_1 = \frac{1}{24}$, see [26] for details).

To see how this stuctural result is important, recall that we aim to find a cycle of length at least $2\delta(G) + \Omega(f(k))$ in a 2-connected graph G with the longest cycle length $2\delta(G) + k$. Our algorithm simply starts with some cycle in G and applies the result of [24] to enlarge it exhaustively. It stops when either a cycle is of length at least $(2+\sigma_1)\cdot\delta(G)$, or the particular structure of G is found.

The crucial observation here is that if a long cycle is found, we can trivially find a good approximation. If $\sigma_1 \cdot \delta(G)$ is, e.g., less than $\sigma_1/10 \cdot f(k)$, then $10\delta(G) < f(k)$. If we just apply the blackbox f-approximation algorithm for the Longest Cycle problem, we get a cycle of length at least $f(2\delta(G) + k) \geq f(k) \geq 2\delta(G) + 4/5 \cdot f(k)$. Hence, by taking the longest of the cycles of length $(2 + \sigma_1) \cdot f(k)$ and of length $f(2\delta(G) + k)$ we always achieve a good approximation guarantee on k.

The most important part of the algorithm is employed when the "particular structure" outcome is received from the structural lemma applied on G and the current cycle C. Here we need to be specific about this structure, and the outcome can be of two types. The first outcome is a bounded vertex cover of the graph. This vertex cover is of size at most $\delta(G) + 2(k' + 1)$, where $k' \geq 0$ is such that $|V(C)| = 2\delta(G) + k'$. Such vertex cover is a guarantee that C is not much shorter than the longest cycle in G: the length of the longest cycle is bounded by twice the vertex cover size, so $k \leq 4(k' + 1)$. Hence, $k' = \Omega(k)$ and C is a sufficient approximation.

The second, and last, structural outcome is the Dirac decomposition, defined in [24]. Basically, this decomposition is obtained by finding a small separator of G (that consists of just two subpaths P_1, P_2 of the cycle C), and the parts of this decomposition are the connected components of G after the separation. The main result on Dirac decomposition proved in [24] is that there always exists a longest cycle that contains an edge in at least one of these parts.

While the definition and properties of Dirac decomposition may seem quite involved, our algorithm does not even require the Dirac decomposition of G to be found. In fact, we show a new nice property of Dirac decomposition. It guarantees that if a Dirac decomposition for G exists, then there also exists a 2-vertex separator $\{u, v\}$ of G that also divides the longest cycle in G into almost even parts. Our contribution is formulated in the following lemma.

▶ **Lemma 3.** *Let G be a 2-connected graph and P_1, P_2 induce a Dirac decomposition for a cycle C of length at most $2\delta(G) + \kappa$ in G such that $2\kappa \leq \delta(G)$. If there exists a cycle of length at least $2\delta(G) + k$ in G, then there exist $u, v \in V(G)$ such that*

- *$G - \{u, v\}$ is not connected, and*
- *there is an (u, v)-path of length at least $\delta(G) + (k - 2)/4$ in G.*

Our algorithm employs Lemma 3 in the following way. Since there are $\mathcal{O}(|V(G)|^2)$ vertex pairs in G, our algorithm iterates over all vertex pairs. If a pair u, v separates the graph into at least two parts, then our algorithm finds a long (u, v)-path that contains vertices in only one of the parts. Formally, it iterates over all connected components in $G - \{u, v\}$. For a fixed connected component H, our algorithm applies the algorithm of Theorem 2 to the graph $G[V(H) \cup \{u, v\}] + uv$ (the edge uv is added to ensure 2-connectivity), to find an approximation of the longest (u, v)-path. By Lemma 3, if u, v is the required separating pair, then for at least one H the length of the found (u, v)-path should be $\delta(G) + \Omega(k)$. And if such a path is found, a sufficiently long (u, v)-path outside H in G is guaranteed by Erdős-Gallai theorem. Together, these two paths form the required cycle of length $2\delta(G) + \Omega(k)$.

With that, the proof overview of Theorem 1 is finished. The formal proof is presented in [26].

2.2 Approximating long (s, t)-paths

While the algorithm of Theorem 1 does not use the underlying Dirac decomposition explicitly, in the case of finding (s, t)-paths (and to prove Theorem 2), we require deeper usage of the obtained graph decomposition. While the Dirac decomposition of Fomin et al. was originally used in [24] to find long cycles above $2\delta(G)$, for finding (s, t)-paths above $\delta(G - \{s, t\})$ the authors introduced the Erdős-Gallai decomposition.

In the formal proof of Theorem 2 in Section 4, we give a complete definition of Erdős-Gallai decomposition. In this overview, we aim to avoid the most technical details in order to provide an intuition of the structure of the decomposition and how our algorithm employs it.

Similarly to Dirac decomposition, the Erdős-Gallai decomposition is obtained through the routine that, given a graph G and an (s,t)-path inside it, either enlarges the path or reports that two subpaths P_1 (that starts with s) and P_2 (that starts with t) of the given path induce (when deleted) an Erdős-Gallai decomposition in G. This routine can be applied to an (s,t)-path until it reaches $(1+\sigma_2)\cdot\delta(G-\{s,t\})$ in length (specifically, $\sigma_2=\frac{1}{4}$, see Lemma 13; in this overview, we also skip the case of a Hamiltonian (s,t)-path for brevity). Note that, in contrast to the cycle enlargement routine of the Dirac decomposition, here the bounded vertex cover outcome is not possible. Similarly to the algorithm of the previous subsection, the only non-trivial part of the algorithm is dealing with the Erdős-Gallai decomposition outcome. In the other case, a single run of the black-box f-approximation algorithm for Longest Cycle provides the desired approximation immediately.

The main property of this decomposition due to [24] is as follows: If an (s,t)-path of length at least $\delta(G-\{s,t\})+k$ exists in G, then there necessarily exists the path of length at least $\delta(G-\{s,t\})+k$ that goes through one of the connected components in the decomposition. Moreover, for each of the connected components G_i there is exactly one pair of distinct entrypoints s_i,t_i: if an (s,t)-path in G goes through G_i, it should necessary enter G_i in s_i (or t_i) once and leave G_i in t_i (or s_i) exactly once as well.

Additionally to that, we have that the degree of each G_i is not much different from G: $\delta(G_i-\{s_i,t_i\})\geq\delta(G-\{s,t\})-2$ holds true. And this constant difference is always compensated by paths from s and t to s_i and t_i: if we succeed to find an (s_i,t_i)-path of length at least $\delta(G_i-\{s_i,t_i\})+k_i$ inside G_i, we can always complete it with *any* pair of disjoint paths from $\{s,t\}$ to $\{s_i,t_i\}$ into an (s,t)-path of length $\delta(G-\{s,t\})+k_i$ in G. Should this pair be longer than the trivial lower bound of 2, it grants the additional length above $\delta(G-\{s,t\})+k_i$.

The previous paragraph suggests the following approach for our approximation algorithm: for each G_i,s_i,t_i, our algorithm applies itself recursively to find an (s_i,t_i)-path of length $\delta(G_i-\{s_i,t_i\}+\Omega(f(k_i))$, where k_i comes from the longest (s_i,t_i)-path length in G_i. Since the other part of the additional length comes from two disjoint paths between $\{s,t\}$, and $\{s_i,t_i\}$, we would like to employ the black-box f-approximation algorithm to find the f-approximation of this pair of paths.

Unfortunately, finding such pair of paths reduces only to finding a long cycle through a given pair of vertices (it is enough to glue s with t and s_i with t_i in G, and ask to find the long cycle through the resulting pair of vertices). In their work, Fomin et al. have shown that the problem of finding such a cycle of length at least k can be done in $2^{\mathcal{O}(k)}\cdot n^{\mathcal{O}(1)}$ time. However, this is of little use to us, as k is only bounded by $\mathcal{O}(\delta(G))$, but we require polynomial time. Simultaneously, we do not know of any way to force the black-box algorithm to find an f-approximation for a cycle through the given pair of vertices.

These arguments bring us away from the idea of a recursive approximation algorithm. Instead, our approximation algorithm will apply the black-box algorithm to a single "complete-picture" graph that is obtained according to the structure brought by the Erdős-Gallai decomposition. However, the recursion here remains in the sense that we apply the path-enlarging routine to each component of the decomposition. This brings us to the idea of the recursive decomposition, which we define as the *nested Erdős-Gallai decomposition* in Section 4. This decomposition can be seen as a tree, where the root is the initial triple (G,s,t), the children of a node represent the triples (G_i,s_i,t_i) given by the Erdős-Gallai decomposition, and the leaves of this decomposition are the graphs G_i where sufficient approximations of long (s_i,t_i)-paths are found (by taking the longest of $(1+\sigma_2)\cdot\delta(G-\{s_i,t_i\})$-long path from the enlarging routine and the approximation obtained from the blackbox algorithm). A schematic picture of this novel decomposition is present in Figure 1.

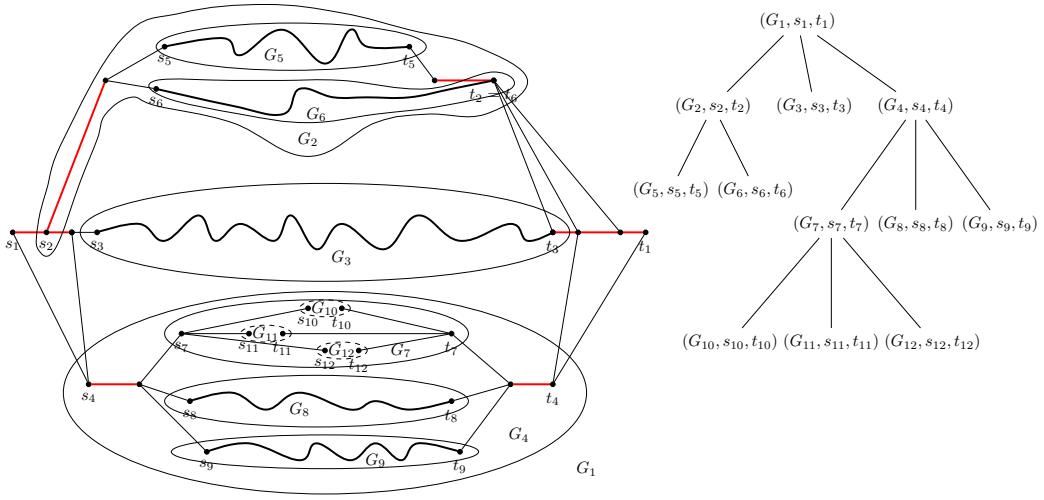

Figure 1 A schematic example of a nested Erdős-Gallai decomposition (left) and the corresponding recursion tree (right). Red straight paths inside G_i denote the pair of paths inducing an Erdős-Gallai decomposition in G_i. Bold (s_i, t_i)-paths are sufficient approximations of the longest (s_i, t_i)-paths in G_i. Dashed contours correspond to G_i with constant $\delta(G_i - \{s_i, t_i\})$, which is one of a few technical cases in the proof.

In Section 4, we show that a long path found inside a leaf (G_i, s_i, t_i) of the decomposition can be contracted into a single edge $s_i t_i$. Moreover, if (G_j, s_j, t_j) is a child of a (G_i, s_i, t_i) in the decomposition, and the longest pair of paths from $\{s_i, t_i\}$ to $\{s_j, t_j\}$ is just a pair of edges (so it does not grant any additional length as described before), we contract these edges. The crucial in our proof is the claim that after such a contraction, if an (s, t)-path of length $\delta(G - \{s, t\}) + k$ exists in the initial graph, an (s, t)-path of length at least $\Omega(k)$ exists in the graph obtained with described contractions. After doing all the contractions, the algorithm applies the black-box algorithm to the transformed graph and finds an (s, t)-path of length $f(\Omega(k))$ (which is $\Omega(f(k))$ by subadditivity) inside it.

The final part of our algorithm (and the proof of Theorem 2) is the routine that *transforms* this (s, t)-path inside the *contracted* graph G into a path of length $\delta(G - \{s, t\}) + \Omega(f(k))$ in the *initial* graph G. In this part, we prove that it is always possible to transform an (s, t)-path of length r in the contracted graph into a path of length $\Omega(r)$ that goes through at least one edge corresponding to a leaf of the nested Erdős-Gallai decomposition (hence, to a good approximation of (s_i, t_i)-path inside G_i). Finally, we observe that reversing the contractions in G transforms this path into the required approximation.

This finishes the overview of the proof of Theorem 2. Section 4 outlines the proof in detail, providing the sequence of intermediate technical results leading to the proof of the theorem.

3 Preliminaries

In this section, we define the notation used throughout the paper and provide some auxiliary results. We use $[n]$ to denote the set of positive integers $\{1, \ldots, n\}$. We remind that a function $f\colon D \to \mathbb{R}$ is *subadditive* if $f(x + y) \leq f(x) + f(y)$ for all $x, y \in D \subseteq \mathbb{R}$. We denote the set of all nonnegative real numbers by $\mathbb{R}_+$.

Recall that our main theorems are stated for arbitrary nondecreasing subadditive functions $f : \mathbb{R}_+ \to \mathbb{R}$, such that an algorithm achieving the respective approximation exists. Throughout the proofs we will, additionally assume that $f(x) \leq x$ for every $x \in \mathbb{R}_+$. For any integer $x \geq 3$, this is already implied by the statement, since a consistent approximation algorithm cannot output an (s,t)-path (respectively, cycle) of length greater than x in a graph where the longest (s,t)-path (respectively, cycle) has length x. However, for a general function $f(\cdot)$ this does not necessarily hold on the whole $\mathbb{R}_+$. If this is the case, for clarity of the proofs we redefine $f(x) := \min\{x, f(x)\}$ for every $x \in \mathbb{R}_+$. Clearly, f remains subadditive and non-decreasing, while also imposing exactly the same guarantee on the approximation algorithm.

Graphs. We consider only finite simple undirected graphs and use the standard notation (see, e.g., the book of Diestel [16]). The following useful observation follows immediately from Menger's theorem (see, e.g., [16, 42]).

▶ **Lemma 4.** *For any 2-connected graph G with a cycle of length L, there is a path of length at least $L/2$ between any pair of vertices in G. Moreover, given a cycle C and two distinct vertices s and t, an (s,t)-path of length at least $|V(C)|/2$ can be constructed in polynomial time.*

We observe that given an approximation algorithm for a longest cycle, we can use it as a black box to approximate a longest path between any two vertices.

▶ **Lemma 5.** *Let $\mathcal{A}$ be a polynomial-time algorithm that finds a cycle of length at least $f(L)$ in a graph with the longest cycle length L. Then there is a polynomial-time algorithm using $\mathcal{A}$ as a subroutine that, given a graph G and two distinct vertices s and t, finds an (s,t)-path of length at least $\frac{1}{2}f(2L)$, where L is the length of a longest (s,t)-path in G.*

We will use as a subroutine an algorithm finding two disjoint paths between two pairs of vertices of total length at least k, where k is the given parameter. For us, constant values of k suffice, though in fact there exists an FPT algorithm for this problem parameterized by the total length. It follows as an easy corollary from the following result of [24] about Long $(s,\ t)$-Cycle, the problem of finding a cycle of length at least k through the given two vertices s and t.

▶ **Theorem 6** (Theorem 4 in [24]). *There exists an FPT algorithm for Long $(s,\ t)$-Cycle parameterized by k.*

For completeness, we state the corollary next.

▶ **Corollary 7.** *There is an FPT algorithm that, given a graph G with two pairs of vertices $\{s,t\}$ and $\{s',t'\}$, and a parameter k, finds two disjoint paths between $\{s,t\}$ and $\{s',t'\}$ in G of total length at least k, or correctly determines that such paths do not exist.*

Finally, it is convenient to use the following corollary, which generalizes the theorem of Erdős and Gallai [19, Theorem 1.16].

▶ **Corollary 8** (Corollary 3 in [24]). *Let G be a 2-connected graph and let s,t be a pair of distinct vertices in G. For any $B \subseteq V(G)$ there exists a path of length at least $\delta(G-B)$ between s and t in G. Moreover, there is a polynomial time algorithm constructing a path of such length.*

4 Approximating (s,t)-path

In this section, we outline the proof of Theorem 2, stating that any guarantee for approximating the longest cycle in a 2-connected graph can be transferred to approximating the longest (s,t)-path above minimum degree. For the convenience of the reader, we recall the precise statement next.

▶ **Theorem 2.** *Let $f : \mathbb{R}_+ \to \mathbb{R}_+$ be a non-decreasing subadditive function and suppose that we are given a polynomial-time algorithm computing an (s,t)-path of length at least $f(L)$ in graphs with given two vertices s and t having the longest (s,t)-path of length L. Then there is a polynomial-time algorithm that outputs an (s,t)-path of length at least $\delta(G-\{s,t\}) + \Omega(f(L-\delta(G-\{s,t\})))$ in a 2-connected graph G with two given vertices s and t having the longest (s,t)-path length L.*

In order to obtain this result, we first recall the concept of Erdős-Gallai decomposition introduced in [24] together with a few of its helpful properties established there. Then we introduce the recursive generalization of this concept, called nested Erdős-Gallai decomposition, and show how to obtain with its help the compression of the graph such that a long (s,t)-path in the compressed graph can be lifted to an (s,t)-path in the original graph with a large offset.

4.1 Erdős-Gallai decomposition

This subsection encompasses the properties of an Erdős-Gallai decomposition, defined next. The definition itself and most of the technical results presented here are due to [24]. Some of the results from [24] need to be modified in order to be used for our purposes, we provide the proofs of such results in [26]. Note that the statements in [24] hold in the more general case where there is also a low-degree vertex subset in the graph, here while recalling the results we automatically simplify the statements. Next, we recall the definition of an Erdős-Gallai decomposition.

▶ **Definition 9** (Erdős-Gallai decomposition and Erdős-Gallai component, Definition 2 in [24])**.** *Let P be a path in a 2-connected graph G. We say that two disjoint paths P_1 and P_2 in G induce* an Erdős-Gallai decomposition for P *in G if*

- *Path P is of the form $P = P_1P'P_2$, where the inner path P' has at least $\delta(G-\{s,t\})$ edges.*
- *There are at least two connected components in $G - V(P_1 \cup P_2)$, and for every connected component H, it holds that $|V(H)| \geq 3$ and one of the following is fulfilled:*
  1. *H is 2-connected and the maximum size of a matching in G between $V(H)$ and $V(P_1)$ is one, and between $V(H)$ and $V(P_2)$ is also one;*
  2. *H is not 2-connected, exactly one vertex of P_1 has neighbors in H, that is $|N_G(V(H)) \cap V(P_1)| = 1$, and no inner vertex from a leaf-block of H has a neighbor in P_2;*
  3. *The same as 2, but with P_1 and P_2 interchanged. That is, H is not 2-connected, $|N_G(V(H)) \cap V(P_2)| = 1$, and no inner vertex from a leaf-block of H has a neighbor in P_1.*

The set of Erdős-Gallai component*s for an Erdős-Gallai decomposition is defined as follows. First, for each component H of type 1, H is an Erdős-Gallai component of the Erdős-Gallai decomposition. Second, for each H of type 2, or of type 3, all its leaf-blocks are also Erdős-Gallai components of the Erdős-Gallai decomposition.*

As long as an Erdős-Gallai decomposition is available, Erdős-Gallai components allow us to bound the structure of optimal solutions in a number of ways. First, Fomin et al. [24] observe that the longest (s,t)-path necessarily visits an Erdős-Gallai component.

▶ **Lemma 10** (Lemma 7 in [24]). *Let G be a graph and P_1, P_2 induce an Erdős-Gallai decomposition for an (s,t)-path P in G. Then there is a longest (s,t)-path in G that enters an Erdős-Gallai component.*

Next, since an Erdős-Gallai component has a very restrictive connection to the rest of the graph, it follows that any (s,t)-path has only one chance of entering the component.

▶ **Lemma 11** (Lemma 5 in [24]). *Let G be a 2-connected graph and P be an (s,t)-path in G. Let paths P_1, P_2 induce an Erdős-Gallai decomposition for P in G. Let M be an Erdős-Gallai component. Then for every (s,t)-path P' in G, if P' enters M, then all vertices of $V(M) \cap V(P')$ appear consecutively in P'.*

For the purposes of recursion, it is convenient to enclose an Erdős-Gallai component together with some of its immediate connections, so that this slightly larger subgraph behaves exactly like an (s,t)-path instance. The subgraph K in the next lemma plays this role.

▶ **Lemma 12** (Lemma 8 in [24]). *Let paths P_1, P_2 induce an Erdős-Gallai decomposition for an (s,t)-path P in graph G. Let M be an Erdős-Gallai component in G. Then there is a polynomial time algorithm that outputs a 2-connected subgraph K of G and two vertices $s', t' \in V(K)$, such for that every (s,t)-path P' in G that enters M, the following hold:*

1. *$V(K) = (V(M) \cup \{s', t'\})$;*
2. *$P'[V(K)]$ is an (s', t')-subpath of P' and an (s', t')-path in K;*
3. *$\delta(K - \{s', t'\}) \geq \delta(G - \{s, t, s', t'\})$.*

Most importantly, Erdős-Gallai decompositions capture extremal situations, where the current (s,t)-path cannot be made longer in a "simple" way. The next lemma formalizes that intuition, stating that in polynomial time we can find either a long (s,t)-path or an Erdős-Gallai decomposition. The lemma is largely an analog of Lemma 4 in [24], however our statement here is slightly modified. Next, we recall the statement from Section 2.

▶ **Lemma 13.** *Let G be a 2-connected graph such that $\delta(G - \{s,t\}) \geq 16$. There is a polynomial time algorithm that*

- *either outputs an (s,t)-path P of length at least $\min\{\frac{5}{4}\delta(G - \{s,t\}) - 3, |V(G)| - 1\}$,*
- *or outputs an (s,t)-path P with paths P_1, P_2 that induce an Erdős-Gallai decomposition for P in G. Additionally, there is no (s,t)-path in G that enters at least two Erdős-Gallai components of this Erdős-Gallai decomposition.*

Finally, to deal with (s,t)-paths that do not enter any Erdős-Gallai component, one can observe the following. Intuitively, such a path should be far from optimal, as going through an Erdős-Gallai component would immediately give at least $\delta(G - \{s,t\}) - \mathcal{O}(1)$ additional edges of the path. The final lemma of this subsection establishes how precisely the length of a path avoiding Erdős-Gallai components can be "boosted" in this fashion. To obtain this result, we first need a technical lemma from [24] that yields long paths inside separable components.

▶ **Lemma 14** (Lemma 6 in [24]). *Let H be a connected graph with at least one cut-vertex. Let I be the set of inner vertices of all leaf-blocks of H. Let $S \subseteq V(H) \setminus I$ separate at least one vertex in $V(H) \setminus I$ from I in H. For any vertex v that is not an inner vertex of a leaf-block of H, there is a cut-vertex c of a leaf-block of H and a (c,v)-path of length at least $\frac{1}{2}(\delta(H) - |S|)$ in H. This path can be constructed in polynomial time.*

Now we move to (s,t)-paths that avoid Erdős-Gallai components. The following Lemma 15 has been already stated in Section 2, here we recall the statement.

▶ **Lemma 15.** *Let P be an (s,t)-path of length at most $\delta(G-\{s,t\})+k$ and let two paths P_1, P_2 induce a Erdős-Gallai decomposition for P in G. There is a polynomial time algorithm that, given an (s,t)-path of length at least $4k+5$ in G that does not enter any Erdős-Gallai component, outputs a path of length at least $\min\{\delta(G-\{s,t\})+k-1, \frac{3}{2}\delta(G-\{s,t\})-\frac{5}{2}k-1\}$ in G.*

4.2 Proof of Theorem 2

To deal with the recursive structure of the solution, we introduce the following *nested* generalization of an Erdős-Gallai decomposition. Intuitively, it captures how the structural observations of the previous subsection allow us to recursively construct Erdős-Gallai decompositions with the aim of finding a long (s,t)-path. For an illustration of a nested Erdős-Gallai decomposition, see Figure 1. We recall the formal definition from Section 2.

▶ **Definition 16** (Nested Erdős-Gallai decomposition)**.** *A sequence of triples (G_1,s_1,t_1), (G_2,s_2,t_2), …, (G_ℓ,s_ℓ,t_ℓ) is called a* nested Erdős-Gallai decomposition *for G and two vertices $s,t \in V(G)$ if*

- $(G_1,s_1,t_1)=(G,s,t)$*;*
- *for each $i \in [\ell]$, either*
  - $\delta(G_i-\{s_i,t_i\})<16$*, or*
  - *Lemma 13 applied to G_i,s_i,t_i gives a path P_i of length at least $\min\{\frac{5}{4}\delta(G_i-\{s_i,t_i\})-3, |V(G_i)|-1\}$ in G_i, or*
  - *Lemma 13 applied to G_i,s_i,t_i gives a path P_i and two paths $P_{i,1},P_{i,2}$ that induce an Erdős-Gallai decomposition for P_i in G_i, and for each Erdős-Gallai component M of this decomposition there is $j>i$ such that (G_j,s_j,t_j) is the result of Lemma 12 applied to M in G_i. In this case, we say that G_i is* decomposed*.*
- *for each $i \in \{2,\dots,\ell\}$, there is $e(i)<i$ such that (G_i,s_i,t_i) is a result of Lemma 12 applied to some Erdős-Gallai component of the Erdős-Gallai decomposition of $G_{e(i)}$ for $P_{e(i)}$.*

The proof of Theorem 2 is performed in two steps: first, we show how to obtain a nested Erdős-Gallai decomposition for a given graph G, and then we use the nested Erdős-Gallai decomposition to recursively construct a good approximation to the longest (s,t)-path. The first part is achieved simply by applying Lemma 13 recursively on each Erdős-Gallai component until components are no longer decomposable. The main hurdle is the second part, on which we focus for the rest of the section. For completeness, first we show that a nested Erdős-Gallai decomposition can always be constructed in polynomial time.

▶ **Lemma 17.** *There is a polynomial time algorithm that, given a 2-connected graph G and its two vertices s and t, outputs a nested Erdős-Gallai decomposition for G, s, t.*

Clearly, it follows that the size of a nested Erdős-Gallai decomposition returned by Lemma 17 is also polynomial. Observe also that the construction algorithm invokes Lemma 13 for all sufficiently large G_i, thus in what follows we assume that the corresponding paths P_i are already computed.

Now we focus on using a constructed nested Erdős-Gallai decomposition for approximating the longest (s,t)-path. First of all, we present the algorithm `long_nested_st_path` that, given a nested Erdős-Gallai decomposition of G, computes a long (s,t)-path by going over

the decomposition. The pseudocode of `long_nested_st_path` is present in Algorithm 3. Intuitively, first the algorithm computes a compression H of the graph G that respects the nested Erdős-Gallai decomposition: components that are not decomposed are replaced by single edges, and edges that are "unavoidable" to visit a component are contracted. The computation of this compression is encapsulated in the `nested_compress` function presented in Algorithm 1. As a subroutine, this function uses the `two_long_disjoint_paths` algorithm given by Corollary 7, that finds two disjoint paths of at least the given length between the given pairs of vertices.

Next, the blackbox approximation algorithm `long_st_path_approx` is used to compute an (s,t)-path Q in H. The function `nested_decompress` reconstructs then this path in the original graph G, see Algorithm 2 for the pseudocode. Later we argue (Lemma 19) that any (s,t)-path in H of length r yields in this way an (s,t)-path in G of length at least $\delta(G-\{s,t\})+r/8-3$. Finally, either the length of Q in H was large enough and the reconstructed path provides the desired approximation or a long path can be found inside one of the components in a "simple" way, and then connected arbitrarily to $\{s,t\}$. Specifically, in this component, it suffices to either take an approximation of the longest path computed by `long_st_path_approx`, or a long Erdős–Gallai path returned by the algorithm from Corollary 8, `long_eg_st_path`. Thus, in the final few lines `long_nested_st_path` checks whether any of these paths is longer than the reconstructed path Q. The path from inside the component is extended to an $\{s,t\}$-path in G by using the algorithm `two_long_disjoint_paths`, given by Corollary 7, with the parameter 0.

Algorithm 1 The algorithm compressing a given graph G with a given nested Erdős-Gallai decomposition.

`nested_compress`$((G_1,s_1,t_1),(G_2,s_2,t_2),\ldots,(G_\ell,s_\ell,t_\ell))$
Input: a nested Erdős-Gallai decomposition for G, s and t.
Output: the compressed graph H.
$H \longleftarrow G$;
foreach $i \in \{2,\ldots,\ell\}$ **do**
  $j \longleftarrow e(i)$;
  $d_i \longleftarrow |\{s_j,t_j\} \setminus \{s_i,t_i\}|$;
  if `two_long_disjoint_paths` $(G_i,\{s_j,t_j\},\{s_i,t_i\},d_i+1)$ *is* NO **then**
    contract all edges of a maximum matching between $\{s_j,t_j\}$ and $\{s_i,t_i\}$ in H;
  end
  if G_i *is not decomposed* **then**
    remove all vertices in $V(G_i) \setminus \{s_i,t_i\}$ from H;
    add edge s_it_i to H and mark it with G_i;
  end
end
return H;

Now, our goal is to show that the path that the `long_nested_st_path` algorithm constructs serves indeed as the desired approximation of the longest (s,t)-path in G. For the rest of this section, let $G_1,\ldots,G_\ell$ be the given nested Erdős-Gallai decomposition for G,s,t. An important piece of intuition about nested Erdős-Gallai decomposition is that, as we go deeper into the nested Erdős-Gallai components, the minimum degree of the component $\delta(G_i \setminus \{s_i,t_i\})$ decreases, but we gain more and more edges that we collect while going

Algorithm 2 The algorithm decompressing a path in H into a long path in G.

`nested_decompress`$((G_1, s_1, t_1), (G_2, s_2, t_2), \ldots, (G_\ell, s_\ell, t_\ell), H, Q)$

Input: a nested Erdős-Gallai decomposition for G, s and t, the compressed graph H and an (s,t)-path Q in H of length r.

Output: an (s,t)-path of length at least $\delta(G - \{s,t\}) + r/8 - 3$ in G.

2.1 **foreach** $i \in \{2, \ldots, \ell\}$ *such that* $d_i > 0$ *and* Q *enters* G_i **do**
2.2 $\quad j \longleftarrow e(i)$;
2.3 $\quad$ **if** *an edge between* $\{s_j, t_j\}$ *and* $\{s_i, t_i\}$ *was contracted in* H **then**
2.4 $\quad\quad$ replace s_i and/or t_i in Q with the respective contracted edges;
2.5 $\quad$ **else**
2.6 $\quad\quad$ $S_1, S_2 \longleftarrow$ `two_long_disjoint_paths`$(G, \{s_j, t_j\}, \{s_i, t_i\}, d_i + 1)$;
2.7 $\quad\quad$ replace the two subpaths of Q going from $\{s_j, t_j\}$ to $\{s_i, t_i\}$ with S_1 and S_2 if the length of Q increases;
2.8 $\quad$ **end**
2.9 **end**
2.10 $h \longleftarrow$ largest $h \in [\ell]$ such that Q enters G_h;
2.11 **if** G_h *is not decomposed* **then**
2.12 $\quad$ replace $s_h t_h$ in Q with P_h;
2.13 **else**
2.14 $\quad k' \longleftarrow \lfloor (|E(Q) \cap E(G_h)| - 5)/8 \rfloor$;
2.15 $\quad$ **if** $|E(P_h)| \geq \delta(G_h - \{s_h, t_h\}) + k'$ **then**
2.16 $\quad\quad R \longleftarrow P_h$;
2.17 $\quad$ **else**
2.18 $\quad\quad R \longleftarrow$ result of Lemma 15 applied to G_h, P_h and the (s_h, t_h)-subpath of Q;
2.19 $\quad$ **end**
2.20 $\quad$ **if** (s_h, t_h)*-subpath of* Q *is shorter than* R **then**
2.21 $\quad\quad$ replace the (s_h, t_h)-subpath of Q with R;
2.22 $\quad$ **end**
2.23 **end**
2.24 **return** Q;

from $\{s,t\}$ to $\{s_i, t_i\}$. We introduce values that help us measure this difference between the nested components: for each $i \in [\ell]$, denote $d_i = |\{s_{e(i)}, t_{e(i)}\} \setminus \{s_i, t_i\}|$. In particular, by Lemma 12 we know that for any $i \in [\ell]$, $\delta(G_i) \geq \delta(G_{e(i)}) - d_i$. On the other hand, any pair of disjoint paths that connects $\{s_{e(i)}, t_{e(i)}\}$ to $\{s_i, t_i\}$ contains at least d_i edges. This leads to the following simple observation about extending an (s_j, t_j)-path in a component G_j to an (s,t)-path in G.

▷ Claim 18. For each $j \in [\ell]$, let $G_{j_1}, \ldots, G_{j_c}$ be such that $j_c = j$ and $j_1 = 1$ and $e(j_{i+1}) = j_i$ for each $i \in [c-1]$. Let P be an (s_j, t_j)-path in G_j. Then P combined with any pair of disjoint paths connecting $\{s,t\}$ to $\{s_j, t_j\}$ yields an (s,t)-path in G of length at least $|E(P)| + \sum_{i \in [c-1]} d_{j_{i+1}}$.

However, there might also exist longer paths connecting nested components $G_{e(i)}$ and G_i. When we construct the compressed graph H in Algorithm 1, we distinguish between two cases. Either any pair of such paths have the total length d_i, meaning that the only option is to use the edges of a matching between $\{s_{e(i)}, t_{e(i)}\}$ and $\{s_i, t_i\}$. In that case we simply contract these edges as we know that there is no choice on how to reach G_i from $G_{e(i)}$. Or, there is a pair of disjoint paths of total length at least $d_i + 1$. This situation is

Algorithm 3 The algorithm finding a long (s,t)-path in a 2-connected graph with a given nested Erdős-Gallai decomposition.

`long_nested_st_path`$((G_1,s_1,t_1),(G_2,s_2,t_2),\dots,(G_\ell,s_\ell,t_\ell))$
Input: a nested Erdős-Gallai decomposition for G, s and t.
Output: an (s,t)-path of length at least $\delta(G-\{s,t\})+f(k)/32-3$ in G where $k=L-\delta(G-\{s,t\})$ for the longest (s,t)-path length L in G.
3.1 $H \longleftarrow$ `nested_compress`$((G_1,s_1,t_1),(G_2,s_2,t_2),\dots,(G_\ell,s_\ell,t_\ell))$;
3.2 $Q \longleftarrow$ `long_st_path_approx`(H,s,t);
3.3 $Q \longleftarrow$ `nested_decompress`$((G_1,s_1,t_1),(G_2,s_2,t_2),\dots,(G_\ell,s_\ell,t_\ell),H,Q)$;
3.4 **foreach** $i \in [\ell]$ **do**
3.5 $P_i \longleftarrow$ the longest of $\{$`long_st_path_approx`(G_i,s_i,t_i), `long_eg_st_path`$(G_i,s_i,t_i)\}$;
3.6 $Q \longleftarrow$ the longest of $\{Q,$ `two_long_disjoint_paths`$(G,\{s,t\},\{s_i,t_i\},0)\cup P_i\}$;
3.7 **end**
3.8 **return** Q;

beneficial to us in a different way: since we can find such a pair of paths in polynomial time, we can traverse at least d_i+1 edges going from $G_{e(i)}$ to G_i, while we only lose at most d_i in the minimum degree. This dichotomy on the structure of the "slice" between two nested components is the main leverage that allows us to lift the length of an (s,t)-path in H to an offset above the minimum degree in G. We formally show this crucial property of the compressed graph H and the `nested_decompress` routine in the next lemma.

▶ **Lemma 19.** *The `nested_decompress` routine transforms an (s,t)-path Q in H of length r into an (s,t)-path in G of length at least $\delta(G-\{s,t\})+r/8-3$.*

It will also be helpful to observe that in the "slice" between a decomposed component and the nested components, at most two edges of any path can be contracted. Note that this does not follow immediately, as a pair of edges to *each* of the nested components is potentially contracted.

▷ Claim 20. Let Q be an (s_j,t_j)-path inside a decomposed graph G_j. Then all edges $E(Q)\cap E(G_j)\setminus\bigcup_{e(i)=j}E(G_i)$ are unchanged in H except for, possibly, contraction of the first and the last edge of Q.

Now we are ready to prove the main lemma that bounds the length of the (s,t)-path returned by Algorithm 3.

▶ **Lemma 21.** *`long_nested_st_path` outputs an (s,t)-path in G of length at least $\delta(G-\{s,t\})+f(k)/32-3$, where $k=L-\delta(G-\{s,t\})$ and L is the length of the longest (s,t)-path in G.*

Finally, observe that the running time of Algorithm 3 is polynomial in the size of the given nested Erdős-Gallai decomposition. By Lemma 17, its size is polynomial in the size of the input graph G. This concludes the proof of Theorem 2.

5 Conclusion

In this article, we have shown a general theorem that allows us to leverage all the algorithmic machinery for approximating the length of the longest cycle to approximate the "offset" of the longest cycle provided by the classical Dirac's theorem. As far as one can compute

a cycle of length $f(L)$ in a 2-connected graph G with the longest cycle length L, we can also construct a cycle of length $2\delta(G) + \Omega(f(L - 2\delta(G)))$. In particular, we can use the state-of-the-art approximation algorithm for Longest Cycle due to Gabow and Nie [31]. They achieve an algorithm finding a cycle of length $f(L) = c^{\sqrt{\log L}}$ for some constant $c > 1$ in a graph with the longest cycle length L. Note that f is non-decreasing and subadditive (as f is concave on $[1, +\infty]$, and any concave function is subadditive; we also can formally set $f(x) = \min\{x, c^{\sqrt{\log x}}\}$ for $x \geq 1$ and $f(x) = x$ for $x < 1$ to fit the statement of Theorem 1). By substituting this to Theorem 1, we achieve a polynomial-time algorithm that outputs a cycle of length $2\delta(G) + 2^{\Omega(\sqrt{\log(L-2\delta(G))})}$ in a 2-connected graph G with the longest cycle length $L > 2\delta(G)$.

In the field of parameterized algorithms, there are many results on computing longest cycles or paths above some guarantees. It is a natural question, whether approximation results similar to ours hold for other types of "offsets". To give a few concrete questions, recall that the *degeneracy* $\mathrm{dg}(G)$ of a graph G is the maximum d such that G has an induced subgraph of minimum degree d. By Erdős and Gallai [19], a graph of degeneracy $d \geq 2$ contains a cycle of length at least $d + 1$. It was shown by Fomin et al. in [22] that a cycle of length at least $L = \mathrm{dg}(G) + k$ in a 2-connected graph can be found in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ time. This immediately yields a polynomial-time algorithm for computing a cycle of length at least $\mathrm{dg}(G) + \Omega(\log(L - \mathrm{dg}(G)))$. Is there a better approximation of the longest cycle above the degeneracy?

Another concrete question. Bezáková et al. [4] gave an FPT algorithm that for $s, t \in V(G)$ finds a detour in an undirected graph G. In othere words, they gave an algorithm that finds an (s, t)-path of length at least $L = \mathrm{dist}_G(s, t) + k$ in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ time. Here $\mathrm{dist}_G(s, t)$ is the distance between s and t. Therefore, in undirected graph we can find an (s, t)-path of length $\mathrm{dist}_G(s, t) + \Omega(\log(L - \mathrm{dist}_G(s, t))$ in polynomial time. The existence of any better bound is open. For directed graphs, the question of whether finding a long detour is FPT is widely open [4]. Nothing is known about the (in)approximability of long detours in directed graphs.

Abstract

We introduce a novel model-theoretic framework inspired from graph modification and based on the interplay between model theory and algorithmic graph minors. The core of our framework is a new *compound logic* operating with two types of sentences, expressing graph modification: the *modulator sentence*, defining some property of the modified part of the graph, and the *target sentence*, defining some property of the resulting graph. In our framework, modulator sentences are in counting monadic second-order logic (CMSOL) and have models of bounded treewidth, while target sentences express first-order logic (FOL) properties along with minor-exclusion. Our logic captures problems that are not definable in first-order logic and, moreover, may have instances of unbounded treewidth. Also, it permits the modeling of wide families of problems involving vertex/edge removals, alternative modulator measures (such as elimination distance or $\mathcal{G}$-treewidth), multistage modifications, and various cut problems. Our main result is that, for this compound logic, model-checking can be done in quadratic time. All derived algorithms are constructive and this, as a byproduct, extends the constructibility horizon of the algorithmic applications of the Graph Minors theorem of Robertson and Seymour. The proposed logic can be seen as a general framework to capitalize on the potential of the *irrelevant vertex technique*. It gives a way to deal with problem instances of unbounded treewidth, for which Courcelle's theorem does not apply.

1 Introduction

Our work is kindled by the current algorithmic advances in graph modification. The core of our approach is a novel model-theoretic framework that is based on the interplay between model theory and algorithmic graph minors. Departing from this new perspective, we obtain algorithmic meta-theorems that encompass, unify, and extend all known meta-algorithmic results on minor-closed graph classes.

1.1 State of the art and our contribution

Modification problems. A *graph modification problem* asks whether it is possible to apply a series of modifications to a graph in order to transform it to a graph with some desired target property. Such problems have been the driving force of Parameterized Complexity where parameterization quantifies the concept of "distance from triviality" [48] and measures the amount of the applied modification. Classically, modification operations may be vertex or edge deletions, edge additions/contractions, or combinations of them like taking a minor. In their generality, such problems are NP-complete [60] and much research in Parameterized Complexity is on the design of algorithms in time $f(k) \cdot n^{\mathcal{O}(1)}$, where the parameter k is some measure of the modification operation [20]. The target property may express desired structural properties that respond to certain algorithmic or combinatorial demands. A widely studied family of target properties are minor-closed graph classes such as edgeless graphs [14], forests [13], bounded treewidth graphs [35, 54], planar graphs [50, 62], bounded genus graphs [55], or, most generally, minor-excluding graphs [72, 73]. However, other families of target properties have also been considered, such as those that exclude an odd cycle [29], a topological minor [36], an (induced) subgraph [22, 69], an immersion [40], or an induced minor [41]. A broad class of graph modification problems concerns cuts. In a typical cut problem, one wants to find a minimum-size set of edges or vertices X in a graph G such that in the new graph $G \setminus X$, obtained by deleting X from G, some terminal-connectivity conditions are satisfied. For example, the condition can be that a set of specific terminals becomes separated or that at least one connected component in the new graph is of a specific size. The development of parameterized algorithms for cut problems is a popular trend in parameterized algorithms [21, 61]. More involved modification measures of vertex set removals, related to treewidth or treedepth, have been considered very recently [1, 12, 27, 49].

Algorithmic meta-theorems. A vibrant line of research in Logic and Algorithms is the development of *algorithmic meta-theorems*. According to Grohe and Kreutzer [45], algorithmic meta-theorems state that certain families of algorithmic problems, typically defined by some logical and some combinatorial condition, can be solved "efficiently", under some suitable definition of this term. Algorithmic meta-theorems play an important role in the theory of algorithms as they reveal deep interplays between Algorithms, Logic, and Combinatorics. One of the most celebrated meta-theorems is Courcelle's theorem asserting that graph properties definable in CMSOL (counting monadic second-order logic) are decidable in linear time on graphs of bounded treewidth [15]; see also [2, 10]. Another stream of research concerns identifying wide combinatorial structures where model-checking for FOL (first-order logic) can be done in polynomial time. This includes graph classes of bounded degree [76], graph classes of bounded local treewidth [37], *minor-closed graph classes* [30], graph classes locally excluding a minor [23], and more powerful concepts of sparsity, such as having bounded expansion [26, 63], nowhere denseness [46], or having bounded twin-width [9]. (See [44, 58] for surveys. Also for results on the combinatorial horizon of FOL and CMSOL (and its variants) see [8, 9, 46] and [57] respectively.)

Another line of research, already mentioned in [44], is to prove algorithmic meta-theorems for extensions of FOL of greater expressibility. Two such extensions have been recently presented. The first one consists in enhancing FOL with predicates that can express k-connectivity for every $k \geq 1$. This extension of FOL was introduced independently by Schirrmacher, Siebertz, and Vigny in [75] (under the name FOL+conn) and by Bojańczyk in [6] (under the name *separator logic*). The second and more expressive extension, also introduced by Schirrmacher, Siebertz, and Vigny in [75], is FOL+DP, that enhances FOL with predicates expressing the existence of disjoint paths between certain pairs of vertices. For FOL+conn, an algorithmic meta-theorem for model-checking on graphs excluding a topological minor has been very recently given by Pilipczuk, Schirrmacher, Siebertz, Torunczyk, and Vigny [66]. For the more expressive FOL+DP, an algorithmic meta-theorem for model-checking on graphs excluding a minor has been very recently given by Golovach, Stamoulis, and Thilikos in [43] (see [42] for the full version).

Research on the meta-algorithmics of FOL is quite active and has moved to several directions such as the study of FOL-interpretability [7, 39, 64, 65] or the enhancement of FOL with counting/numerical predicates [25, 47, 59].

In this paper, we initiate an alternative approach consisting in combining the expressive power of FOL and CMSOL. A typical family of problems where such an approach becomes relevant is the one of modification problems. Courcelle's theorem implies that if the target property corresponds to a class of bounded treewidth and the modification conditions are definable in CMSOL, then such modification problems are fixed-parameter tractable when parameterized by the length of the sentence and the treewidth of the graph. However, when the target class graph is of unbounded treewidth, none of the aforementioned algorithmic meta-theorems encompasses broad families of modification problems. As an illustrative example, consider the Planarization problem, which consists in deciding whether at most k vertices can be removed from an input graph to make it planar (or equivalently, minor-excluding K_5 and $K_{3,3}$). While this problem is definable in CMSOL, Courcelle's theorem cannot be applied as we cannot assume that yes-instances are of bounded treewidth. On the other hand, we can easily assume that yes-instances minor-exclude K_{k+6}. However, all known meta-theorems whose combinatorial condition encompasses the minor-exclusion are about FOL, and FOL cannot express the Planarization problem. On the positive side, an algorithm in time $f(k) \cdot n^2$ for Planarization is an algorithmic consequence of Robertson-Seymour's theorem [68] (combined with [51, 67]). This automatic implication follows directly (albeit non-constructively) for a wide family of modification problems whose yes-instances are minor-closed. There is a long line of research in parameterized algorithms towards providing constructive and reasonable estimations of $f(k)$ [50, 62, 72, 73]. Note that Robertson-Seymour's theorem, besides not being constructive in general, automatically offers results only for problems whose yes-instances are minor-closed.

Our contribution. We introduce a *compound logic* that models computational problems through the lens of the "modulator vs target" duality of graph modification problems. Each sentence of this logic is a composition of two types of sentences. The first one, called the *modulator sentence*, models a modification operation, while the second one, called the *target sentence*, models a target property. Informally, our result, in its simplest form, asserts that if some appropriate version of the modulator sentence meets the meta-algorithmic assumptions of Courcelle's theorem [15] (i.e., CMSOL-definability and bounded treewidth) and the target sentence meets the meta-algorithmic assumptions of the theorem of Flum and Grohe [30] (i.e., FOL-definability and minor-exclusion), then model-checking for the composed compound

sentence can be done, constructively, in quadratic time. Our main result (Theorem 5) can be seen as a "two-dimensional product" of the two aforementioned meta-algorithmic results, contains both of them as special cases, and automatically implies the tractability of wide families of problems that *neither* are FOL-definable *nor* have instances of bounded treewidth.

1.2 Our results

In this subsection we give formal statements of our results. We need first some definitions.

Preliminaries on graphs. Given a graph G, we denote by $\mathsf{cc}(G)$ the set of all connected components of G. For a graph G and a set $X \subseteq V(G)$, the *stellation* of X in G is the graph $\mathsf{stell}(G, X)$ obtained from G if, for every $C \in \mathsf{cc}(G \setminus X)$, we contract all edges of C to a single vertex v_C. The *torso* of X in G is the graph $\mathsf{torso}(G, X)$ obtained from $\mathsf{stell}(G, X)$ if, for every v_C where $C \in \mathsf{cc}(G \setminus X)$, we add all edges between neighbors of v_C and finally remove all v_C's from the resulting graph. Given a family of graphs $\mathcal{H}$, we define $\mathsf{excl}(\mathcal{H})$ as the class of all graphs minor-excluding the graphs in $\mathcal{H}$ and note that $\mathsf{excl}(\mathcal{H})$ is minor-closed. The *Hadwiger number* of a graph G, denoted by $\mathbf{hw}(G)$, is the minimum k where $G \in \mathsf{excl}(\{K_k\})$ and K_k is the complete graph on k vertices. We also use the well-known parameter of *treewidth* of a graph G, denoted by $\mathbf{tw}(G)$. Given a graph class $\mathcal{G}$, we define $\mathbf{tw}(\mathcal{G}) = \max\{\mathbf{tw}(G) \mid G \in \mathcal{G}\}$. We define $\mathbf{hw}(\mathcal{G})$ analogously. We use $\mathcal{G}_{\mathrm{all}}$ for the set of all graphs.

Preliminaries on logic. We use CMSOL (resp. FOL) for the set of sentences in counting monadic second-order logic (resp. first-order logic). Given some vocabulary τ and a sentence $\varphi \in \mathsf{CMSOL}[\tau]$, we denote by $\mathrm{Mod}(\varphi)$ the set of all finite models of φ, i.e., all structures that are models of φ. In this introduction, in order to simplify our presentation, all structures that we consider are either graphs or annotated graphs, i.e., pairs (G, X) where G is a graph and $X \subseteq V(G)$. In the first case $\tau = \{\mathsf{E}\}$, and in the second $\tau = \{\mathsf{E}, \mathsf{X}\}$.

Given a $\varphi \in \mathsf{CMSOL}[\{\mathsf{E}\}]$, we define the *connectivity extension* $\varphi^{(\mathsf{c})}$ of φ so that $G \models \varphi^{(\mathsf{c})}$ if $\forall C \in \mathsf{cc}(G), C \models \varphi$. Similarly, for every $\mathcal{L} \subseteq \mathsf{CMSOL}[\{\mathsf{E}\}]$, we define $\mathcal{L}^{(\mathsf{c})} = \mathcal{L} \cup \{\varphi^{(\mathsf{c})} \mid \varphi \in \mathcal{L}\}$. Notice that $\{\varphi\}^{(\mathsf{c})} = \{\varphi, \varphi^{(\mathsf{c})}\}$. Also by $\mathbf{PB}(\mathcal{L})$ we denote the set of all positive Boolean combinations (i.e., using only the Boolean connectives $\vee$ and $\wedge$) of sentences in $\mathcal{L}$. We next define the following sets of sentences:

- The set $\mathsf{CMSOL}^{\mathsf{tw}}[\{\mathsf{E}, \mathsf{X}\}]$ contains every sentence $\beta \in \mathsf{CMSOL}[\{\mathsf{E}, \mathsf{X}\}]$ for which there exists some c_β such that the torsos of all the models of β have treewidth at most c_β. Formally,
  $\mathsf{CMSOL}^{\mathsf{tw}}[\{\mathsf{E}, \mathsf{X}\}] = \{\beta \in \mathsf{CMSOL}[\{\mathsf{E}, \mathsf{X}\}] \mid \exists c_\beta : \mathbf{tw}\{\mathsf{torso}(G, X) \mid (G, X) \models \beta\} \leq c_\beta\}$.
- The set $\mathsf{EM}[\{\mathsf{E}\}]$ is the set of all sentences in $\mathsf{CMSOL}[\{\mathsf{E}\}]$ that express the minor-exclusion of a non-empty set of graphs. Formally,
  $\mathsf{EM}[\{\mathsf{E}\}] = \{\mu \in \mathsf{CMSOL}[\{\mathsf{E}\}] \mid \exists \mathcal{H} \subseteq \mathcal{G}_{\mathrm{all}}, \mathcal{H} \neq \emptyset : \mathrm{Mod}(\mu) = \mathsf{excl}(\mathcal{H})\}$.
- $\Theta_0[\{\mathsf{E}\}]$ contains every sentence $\sigma \wedge \mu$ where $\sigma \in \mathsf{FOL}[\{\mathsf{E}\}]$ and $\mu \in \mathsf{EM}[\{\mathsf{E}\}]$.

For simplicity, we use $\mathsf{CMSOL}^{\mathsf{tw}}$, EM, and Θ_0 as shortcuts for $\mathsf{CMSOL}^{\mathsf{tw}}[\{\mathsf{E}, \mathsf{X}\}]$, $\mathsf{EM}[\{\mathsf{E}\}]$, and $\Theta_0[\{\mathsf{E}\}]$, respectively. Note that both $\mathsf{CMSOL}^{\mathsf{tw}}$ and Θ_0 are undecidable.

Algorithmic meta-theorems. We are now in position to restate three major meta-algorithmic results that were mentioned in the previous subsection.

▶ **Proposition 1** (Courcelle [15]). *For every $\beta \in \mathsf{CMSOL}^{\mathsf{tw}}$, there is an algorithm deciding $\mathrm{Mod}(\beta)$ in linear time.*

▶ **Proposition 2** (Robertson and Seymour [67,68] and Kawarabayashi, Kobayashi, and Reed [51]). *For every minor-closed graph class $\mathcal{G}$, deciding membership in $\mathcal{G}$ can be done in quadratic time.*

▶ **Proposition 3** (Flum and Grohe [30]). *For every $\gamma \in \Theta_0$, there is an algorithm deciding* $\mathrm{Mod}(\gamma)$ *in quadratic time.*

Some comments are in order. The statements of Proposition 1 and Proposition 3 have been adapted so to incorporate the combinatorial demands in the logical condition. While they can both be stated for structures, we state Proposition 1 for annotated graphs and Proposition 3 for graphs in order to facilitate our presentation. In the classic formulation of Courcelle's theorem, we are given a sentence $\beta \in \mathsf{CMSOL}$ and a tree decomposition of bounded treewidth. As such a decomposition can be found in linear time, using e.g., [4,56], the linearity in the running time of Courcelle's theorem is preserved when it is stated in the form of Proposition 1. For the theorem of Flum and Grohe, the situation is different as the combinatorial demand is minor-exclusion of a clique, which is not definable is FOL. For this reason we state Proposition 3 using the logic Θ_0 that contains *compound* sentences of the form $\sigma \wedge \mu$, where $\sigma \in \mathsf{FOL}$ and μ expresses minor-exclusion. For the running time of the algorithm of Proposition 3, we also need to take into account Proposition 2. As we already mentioned, Proposition 1 and Proposition 3 cannot deal, in general, with modification problems to properties of unbounded treewidth. Moreover, recall that Proposition 2 applies only to problems whose yes-instances are minor-closed.

We stress that Proposition 1, Proposition 2, and Proposition 3 are non-constructive. In order to construct the algorithms promised by Proposition 1, one should also know the bound c_β on the treewidth of the models of $\beta \in \mathsf{CMSOL}^{\mathsf{tw}}$ (note that bounded treewidth is also CMSOL-definable since it is characterized by a finite set of forbidden minors) and this appears in the hidden constants in the running time in Proposition 1. Similarly, for Proposition 2 (resp. Proposition 3), one should have an upper bound on the Hadwiger number of the graphs in $\mathcal{G}$ (resp. the models of γ).

A logic for modification problems. As a key ingredient of our result, we define the following operation between sentences. Let $\beta \in \mathsf{CMSOL}[\{\mathsf{E},\mathsf{X}\}]$ and $\gamma \in \mathsf{CMSOL}[\{\mathsf{E}\}]$. We refer to β as the *modulator* sentence on annotated graphs and to γ as the *target* sentence on graphs. We define $\beta \triangleright \gamma$ so that

$$G \models \beta \triangleright \gamma \text{ if there is } X \subseteq V(G) \text{ such that } (\mathsf{stell}(G,X),X) \models \beta \text{ and } G \setminus X \models \gamma. \tag{1}$$

In other words, $G \models \beta \triangleright \gamma$ means that the stellation of X in G, along with X, is a model of the modulator sentence β and the $G \setminus X$ is a model of the target sentence γ. That way, β implies the modification operation and γ expresses the target graph property. It is easy to see that $\beta \triangleright \gamma \in \mathsf{CMSOL}[\{\mathsf{E}\}]$. This will allow us to apply the operation $\triangleright$ iteratively.

As an example, the problem of removing a set X of k vertices so that $G \setminus X$ is a triangle-free planar graph can be expressed by $\beta \triangleright \gamma$ if β asks that X has k vertices and $\gamma = \sigma \wedge \mu$, where σ expresses triangle-freeness and μ expresses planarity by the exclusion of $K_{3,3}$ and K_5.

Before we present our result in full generality, we give first the following indicative special case, which already expresses the conditions of Proposition 1 and Proposition 3.

▶ **Theorem 4.** *For every $\beta \in \mathsf{CMSOL}^{\mathsf{tw}}$ and every $\gamma \in \Theta_0$, there is an algorithm deciding* $\mathrm{Mod}(\beta \triangleright \gamma)$ *in quadratic time.*

Indeed, Proposition 1 follows if β expresses that $X = V(G)$ and γ demands that $G \setminus X$ is the empty graph (in particular, Theorem 4 contains Proposition 1 as a linear-time black-box procedure for deciding models of bounded treewidth) and Proposition 3 follows if β demands that $X = \emptyset$. In other words, Proposition 1 follows if the target sentence becomes void while Proposition 3 follows if the modulator sentence is void.

As a first step towards a more general statement, Theorem 4 also holds if we replace $\gamma \in \Theta_0$ by $\gamma \in \Theta_0^{(c)}$ or even by positive Boolean combinations of sentences in $\Theta_0^{(c)}$, i.e., $\gamma \in \mathbf{PB}(\Theta_0^{(c)})$. Moreover, in order to present our result in full generality, we recursively define, for every $i \geq 1$,

$$\Theta_i \quad = \quad \{\beta \triangleright \gamma \mid \beta \in \mathsf{CMSOL}^{\mathsf{tw}} \text{ and } \gamma \in \mathbf{PB}(\Theta_{i-1}^{(c)})\}. \tag{2}$$

Notice that the sentences of Theorem 4 (hence also of Proposition 1 and Proposition 3) are already contained in Θ_1. We set $\Theta = \bigcup_{i \geq 1} \Theta_i$. The full strength of our results, stated in the vocabulary of graphs, is given by our main theorem.

▶ **Theorem 5.** *For every $\theta \in \Theta$, model-checking for θ can be done in quadratic time.*

An alternative statement. Our results can also be seen under the typical meta-algorithmic framework where a logical and a combinatorial condition are given. For this, consider an alternative of Θ, called $\tilde{\Theta}$, that is defined as in (2) by taking $\tilde{\Theta}_0 = \mathsf{FOL}$ as the base case, i.e., by discarding the minor-exclusion from the definition of Θ_0. Notice that $\tilde{\Theta}$ contains FOL and can be seen as a natural extension of it. A direct consequence of Theorem 5 is the following.

▶ **Theorem 6.** *For every $\tilde{\theta} \in \tilde{\Theta}$, model-checking for $\tilde{\theta}$ can be done in quadratic time on every graph class of bounded Hadwiger number.*

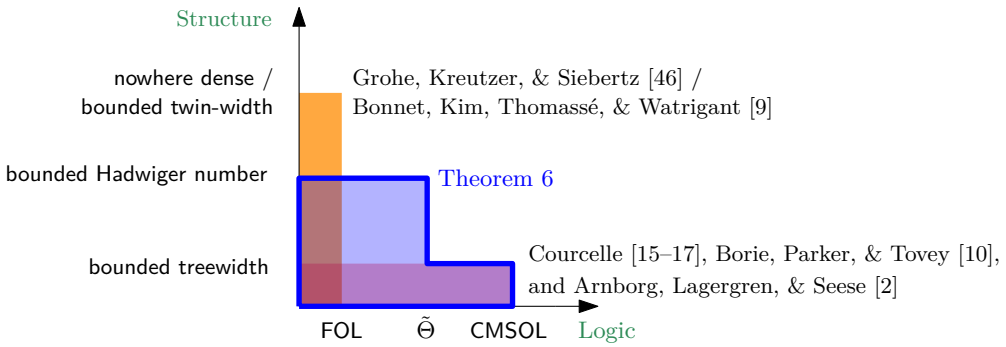

Figure 1 Theorem 6 in the current meta-algorithmic landscape. The vertical axis is the combinatorial one and is marked by four different types of (structural) sparsity, while the horizontal one is the logical one and is marked with FOL, $\tilde{\Theta}$, and CMSOL.

Theorem 6 is a corollary of Theorem 5 and provides an alternative meta-algorithmic set up between the logical and the combinatorial condition (see Figure 1): for each sentence θ in Θ, one may consider a sentence $\tilde{\theta}$ in $\tilde{\Theta}$ where we discard minor-exclusion from all its target sentences and then consider the problem of deciding $\mathrm{Mod}(\theta)$ on some minor-excluding graph class. This correspondence is many-to-one, as many different $\theta \in \Theta$ correspond to the same $\tilde{\theta} \in \tilde{\Theta}$. We opted for presenting and proving our results in the form of Theorem 5, as it is more general and more versatile in expressing modification problems. In the full version of the paper [31], we define we define Θ on general structures.

Compound logics based on FOL+DP. In the full version of the paper [31], by combining our proofs with the meta-algorithmic results of [42, 43], we extend Theorem 5 (resp. Theorem 6) in the cases of the logic Θ^{DP} (resp. $\tilde{\Theta}^{\mathsf{DP}}$) that are obtained if in the definition of Θ (resp. $\tilde{\Theta}$) we now consider the (more expressive) logic FOL+DP instead of FOL in the target sentences. That way, the derived extensions of Theorem 5 and Theorem 6 (that is, Theorem 8 and Theorem 9) encompass, as special cases, all results and applications in [42, 43] (see Figure 3 for a visualization of the overall state-of-the-art on the related algorithmic meta-theorems on subgraph-closed graph classes). While presenting our results and techniques, for the sake of simplicity, we chose to focus on the statement and the proof of our meta-theorems for Θ (Theorem 5) and $\tilde{\Theta}$ (Theorem 6) and then, in the full version of the paper [31], present the modifications that should be applied in order to extend them for Θ^{DP} and $\tilde{\Theta}^{\mathsf{DP}}$.

A parametric variant of our results. A *graph parameter* is a function $\mathbf{p} : \mathcal{G}_{\text{all}} \to \mathbb{N}$. We say that $\mathbf{p}$ is *treewidth-bounded* if there is a function $f : \mathbb{N} \to \mathbb{N}$ such that for each $G \in \mathcal{G}_{\text{all}}$, $\mathbf{p}(G) \leq f(\mathsf{tw}(G))$. We say that $\mathbf{p}$ is CMSOL-*definable* if for every $k \in \mathbb{N}$ there is a CMSOL-sentence (on graphs) β_k such that the set of all models of β_k is $\text{Mod}(\beta_k) = \{G \mid \mathbf{p}(G) \leq k\}$. Clearly, if $\mathbf{p}$ is treewidth-bounded then we can also assume that each β_k is a sentence in $\mathsf{CMSOL}^{\mathsf{tw}}$ and in this case we say that $\mathbf{p}$ is $\mathsf{CMSOL}^{\mathsf{tw}}$-definable. There are several known graph parameters that are $\mathsf{CMSOL}^{\mathsf{tw}}$-definable, such as treewidth, pathwidth, tree-depth, bridge-depth, block tree-depth, vertex cover, feedback vertex set, branch-width, carving-width, or cutwidth.

For a graph parameter $\mathbf{p}$ and a graph class $\mathcal{G}$, we define the new graph parameter $\mathbf{p}_{\mathcal{G}} : \mathcal{G}_{\text{all}} \to \mathbb{N}$ such that

$$\mathbf{p}_{\mathcal{G}}(G) = \min\{k \mid \exists X \subseteq V(G) \mid \mathbf{p}(\mathsf{torso}(G, X)) \leq k \ \wedge \ G \setminus X \in \mathcal{G}\}.$$

Thus $\mathbf{p}_{\mathcal{G}}$ measures by $\mathbf{p}$ the quality of a modulator X to property $\mathcal{G}$. For example, when $\mathbf{p}$ is the size of the modulator, then this is just the *vertex deletion distance to* $\mathcal{G}$, that is, the minimum number of vertices X such that $G \setminus X \in \mathcal{G}$. When $\mathbf{p}$ is the tree-depth of a graph, then $\mathbf{p}_{\mathcal{G}}$ is the elimination distance to $\mathcal{G}$. Or when $\mathbf{p}$ is the treewidth of a graph, then $\mathbf{p}_{\mathcal{G}}$ corresponds to $\mathcal{G}$-treewidth. We consider the general setting where $\mathbf{p}$ is a $\mathsf{CMSOL}^{\mathsf{tw}}$-definable graph parameter and $\mathcal{G}$ is a Θ-definable graph class, that is, $\text{Mod}(\theta) = \mathcal{G}$ for some $\theta \in \Theta$. By setting $\theta_k = \beta_k \triangleright \theta \in \Theta$, we have that $\text{Mod}(\theta_k) = \{G \mid \mathbf{p}_{\mathcal{G}}(G) \leq k\}$. Then the following theorem is a direct consequence of Theorem 5 and Theorem 6.

▶ **Theorem 7.** *Let* $\mathbf{p}$ *be a* $\mathsf{CMSOL}^{\mathsf{tw}}$*-definable graph parameter and* $\mathcal{G} = \text{Mod}(\theta)$ *for some* $\theta \in \Theta$*. Then there is an algorithm that, with input a graph* G *and* $k \in \mathbb{N}$*, checks whether* $\mathbf{p}_{\mathcal{G}}(G) \leq k$ *in time* $\mathcal{O}_{k,|\theta|}(n^2)$*. Moreover, if* $\mathcal{G} = \text{Mod}(\tilde{\theta})$ *for some* $\tilde{\theta} \in \tilde{\Theta}$*, then there is an algorithm that, with the same input, checks whether* $\mathbf{p}_{\mathcal{G}}(G) \leq k$ *in time* $\mathcal{O}_{k,|\theta|,\mathsf{hw}(G)}(n^2)$*.*

All the results mentioned in this subsection, in what concerns minor-excluded graphs, are subsumed by Theorem 7. Moreover, by allowing FOL-definability in the target sentence and $\mathsf{CMSOL}^{\mathsf{tw}}$-definability in the modulator sentence, we vastly extend Proposition 2 to graph classes and parameters that are not necessarily minor-closed or hereditary. We stress that none of the results in [43, 66] is able to deal with the problems captured by Theorem 7 in their full generality.

Constructibility. While Robertson-Seymour's theorem (Proposition 2) implies the existence of an algorithm, its proof is not constructive and cannot be used to construct such an algorithm [28]. An extra feature of the proof of Theorem 5 (as well as of its corollary Theorem 6) is that it is *constructive*, in the sense that the implied algorithms can be constructed

if we are given some bound on the Hadwiger number of the models of θ. This considerably extends the constructibility horizon of Proposition 2 for graph classes that are not necessarily minor-closed or even hereditary. See the full version of the paper [31] for more details.

Techniques. The algorithm and the proofs of Theorem 5 use as departure point core techniques from the proofs of Propositions 1, 3, and 2 such as Courcelle's theorem for dealing with CMSOL-sentences, the use of Gaifman's theorem for dealing with FOL-sentences, and an extended version of the *irrelevant vertex technique*, introduced by Robertson and Seymour in [67], along with some suitable version of the Flat Wall theorem which appeared recently in [53, 71] (see also [3, 70, 72, 73]). The algorithm produces equivalent and gradually "strictly simpler" instances of an annotated version of the problem. Each equivalent instance is produced in linear time and this simplification is repeated until the graph has bounded treewidth (here we may apply Courcelle's theorem, that is Proposition 1). This yields a (constructive) quadratic-time algorithm. We stress that our approach avoids techniques that have been recently used for this type of problems such as *recursive understanding* (in [1]) or the use of *important separators* (in [49]) that give worst running times in n.

Natural limitations. We wish to comment on why the three basic ingredients of the definition of our logic Θ are necessary for the statement and the proof of our meta-algorithmic results.

The first ingredient of Θ is that the modulator sentences belong in $\mathsf{CMSOL}^{\mathsf{tw}}[\{\mathsf{E},\mathsf{X}\}]$ which is defined so that the treewidth of $\mathsf{torso}(G,X)$ is bounded. While it is known that bounding the treewidth is necessary for CMSOL-model-checking [19, 58], one may ask why it is not enough to just bound the treewidth of $G[X]$. To see why this unavoidable, consider a graph G and let G' be the graph obtained from G by subdividing each edge once. Then, asking whether G is Hamiltonian, which is a well-known NP-complete problem, is equivalent to asking whether G' has a vertex set S' such that $G'[S']$ is a cycle and such that $G' \setminus S'$ is an edgeless graph, that is, a K_2-minor-free graph. Notice that, while $\mathbf{tw}(G'[S']) = 2$, $\mathsf{torso}(G', S') = G$ has unbounded treewidth.

The second ingredient of Θ is minor-exclusion, that is materialized by the conjunction with μ in the definition of Θ_0. Notice first that expressing whether a graph G contains a clique on k vertices can be done by a FOL-sentence, while the k-Clique problem is W[1]-hard [20]. Therefore, the minor-exclusion condition cannot be dropped. Moreover, even if we consider a *fixed* target FOL-sentence, it was proved in [33] that there exists a FOL-sentence σ such that checking whether a graph G has a set $S \subseteq V(G)$ with $|S| = k$ such that $G \setminus S \models \sigma$ is a W[1]-hard problem, when parameterized by k. This implies that, even for this restricted problem where the FOL-sentence σ is fixed, an algorithm running in time $f(k) \cdot n^{\mathcal{O}(1)}$ cannot be expected.

The third ingredient of Θ is the FOL demand, that is materialized by the conjunction with σ in the definition of Θ_0. This is also necessary, as otherwise we may choose some property σ not definable in FOL, such as Hamiltonicity, which is CMSOL-definable and NP-complete on planar graphs. Without the restriction that σ needs to be FOL-definable, a void modulator and a sentence μ expressing planarity would be able to model this NP-complete problem. Nevertheless, we may consider extensions of FOL in the target sentence, as done in Section 3.

2 Overview of the proof

In this section we summarize some of the main ideas involved in the proof of Theorem 5, while keeping the description at an intuitive level. We would like to stress that some of the informal definitions given in this section are deliberately *imprecise*, since providing the

precise ones would result in a huge overload of technicalities that would hinder the flow of the proof. Our algorithms consider as input a general structure $\mathfrak{A}$ (not necessarily a graph), and most of the arguments in the proofs concern its Gaifman graph $G_{\mathfrak{A}}$. Dealing with general structures, besides making our results more versatile, turns out to be useful in the proofs, in particular for using tools such as the *Backwards Translation Theorem* [18, Theorem 1.40], or for extending our results to other modification operations beyond vertex removal (see the full version of the paper [31]). Since the Gaifman graph of a graph is the graph itself, in this overview we will assume for simplicity that the input of our algorithms is a graph G, instead of a general structure $\mathfrak{A}$. In Subsection 2.1 we present the general scheme of the algorithm. In Subsection 2.2 we present a simplified and illustrative setting, where the input sentence θ belongs to the fragment $\bar{\Theta}_1$. This (very) particular case of Theorem 5 is helpful to illustrate our main conceptual ideas. For a more detailed proof-overview and formal proofs (up to the general compound logic Θ considered in Theorem 5), we refer the reader to the full version of the paper [31].

2.1 General scheme of the algorithm

We use the *irrelevant vertex technique* introduced by Robertson and Seymour [67]. Our overall strategy is the "typical" one when using this technique: if the treewidth of the input graph G is bounded by an appropriately chosen function, depending only on the sentence $\theta \in \Theta$, then we use Courcelle's theorem [15] and solve the problem in linear time, using the fact that our compound logic Θ is a fragment of counting monadic second-order logic. Otherwise, we identify an irrelevant vertex in linear time, that is, a vertex whose removal produces an equivalent instance. Naturally, the latter case concentrates all our efforts and, in what follows, we sketch the main ingredients that we use in order to identify such an irrelevant vertex. In a nutshell, our approach is based on introducing a robust combinatorial framework for finding irrelevant vertices. In fact, what we find is *annotation-irrelevant flat territories*, building on our previous recent work [3, 3, 32, 70–73], which is formulated with enough generality so as to allow for the application of powerful tools such as Gaifman's locality theorem [38] or a variant of Courcelle's theorem on boundaried graphs, intuitively saying that the dynamic programming tables constructed by the proof of Courcelle's theorem are also definable in CMSOL (see [5, Lemma 3.2]).

Flat walls. An essential tool of our approach is the notion of *flat wall*, originating in the work of Robertson and Seymour [67]. Informally speaking, a flat wall W is a structure made up of (non-necessarily planar) pieces, called *flaps*, that are glued together in a bidimensional grid-like way defining the so-called *bricks* of the wall. While such a structure may not be planar, it enjoys topological properties similar to those of planar graphs, in the sense that two paths that are not routed entirely inside a flap cannot "cross", except at a constant-sized vertex set A whose vertices are called *apices*. Hence, flat walls are only "locally non-planar", and after removing apices we can apply useful locality arguments, in the sense that two vertices that are in "distant" flaps should also be "distant" in the whole graph without the apices. One of the most celebrated results in the theory of Graph Minors by Robertson and Seymour [67, 68], known as the Flat Wall theorem (see also [53, 71] for recently proved variants), informally states that graphs of large treewidth contain either a large clique minor or a large flat wall. In this article we use the framework recently introduced in [71] that provides a more accurate view of some previously defined notions concerning flat walls, particularly in [53]. Precise definitions of the concepts of *flatness pair*, *homogeneity*, *regularity*, *tilt*, and *influence* can be found in the full version of this article [31] and we stress that they are *not* critical in order to

understand the main technical contributions of the current article (however, they are critical for their formal correctness). In what follows, when considering a flat wall W with an apex set A in a graph G, for simplicity we refer to W by using indistinguishably the terms "wall" and "compass of a wall", which can be roughly described as the component containing W in the graph obtained from G by removing A and the "boundary" of W.

Working with an annotated version of the problem. We start by defining a convenient equivalent version of the problem, by replacing our sentence $\theta \in \Theta$ with an equivalent *enhanced* sentence $\theta_{\mathsf{R},\mathbf{c}}$. This is done in two steps, as we explain in the following two paragraphs.

Assuming the existence of a flat wall and an apex set in our input graph G, we first transform the question θ on G to a question on a structure obtained from G by "neutralizing" the apex set (see the full version of the paper [31]). The goal of this step is to ask the final FOL-sentences σ of our sentence θ in a "flattened" structure, where apices can no longer "bring close" any distant parts of the wall. This transformation of the problem, which we call *apex-projection*, will allow for the application of the locality-based strategy discussed in the definition of the *in-signature* of a wall in Subsection 2.2. To do this, we introduce some additional constant symbols $\mathbf{c}$ to our vocabulary that will be interpreted as the apex vertices.

The second step consists in defining an equivalent *annotated* version of the problem in order to deal with the FOL-sentences of θ, inspired by the approach of [32]. To do so, we introduce a vertex set $R \subseteq V(G)$, and require, for each FOL-sentence σ of θ, that the vertices interpreting the variables of (the equivalent Gaifman sentence of) σ belong to the annotated set R. We prove that the initial sentence θ and the obtained sentence, denoted by $\theta_{\mathsf{R},\mathbf{c}}$ and called an *enhanced sentence*, are equivalent for *any* choice of the apex set interpreting $\mathbf{c}$ and when R is interpreted as the whole vertex set of the graph. This independence of the choice of the apex set is strongly used in the proofs since, as discussed below, we will consider a number of different flat walls, each of which associated with a different apex set.

Our algorithms will work with the enhanced sentence $\theta_{\mathsf{R},\mathbf{c}}$. Starting with the input graph G with $V(G)$ as the annotated set R, we will create successive equivalent annotated instances, in which vertices from G are removed and such that the annotated set R is only reduced.

Zooming inside a flat wall. Our next step is to find, in G, a large flat wall W_0 to work with. The definition of our logic Θ implies that models of θ exclude a fixed complete graph K_c as a minor, where c depends only on θ. Therefore, we can apply the algorithmic version of the Flat Wall Theorem [72, Proposition 10] (see also [53, 67, 71]) to the input graph G and, assuming that the treewidth of G is large enough, we can find in linear time a flat wall W_0 and an apex set A in G such that the height of W_0 is a sufficiently large function of θ. Moreover, another crucial property guaranteed by this algorithm is that the treewidth of W_0 is bounded from above by a function of θ. This will be exploited in Subsection 2.2 in order to compute the so-called θ-*characteristic* of a wall. We will now apply a series of "zooming" arguments to the wall W_0, which are illustrated in Figure 2.

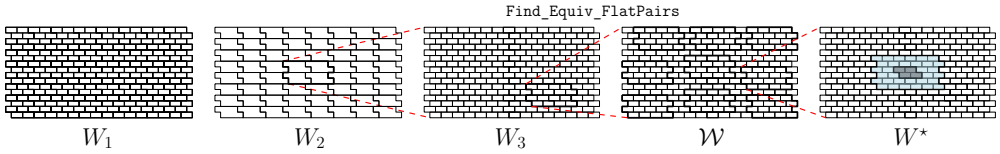

Figure 2 Sequence of walls in the general scheme of our algorithm. The first wall is obtained by applying the algorithm of [72, Proposition 14] for the wall W_0 in the input graph G.

Starting from W_0 and its associated apex set A, we apply the algorithm of [72, Proposition 14] and find, in linear time, a large (again, as a function of θ) subwall W_1 that is λ-*homogeneous*, where λ depends only on θ. The definition of a homogenous flat wall can be found in the full version of the paper [31], and roughly means that each of its bricks can route the same set of partial minors of the graphs corresponding to the minor-exclusion part of the sentence θ. We now apply the algorithm of [73, Lemma 16] to W_1, and obtain in linear time a large subwall W_2 that is *irrelevant* with respect to the minor-exclusion part of θ after the removal of a vertex set $X \subseteq V(G)$ of small enough *bidimensionality* (see Subsection 2.2). Intuitively, working "inside" W_2 allows us to "forget" the minor-exclusion part of θ in what follows. As our next step, we obtain in linear time a still large subwall W_3 of W_2 such that its associated apex set A_3 is "tightly tied" to W_3, in the sense that the neighbors in W_3 of every vertex in A_3 are spread in a "bidimensional" way.

Finding an irrelevant subwall. So far, we have found a large wall W_3 that satisfies the conditions of the above paragraph. Now, in order to identify an irrelevant vertex inside W_3, we find, inside the wall W_3, a collection $\mathcal{W}$ of pairwise disjoint subwalls, and to associate each of these subwalls with an appropriately defined θ-*characteristic* that captures its behavior with respect to the partial satisfaction of the sentence θ. Then the idea is that, if there are sufficiently many subwalls in $\mathcal{W}$ with the same θ-characteristic (called θ-*equivalent*), then some subwall in the interior of one of them can be declared *annotation-irrelevant* and this implies some progress in simplifying the current problem instance.

The above strategy allows to identify a subwall $W^\star$ inside $\mathcal{W}$ such that its central part can be removed from the annotated set R, and such that a smaller central part can be removed from G (the blue and grey subwalls in the rightmost wall of Figure 2, respectively). This is done by an algorithm, called `Find_Equiv_FlatPairs`, that is based on an appropriate definition of the θ-*characteristic* of a wall. In what follows we sketch the main ingredients and key ideas.

2.2 A simplified and illustrative setting

In order to provide some intuition, in this subsection we focus on formulas $\theta \in \Theta$ of a particular form, i.e., belonging to $\bar{\Theta}_1$, a set of formulas which we proceed to define informally in a semantical level: Given a general graph G as input, we seek for a vertex set $X \subseteq V(G)$, called *modulator*, such that, using the notation defined in the introduction, $\mathsf{stell}(G, X)$ satisfies the so-called *modulator sentence* β, and either every connected component C of $G \setminus X$, or the whole graph $G \setminus X$, satisfies the so-called *target sentence* γ, where $\gamma = \sigma \wedge \mu$ with σ being an arbitrary FOL-sentence and μ expressing the property of belonging to a proper minor-closed graph class.

Note that when $\theta \in \bar{\Theta}_1$, the target sentence γ needs to be satisfied either by each of the resulting connected components separately, or jointly by their union. We deal with this easily, by introducing a $\circ/\bullet$ -flag into the corresponding sentences that distinguishes both cases. The latter case is simpler, but in this description, in order to better illustrate our techniques, we assume the former.

Identifying the privileged component. A very useful tool in our algorithms is to identify, for every given X, a *unique* connected component among those of $G \setminus X$, which we call the *privileged component*, that contains "most" of the wall W_3. Let us formalize a bit this idea. For a positive integer q, a *pseudogrid* $\mathbf{W}_q$, is a collection of q "vertical" and q "horizontal" paths that intersect in a "grid-like" way. Note that the considered wall W_3 naturally defines a (large, as a function of θ) pseudogrid. A connected component C of a graph G is *privileged*

with respect to a set $X \subseteq V(G)$ and a pseudogrid $\mathbf{W}_q$ if C is a connected component of $G \setminus X$ that contains entirely at least one vertical and one horizontal path of $\mathbf{W}_q$. It is easy to see that such a privileged component, if it exists, is unique.

Moreover, when X is a modulator, the fact that $\mathsf{torso}(G, X)$ has bounded treewidth implies that every connected component of $G \setminus X$ has a "small interface" to X and thus the flat wall W_0 (and any large subwall of it) is not significantly "damaged" by X, which we formalize via the notion of having small *bidimensionality*. Intuitively for the definition), this means that X intersects a small number of so-called "bags" of the wall. Informally, the *bags* of a wall W in a graph G with apex set A define a partition of $G \setminus A$ into connected sets, such that each bag, except the external one, contains the part of the wall W between two neighboring degree-3 vertices of the wall. This property is used extensively in the proofs and, in particular, it defines, assuming the existence of a large flat wall W_0 and a modulator X, a *unique* privileged component C in $G \setminus X$ (regardless of the $\circ/\bullet$-flag). In our sentences, in order to identify such a component, we need to integrate the "recognition" of a pseudogrid $\mathbf{W}_q$ and its associated privileged component with respect to a modulator X: it is easy to see that these properties can be defined in CMSOL.

Splitting the sentence $\theta_{\mathsf{R},\mathbf{c}}$. The existence of a privileged component C allows us to see the sentence $\theta_{\mathsf{R},\mathbf{c}}$ as a conjunction of two subsentences: one that concerns the privileged component C (where we will find the irrelevant vertex) and another one concerning the modulator X and the other (non-privileged) components of $G \setminus X$. Namely, we define a sentence $\tilde{\theta}_q$, called the *split version* of $\theta_{\mathsf{R},\mathbf{c}}$, that allows us to "break" θ into two questions: one denoted by θ_q^{out} that is the conjunction of the modulator sentence β and the target sentence γ in the non-privileged components of $G \setminus X$ and another one that concerns the target sentence γ in the privileged component C. This latter question is composed of two subsentences, namely one about the satisfaction of the FOL-sentence σ and another one about the minor-exclusion given by μ. Given this decomposition of θ into three questions (one "external" and two "internal" ones), our "irrelevancy" arguments also decompose into three parts. Concerning the "irrelevancy" for minor-exclusion, as discussed above, the fact that the whole wall W_2 is irrelevant with respect to μ allows us to focus on the other two questions. For this, we need to define the *characteristic* of a wall with respect to θ, denoted by θ-char. This characteristic is composed of two parts: the *out-signature* corresponding to the satisfiability of the sentence θ_q^{out}, and the *in-signature* corresponding to the FOL-sentence σ. Let us now explain how we define the out-signature and the in-signature, and sketch why we can eventually declare a subwall irrelevant.

Defining the out-signature of a wall. Dealing with the irrelevancy with respect to the "external" sentence θ_q^{out} turns out to be the most interesting part of the proof and we introduce several ideas which are, in our opinion, one of the main conceptual contributions of this article. The goal is, for each wall W in the collection $\mathcal{W}$, to encode all the necessary information that concerns the satisfiability of θ_q^{out} in the "non-privileged" part of the graph and the modulator X. To do this, for each $W \in \mathcal{W}$ with apex set A, we define a set of *ℓ-boundaried graphs* (i.e., graphs in which ℓ "boundary" vertices are equipped with labels), constructed as we describe below, and where ℓ depends only on θ. The boundary corresponds to where the sentence has been "split" and we need to "guess" how to complement this boundary by the part of the modulator that is not inside the wall. Note that, since θ_q^{out} is a CMSOL-sentence, by a variant of Courcelle's theorem for boundaried graphs [15], there exists a *finite* collection $\mathsf{rep}^{(\ell)}(\theta_q^{\mathsf{out}})$ of sentences on ℓ-boundaried graphs that are "representatives" of the sentence θ_q^{out} and that can be effectively constructed. We next described how these ℓ-boundaried graphs are constructed.

We observe that, using the bounded-treewidth property of the modulator sentence β, there exists a "buffer" I in W, consisting of a set of consecutive layers of the wall, which is disjoint from a hypothetical modulator X. We guess with an integer d where this "buffer" I is placed in the wall and we denote its inner part by $I^{(d)}$. This naturally induces a partition of X into X_{in} and X_{out}, with X_{in} being the part of X that is inside $I^{(d)}$. We also guess which subset of the apex set A will belong to the modulator X and we denote it by $V_L(\mathbf{a})$, where L is the set containing the indices of the corresponding apex vertices. Since parts of the "non-privileged" vertex set of the graph may lie outside the considered wall, we need to guess the part of the modulator (namely, its boundary towards the component) that lies outside the wall. More precisely, we need to guess as well which subset F' of X_{out}, other than $V_L(\mathbf{a})$, will belong to the neighborhood of the privileged component. This is achieved by guessing all ways an (abstract) graph F' with a bounded number of vertices can extend the boundary. We let F be the graph obtained from the union of $V_L(\mathbf{a})$ and F'. Finally, we also need to consider a set Z that corresponds to X_{in} together with the part inside $I^{(d)}$ that has been "chopped off" by the modulator X, that is, the part of W inside $I^{(d)}$ that will not belong to the privileged component after the removal of the modulator X. We denote by $\partial(Z)$ the set of vertices in Z that have a neighbor in $I^{(d)}$. Altogether, these guesses result in the ℓ-boundaried graph $K^{(d,Z,L,F)}$ obtained from the graph induced by $I^{(d)}$ and the set F, whose boundary is the set $\partial(Z) \cup F$.

With each such a guess (R, d, L, Z) we associate the out-signature defined as follows and denoted by $\mathsf{out\text{-}sig}$. Its elements are pairs $(\mathbf{H}, \bar{\theta})$, where $\mathbf{H}$ encodes how the set $V_L(\mathbf{a})$ in the boundary has been extended by the "abstract" graph F', and $\bar{\theta} \in \mathsf{rep}^{(\ell)}(\theta_q^{\mathsf{out}})$ prescribes the equivalence class, within the set of Courcelle's representatives mentioned above, of the considered ℓ-boundaried graph. This concludes the description of the out-signature.

While this out-signature indeed encodes the behavior of the considered wall with respect to the "external" sentence θ_q^{out}, a crucial issue has been overlooked so far: in order to be able to identify an irrelevant subwall inside the collection $\mathcal{W}$ within the claimed running time, we need to be able to *compute* the (in- and out-)signature of a wall in linear time. To do this using Courcelle's theorem, we need to consider a graph that has treewidth bounded by a function of θ. Recall that θ_q^{out} is the conjunction of the modulator sentence β (which is evaluated in the graph $\mathsf{stell}(G, X)$) and the target sentence γ in the "non-privileged" components of $G \setminus X$. It follows that the treewidth of W is bounded by a function of θ, hence the treewidth of the ℓ-boundaried "subwall" $K^{(d,Z,L,F)}$, for which we want to compute the out-signature, is also bounded by a function of θ. However, the graph $K^{(d,Z,L,F)} \setminus V(F)$ "lives" inside the *whole* privileged component C, and we cannot guarantee that the treewidth of C is bounded by a function of θ. We overcome this problem with the following trick. We observe that the satisfaction of θ_q^{out} is preserved if, instead of the whole privileged component C, we consider the graph $K^{(d,Z,L,F)}$, which is obtained by "shrinking" C to the subwall $I^{(d)}$, and which has bounded treewidth as we need. Indeed, this modification does not change any of the non-privileged components in which the target sentence γ is evaluated and, by adding edges from the "guessed extended boundary" F' to $I^{(d)}$ in order to preserve connectivity, the resulting graph $\mathsf{stell}(G, X)$ remains unchanged with this transformation, and therefore the satisfaction of the modulator sentence β is also preserved.

Defining the in-signature of a wall. To deal with the irrelevancy with respect to the FOL-sentence σ, we use arguments strongly inspired by those of [32]. The core tool here is Gaifman's locality theorem, which states that every FOL-sentence σ is a Boolean combination of basic local sentences $\sigma_1, \ldots, \sigma_p$, in the sense that the satisfaction of each σ_i depends only

on the satisfaction of a set of sentences $\psi_1, \ldots, \psi_{\ell_i}$ evaluated on single vertices that can be assumed to be pairwise far apart. As discussed before, taking care of the domain of these vertices is the main reason why we consider a annotated version of the problem, corresponding to the enhanced sentence $\theta_{\mathsf{R},\mathbf{c}}$. Extending the approach of [32] (which does not deal with apices), the in-signature of a wall, denoted by $\mathsf{in\text{-}sig}$, encodes all (partial) sets of variables, one set for each basic local sentence of the so-called Gaifman sentence $\breve{\sigma}$, such that these variables lie inside an "inner part" of the wall, they are scattered in the "apex-projection" of this inner part, and they satisfy the local sentences ψ_i.

Declaring a subwall irrelevant. We now sketch the remaining of the proof for sentences in $\bar{\Theta}_1$. As mentioned above, suppose that we have already found, inside the collection $\mathcal{W}$, a large (as a function of θ) subcollection $\mathcal{W}' \subseteq \mathcal{W}$ of walls all having the same θ-characteristic. We pick one of these walls, say $W^\star \in \mathcal{W}'$, and we declare its central part irrelevant (see Figure 2). We need to prove that, if the input graph G satisfies θ, then the graph G' obtained from G by removing the central part of $W^\star$, also satisfies θ. That is, given a modulator X in the original instance G, we need to construct another set $X' \subseteq V(G)$ that is disjoint from $W^\star$ and that is a modulator in G'. For this, we proceed as follows.

The cardinality of $\mathcal{W}'$ and the fact that X intersects few bags of the wall W_3 imply that there is a large (again, as a function of θ) subcollection $\mathcal{W}'' \subseteq \mathcal{W}'$ of walls that are disjoint from X. We take such a wall $\hat{W} \in \mathcal{W}''$ and, using the fact that $W^\star$ and $\hat{W}$ have the same θ-characteristic, we show that we can "replace" the part of the modulator X that intersects $W^\star$ with another part in $\hat{W}$, together with an alternative assignment of variables that satisfies the corresponding sentences. This results in another set X' that is a modulator in G', hence yielding the annotation-irrelevancy of (the central part of) $W^\star$.

Showing these facts is far from being easy and we need a number of technical details dealing with the irrelevancy with respect to θ_q^{out} (which incorporates β), σ, and μ. In particular, an important idea is that, changing from X to X', we obtain a new boundaried graph, which is in fact the same graph but with a new boundary. The replacement arguments for the in-signature work because of the aforementioned distance-preservation property of the apex-projection. See the full version of the paper [31] for more details.

3 From FOL to FOL+DP: the compound logic Θ^{DP}

In the definition of Θ_0, the base case of Θ, we consider compound sentences $\sigma \wedge \mu$, where $\sigma \in \mathsf{FOL}$ and μ expresses minor-exclusion. However, one can consider extensions of FOL in the compound sentences. A possible candidate is first-order logic with disjoint-paths predicates defined in [75] (see the paragraph below for a formal definition). This way we can define a more general logic Θ^{DP} and prove an algorithmic meta-theorem that encompasses also the results in [42, 43]. To ease reading, in this subsection we deal only with graphs and not with general structures. However, our results can be straightforwardly be extended to general structures. All proofs of the results of this section can be found in Section 3.

The disjoint-paths logic. We define the $2k$-ary predicate $\mathsf{dp}_k(\mathsf{x}_1, \mathsf{y}_1, \ldots, \mathsf{x}_k, \mathsf{y}_k)$, which evaluates true in a graph G if and only if there are paths $P_1, \ldots, P_k$ of G of length at least two between (the interpretations of) x_i and y_i for all $i \in [k]$ such that for every $i, j \in [k]$, $i \neq j$, $V(P_i) \cap V(P_j) = \emptyset$. We let $\mathsf{FOL+DP}$ be the logic obtained from FOL after allowing $\mathsf{dp}_k(\mathsf{x}_1, \mathsf{y}_1, \ldots, \mathsf{x}_k, \mathsf{y}_k), k \geq 1$ as atomic predicates.

The compound logic Θ^{DP}. We define an extension Θ^{DP} of Θ by considering, as the base case, instead of Θ_0, the logic $\Theta_0^{\mathsf{DP}} = \{\sigma \wedge \mu \mid \sigma \in \mathsf{FOL{+}DP} \text{ and } \mu \in \mathsf{EM}[\{\mathsf{E}\}]\}$.

▶ **Theorem 8.** *For every $\theta \in \Theta^{\mathsf{DP}}$, there exists an algorithm that, given a graph G, outputs whether $G \models \theta$ in time $\mathcal{O}_{|\theta|}(n^2)$.*

As we define the alternative $\tilde{\Theta}$ of Θ, we can also define $\tilde{\Theta}^{\mathsf{DP}}$ by taking $\tilde{\Theta}_0^{\mathsf{DP}} = \mathsf{FOL{+}DP}$ as the base case, i.e., by discarding the minor-exclusion from the definition of Θ_0^{DP}. Notice that $\tilde{\Theta}^{\mathsf{DP}}$ contains $\mathsf{FOL{+}DP}$ and can be seen as a natural extension of it. As a corollary of Theorem 8, we get the following analogue of Theorem 6.

▶ **Theorem 9.** *For every $\tilde{\theta} \in \tilde{\Theta}^{\mathsf{DP}}$, there exists an algorithm that, given a graph G, outputs whether $G \models \theta$ in time $\mathcal{O}_{|\theta|,\mathbf{hw}(G)}(n^2)$.*

Theorem 9 contains all results and applications of [42, 43] as a (very) special case. For a visualization of the current meta-algorithmic landscape on subgraph-closed classes, see Figure 3.

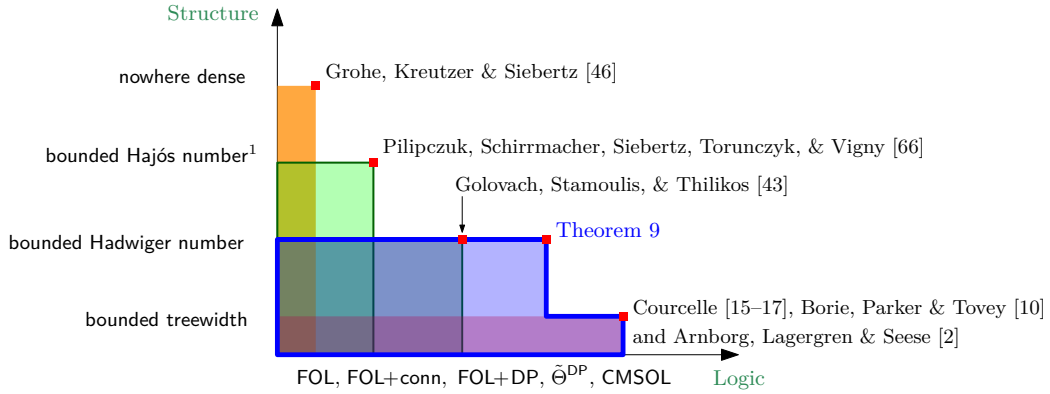

Figure 3 The current meta-algorithmic landscape on subgraph-closed classes and the position of Theorem 9 in it.

4 Further research

The minor-exclusion framework. The graph-structural horizon in both Theorem 5 and Theorem 6 is delimited by minor-exclusion. In the case of Theorem 5, this restriction is applied to the target property defined by μ in the logic Θ, while in Theorem 6 this is the promise combinatorial restriction that yields efficient model-checking for $\tilde{\Theta}$. This restriction is hard-wired in our proof in the way it combines the Flat Wall theorem with Gaifman's theorem. Recently, several efficient algorithms appeared for modification problems targeting or assuming topological minor-freeness (see [1, 36, 49] and the meta-algorithmic results in [66, 74]). For such classes, to achieve efficient model-checking for Θ, or some fragment of it, is an interesting open challenge.

Quadratic time. The proof of Theorem 5 can be seen as a possible "meta-algorithmization" of the *irrelevant vertex technique* introduced by Robertson and Seymour [67], going further than the two known recent attempts in this direction [32, 43]. The main routine of the

[1] The *Hajós number* of a graph G is the maximum k for which G contains K_k as a topological minor.

algorithm transforms the input of the problem to a simpler graph by detecting territories in it that can be safely discarded, therefore producing a simpler instance. This routine is applied repetitively until the graph has "small" treewidth, so that the problem can be solved in linear time by using Courcelle's theorem. This approach gives an algorithm running in quadratic time. Any improvement of this quadratic running time should rely on techniques escaping the above scheme of gradual simplification. The only results in this direction are the cases of making a graph planar by deleting at most k vertices (resp. edges) in [50] (resp. [52]) that run in time $\mathcal{O}_k(n)$.

Further than connectivity closure. One of the key operations defining Θ is the connectivity extension operation, that is, given a sentence φ, to consider the (conjunctive) sentence $\varphi^{(\mathsf{c})}$. We incorporated this operation to our logic in order to express elimination distance modifications (such as those of tree-depth [12] and bridge-depth [11]) where, at each step, we remove some tree-like structure and then we apply the current target sentence to the connected components of the remaining graph. In [24], the notion of *block elimination distance* has been introduced, where the target property is applied to the biconnected components of the remaining graph (instead of the connected components). We are confident that our results can be adapted so to include the biconnectivity extension – or even the 3-connectivity extension, as defined by Tutte's decomposition. However, we prefer to avoid this here as it would add undesirable burden to the statement of our results (and to the proofs as well). Another direction is to consider different versions of $\varphi^{(\mathsf{c})}$. One of them might be a *disjunctive* version, namely $\varphi^{\vee(\mathsf{c})}$, where $G \models \varphi^{\vee(\mathsf{c})}$ if *at least one* of the connected components of G is a model of φ. Another one is a *selective* version, namely $\varphi^{\exists(\mathsf{c})}$, where $G \models \varphi^{\wedge(\mathsf{c})}$ if there is some subset of the connected components of G whose union is a model of φ. Our proof fails if we wish to incorporate any of these two variants of $\varphi^{(\mathsf{c})}$ in Θ. However, it can be easily adapted so to incorporate $\varphi^{\vee(\mathsf{c})}$ in $\tilde{\Theta}$.

Descriptive complexity and the Θ-hierarchy. Recall that $\Theta = \bigcup_{i\in\mathbb{N}} \Theta_i$, where each level of the sentence set Θ_i is defined by adding an extra modulator sentence, followed by some positive Boolean combination of the connectivity closure of the lower level. We extended our result from Θ_1 to every Θ_i because Θ is quite versatile and makes it easier to express more complex hierarchical modification problems. However, it is an open problem whether this hierarchy is proper with respect to the descriptive complexity of the problems that it defines in each of its levels. In simple cases where the modulator sentence asks for a set of bounded size, and under the absence of positive Boolean combinations, it is possible to express any Θ-definable problem using Θ_1. For instance, elimination ordering to some Θ_0-definable class can be straightforwardly expressed in Θ, however with a more technical proof one can also express it in Θ_1 (see [34]). Is this collapse maintained when we consider the full expressive power of Θ? We conjecture a negative answer to this question for both Θ and Θ^{DP}.

Abstract

A recent trend in the context of graph theory is to bring theoretical analyses closer to empirical observations, by focusing the studies on random graph models that are used to represent practical instances. There, it was observed that geometric inhomogeneous random graphs (GIRGs) yield good representations of complex real-world networks, by expressing edge probabilities as a function that depends on (heterogeneous) vertex weights and distances in some underlying geometric space that the vertices are distributed in. While most of the parameters of the model are understood well, it was unclear how the dimensionality of the ground space affects the structure of the graphs.

In this paper, we complement existing research into the dimension of geometric random graph models and the ongoing study of determining the dimensionality of real-world networks, by studying how the structure of GIRGs changes as the number of dimensions increases. We prove that, in the limit, GIRGs approach non-geometric inhomogeneous random graphs and present insights on how quickly the decay of the geometry impacts important graph structures. In particular, we study the expected number of cliques of a given size as well as the clique number and characterize phase transitions at which their behavior changes fundamentally. Finally, our insights help in better understanding previous results about the impact of the dimensionality on geometric random graphs.

1 Introduction

Networks are a powerful tool to model all kinds of processes that we interact with in our day-to-day lives. From connections between people in social networks, to the exchange of information on the internet, and on to how our brains are wired, networks are everywhere. Consequently, they have been in the focus of computer science for decades. There, one of the most fundamental techniques used to model and study networks are *random graph models*. Such a model defines a probability distribution over graphs, which is typically done by

specifying a random experiment on how to construct the graph. By analyzing the rules of the experiment, we can then derive structural and algorithmic properties of the resulting graphs. If the results match what we observe on real-world networks, i.e., if the model represents the graphs we encounter in practice well, then we can use it to make further predictions that help us understand real graphs and utilize them more efficiently.

The quest of finding a good model starts several decades ago, with the famous Erdős-Rényi (ER) random graphs [19, 24]. There, all edges in the graph exist independently with the same probability. Due to its simplicity, this model has been studied extensively. However, because the degree distribution of the resulting graphs is rather homogeneous and they lack clustering (due to the independence of the edges), the model is not considered to yield good representations of real graphs. In fact, many networks we encounter in practice feature a degree distribution that resembles a power-law [3, 38, 39] and the clustering coefficient (the probability for two neighbors of a vertex to be adjacent) is rather high [35, 40]. To overcome these drawbacks, the initial random graph model has been adjusted in several ways.

In *inhomogeneous random graphs (IRGs)*, often referred to as *Chung-Lu random graphs*, each vertex is assigned a weight and the probability for two vertices to be connected by an edge is proportional to the product of the weights [1, 11, 12]. As a result, the expected degrees of the vertices in the resulting graphs match their weight. While assigning weights that follow a power-law distribution yields graphs that are closer to the complex real-world networks, the edges are still drawn independently, leading to vanishing clustering coefficients.

A very natural approach to facilitate clustering in a graph model is to introduce an underlying geometry. This was done first in *random geometric graphs (RGGs)*, where vertices are distributed uniformly at random in the Euclidean unit square and any two are connected by an edge if their distance lies below a certain threshold, i.e., the neighborhood of a vertex lives in a disk centered at that vertex [36]. Intuitively, two vertices that connect to a common neighbor cannot be too far away from each other, increasing the probability that they are connected by an edge themselves. In fact, random geometric graphs feature a non-vanishing clustering coefficient [13]. However, since all neighborhood disks have the same size, they all have roughly the same expected degree, again, leading to a homogeneous degree distribution.

To get a random graph model that features a heterogeneous degree distribution *and* clustering, the two mentioned adjustments were recently combined to obtain *geometric inhomogeneous random graphs (GIRGs)* [28]. There, vertices are assigned a weight *and* a position in some underlying geometric space and the probability for two vertices to connected increases with the product of the weights but decreases with increasing geometric distance between them. As a result, the generated graphs have a non-vanishing clustering coefficient and, with the appropriate choice of the weight sequence, they feature a power-law degree distribution. Additionally, recent empirical observations indicate that GIRGs represent real-world networks well with respect to certain structural and algorithmic properties [5].

We note that GIRGs are not the first model that exhibits a heterogeneous degree distribution and clustering. In fact, *hyperbolic random graphs (HRGs)* [30] feature these properties as well and have been studied extensively before (see, e.g., [7, 20, 21, 23, 26]). However, in the pursuit of finding good models to represent real-world networks, GIRGs introduce a parameter that sets them apart from prior models: the choice of the underlying geometric space and, more importantly, the dimensionality of that space.

Unfortunately, this additional parameter that sets GIRGs apart from previous models, has not gained much attention at all. In fact, it comes as a surprise that, while the underlying dimensionality of real-world networks is actively researched [2, 8, 15, 25, 31] and there is a large body of research examining the impact of the dimensionality on different homogeneous graph

models [13, 17, 18] with some advancements being made on hyperbolic random graphs [41], the effects of the dimension on the structure of GIRGs have only been studied sparsely. For example, while it is known that GIRGs exhibit a clustering coefficient of $\Theta(1)$ for any fixed dimension [28], it is not known how the hidden constants scale with the dimension.

In this paper, we initiate the study of the impact of the dimensionality on GIRGs. In particular, we investigate the influence of the underlying geometry as the dimensionality increases, proving that GIRGs converge to their non-geometric counterpart (IRGs) in the limit. With our results we are able to explain seemingly disagreeing insights from prior research on the impact of dimensionality on geometric graph models. Moreover, by studying the clique structure of GIRGs and its dependence on the dimension d, we are able to quantify how quickly the underlying geometry vanishes. In the following, we discuss our results in greater detail. We note that, while we give general proof sketches for our results, the complete proofs are deferred to the full version [22].

2 (Geometric) Inhomogeneous Random Graphs

Before stating our results in greater detail, let us recall the definitions of the two graph models we mainly work with throughout the paper.

Inhomogeneous Random Graphs (IRGs). The model of inhomogeneous random graphs was introduced by Chung and Lu [1, 11, 12] and is a natural generalization of the Erdős-Rényi model. Starting with a vertex set V of n vertices, each $v \in V$ is assigned a weight w_v. Each edge $\{u, v\} \in \binom{V}{2}$ is then independently present with probability

$$\Pr[u \sim v] = \min\left\{1, \frac{\lambda w_u w_v}{n}\right\},$$

for some constant $\lambda > 0$ controlling the average degree of the resulting graph. Note that assigning the same weight to all vertices yields the same connection probability as in Erdős-Rényi random graphs. For the sake of simplicity, we define $\kappa_{uv} = \min\{\lambda w_u w_v, n\}$ such that $\Pr[u \sim v] = \kappa_{uv}/n$. Additionally, for a set of vertices $U_k = \{v_1, \dots, v_k\}$ with weights $w_1, \dots, w_k$, we introduce the shorthand notation $\kappa_{ij} = \kappa_{v_i v_j}$ and write $\{\kappa\}^{(k)} = \{\kappa_{ij} \mid 1 \leq i < j \leq k\}$.

Throughout the paper, we mainly focus on inhomogeneous random graphs that feature a power-law degree distribution in expectation, which is obtained by sampling the weights accordingly. More precisely, for each $v \in V$, we sample a weight w_v from the Pareto distribution $\mathcal{P}$ with parameters $1 - \beta, w_0$ and distribution function

$$\Pr[w_v \leq x] = 1 - \left(\frac{x}{w_0}\right)^{1-\beta}.$$

Then the density of w_v is $\rho_{w_v}(x) = \frac{\beta-1}{w_0^{1-\beta}} x^{-\beta}$. Here, $w_0 > 0$ is a constant that represents a lower bound on the weights in the graph and β denotes the power-law exponent of the resulting degree distribution. Throughout the paper, we assume $\beta > 2$ such that a single weight has finite expectation (and thus the average degree in the graph is constant), but possibly infinite variance. We denote a graph obtained by utilizing the above weight distribution and connection probabilities with $\mathrm{IRG}(n, \beta, w_0)$. For a fixed weight sequence $\{w\}_1^n$, we denote the corresponding graph by $\mathrm{IRG}(\{w\}_1^n)$.

Geometric Inhomogeneous Random Graphs (GIRGs). Geometric inhomogeneous random graphs are an extension of IRGs, where in addition to the weight, each vertex v is also equipped with a position $\mathbf{x}_v$ in some geometric space and the probability for edges to form depends on their weights and the distance in the underlying space [28]. While, in its raw form, the GIRG framework is rather general, we align our paper with existing analysis on GIRGs [6, 29, 34] and consider the d-dimensional torus $\mathbb{T}^d$ equipped with L_∞-norm as the geometric ground space. More precisely, in what we call the *standard* GIRG model, the positions $\mathbf{x}$ of the vertices are drawn independently and uniformly at random from $\mathbb{T}^d$, according to the standard Lebesgue measure. We denote the i-th component of $\mathbf{x}_v$ by $\mathbf{x}_{vi}$. Additionally, the geometric distance between two points $\mathbf{x}_u$ and $\mathbf{x}_v$, is given by

$$d(\mathbf{x}_u, \mathbf{x}_v) = \|\mathbf{x}_u - \mathbf{x}_v\|_\infty = \max_{1\le i\le d}\{|\mathbf{x}_{ui} - \mathbf{x}_{vi}|_C\},$$

where $|\cdot|_C$ denotes the distance on the circle, i.e,

$$|\mathbf{x}_{ui} - \mathbf{x}_{vi}|_C = \min\{|\mathbf{x}_{ui} - \mathbf{x}_{vi}|, 1 - |\mathbf{x}_{ui} - \mathbf{x}_{vi}|\}.$$

In a standard GIRG, two vertices $u \neq v$ are adjacent if and only if their distance $d(\mathbf{x}_u, \mathbf{x}_v)$ in the torus is less than or equal to a *connection threshold* t_{uv}, which is given by

$$t_{uv} = \frac{1}{2}\left(\frac{\lambda w_u w_v}{n}\right)^{1/d} = \left(\frac{w_u w_v}{\tau n}\right)^{1/d},$$

where $\tau = 2^d/\lambda$. Using L_∞ is motivated by the fact that it is the most widely used metric in the literature because it is arguably the most natural metric on the torus. In particular, it has the "nice" property that the ball of radius r is a cube and "fits" entirely into $\mathbb{T}^d$ for all $0 \le r \le 1$.

Note that, as a consequence of the above choice, the marginal connection probability $\Pr[u \sim v]$ is the same as in the IRG model, i.e., $\Pr[u \sim v] = \kappa_{uv}/n$. However, while the probability that any given edge is present is the same as in the IRG model, the edges in the GIRG model are *not* drawn independently. We denote a graph obtained by the procedure described above with $\mathrm{GIRG}(n, \beta, w_0, d)$. As for IRGs, we write $\mathrm{GIRG}(\{w\}_1^n, d)$ when considering standard GIRGs with a fixed weight sequence $\{w\}_1^n$.

As mentioned above, the standard GIRG model is a commonly used instance of the more general GIRG framework [28]. There, different geometries and distance functions may be used. For example, instead of L_∞-norm, any L_p-norm for $1 \le p < \infty$ may be used. Then, the distance between two vertices u, v is measured as

$$\|\mathbf{x}_u - \mathbf{x}_v\|_p := \begin{cases} \left(\sum_{i=1}^d |\mathbf{x}_{ui} - \mathbf{x}_{vi}|^p\right)^{1/p} & \text{if } p < \infty \\ \max_{1\le i\le d}\{|\mathbf{x}_{ui} - \mathbf{x}_{vi}|\} & \text{otherwise.} \end{cases}$$

With this choice, the volume (Lebesgue measure) of the ball $B_p(r)$ of radius r under L_p-norm is equal to the probability that a vertex u falls within distance at most r of v (if $r = o(1)$). We denote this volume by $\nu(r)$. We call the corresponding graphs *standard GIRGs with any L_p-norm* and note that some of our results extend to this more general model. Finally, whenever our insights consider an even broader variant of the model (e.g., variable ground spaces, distances functions, weight distributions), we say that they hold for *any GIRG* and mention the constraints explicitly.

3 Asymptotic Equivalence

Our first main observations is that large values of d diminish the influence of the underlying geometry until, at some point, our model becomes strongly equivalent to its non-geometric counterpart, where edges are sampled independently of each other. We prove that the *total variation distance* between the distribution over all graphs of the two models tends to zero as n is kept fixed and $d \to \infty$. We define the total variation distance of two probability measures P and Q on the measurable space $(\Omega, \mathcal{F})$ as

$$\|P, Q\|_{\mathrm{TV}} = \sup_{A \in \mathcal{F}} |P(A) - P(B)| = \frac{1}{2} \sum_{\omega \in \Omega} |P(\omega) - Q(\omega)|,$$

where the second equality holds if Ω is countable. In our case, Ω is the set $\mathcal{G}(n)$ of all possible graphs on n vertices, and P, Q are distributions over these graphs. If G_1, G_2 are two random variables mapping to Ω, we refer to $\|G_1, G_2\|_{\mathrm{TV}}$ as the total variation distance of the induced probability measures by G_1 and G_2, respectively. Informally, this measures the maximum difference in the probability that any graph G is sampled by G_1 and G_2.

▶ **Theorem 1.** *Let $\mathcal{G}(n)$ be the set of all graphs with n vertices, let $\{w\}_1^n$ be a weight sequence, and consider $G_{IRG} = \mathrm{IRG}(\{w\}_1^n) \in \mathcal{G}(n)$ and a standard GIRG $G_{GIRG} = \mathrm{GIRG}(\{w\}_1^n, d) \in \mathcal{G}(n)$ with any L_p-norm. Then,*

$$\lim_{d \to \infty} \|G_{GIRG}, G_{IRG}\|_{TV} = 0.$$

We note that this theorem holds for arbitrary weight sequences that do not necessarily follow a power law and for arbitrary L_p-norms used to define distances in the ground space. For $p \in [1, \infty)$, the proof is based on the application of a multivariate central limit theorem [37], in a similar way as used to prove a related statement for *spherical random geometric graphs (SRGGs)*, i.e., random geometric graphs with a hypersphere as ground space [17]. Our proof generalizes this argument to arbitrary L_p-norms and arbitrary weight sequences. For the case of L_∞-norm, we present a proof based on the inclusion-exclusion principle and the bounds we develop in the full version [22, Section 4].

Remarkably, while a similar behavior was previously established for SRGGs, there exist works indicating that RGGs on the hypercube do not converge to their non-geometric counterpart [13, 18] as $d \to \infty$. We show that this apparent disagreement is due to the fact that the torus is a homogeneous space while the hypercube is not. In fact, our proof shows that GIRGs on the hypercube *do* converge to a non-geometric model in which edges are, however, not sampled independently. This lack of independence is because, on the hypercube, there is a positive correlation between the distances from two vertices to a given vertex, leading to a higher tendency to form clusters, as was observed experimentally [18]. Due to the homogeneous nature of the torus, the same is not true for GIRGs and the model converges to the plain IRG model with independent edges.

4 Clique Structure

To quantify for which dimensions d the graphs in the GIRG model start to behave similar to IRGs, we investigate the number and size of cliques. Previous results on SRGGs indicate that the dimension of the underlying space heavily influences the clique structure of the model [4, 17]. However, it was not known how the size and the number of cliques depends on d if we use the torus as our ground space, and how the clique structure in high-dimensions behaves for inhomogeneous weights.

Table 1 Asymptotic behavior of the expected number of k-cliques. The behavior in the first column is the same as in hyperbolic random graphs [7], and the behavior in the third column is the same as in the IRG model [14]. Results marked with * were previously known for constant k [34].

	$\mathbb{E}[K_k]$ for $k \geq 4$		
	$d = \Theta(1)$	$d = o(\log(n))$	$d = \omega(\log(n))$
$2 < \beta < 3, k > \frac{2}{3-\beta}$	$n^{\frac{k}{2}(3-\beta)}\Theta(k)^{-k}*$	$n^{\frac{k}{2}(3-\beta)}\Theta(k)^{-k}$	$n^{\frac{k}{2}(3-\beta)}\Theta(k)^{-k}$
$2 < \beta < 3, k < \frac{2}{3-\beta}$	$n\Theta(k)^{-k}*$	$ne^{-\Theta(1)dk}\Theta(k)^{-k}$	$n^{\frac{k}{2}(3-\beta)}\Theta(k)^{-k}$
$\beta > 3$	$n\Theta(k)^{-k}$	$ne^{-\Theta(1)dk}\Theta(k)^{-k}$	$o(1)$

We give explicit bounds on the expected number of cliques of a given size k, which we afterwards turn into bounds on the *clique number* $\omega(G)$, i.e., the size of the largest clique in the graph G. While the expected number of cliques in the GIRG model was previously studied by Michielan and Stegehuis [34] when the power-law exponent of the degree distribution satisfies $\beta \in (2,3)$, to the best of our knowledge, the clique number of GIRGs remains unstudied even in the case of constant (but arbitrary) dimensionality. We close this gap, reproduce the existing results, and extend them to the case $\beta \geq 3$ and the case where d can grow as a function of the number of vertices n in the graph. Furthermore, our bounds for the case $\beta \in (2,3)$ are more explicit and complement the work of Michielan and Stegehuis, who expressed the (rescaled) asymptotic number of cliques as converging to a non-analytically solvable integral. Furthermore, we show that the clique structure in our model eventually behaves asymptotically like that of an IRG if the dimension is sufficiently large. In summary, our main contributions are outlined in Tables 1, 2, and Table 3.

We observe that the structure of the cliques undergoes three phase transitions in the size of the cliques k, the dimension d, and the power-law exponent β.

Transition in k. When $\beta \in (2,3)$ and $d \in o(\log(n))$, the first transition is at $k = \frac{2}{3-\beta}$, as was previously observed for hyperbolic random graphs [7] and for GIRGs of constant dimensionality [34]. The latter work explains this behavior by showing that for $k < \frac{2}{3-\beta}$, the number of cliques is strongly dominated by "geometric" cliques forming among vertices whose distance is of order $n^{-1/d}$ regardless of their weight. For $k > \frac{2}{3-\beta}$, on the other hand, the number of cliques is dominated by "non-geometric" cliques forming among vertices with weights in the order of $\sqrt{n}$. This behavior is in contrast to the behavior of cliques in the IRG model, where this phase transition does not exist and where the expected number of k cliques is $\Theta\left(n^{\frac{k}{2}(3-\beta)}\right)$ for all $k \geq 3$ (if $\beta \in (2,3)$) [14].

Transition in d. Still assuming $\beta \in (2,3)$, the second phase transition occurs as d becomes superlogarithmic. More precisely, we show that in the high-dimensional regime, where $d = \omega(\log(n))$, the phase transition in k vanishes, as the expected number of cliques of size $k \geq 4$ behaves asymptotically like its counterpart in the IRG model. Nevertheless, we can still differentiate the two models as long as $d = o(\log^{3/2}(n))$, by counting triangles among low degree vertices as can be seen in Table 2.

The reason for this behavior is that the expected number of cliques in the case $d = \omega(\log(n))$ is already dominated by cliques forming among vertices of weight close to $\sqrt{n}$. For those, the probability that a clique is formed already behaves like in an IRG although, for vertices of small weight, said probability it is still larger.

Table 2 Asymptotic behavior of the expected number of triangles. The case $\beta = \infty$ refers to the case of constant weights. While in the case $\beta < 3$, the number of triangles already behaves like that of the IRG model if $d = \omega(\log(n))$, in the case $\beta > 3$, the number of triangles remains superconstant as long as $d = o\left(\log^{3/2}(n)\right)$.

Expected number of triangles $\mathbb{E}[K_3]$			
	$d = o(\log(n))$	$d = \omega(\log(n))$	$d = \omega(\log^2(n))$
$2 < \beta < \frac{7}{3}$	$n^{\frac{3}{2}(3-\beta)}\Theta(1)$	$n^{\frac{3}{2}(3-\beta)}\Theta(1)$	$n^{\frac{3}{2}(3-\beta)}\Theta(1)$
$\frac{7}{3} < \beta < 3$	$ne^{-\Theta(1)d}\Theta(1)$	$n^{\frac{3}{2}(3-\beta)}\Theta(1)$	$n^{\frac{3}{2}(3-\beta)}\Theta(1)$
$\beta > 3$	$ne^{-\Theta(1)d}\Theta(1)$	$\Omega\left(\exp\left(\frac{\ln^3(n)}{d^2}\right)\right)$	$\Theta(1)$
$\beta = \infty$	$ne^{-\Theta(1)d}\Theta(1)$	$\Theta\left(\exp\left(\frac{\ln^3(n)}{d^2}\right)\right)$	$\Theta(1)$

Regarding the clique number, in the case $\beta > 3$, we observe a similar phase transition in d. For constant d, the clique number of a GIRG is $\Theta(\log(n)/\log\log(n)) = \omega(1)$. We find that this asymptotic behavior remains unchanged if $d = \mathcal{O}(\log\log(n))$. However, if $d = \omega(\log\log(n))$ but $d = o(\log(n))$, the clique number scales as $\Theta(\log(n)/d)$, which is still superconstant. Additionally if $d = \omega(\log(n))$, we see that, again, GIRGs show the same behavior as IRGs. That is, there are asymptotically no cliques of size larger than 3.

Transition in β. The third phase transition occurs at $\beta = 3$ in the high-dimensional case, which is in line with the fact that networks with a power-law exponent $\beta \in (2, 3)$ contain with high probability (w.h.p., meaning with probability $1 - O(1/n)$) a densely connected "heavy core" of $\Theta\left(n^{\frac{1}{2}(3-\beta)}\right)$ vertices with weight $\sqrt{n}$ or above, which vanishes if β is larger than 3. This heavy core strongly dominates the number of cliques of sufficient size and explains why the clique number is $\Theta\left(n^{\frac{1}{2}(3-\beta)}\right)$ regardless of d if $\beta \in (2, 3)$. As β grows beyond 3, the core disappears and leaves only very small cliques. Accordingly for $\beta > 3$ IRGs contain asymptotically almost surely (a.a.s., meaning with probability $1 - o(1)$) no cliques of size greater than 3. In contrast to that, for GIRGs of dimension $d = o(\log(n))$ (and HRGs), the clique number remains superconstant and so does the number of k-cliques for any constant $k \geq 3$. If $d = \omega(\log(n))$, there are no cliques of size greater than 3 like in an IRG. However, as noted before, GIRGs feature many more triangles than IRGs as long as $d = o(\log^{3/2}(n))$.

Beyond the three mentioned phase transitions, we conclude that, for constant d, the main difference between GIRGs and IRGs is that the former contain a significant number of cliques that form among vertices of low weight, whereas, in the latter model only high-weight vertices contribute significantly to the total number of cliques. In fact, here, the expected number of k cliques in the heavy core is already of the same order as the total expectation of K_k in the whole graph. Similarly, in the GIRG model, the expected number of cliques forming in the low-weight subgraph $G_{\leq w}$ for some constant w, is already of the same order as the total number of cliques if $k < \frac{2}{3-\beta}$ or $\beta \geq 3$ (otherwise, this number is, again, dominated by cliques from the heavy core).

The proofs of our results (i.e., the ones in the above tables) are mainly based on bounds on the probability that a set of k randomly chosen vertices forms a clique. To obtain concentration bounds on the number of cliques as needed for deriving bounds on the clique number, we use the second moment method and Chernoff bounds.

For the case of $d = \omega(\log(n))$, many of our results are derived from the following general insight. We show that for and all $\beta > 2$, the probability that a set of vertices forms a clique already behaves similar as in the IRG model if the weights of the involved nodes are sufficiently large. For $d = \omega(\log(n)^2)$, this holds in the entire graph, that is, regardless of the weights of the involved vertices. In fact our statement holds even more generally. That is, the described behavior not only applies to the probability that a clique is formed but also to the probability that any set of edges (or a superset thereof) is created.

▶ **Theorem 2.** *Let G be a standard GIRG and let $k \geq 3$ be a constant. Furthermore, let $U_k = \{v_1, \dots, v_k\}$ be a set of vertices chosen uniformly at random and let $\{\kappa\}^{(k)} = \{\kappa_{ij} \mid 1 \leq i, j \leq k\}$ describe the pairwise product of weights of the vertices in U_k. Let $E(U_k)$ denote the (random) set of edges formed among the vertices in U_k. Then, for $d = \omega\left(\log^2(n)\right)$ and any set of edges $\mathcal{A} \subseteq \binom{U_k}{2}$,*

$$\Pr\left[E(U_k) \supseteq \mathcal{A} \mid \{\kappa\}^{(k)}\right] = (1 \pm o(1)) \prod_{\{i,j\} \in \mathcal{A}} \frac{\kappa_{ij}}{n}.$$

If $d = \omega\left(\log(n)\right)$,

$$\Pr\left[E(U_k) \supseteq \mathcal{A} \mid \{\kappa\}^{(k)}\right] = (1 \pm o(1)) \prod_{\{i,j\} \in \mathcal{A}} \left(\frac{\kappa_{ij}}{n}\right)^{1 \mp \mathcal{O}\left(\frac{\log(n)}{d}\right)}.$$

For the proof we derive elementary bounds on the probability of the described events and use series expansions to investigate their asymptotic behavior. Remarkably, in contrast to our bounds for the case $d = o(\log(n))$, the high-dimensional case requires us to pay closer attention to the topology of the torus.

We leverage the above theorem to prove that GIRGs eventually become equivalent to IRGs with respect to the total variation distance. Theorem 2 already implies that the expected number of cliques in a GIRG is asymptotically the same as in an IRG for all $k \geq 3$ and all $\beta > 2$ if $d = \omega(\log^2(n))$. However, we are able to show that the expected number of cliques for $\beta \in (2, 3)$ actually already behaves like that of an IRG if $d = \omega(\log(n))$. The reason for this is that the clique probability among high-weight vertices starts to behave like that of an IRG earlier than it is the case for low-weight vertices and cliques forming among these high-weight vertices already dominate the number of cliques. Moreover, the clique number behaves like that of an IRG if $d = \omega(\log(n))$ for all $\beta > 2$. However, the number of triangles among vertices of constant weight asymptotically exceeds that of an IRG as long as $d = o(\log^{3/2}(n))$, which we prove by deriving even sharper bounds on the expected number of triangles. Accordingly, convergence with respect to the total variation distance cannot occur before this point (this holds for all $\beta > 2$).

In contrast to this, for the low-dimensional case (where $d = o(\log(n))$), the underlying geometry still induces strongly notable effects regarding the number of sufficiently small cliques for all $\beta > 2$. However, even here, the expected number of such cliques decays exponentially in dk. The main difficulty in showing this is that we have to handle the case of inhomogeneous weights, which significantly influence the probability that a set of k vertices chosen uniformly at random forms a clique. To this end, we prove the following theorem that bounds the probability that a clique among k vertices is formed if the ratio of the maximal and minimal weight is at most c^d. Note that the vertices forming a star is necessary for a clique to form. For this reason we consider the event $\mathbf{E}^c_{\text{star}}$ of the vertices forming a star centered at the lowest weight vertex. The theorem generalizes a result of Decreusefond et al. [16].

Table 3 Asymptotic behavior of the clique number of G for different values of d in the GIRG model. The behavior of the first column is the same as in hyperbolic random graphs established in [7], and the behavior in the third column is the same as that of IRG graphs established in [27]. All results hold a.a.s. and under L_∞-norm.

	$\omega(G)$		
	$d = \mathcal{O}(\log\log(n))$	$d = o(\log(n))$	$d = \omega(\log(n))$
$\beta < 3$	$\Theta\left(n^{(3-\beta)/2}\right)$	$\Theta\left(n^{(3-\beta)/2}\right)$	$\Theta\left(n^{(3-\beta)/2}\right)$
$\beta = 3$	$\Theta\left(\frac{\log(n)}{\log\log(n)}\right)$	$\Omega\left(\frac{\log(n)}{d}\right)$	$\mathcal{O}(1)$
$\beta > 3$	$\Theta\left(\frac{\log(n)}{\log\log(n)}\right)$	$\Theta\left(\frac{\log(n)}{d}\right)$	≤ 3
	equivalent to HRGs [7]		equivalent to IRGs [27]

▶ **Theorem 3.** *Let G be a standard GIRG and consider $k \geq 3$. Furthermore, let $U_k = \{v_1, v_2, \dots, v_k\}$ be a set of vertices chosen uniformly at random and assume without loss of generality that $w_1 \leq \dots \leq w_k$. Let $\mathbf{E}^c_{star}$ be the event that v_1 connects to all vertices in $U_k \setminus \{v_1\}$ and that $w_k \leq c^d w_1$ for some constant $c \geq 1$ with $c^2 \left(w_1^2/(\tau n)\right)^{1/d} \leq 1/4$. Then, the probability that U_k is a clique conditioned on $\mathbf{E}^c_{star}$ fulfills*

$$\left(\frac{1}{2}\right)^{d(k-1)} k^d \leq \Pr\left[U_k \text{ is clique} \mid \mathbf{E}^c_{star}\right] \leq c^{d(k-2)} \left(\frac{1}{2}\right)^{d(k-1)} k^d.$$

Building on the variant by Decreusefond et al. [16], we provide an alternative proof of the original statement, showing that the clique probability conditioned on the event $\mathbf{E}^c_{\text{star}}$ is monotonous in the weight of all other vertices. Remarkably, this only holds if we condition on the event that the center of our star is of minimal weight among the vertices in U_k.

We apply Theorem 3 to bound the clique probability in the whole graph (where the ratio of the maximum and minimum weight of vertices in U_k is not necessarily bounded). Afterwards, we additionally use Chernoff bounds and the second moment method to bound the clique number.

5 Relation to Previous Analyses

In the following, we discuss how our results compare to insights obtained on similar graph models that (apart from not considering weighted vertices) mainly differ in the considered ground space. We not that, in the following, we consider GIRGs with uniform weights in order to obtain a valid comparison.

Random Geometric Graphs on the Sphere. Our results indicate that the GIRG model on the torus behaves similarly to the model of Spherical Random Geometric Graphs (SRGGs) in the high-dimensional case. In this model, vertices are distributed on the surface of a $d-1$ dimensional sphere and an edge is present whenever the Euclidean distance between two points (measured by their inner product) falls below a given threshold. Analogous to the behavior of GIRGs, when keeping n fixed and considering increasing $d \to \infty$, this model converges to its non-geometric counterpart, which in their case is the Erdős–Rényi model [17]. It is further shown that the clique number converges to that of an Erdős–Rényi graph (up to a factor of $1 + o(1)$) if $d = \omega(\log^3(n))$.

Although the overall behavior of SRGGs is similar to that of GIRGs, the magnitude of d in comparison to n at which non-geometric features become dominant seems to differ. In fact, it is shown in [10, proof of Theorem 3] that the expected number of triangles in sparse SRGGs still grows with n as long as $d = o(\log^3(n))$, whereas its expectation is constant in the non-geometric, sparse case (as for Erdős–Rényi graphs). On the other hand, in the GIRG model, we show that the expected number of triangles in the sparse case converges to the same (constant) value as that of the non-geometric model if only $d = \omega(\log^{3/2}(n))$. This indicates that, in the high-dimensional regime, differences in the nature of the underlying geometry result in notably different behavior, whereas in the case of constant dimensionality, the models are often assumed to behave very similarly.

Random Geometric Graphs on the Hypercube. The work of Dall and Christensen [13] and the recent work of Erba et al. [18] show that RGGs on the hypercube do *not* converge to Erdős–Rényi graphs as n is fixed and $d \to \infty$. However, our results imply that this is the case for RGGs on the torus. These apparent disagreements are despite the fact that Erba et al. use a similar central limit theorem for conducting their calculations and simulations [18].

The tools established in our paper yield an explanation for this behavior. Our proof of Theorem 1 relies on the fact that, for independent zero-mean variables $Z_1, \dots, Z_d$, the covariance matrix of the random vector $Z = \sum_{i=1}^{d} Z_i$ is the identity matrix. This, in turn, is based on the fact that the torus is a *homogeneous space*, which implies that the probability measure of a ball of radius r (proportional to its Lebesgue measure or volume, respectively) is the same, regardless of where this ball is centered. It follows that the random variables $Z_{(u,v)}$ and $Z_{(u,s)}$, denoting the normalized distances from u to s and v, respectively, are independent. As a result their covariance is 0 although both "depend" on the position of u.

For the hypercube, this is not the case. Although one may analogously define the distance of two vertices as a sum of independent, zero-mean random vectors over all dimensions just like we do in this paper, the random variables $Z_{(u,v)}$ and $Z_{(u,s)}$ do *not* have a covariance of 0.

6 Conjectures & Future Work

While making the first steps towards understanding GIRGs and sparse RGGs on the torus in high dimensions, we encountered several questions whose investigation does not fit into the scope of this paper. In the following, we give a brief overview of our conjectures and possible starting points for future work.

In addition to investigating how the number and size of cliques depends on d, it remains to analyze among which vertices k-cliques form dominantly. For constant d and $\beta \in (2, 3)$ this was previously done by Michielan and Stegehuis who noted that cliques of size $k > \frac{2}{3-\beta}$ are dominantly formed among vertices of weight in the order of $\sqrt{n}$ like in the IRG model, whereas cliques of size $k < \frac{2}{3-\beta}$ dominantly appear among vertices within distance in the order of $n^{-1/d}$ [34]. This characterizes the geometric and non-geometric nature of cliques of size larger and smaller than $\frac{2}{3-\beta}$, respectively. As our work indicates that this phase transition vanishes as $d = \omega(\log(n))$, we conjecture that in this regime cliques of all sizes are dominantly found among vertices of weight in the order $\sqrt{n}$. For the case $\beta \geq 3$ it remains to analyze the position of cliques of all sizes. It would further be interesting to find out where cliques of superconstant size are dominantly formed as previous work in this regard only holds for constant k.

Additionally, it would be interesting to extend our results to a noisy variant of GIRGs. While the focus in this paper lies on the standard GIRGs, where vertices are connected by an edge if their distance is below a given threshold, there is a *temperate* version of the model, where the threshold is softened using a *temperature* parameter. That is, while the

probability for an edge to exist still decreases with increasing distance, we can now have longer edges and shorter non-edges with certain probabilities. The motivation of this variant of GIRGs is based on the fact that real data is often noisy as well, leading to an even better representation of real-world graphs.

We note that we expect our insights to carry over to the temperate model, as long as we have constant temperature. Beyond that, we note that both temperature and dimensionality affect the influence of the underlying geometry. Therefore, it would be interesting to see whether a sufficiently high temperature has an impact on how quickly GIRGs converge to the IRGs.

Furthermore, it remains to investigate the dense case of our model, where the marginal connection probability of any pair of vertices is constant and does not decrease with n. For dense SRGGs, an analysis of the high-dimensional case has shown that the underlying geometry remains detectable as long as $d = o(n^3)$. As mentioned above, GIRGs and their non-geometric counterpart can be distinguished as long as $d = o(\log^{3/2}(n))$, by considering triangles among low-weight vertices. For dense SRGGs the geometry can be detected by counting so-called *signed triangles* [10]. Although for the sparse case, signed triangles have no advantage over ordinary triangles, they are much more powerful in the dense case and might hence prove useful for our model in the dense case as well.

Another crucial question is under which circumstances the underlying geometry of our model remains detectable by means of statistical testing, and when (i.e. for which values of d) our model converges in total variation distance to its non-geometric counterpart. A large body of work has already been devoted to this question for RGGs on the sphere [17, 10, 9, 33, 32] and recently also for random intersection graphs [9]. While the question when these models lose their geometry in the dense case is already largely answered, it remains open for the sparse case (where the marginal connection probability is proportional to $1/n$) and progress has only been made recently [9, 32]. It would be interesting to tightly characterize when our model loses its geometry both for the case of constant and for the case of inhomogeneous weights. Our bounds show that the number of triangles in our model for the sparse case (constant weights) is in expectation already the same as in a Erdős-Rényi graph if $d = \omega(\log^{3/2}(n))$, while on the sphere this only happens if $d = \omega(\log^3(n))$ [10]. Accordingly, we expect that our model loses its geometry earlier than the spherical model.

Abstract

We present an $O(\log k)$-approximation for both the edge-weighted and node-weighted versions of Directed Steiner Tree in planar graphs where k is the number of terminals. We extend our approach to Multi-Rooted Directed Steiner Tree[1], in which we get a $O(R + \log k)$-approximation for planar graphs for where R is the number of roots.

1 Introduction

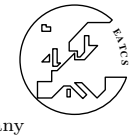
In the Directed Steiner Tree (DST) problem, we are given a directed graph $G = (V, E)$ with edge costs $c_e \geq 0, e \in E$, a root node $r \in V$, and a collection of terminals $X \subseteq V \setminus \{r\}$. The nodes in $V \setminus (X \cup \{r\})$ are called *Steiner* nodes. The goal is to find a minimum cost subset $F \subseteq E$ such that there is an $r - t$ directed path (dipath for short) using only edges in F for every terminal $t \in X$. Note any feasible solution that is inclusion-wise minimal must be an arborescence rooted at r, hence the term "tree". Throughout, we let $n := |V|$ and $k := |X|$.

One key aspect of DST lies in the fact that it generalizes many other important problems, e.g. Set Cover, (non-metric, multilevel) Facility Location, and Group Steiner Tree. Halperin and Krauthgamer [13] show Group Steiner Tree cannot be approximated within $O(\log^{2-\epsilon} n)$ for any $\epsilon > 0$ unless NP $\subseteq$ DTIME $(n^{\text{polylog}\,(n)})$ and therefore the same result holds for DST.

Building on a height-reduction technique of Calinescu and Zelikovsky [6, 21], Charikar et al. give the best approximation for DST which is an $O(k^\epsilon)$-approximation for any constant $\epsilon > 0$ [7] and also an $O(\log^3 k)$-approximation in $O(n^{\text{polylog}(k)})$ time (quasi-polynomial time). This was recently improved by Grandoni, Laekhanukit, and Li [12], who give a quasi-polynomial time $O(\frac{\log^2 k}{\log \log k})$-approximation factor for DST. They also provide a matching lower bound in that no asymptotically-better approximation is possible even for quasi-polynomial time algorithms, unless either the Projection Games Conjecture fails to hold or NP $\subseteq$ ZPTIME(2^{n^δ}) for some $0 < \delta < 1$.

The undirected variant of DST (i.e., Undirected Steiner Tree) is better understood.A series of papers steadily improved over the simple 2-approximation [22, 14, 17, 19] culminating in a $\ln 4 + \epsilon$ for any constant $\epsilon > 0$ [5]. Bern and Plassmann [3] showed that unless P = NP there is no approximation factor better than $\frac{96}{95}$ for Undirected Steiner Tree.

[1] In general graphs Multi-Rooted Directed Steiner Tree and Directed Steiner Tree are easily seen to be equivalent but in planar graphs this is not the case necessarily.



Studying the complexity of network design problems on restricted metrics such as planar graphs and more generally, graphs that exclude a fixed minor has been a fruitful research direction. For example, [4] gives the first *polynomial time approximation scheme* (PTAS) for Undirected Steiner Tree on planar graphs and more generally [2] obtains a PTAS for Steiner Forest on graphs of bounded-genus. Very recently, Cohen-Addad [8] presented a *quasi-polynomial time approximation scheme* (QPTAS) for Steiner tree on minor-free graphs.

A clear distinction in the complexity of Undirected Steiner Tree on planar graphs and general graphs have been established; however, prior to our work we did not know if DST on planar graphs is "easier" to approximate than in general graphs. Demaine, Hajiaghayi, and Klein [9] show that if one takes a standard flow-based relaxation for DST in planar graphs and further constraints the flows to be "non-crossing", then the solution can be rounded to a feasible DST solution while losing only a constant factor in the cost. However, the resulting relaxation is non-convex and, to date, we do not know how to compute a low-cost, non-crossing flow in polynomial time for DST instances on planar graphs. Recently, in [10] a constant factor approximation for planar DST was given for quasi-bipartite instances (i.e. no two Steiner nodes are connected by an edge). Though, we remark that the techniques in that paper are quite different than the techniques we use in this paper; [10] uses a primal-dual algorithm based on a standard LP relaxation whereas the techniques we use in this paper rely on planar separators.

In this paper, we show DST on planar graphs admits a $O(\log k)$-approximation, while DST on general graphs does not have an approximation factor better than $O(\log^{2-\epsilon} n)$ for any $\epsilon > 0$ unless NP $\subseteq$ DTIME $(n^{\text{polylog}\,(n)})$.

Our approach is based on planar separators presented by Thorup [20][2] which states given an undirected graph G with n vertices, one could find a "well-structured" subgraph F such that each connected component of $G \setminus F$ has at most $\frac{n}{2}$ vertices. We show using this separator and an aggressive guessing of optimal value of each subproblems lead to an $O(\log k)$-approximation algorithm in quasi-polynomial time. Then, we show how to modify the guessing part to make the algorithm run in polynomial time. Well-structured separators are useful in enabling divide-and-conquer approach for some problems, such as Maximum Independent Set and Pebbling [16]. Also very recently, Cohen-Addad [8] uses the same separator we consider to design QPTASes for k-MST and Undirected Steiner Tree on planar graphs. He also develops a new separator to deal with these problems in minor-free graphs.

We show the separator theorem of Thorup can be used to obtain a simple logarithmic approximation algorithm for planar DST.

▶ **Theorem 1.** *There is a $O(\log k)$-approximation for planar Directed Steiner Tree, where k is the number of terminals.*

We remark that it is trivial to generalize our algorithm to the node-weighted setting of DST in planar graphs. That is, to instances where Steiner nodes $v \in V \setminus (X \cup \{r\})$ have costs $c_v \geq 0$ and the goal is to find the cheapest S of Steiner Nodes such that the graph $G[\{r\} \cup X \cup S]$ contains an $r - t$ dipath for each $t \in X$. Clearly node-weighted DST generalizes edge-weighted DST even in planar graphs settings since we can subdivide an edge with cost c_e and include this cost on the new node. In general graphs, edge-weighted DST generalizes node-weighted DST because a node v with cost c_v can be turned into two nodes v^+, v^- connected by an edge (v^+, v^-) with cost c_v; edges entering v now enter v^+ and edges exiting v now exit v^-. But this operation does not preserve planarity, it is easy to find examples where this results in a non-planar graph.

[2] As stated in [20] this separator theorem was implicitly proved in [15].

We also extend our result to multi-rooted case. In Multi-Rooted Directed Steiner Tree (MR-DST), instead of one root, we are given multiple roots $r_1, \ldots, r_R$ and the set of terminals $X \subseteq V \setminus \{r_1, \ldots, r_R\}$. The goal here is to find a minimum cost subgraph such that every terminal is reachable from one of the roots.

Note that MR-DST on general graphs is equivalent to DST by adding an auxiliary root node r and adding edges (r, r_i) for $1 \leq i \leq R$ with zero cost. However, this reduction also does not preserve planarity. We prove our result for MR-DST by constructing a "well-structured" separator for the multi-rooted case.

▶ **Theorem 2.** *There is a $O(R + \log k)$-approximation for planar Multi-Rooted Directed Steiner Tree, where R is the number of roots and k is the number of terminals.*

2 Preliminaries

For convenience, we allow our input graphs to contain multiple directed edges between two nodes. All directed paths (dipath for short) in this paper are simple. Fix a digraph $G = (V, E)$ with edge costs $c_e \geq 0$ for all $e \in E$. We identify a dipath P by its corresponding sequence vertices, i.e., $P = v_1, \ldots, v_a$ and we say P is a $v_1 - v_a$-dipath. The *start* and *end* vertices of P are v_1 and v_a, respectively. For a subgraph H of G, we define the cost of a subgraph H by $\text{cost}_c(H) := \sum_{e \in E(H)} c_e$

We say a vertex v is *reachable* from u if there is a dipath from u to v. We denote by $d_c(u, v)$ the cost of a shortest dipath from u to v, in particular, $d_c(u, u) = 0$. The *diameter* of a digraph is defined as the maximum $d_c(u, v)$ for all $u \neq v$ where v is reachable from u. For both $d_c(.)$ and $\text{cost}_c(.)$ we drop the subscript c if the edge costs is clear from the context. For a subset $S \subseteq V$ and a vertex u, we define $d(S, v) := \min_{u \in S}\{d(u, v)\}$. Denote by $G[S]$ the *induced subgraph* of G on the subset of vertices S, i.e., $G[S] = (S, E[S])$ where $E[S]$ is the set of edges of G with both endpoints in S. A *weakly connected component* of G is a connected component of the undirected graph obtained from G by ignoring the orientation of the edges. The *indegree* of a vertex v with respect to $F \subseteq E$ is the number of edges in F oriented towards v.

A *partial arborescence* $T = (V_T, E_T)$ rooted at r in G, is a (not necessarily spanning) subgraph of G such that $r \in V_T$ and T is a directed tree oriented away from r. An arborescence is a partial arborescence that spans all the vertices. A *breadth first search* (BFS) arborescence B_G rooted at r is a (perhaps partial) arborescence including all nodes reachable from r where the dipath from r to any vertex v on B_G is a shortest dipath from r to v.

For two disjoint subsets of vertices $S, T \subseteq V$ denote by $\delta(S, T)$ the set of edges with one endpoint in S and the other endpoint in T (regardless of the orientation).

Given a subgraph H of G, for notational simplicity we write G/H the resulting graph from contracting all the edges in H. Also we denote by $G \setminus H$ the resulting graph by removing H from G, i.e., removing all the vertices of H and the edges incident to these vertices.

Our algorithm is based on planar separators described by Thorup [20].

▶ **Theorem 3** (Lemma 2.3 in [20]). *Let $G = (V, E)$ be a connected and undirected planar graph with non-negative vertex weights, and let T be a spanning tree rooted at a vertex $r \in V$. In linear time, one can find three vertices v_1, v_2, and v_3 such that the union of vertices on paths P_i between r and v_i in $V(T)$ for $i = 1, 2, 3$ forms a separator of G, i.e., every connected component of $G \setminus (P_1 \cup P_2 \cup P_3)$ has at most half the weight of G.*

An immediate consequence of the above result is that given a directed graph and a BFS arborescence rooted at r instead of a spanning tree, one can obtain a separator consisting three shortest dipaths each starting at r.

▶ **Corollary 4** (Directed separator). *Let $G = (V, E)$ be a planar digraph with edge costs $c_e \geq 0$ for all $e \in E$, and non-negative vertex weights such that every vertex $v \in V$ is reachable from r. Given a vertex $r \in V$, in polynomial time, we can find three shortest dipaths P_1, P_2, and P_3 each starting at r such that every weakly connected component of $G \setminus (P_1 \cup P_2 \cup P_3)$ has at most half the weight of G.*

Throughout this paper, we create subinstances from I by contracting a subset of edges F in G. Whenever, we create a subinstance I' we let the edge cost for the subinstance to be the natural restriction of c to G/F, i.e., if e is in both $E(G)$ and $E(G/F)$ then e has cost c_e in I' and if e is in $E(G/F)$ but not in $E(G)$, then its cost in I' is set to be the cost of the corresponding edge in $E(G)$.

Let $I = \big(G = (V, E), c, \{r_1, \ldots, r_R\}, X\big)$ be an instance of MR-DST on planar graphs where G is a planar digraph, $c_e \geq 0$ for all $e \in E$ is the edge costs, $\{r_1, \ldots, r_R\}$ are the roots, and $X \subseteq V \setminus \{r_1, \ldots, r_R\}$ is the set of terminals. By losing a small factor in the approximation guarantee, one can assume in an instance of MR-DST that all the costs are positive integers and $d\big(\{r_1, \ldots, r_R\}, v\big)$ is polynomially bounded by n for all $v \in V$. The very standard proof appears in Appendix 6.

▶ **Lemma 5** (Polynomial bounded distances). *For any constant $\epsilon > 0$, if there is an α-approximation for MR-DST instances in planar graphs where all edges e have positive integer costs $c_e \geq 1$ and $d_c(r, v) \leq \frac{|X| \cdot |V|}{\epsilon} + |V|$ for each $v \in V$, then there is an $(\alpha \cdot (1 + \epsilon))$-approximation for general instances of MR-DST in planar graphs.*

3 Planar DST

In this section we prove Theorem 1. Fix an instance $I = \big(G = (V, E), c, r, X\big)$ of DST on planar graphs that satisfies the assumptions in Lemma 5 for, say, $\epsilon = 1/2$. Let $n := |V|$ and $k := |X|$. Furthermore, fix an optimal solution OPT for this instance and let opt denote its cost. So the distance of every vertex from r is at most $O(n \cdot k)$.

Our algorithm recursively constructs smaller subinstances based on a partial arborescence (as a separator) and disjoint subsets of vertices (as the weakly connected components after removing the separator). The following is a more formal definition of these subinstances.

▶ **Definition 6** (Induced subinstances). *Let $I = (G = (V, E), c, r, X)$ be an instance of DST on planar graphs. Let T be a partial arborescence rooted at r, and let $C_1, \ldots, C_h$ be the weakly connected components of $G \setminus T$. The subinstances of DST induced by tuple $(G, T, C_1, \ldots, C_h)$ are defined as follows: let G_{contract} be the graph obtained from G by contracting T into r. For each C_i where $1 \leq i \leq h$ we construct instance $I_{C_i} := \big(G_{C_i}, c, r, C_i \cap X\big)$ where $G_{C_i} := G_{\text{contract}}[C_i \cup \{r\}]$. See Figure 1.*

Given solutions $\mathcal{F}_1, \mathcal{F}_2, \ldots, \mathcal{F}_h$ for the subinstances induced by $(G, T, C_1, \ldots, C_h)$, one can naturally consider the corresponding subset of edges of $E(T) \cup \mathcal{F}_1 \cup \mathcal{F}_2 \cup \ldots \cup \mathcal{F}_h$ in G and it is easy to see this forms a feasible solution for instance I. We formalize this in the next lemma.

▶ **Lemma 7** (Merged solution). *Consider the subinstances I_{C_i} for $1 \leq i \leq h$ as defined in Definition 6. Let $\mathcal{F}_{C_i}$ be a solution for I_{C_i}. Let $\mathcal{F} \subseteq E(G)$ be the corresponding edges of $E(T) \cup (\bigcup_{i=1}^{h} \mathcal{F}_{C_i})$ in G. Then, $\mathcal{F}$ is a feasible solution for instance I and furthermore $\text{cost}(\mathcal{F}) = \text{cost}(T) + \sum_{i=1}^{h} \text{cost}(\mathcal{F}_{C_i})$. See Figure 1.*

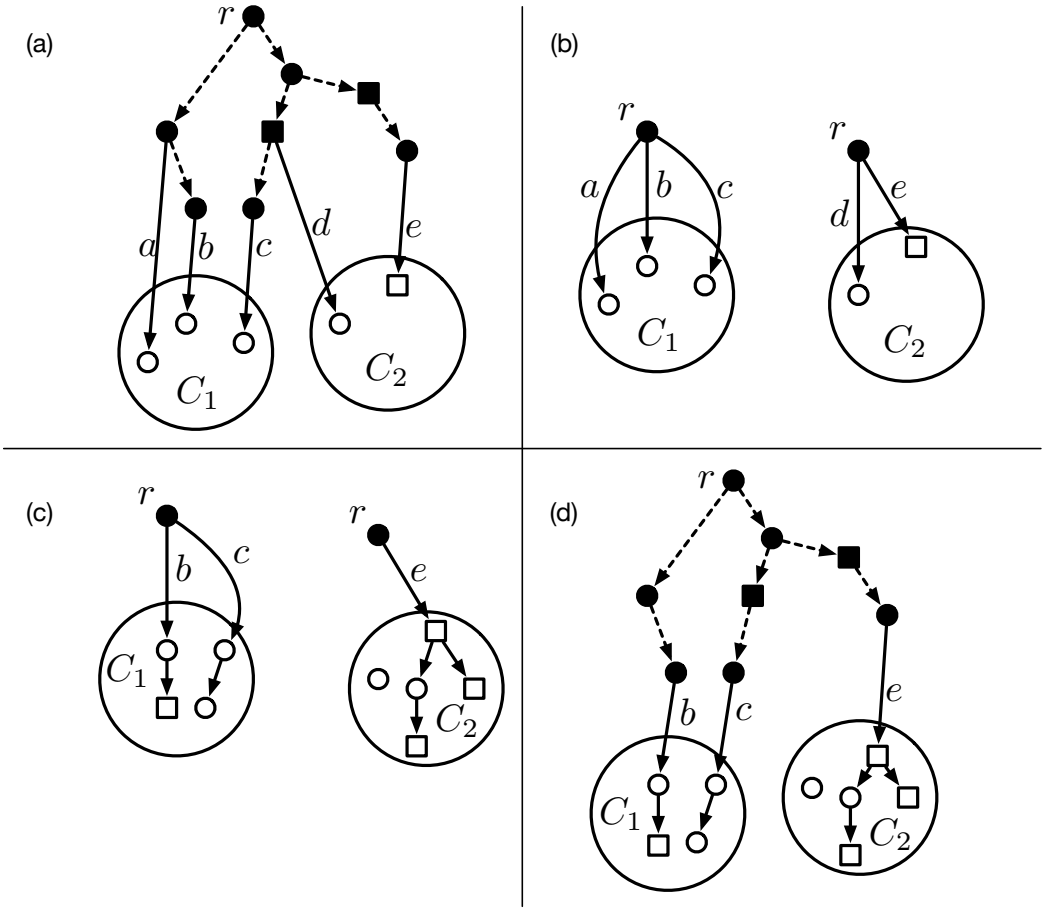


Figure 1 Throughout, squares are terminals and circles are Steiner nodes or the root node r. In (a) the separator is shown with dashed edges and solid vertices. The weakly connected components of $G \setminus T$ are shown as circles denoted by C_1 and C_2. Note that we did not show any edge directed from C_1 or C_2 into the separator because we can safely remove these edges. In (b) the subinstances I_{C_1} and I_{C_2} induced by (G, T, C_1, C_2) are depicted. In (c), the solutions for each subinstances are shown. Finally, (d) shows how to merge the solutions in (c) to get a solution for the original instance. Note that leaf nodes are not necessarily terminals. One could prune them as a post-processing step, but that is not required by our algorithm.

Proof. The furthermore part is obvious so we prove that $\mathcal{F}$ is feasible for I. Consider a terminal node $t \in C_i$. Since $\mathcal{F}_i$ is feasible for I_{C_i}, then there is a dipath P from r to t. Let (r, v) be the first edge on P and let (u, v) be the corresponding edge to (r, v) in $E(G)$. Then, we must have $u \in V(T)$ as $\delta(C_i, C_j) = \emptyset$ for all $1 \leq i \neq j \leq h$. So we can go from r to u in T, then take the edge (u, v) and then go from v to t in $\mathcal{F}_{C_i}$. Since all these edges are present in $\mathcal{F}$ and t is an arbitrary terminal, $\mathcal{F}$ is a feasible solution for I. ◀

We first present a high-level idea of a simple $O(\log k)$-approximation that runs in quasi-polynomial time and then with a little extra work, we can make it run in polynomial time with small loss in the approximation guarantee.

3.1 Warm-up: An overview of a quasi-polynomial time approximation

The algorithm is simple. Fix an optimal solution OPT with cost opt. First we guess opt. Note by Lemma 5, opt is polynomial in n and integral so there are polynomial guesses. Then, we remove all vertices such that their distance from r is more than our guessed value (this is

the preprocessing step). For the purpose of separating into subinstances with balanced weight, we let the weight of each terminal to be 1 and the rest of vertices have zero weight. Apply Corollary 4 and let P_1, P_2, and P_3 be the resulting shortest dipaths each starting at r. Note that $\text{cost}(P_i) \leq \text{opt}$ for $i = 1, 2, 3$ because of the preprocessing step. Let $T := P_1 \cup P_2 \cup P_3$, then T is a branching rooted at r. Let C_i for $1 \leq i \leq h$ be the weakly connected components of $G \setminus T$. Then, we recursively solve the subinstances induced by $(G, T, C_1, \ldots, C_h)$ (see Definition 6), and finally return the corresponding solution of $E(T) \cup \bigcup_{i=1}^{h} \mathcal{F}_{C_i}$ in G. When the number of terminals in a subinstance becomes one, we can solve the problem exactly by finding the shortest dipath between the root and the only terminal.

Note that each recursive call reduces the number of terminals by half. The guess work for each instance is polynomial in n. So it is easy to see the total number of recursive calls is bounded by $n^{O(\log k)}$. Since each time we apply the separator result on an instance I, we buy a branching (union of up to three dipaths) of cost at most $3 \cdot \text{opt}$, and since the *total* cost of optimal solutions across all of the resulting subinstances I_{C_i} is at most opt, a simple induction on the number of terminals shows the final cost is within $(3 \cdot \log k + 1) \cdot \text{opt}$. A slight improvement to the running time could be made by guessing OPT within a constant factor (thus only making $O(\log n)$ guesses since all distances are integers bounded by a polynomial in n), but the size of the recursion tree would still be $O(\log n)^{O(\log k)}$ which is still not quite polynomial.

In the next section, we show how to avoid the above aggressive guessing which gives us the polynomial running time. We remark there are some similarities between our algorithm with the one presented in [11] for quasi-polynomial time algorithm for Submodular Tree Orienteering in the sense that both need to guess some value (in our case opt and in their case the budget) for the subproblems and performing this guess naively is too slow. However, the approaches to overcoming this barrier are different.

3.2 The polynomial-time algorithm

The idea here is similar to the quasi-polynomial time algorithm; however, instead of guessing the diameter of an optimal arborescence for each instance, we keep an estimate of it. Our recursive algorithm tries two different recursive calls: (1) divide the current estimate by half and recurse, or (2) buy a separator and divide the instance into smaller instances and recurs on these instances using the current estimate as the current estimate passed to each smaller instance.

The rationale behind this idea is that if the estimate is close to the optimal value, then our separator is "cheap" compared to optimal value so (2) is a "good progress" otherwise we make the estimate smaller so (1) is a "good progress". The key idea here that leads to polynomial time is that we do not "reset" our guess for the optimal solution cost in each recursive call since we know that if our guess is correct for the current instance, then it is an upper bound for the optimal solution cost in each subinstance.

As we mentioned at the beginning, the algorithm is recursive. The input to the algorithm is a tuple $(I, \widetilde{\text{opt}})$ where $\widetilde{\text{opt}}$ is an estimate of opt. The algorithm computes two solutions and take the better of the two. One solution is by a recursive call to $(I, \frac{\widetilde{\text{opt}}}{2})$ and the other one is obtained by applying Corollary 4 to get smaller subinstances and solve each subinstance recursively and merge the solutions as described in Lemma 7. See Algorithm 1 for the pseudocode.

By Lemma 5, we can assume the edge costs are positive integers and hence $\text{opt} \geq 1$. So if $\widetilde{\text{opt}} < 1$, then the output of $\text{DST}(I, \widetilde{\text{opt}})$ is infeasible. The algorithm will terminate since each recursive call either halves $\widetilde{\text{opt}}$ or halves the number of terminals.

Algorithm 1 $\mathrm{DST}(I, \widetilde{\mathrm{opt}})$.

Input: $I := \big(G = (V, E), c, r, X\big)$ and an estimate $\widetilde{\mathrm{opt}}$.
Output: A feasible solution for instance I or output infeasible.

if $\widetilde{\mathrm{opt}} < 1$ or $d(r, t) > \widetilde{\mathrm{opt}}$ for some terminal $t \in X$ **then**
  return `infeasible`
else if $|X_I| = 1$ **then**
  Let $\mathcal{F}$ be the shortest dipath from r to the only terminal in X_I.
else
  $\mathcal{F}_1 \leftarrow \mathrm{DST}(I, \frac{\widetilde{\mathrm{opt}}}{2})$, if $\mathcal{F}_1$ is `infeasible` solution then set $\mathrm{cost}(F_1) \leftarrow \infty$.
  Remove all vertices v with $d(r, v) > \widetilde{\mathrm{opt}}$. {This is the preprocessing step.}
  Apply Corollary 4 to obtain a partial arborescence T consists of up to 3 shortest dipaths starting at r. Let $C_1, \ldots, C_h$ be the weakly connected components of $G \setminus T$. Let I_{C_i} be the i-th subinstance induced by $(G, T, C_1, \ldots, C_h)$ for $i = 1, \ldots, h$.
  for $i = 1, \ldots, h$ **do**
    $\mathcal{F}'_i \leftarrow \mathrm{DST}(I_{C_i}, \widetilde{\mathrm{opt}})$
  $\mathcal{F}_2 \leftarrow E(T) \cup (\bigcup_{i=1}^{h} \mathcal{F}'_i)$, if any $\mathcal{F}'_i$ is `infeasible` then set $\mathrm{cost}(\mathcal{F}_2) \leftarrow \infty$.
  if both $\mathrm{cost}(\mathcal{F}_1)$ and $\mathrm{cost}(\mathcal{F}_2)$ are ∞ **then**
    return `infeasible`
  $\mathcal{F} \leftarrow \arg\min\{\mathrm{cost}(\mathcal{F}_1), \mathrm{cost}(\mathcal{F}_2)\}$
return $\mathcal{F}$.

3.3 Analysis

In this section, we analyze the cost and the running time of Algorithm 1.

▶ **Lemma 8** (Cost and running time). *Consider an instance $I = \big(G = (V, E), c, r, X\big)$ and a pair $(I, \widetilde{\mathrm{opt}})$. Let ℓ and $\mathcal{O}$ be non-negative integers such that $|X| \le 2^\ell$ and $\widetilde{\mathrm{opt}} \le 2^{\mathcal{O}}$. If $\widetilde{\mathrm{opt}} \ge \mathrm{opt}$ where opt is the optimal value of I, then $\mathrm{DST}(I, \widetilde{\mathrm{opt}})$ returns a solution with cost at most $(6 \cdot \ell + 1) \cdot \mathrm{opt}$. Furthermore, the total number of recursive calls made by $\mathrm{DST}(I, \widetilde{\mathrm{opt}})$ and its subsequent recursive calls is at most $|X| \cdot 2^{2 \cdot \ell + \mathcal{O}}$.*

Proof. First we analyze the cost of the output solution. If $\ell = 0$ then we solve I exactly so the statement holds. So for the rest of the proof we assume $\ell \ge 1$. We proceed by induction on $\ell + \mathcal{O} \ge 1$.

We assume $\widetilde{\mathrm{opt}} \le 2 \cdot \mathrm{opt}$, otherwise we have $\mathrm{DST}(I, \widetilde{\mathrm{opt}}) \le \mathrm{DST}(I, \frac{\widetilde{\mathrm{opt}}}{2}) \le (6 \cdot \ell + 1) \cdot \mathrm{opt}$ by induction where the last inequality holds because $\log \frac{\widetilde{\mathrm{opt}}}{2} \le \log(\widetilde{\mathrm{opt}}) - 1$.

Let $\mathcal{F}$ be the solution returned by $\mathrm{DST}(I, \widetilde{\mathrm{opt}})$. Since $\mathrm{cost}(\mathcal{F}) \le \mathrm{cost}(\mathcal{F}_2)$, it suffices to prove $\mathrm{cost}(\mathcal{F}_2) \le (6 \cdot \ell + 1) \cdot \mathrm{opt}$. Let $\mathcal{F}'_i = \mathrm{DST}(I_{C_i}, \widetilde{\mathrm{opt}})$ for $i = 1, \ldots, h$ be the solutions constructed recursively for the subinstances. Note that each I_{C_i} for $i = 1 \ldots, h$ has at most $2^{\ell - 1}$ terminals and $\widetilde{\mathrm{opt}} \ge \mathrm{opt}_{I_{C_i}}$ where $\mathrm{opt}_{I_{C_i}}$ is the optimal value of I_{C_i}. By the induction hypothesis, we conclude

$$\mathrm{cost}(\mathcal{F}'_i) \le (6 \cdot (\ell - 1) + 1) \cdot \mathrm{opt}_{I_{C_i}} \le 6 \cdot \ell \cdot \mathrm{opt}_{I_{C_i}}, \ \textit{for } i = 1, \ldots, h \tag{1}$$

Note that T is the union of up to three shortest dipaths and because of the preprocessing step, each shortest dipath starting at r has cost at most $\widetilde{\mathrm{opt}} \le 2 \cdot \mathrm{opt}$. So the following holds:

$$\mathrm{cost}(T) \le 3 \cdot \widetilde{\mathrm{opt}} \le 6 \cdot \mathrm{opt}\,. \tag{2}$$

Combining (1) and (2) we get:

$$\begin{aligned}
\mathrm{cost}(\mathcal{F}) &= \mathrm{cost}(T) + \sum_{i=1}^{h} \mathrm{cost}(\mathcal{F}'_i) \\
&\leq \mathrm{cost}(T) + \sum_{i=1}^{h} 6 \cdot \ell \cdot \mathrm{opt}_{I_{C_i}} \\
&\leq 6 \cdot \mathrm{opt} + 6 \cdot \ell \cdot \sum_{i=1}^{h} \mathrm{opt}_{I_{C_i}} \\
&\leq 6 \cdot \mathrm{opt} + 6 \cdot \ell \cdot \mathrm{opt} \\
&= (6 \cdot \ell + 1) \cdot \mathrm{opt},
\end{aligned}$$

where the first equality follows from Lemma 7, the first and the second inequalities follow from (1) and (2), respectively, and finally the last inequality follows from the fact that $\sum_{i=1}^{h} \mathrm{opt}_{I_{C_i}} \leq \mathrm{opt}$ as the restriction of OPT on each G_{C_i} is a feasible solution for I_{C_i} and G_{C_i}'s are edge-disjoint.

Next, we analyze the number of recursive calls $R(\ell, \wp)$ in $\mathrm{DST}(I, \widetilde{\mathrm{opt}})$. We prove by induction on $\ell + \wp$ that $R(\ell, \wp) \leq |X| \cdot 2^{2 \cdot \ell + \wp}$. If $\ell = 0$, then there is no recursive call. So suppose $\ell \geq 1$. Let $X_i := |X \cap C_i| \leq \frac{|X|}{2}$ be the number of terminals in subinstance I_{C_i} and let ℓ_i be the smallest integer where $|X_i| \leq 2^{\ell_i}$. Since the number of terminals in the subinstances are halved, we have $\ell_i \leq \ell - 1$ for all $1 \leq i \leq h$. So we can write

$$\begin{aligned}
R(\ell, \wp) &= 1 + R(\ell, \wp - 1) + \sum_{i=1}^{h} R(\ell_i, \wp) \\
&\leq 1 + |X| \cdot 2^{2 \cdot \ell + \wp - 1} + \sum_{i=1}^{h} |X_i| \cdot 2^{2 \cdot \ell_i + \wp} \\
&\leq 1 + |X| \cdot 2^{2 \cdot \ell + \wp - 1} + 2^{2(\ell - 1) + \wp} \cdot \sum_{i=1}^{h} |X_i| \\
&\leq 1 + |X| \cdot 2^{2 \cdot \ell + \wp - 1} + 2^{2 \cdot \ell + \wp - 2} \cdot |X| \\
&= 1 + |X| \cdot 2^{2 \cdot \ell + \wp - 1} + (2^{2 \cdot \ell + \wp - 1} - 2^{2 \cdot \ell + \wp - 2}) \cdot |X| \\
&= 1 + |X| \cdot 2^{2 \cdot \ell + \wp} - |X| \cdot 2^{2 \cdot \ell + \wp - 2} \\
&\leq |X| \cdot 2^{2 \cdot \ell + \wp},
\end{aligned}$$

where the first inequality follows from the induction hypothesis, the second inequality comes from the fact that $\ell_i \leq \ell - 1$, the third inequality holds because $\sum_{i=1}^{h} |X_i| \leq |X|$, and the last inequality follows from the fact that $|X| \geq 1$ and $\ell \geq 1$. ◀

Proof of Theorem 1. For any $\epsilon > 0$, we can assume all the shortest dipaths starting at the root are bounded by $\mathrm{poly}(n, \epsilon)$ by losing a $(1 + \epsilon)$ multiplicative factor in the approximation guarantee, see Lemma 5. So we assume properties of Lemma 5 holds for the rest of the proof.

Let Δ be the maximum distance from the root to any terminal. Let $\widetilde{\mathrm{opt}} := k \cdot \Delta \leq \mathrm{poly}(n)$. We find a solution by calling $\mathrm{DST}(I, \widetilde{\mathrm{opt}})$. Applying Lemma 8 with $\widetilde{\mathrm{opt}} := k \cdot \Delta$, $\ell := \lceil \log k \rceil \leq \log k + 1$ and $\wp := \lceil \log \widetilde{\mathrm{opt}} \rceil$ guarantees the solution has cost at most $(6 \cdot (\log k + 1) + 1) \cdot \mathrm{opt}$.

For running time of Algorithm 1, we have by Lemma 8 that the number of recursive calls is at most $k \cdot 2^{2 \cdot \ell + \wp} = O(k^4 \cdot \Delta)$. So the total number of recursive calls is $\mathrm{poly}(n)$ (recall $k \cdot \Delta = \mathrm{poly}(n)$). The running time within each recursive call is also bounded by $\mathrm{poly}(n)$ so the algorithm runs in polynomial time. ◀

4 Multi-rooted planar DST

The algorithm for the multi-rooted case is similar to Algorithm 1. We need analogous versions of the separator, how we define the subinstances, and how we merge the solutions of smaller subinstances to get a solution for the original instance for the multi-rooted case.

We start by a generalization of partial arborescence in the single rooted case to multiple roots.

▶ **Definition 9** (Multi-rooted partial arborescence). *Given a digraph $G = (V, E)$, R vertices $r_1, \ldots, r_R$ designated as roots. We say a subgraph T of G is a multi-rooted partial arborescence if it satisfies the following properties:*

1. *There are vertex-disjoint partial arborescences $T_{i_1}, \ldots, T_{i_q}$ rooted at $r_{i_1}, \ldots, r_{i_q}$, respectively, and a subset of edges $F \subseteq E \setminus \left(\bigcup_{j=1}^{q} E(T_{i_j})\right)$, where the endpoints of each edge in F belong to $\bigcup_{j=1}^{q} V(T_{i_j})$, such that $T = F \cup (\bigcup_{j=1}^{q} T_{i_q})$.*
2. *T is weakly connected and has no cycle (in the undirected sense).*

If a multi-rooted partial arborescence T covers all the vertices in G, then we say T is a *multi-rooted arborescence* for G. See Figure 2 for an example.

Fix an instance $I = (G, c, \{r_1, \ldots, r_R\}, X)$ of R-rooted DST on planar graphs. Next, we present subinstnaces induced by a partial multi-rooted arborescence and bunch of disjoint subsets analogous to Definition 6.

▶ **Definition 10** (Induced subinstances, multi-rooted). *Let $I = (G, c, \{r_1, \ldots, r_R\}, X)$ of R-rooted DST on planar graphs. Let $T = F \cup (\bigcup_{j=1}^{q} T_{p_j})$ be a multi-rooted partial arborescence where T_{p_j} is a partial arborescence rooted at r_{p_j} for $1 \le j \le q$. In addition, let $C_1, \ldots, C_h$ be the weakly connected components of $G \setminus T$. The subinstances of multi-rooted DST induced by tuple $(G, T, C_1, \ldots, C_h)$ are defined as follows: let G_{contract} be the graph obtained from G by contracting T into a singleton vertex called r_T. For each C_i where $1 \le i \le h$ we construct instance $I_{C_i} := \left(G_{C_i}, c, \{r_T\} \cup \left(C_i \cap \left(\{r_1, \ldots, r_R\} \setminus \{r_{p_1}, \ldots, r_{p_q}\}\right)\right), C_i \cap X\right)$ where $G_{C_i} := G_{\text{contract}}[C_i \cup \{r_T\}]$.*

The following is analogous to Lemma 7 for merging solution in the multi-rooted case.

▶ **Lemma 11** (Merged solutions, multi-rooted). *Let $T = F \cup (\bigcup_{j=1}^{q} T_{p_j})$ be a partial multi-rooted arborescence in G. Consider the subinstances I_{C_i} for $1 \le i \le h$ as defined in Definition 10 and let $\mathcal{F}_{C_i}$ be a solution for I_{C_i}. Let $\mathcal{F} \subseteq E(G)$ be the corresponding edges in $(E(T) \setminus F) \cup (\bigcup_{i=1}^{h} \mathcal{F}_{C_i})$. Then, $\mathcal{F}$ is a feasible solution for instance I and furthermore* $\text{cost}(\mathcal{F}) = \text{cost}(T \setminus F) + \sum_{i=1}^{h} \text{cost}(\mathcal{F}_{C_i})$.

Proof. The furthermore part follows directly from the definition of $\mathcal{F}$. We prove $\mathcal{F}$ is feasible for I.

Consider a terminal t. If $t \in V(T)$, then $t \in V(T_{p_j})$ for some $1 \le j \le q$ (recall the vertices in T is the union of the vertices in all the partial arborescences T_{p_j}'s) so t is reachable from r_{p_j}, the root of T_{p_j}, in $\mathcal{F}$. Suppose $t \in C_i$ for some $1 \le i \le h$. If t is reachable from a root other than r_T in $\mathcal{F}_{C_i}$ then we are done because the same dipath exists in $\mathcal{F}$. So we suppose not and let P be the dipath in $\mathcal{F}_{C_i}$ from r_T to t. Let (u, v) be the corresponding edge to (r_T, v) in G. Note that $u \in V(T_{p_j})$ for some $1 \le j \le q$ because $\delta(C_s, C_{s'}) = \emptyset$ for $1 \le s \ne s' \le h$. Hence, t is reachable from r_{p_j}, the root of T_{p_j}, in $\mathcal{F}$ as $E(T_{p_j}) \subseteq \mathcal{F}$. ◀

Given an instance I with roots $r_1, \ldots, r_R$, temporarily add an auxiliary node r and add edges (r, r_i) for all $1 \le i \le R$ with zero cost (it might destroy the planarity). Run the BFS algorithm as usual rooted at r. Then, remove r and all the edges incident to r. The result is a vertex-disjoint BFS arborescences $A_1, A_2, \ldots, A_R$ rooted at $r_1, \ldots, r_R$. Note that for every $v \in V(A_i)$, v is closest to r_i than any other roots, i.e., the dipath from r_i to v has cost $d\big(\{r_1, \ldots, r_R\}, v\big)$.

Finally, we present the separator result for the multi-rooted case.

▶ **Lemma 12** (A structured separator, multi-rooted). *Let $I = (G = (V, E), c, \{r_1, \ldots, r_R\}, X)$ be an instance of multi-rooted DST on planar graphs, and let $A_1, \ldots, A_R$ be the vertex-disjoint BFS arborescence rooted at $r_1, \ldots, r_R$. There is a multi-rooted partial arborescence $T = F \cup (\bigcup_{j=1}^{R} T_{i_j})$, where T_{i_j} could possibly be empty (i.e., with no vertices) such that the following hold:*

- **(a)** *T_j is either empty or is a subtree of A_j rooted at r_j that consists of the union of up to four shortest dipaths each starting at r_j.*
- **(b)** *Let $C_1, \cdots, C_h$ be the weakly connected components of $G \setminus T$. Then, each subinstance I_{C_i} induced by $(G, T, C_1, \ldots, C_h)$ has at most $\frac{|X|}{2}$ terminals for $1 \le i \le h$.*
- **(c)** *Let $\mathcal{F}_i$ be a solution to subinstance I_{C_i} for $1 \le i \le h$. Then, the corresponding solution $(E(T) \setminus F) \cup (\bigcup_{i=1}^{h} \mathcal{F}_i)$ in G is feasible for I with cost exactly $\mathrm{cost}(T \setminus F) + \sum_{i=1}^{h} \mathrm{cost}(\mathcal{F}_i)$.*

Proof. Figure 2 helps to visualize this proof.

Since G is weakly connected, there is a subset of edges F' in G such that $T' := F' \cup (\bigcup_{i=1}^{R} A_i)$ is a multi-rooted arborescence of G (spanning all the vertices) and the endpoints of edges in F are in $\bigcup_{i=1}^{R} V(A_i)$. Make T' rooted at an arbitrarily chosen root, say r_1. Apply Theorem 3 with terminal vertices having weight 1 and the rest of vertices having weight 0, and T' as the spanning tree (in the undirected sense). This gives three paths P_1, P_2, and P_3 in T' each with starting vertex r_1 such that every weakly connected component C_i of $G \setminus (P_1 \cup P_2 \cup P_3)$ has at most $\frac{|X|}{2}$ terminals for $1 \le i \le h$. Note, these three paths do not necessarily follow the directions of the edges.

Fix A_i for some $1 \le i \le R$ and a path $P_j := (r_1 = v_1), v_2, \ldots, v_N$ for $1 \le j \le 3$. Let a and b (possibly $a = b$) be the smallest and the largest indices, respectively, such that v_a and v_b are in $V(A_i)$. We claim the subpath $P_{[a,b]} := v_a, v_{a+1}, \ldots, v_b$ is a subgraph of A_i. Suppose not, so there must be two indices $a \le a' < b' \le b$ such that $v_{a'}, v_{b'} \in V(A_i)$ and $v_{a'+1}, v_{a'+2}, \ldots, v_{b'-1} \notin V(A_i)$. Let $P_{A_i}^{a'}$ and $P_{A_i}^{b'}$ be the paths from r_i to a' and b' in $V(A_i)$, respectively. So $P_{A_i}^{a'} \cup P_{A_i}^{b'} \cup P_{[a',b']}$ forms a cycle in T', a contradiction. Furthermore, for $j = 1, 2, 3$ let v_j be the closest vertex to r_1 on P_j (in terms of edge hops) that is in A_i as well (if exists). Then, $v_1 = v_2 = v_3$ as otherwise we have a cycle in T' because all P_j's start at r_1.

For each $1 \le i \le R$ and $1 \le j \le 3$, we **mark** the nodes with smallest and largest indices in P_j that are in A_i. We proved above, that the number of these marked vertices in each A_i is at most 4. Furthermore, $(P_1 \cup P_2 \cup P_3) \cap A_i$ is a subgraph of the union of dipaths from r_i to each marked vertices in A_i for all $1 \le i \le h$.

We construct our partial multi-rooted arborescence T as follows: let T_i be the union of (up to four) shortest dipaths from r_i to the marked vertices in A_i. Let $F := E\big(P_1 \cup P_2 \cup P_3\big) \setminus (\bigcup_{i=1}^{R} E(T_i))$ which is the subset of edges whose endpoints are in different $V(A_i)$'s, i.e., $F \subseteq F'$. Let $T := F \cup (\bigcup_{i=1}^{R} T_i)$. Note that for A_i's with no marked vertices, T_i is empty

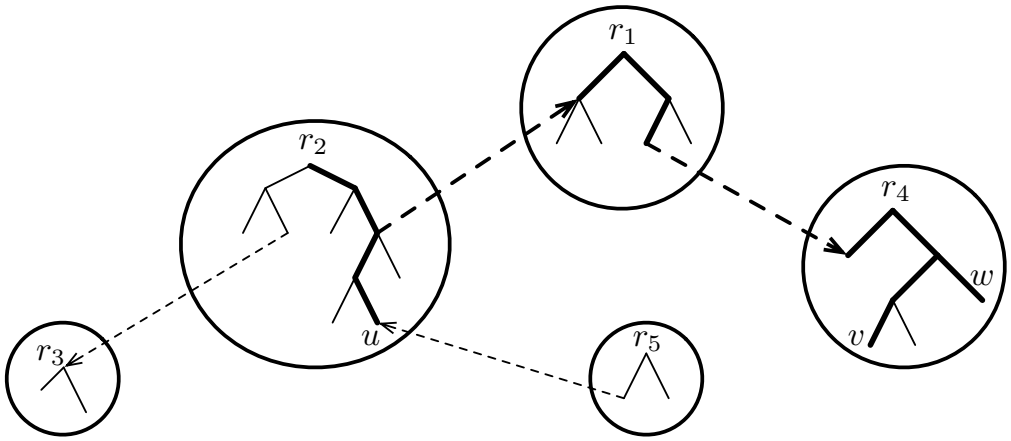

Figure 2 A depiction of the multirooted separator in an instance with $R = 5$ roots. The solid edges (thick and thin) are the shortest-path arborescences A_i for $i = 1, \ldots, R$. The dashed edges are F', they exist solely to allow us to apply Theorem 3 starting from a spanning tree of the underlying undirected graph and to witness the contraction of all vertices on the thick edges results in a planar graph. After applying Theorem 3, we get three vertices depicted as u, v, w. The vertices touching the thick and solid edges then form the multirooted separator: these include all vertices lying on paths from r to u, v, or w (as in Theorem 3). Additionally, for each $i = 1, \ldots, R$ that includes at least one node from some $r_1 - a$ path for some $a \in \{u, v, w\}$, the multirooted separator includes vertices on the unique path connecting r_i to the $r - a$ path (eg. the path from r_2 to the $r_1 - u$ path). In the algorithm, the solution will purchase the thick solid edges, but not the thick dashed edges. However, we do contract all thick edges (dashed and solid) to generate the subproblems: the number of roots also drops by 2 since the separator touches 3 shortest-path arborescences. Any solution that is connected from the new contracted root will be connected from either r_1, r_2 or r_4 using the thick and solid edges after uncontracting.

(with no vertices not even r_i). Since T is a partial multi-rooted arborescence that contains $P_1 \cup P_2 \cup P_3$ as a subgraph, every weakly connected components of $G \setminus T$ has at most $\frac{|X|}{2}$ terminals. This finishes the proof of parts (a) and (b).

Property (c) follows from Lemma 11 and the fact that the conditions in Lemma 11 are satisfied. ◀

The algorithm for the multi-rooted version is the same as Algorithm 1 with the following two tweaks: (1) in the preprocessing step we remove vertices v where $d\big(\{r_1, \ldots, r_R\}, v\big) > \widetilde{\text{opt}}$, and (2) instead of Corollary 4 we apply Lemma 12 to obtain the subinstances.

Next, we analyze the cost and the running time of this algorithm.

▶ **Lemma 13** (Cost and running time, multi-rooted). *Consider an instance* $I = \big(G = (V, E), w, \{r_1, \ldots, r_R\}, X\big)$ *and a pair* $(I, \widetilde{\text{opt}})$. *Let* ℓ *and* $\mathcal{O}$ *be non-negative integers such that* $|X| \leq 2^\ell$ *and* $\widetilde{\text{opt}} \leq 2^{\mathcal{O}}$. *If* $\widetilde{\text{opt}} \geq \text{opt}$ *where* opt *is the optimal value of* I, *then* $\text{DST}(I, \widetilde{\text{opt}}) \leq \big(8 \cdot (R + \ell) + 1\big) \cdot \text{opt}$ *and the number of recursive calls is at most* $|X| \cdot 2^{2 \cdot \ell + \mathcal{O}}$.

Proof. The proof of the number of recursive calls is exactly the same as in the proof of Lemma 8. So we turn to proving the bound on the returned solution's cost.

The proof is by induction on $R + \ell + \mathcal{O}$. As in the proof of Lemma 8, we only need to focus on the case that $\widetilde{\text{opt}} \leq 2 \cdot \text{opt}$ and show that $\text{cost}(\mathcal{F}_2) \leq \big(8 \cdot (R + \ell) + 1\big) \cdot \text{opt}$.

Let $T = F \cup (\bigcup_{i=1}^{R} T_i)$ be the partial multi-rooted arborescence obtained from Lemma 12. Suppose T contains R' many of the roots. Then, exactly R' many of T_i's are non-empty. By Lemma 12 (a) we have that each non-empty T_i is consists of up to four shortest dipaths rooted at r_i so $\text{cost}(T_i) \leq 4 \cdot \widetilde{\text{opt}}$ because of the preprocessing step plus the fact that $\widetilde{\text{opt}} \leq 2 \cdot \text{opt}$, we conclude

$$\text{cost}(T \setminus F) \leq 8 \cdot R' \cdot \text{opt}\,. \tag{3}$$

Since T contains R' many roots, each subinstance I_{C_i} induced by $(G, T, C_1, \ldots, C_h)$ has at most $R - R' + 1$ many roots for $1 \leq i \leq h$. Furthermore, by Lemma 12 (b) each I_{C_i}'s has at most $\frac{|X|}{2} \leq 2^{\ell-1}$ many terminals. So by induction hypothesis, for $i = 1, \ldots, h$ we have

$$\text{cost}(\mathcal{F}_{C_i}) \leq \Big(8 \cdot \big((R - R' + 1) + \ell - 1\big) + 1\Big) \cdot \text{opt}_{I_{C_i}} \leq \big(8 \cdot (R - R' + \ell) + 1\big) \cdot \text{opt}_{I_{C_i}}\,. \tag{4}$$

Using Lemma 12 (c), the bounds in (3) and (4) we have

$$\begin{aligned}
\text{cost}(\mathcal{F}) &\leq \text{cost}(T \setminus F) + \sum_{i=1}^{h} \text{cost}(\mathcal{F}_{I_{C_i}}) \\
&\leq 8 \cdot R' \cdot \text{opt} + \big(8 \cdot (R - R' + \ell) + 1\big) \cdot \sum_{i=1}^{h} \text{opt}_{I_{C_i}} \\
&\leq 8 \cdot R' \cdot \text{opt} + \big(8 \cdot (R - R' + \ell) + 1\big) \cdot \text{opt} \\
&= \big(8 \cdot (R + \ell) + 1\big) \cdot \text{opt},
\end{aligned}$$

where the third inequality follows from the fact that $\sum_{i=1}^{h} \text{opt}_{I_{C_i}} \leq \text{opt}$ as the restriction of OPT on each G_{C_i} is a feasible solution for I_{C_i} and G_{C_i}'s are edge-disjoint.. ◀

Proof of Theorem 2. Note both of the tweaks in Algorithm 1 are implementable in polynomial time. The proof has exactly the same structure as in the proof of Theorem 1 with the difference that we use Lemma 13 here instead of Lemma 8. ◀

5 Concluding Remarks

One possible direction is to extend our result to minor-free families of graphs. However, as pointed out in [1, 8], minor-free (undirected) graphs do not have shortest-path separators. In [8], Cohen-Addad bypassed this difficulty by designing a new separator called a *mixed separator* for undirected minor-free graphs. It is not clear that analogous separators exist in directed graphs. For example, the mixed separators in [8] are obtained, in part, by contracting certain paths. These paths are obtained using structural results in minor-free graphs [18] and it is not clear how to find analogous paths in the directed case. Obtaining an $O(\log k)$-approximation for DST in minor-free graphs remains an interesting open problem.

6 Proof of Lemma 5

Proof. Let $\Delta := \max_{t \in X} \Big\{ d\big(\{r_1, \ldots, r_R\}, t\big) \Big\}$, i.e., Δ is the maximum distance from any root to a terminal. Let opt_I be the optimal value of instance I. Then, $\Delta \leq \text{opt}_I \leq k \cdot \Delta$.

If $\Delta = 0$, then $\text{opt}_I = 0$ and the collection of all shortest dipaths from the roots to the terminals is a solution of cost 0. So we assume $\Delta > 0$.

We can safely remove any edge e having $c_e > k \cdot \Delta$ and any Steiner node v (along with its incident edges) having $d(\{r_1, \ldots, r_R\}, v) > k \cdot \Delta$ since no optimal solution of I uses e or v. Since we have only deleted elements of G, it remains planar.

Define a new edge costs $c'_e := \lceil c_e \cdot \frac{n}{\epsilon \cdot \Delta} \rceil$ and form the instance $I' = (G, c', \{r_1, \ldots, r_R\}, X)$. Note for any shortest dipath P starting at root r_i, we have

$$\text{cost}_{c'}(P) \leq \sum_{e \in P} c'_e \leq \sum_{e \in P} (c_e \cdot \frac{n}{\epsilon \cdot \Delta} + 1) \leq \text{cost}_c(P) \cdot \frac{n}{\epsilon \cdot \Delta} + n \leq \frac{n \cdot k}{\epsilon} + n,$$

where the last inequality follows because all the distances from the root has length at most $k \cdot \Delta$. So all the shortest dipaths starting at r in I' are bounded by $O(\frac{n^2}{\epsilon})$.

Let $\text{opt}_{I'}$ be the optimal value of instance I'. Similar calculation as before shows $\text{opt}_{I'} \leq \frac{n}{\epsilon \cdot \Delta} \cdot \text{opt}_I + n$.

Let F be an α-approximate solution for I'. Then, we have

$$\begin{aligned}
\text{cost}_c(F) &\leq \frac{\epsilon \cdot \Delta}{n} \cdot \text{cost}_{c'}(F) \\
&\leq \frac{\epsilon \cdot \Delta}{n} \cdot \alpha \cdot \text{opt}_{I'} \\
&\leq \frac{\epsilon \cdot \Delta}{n} \cdot \alpha \cdot (\frac{n}{\epsilon \cdot \Delta} \cdot \text{opt}_I + n) \\
&\leq \alpha \cdot \text{opt}_I + \alpha \cdot \epsilon \cdot \Delta \\
&\leq \alpha \cdot (1 + \epsilon) \cdot \text{opt}_I,
\end{aligned}$$

where the first inequality follows because $c'_e \geq c_e \cdot \frac{n}{\epsilon \cdot \Delta}$ and the last because $\text{opt}_I \geq \Delta$. ◀

Parallel Self-Testing of EPR Pairs Under Computational Assumptions

Abstract

Self-testing is a fundamental feature of quantum mechanics that allows a classical verifier to force untrusted quantum devices to prepare certain states and perform certain measurements on them. The standard approach assumes at least two spatially separated devices. Recently, Metger and Vidick [39] showed that a single EPR pair of a single quantum device can be self-tested under *computational assumptions*. In this work, we generalize their results to give the first parallel self-test of N EPR pairs and measurements on them in the single-device setting under the same computational assumptions. We show that our protocol can be passed with probability negligibly close to 1 by an honest quantum device using $\mathrm{poly}(N)$ resources. Moreover, we show that any quantum device that fails our protocol with probability at most ϵ must be $\mathrm{poly}(N, \epsilon)$-close to being honest in the appropriate sense. In particular, our protocol can test any distribution over tensor products of computational or Hadamard basis measurements, making it suitable for applications such as device-independent quantum key distribution [38] under computational assumptions. Moreover, a simplified version of our protocol is the first that can efficiently certify an arbitrary number of qubits of a single cloud quantum computer using only classical communication.

1 Introduction

Self-testing is a fundamental feature of quantum mechanics that allows a classical verifier to force a quantum device (sometimes called prover) to prepare certain states and measure them in certain bases up to local isometries [4, 47, 50, 43, 7, 35, 48, 18, 25, 8, 36, 37, 41, 42, 13, 20, 46, 45, 19, 28]. In the standard *nonlocal setting*, the key assumption is that there are two

or more spatially separated devices. However, it is difficult to certify spatial separation in practice, especially if the devices fall outside our physical control. Therefore, it is interesting to ask whether we can replace this assumption by another one so that we can self-test a *single* quantum device. We illustrate the nonlocal and single-device settings in Fig. 1.

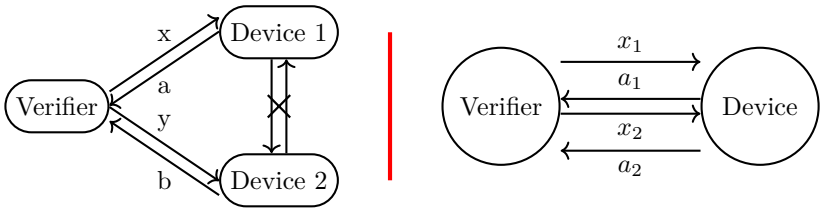

Figure 1 Self-testing in the nonlocal setting (left) involves (at least) two spatially separated devices that cannot communicate. In the single-device setting (right), there is only one device.

Computational self-testing. Recently, beginning with seminal work by Mahadev [33] on the classical verification of quantum computations, a series of works, e.g., [24, 6, 14, 1, 52, 53, 29, 5, 27, 32, 55, 39, 38, 40], have explored how computational assumptions can be leveraged by a classical verifier to control a single quantum device in certain ways. Typically, the assumption used is that the Learning-With-Errors (LWE) [44] problem is hard to solve efficiently, even for quantum computers, which is a standard assumption. However, except for [24, 53, 39, 38, 40], the level of control established in these works is much weaker than in nonlocal self-testing. For example, if a device passes Mahadev's verification protocol [33], it only means that, to quote [39], "*there exists* a quantum state such that the distribution over the prover's answers *could have been* produced by performing the requested measurements on this state". We do not know whether the prover *actually* prepared that state and performed the requested measurements on it.

Metger and Vidick [39] are the first to explicitly propose the self-testing of a single device under computational assumptions. The main limitation of [39] and follow-up work [40] is that they only self-test two and three qubits, respectively. In this work, we introduce a self-test that certifies the preparation and measurement of N EPR pairs in the computational (or single-device) setting. Our work differs from the concurrent work [23] in that [23] certifies the preparation (but not measurement) of BB84 states.

Main results. We give a self-test that certifies the EPR pairs:

$$\left\{ |\tau^{\diamond,v}\rangle \coloneqq \frac{1}{\sqrt{2^N}} \bigotimes_{i=1}^{N} (\sigma^X)^{v_i} \otimes (\sigma^X)^{v_{N+i}} (|0\rangle_i |+\rangle_{N+i} + |1\rangle_i |-\rangle_{N+i}) \;\middle|\; v \in \{0,1\}^{2N} \right\},$$

and states $\{|\tau^{\theta,v}\rangle \mid \theta \in \{0,1\ldots,2N\}, v \in \{0,1\}^{2N}\}$, which is a subset of BB84 states specified in Section 3.

Moreover, our self-test certifies any distribution over tensor products of computational (Pauli-Z) or Hadamard (Pauli-X) basis measurements on $2N$ qubits:

$$\left\{ \left\{ \Pi_q^u \coloneqq |B_{q_1}^{u_1}\rangle\langle B_{q_1}^{u_1}| \otimes \ldots \otimes |B_{q_{2N}}^{u_{2N}}\rangle\langle B_{q_{2N}}^{u_{2N}}| \;\middle|\; u \in \{0,1\}^{2N} \right\} \;\middle|\; q \in \{0,1\}^{2N} \right\}, \tag{1}$$

where $|B_0^0\rangle \coloneqq |0\rangle, |B_0^1\rangle \coloneqq |1\rangle, |B_1^0\rangle \coloneqq |+\rangle$, and $|B_1^1\rangle \coloneqq |-\rangle$.

Our self-test generalizes protocols in [24, 39] and uses the Extended Noisy Trapdoor Claw-Free function Families (ENTCFs) introduced by Mahadev in [33]. An ENTCF consists of two function-pair families, a claw-free family $\mathcal{F}$ and an injective family $\mathcal{G}$, that have certain cryptographic properties under the LWE hardness assumption.

In our self-test, the classical verifier first samples $\theta \in \{0, 1, \ldots, 2N\} \cup \{\diamond\}$ uniformly at random. Then it generates the public keys and trapdoors of $2N$ function pairs from $\mathcal{F} \cup \mathcal{G}$ according to θ as follows.

1. $\theta = 0$: all pairs are from $\mathcal{G}$.
2. $\theta \in \{1, \ldots, 2N\}$: the θ^{th} pair is from $\mathcal{F}$ and the remaining $2N - 1$ pairs are from $\mathcal{G}$.
3. $\theta = \diamond$: all pairs are from $\mathcal{F}$.

The verifier sends the public keys to the device. The device then sends back $2N$ images, $y_1, \ldots, y_{2N}$, of these function pairs – these play the role of a commitment. In the second round, the verifier either (i) checks the commitment by asking for preimages of the y_is and accepts or rejects accordingly, or (ii) asks for an equation involving the preimages of the y_is. In case (ii), there is a final round where the verifier sends with probability $1/2$ a uniformly random $q \in \{0^{2N}, 1^{2N}, 0^N1^N, 1^N0^N\}$ and with probability $1/2$ a random $q \in \{0,1\}^{2N}$ according to some distribution μ of its choosing. The device sends back the result $u \in \{0,1\}^{2N}$ of performing some measurement $\{P_q^u\}_u$. The verifier lastly checks that u is consistent with measuring $|\tau^{\theta,v}\rangle$ using $\{\Pi_q^u\}_u$, where $v \in \{0,1\}^{2N}$ is some bitstring that the verifier can compute efficiently using the trapdoors, and accepts or rejects accordingly. We allow our verifier to pick any distribution μ on $q \in \{0,1\}^{2N}$ so that our protocol can be composed with other protocols. For example, in our applications, the distribution on $q \in \{0,1\}^{2N}$ is non-uniform.

▶ **Theorem 1** (Informal). *Let $\lambda \in \mathbb{N}$ be a security parameter and let $N = \text{poly}(\lambda)$ be a fixed polynomially-bounded function of λ. Assuming the LWE problem of size λ cannot be solved in $\text{poly}(\lambda)$ time, our self-test satisfies the following properties.*

Completeness. *Using $\text{poly}(\lambda)$ qubits and quantum gates, a quantum device can prepare one of the $2N$-qubit states in $\{|\tau^{\theta,v}\rangle \mid \theta \in \{0, 1, \ldots, 2N\} \cup \{\diamond\}, v \in \{0,1\}^{2N}\}$ and measure it using $\{\Pi_q^u \mid u \in \{0,1\}^{2N}\}$ upon question $q \in \{0,1\}^{2N}$ to pass our self-test with probability $\geq 1 - \text{negl}(\lambda)$. Moreover, the verifier can be classical and run in $\text{poly}(\lambda)$ time.*

Soundness. *If a quantum device passes our self-test in $\text{poly}(\lambda)$ time with probability $\geq 1 - \epsilon$, then the device must have prepared a (sub-normalized) state $\sigma^{\theta,v}$, measured it using $\{P_q^u\}_u$, and received outcome u, such that*

$$\sum_{v \in \{0,1\}^{2N}} \|V\sigma^{\theta,v}V^\dagger - |\tau^{\theta,v}\rangle\langle\tau^{\theta,v}| \otimes \alpha^{\theta,v}\|_1 \leq O(N^{7/4}\epsilon^{1/32}) \quad \textit{and} \tag{2}$$

$$\mathbb{E}_{q \leftarrow \mu}\Big[\sum_{u,v \in \{0,1\}^{2N}} \|VP_q^u\,\sigma^{\theta,v}\,P_q^uV^\dagger - \Pi_q^u\,|\tau^{\theta,v}\rangle\langle\tau^{\theta,v}|\,\Pi_q^u \otimes \alpha^{\theta,v}\|_1\Big] \leq O(N^2\epsilon^{1/32}), \tag{3}$$

where $\theta \in \{0, 1, \ldots, 2N\} \cup \{\diamond\}$, μ is the distribution on $\{0,1\}^{2N}$ chosen by the verifier in our self-test, $u, v \in \{0,1\}^{2N}$ are known to the verifier, V is an efficient isometry independent of $\{\theta, \mu, u, v\}$, and the $\alpha^{\theta,v}$s are some auxiliary states that are computationally indistinguishable from some fixed state α.

Note that $\theta = \diamond$ corresponds to self-testing EPR pairs. We also highlight the $\text{poly}(N, \epsilon)$ soundness error (or robustness) that we achieve. Good robustness is critical if we want to use our self-test in practice because real quantum devices are imperfect. The more imperfect a device is, the more robust a self-test needs to be to control it.

Techniques. The main challenge is to prove soundness. We give a high-level overview here and provide more details in Section 4. We start by defining $4N$ observables of the device $\{X_i, Z_i \mid i \in [2N]\}$ using its measurement operators. The strategy is to characterize these observables as the standard σ_i^X and σ_i^Z Pauli observables on $2N$ qubits where i indexes

those qubits. Then, we characterize the device's states by their invariance under products of projectors corresponding to these observables and the device's measurements as products of these projectors. To characterize X_i and Z_j, we first generalize techniques in [39] to show that X_i and Z_j obey certain state-dependent commutation and anti-commutation relations (Proposition 10). To carry out the generalization, it is important for the verifier to select θ from the set $[2N] \cup \{0, \diamond\}$ for two reasons. The first is that they allow us to bound the failure probability associated with *each* σ^θ by $2N + 2$ (the number of possible θs) times the *average* failure probability over all θs. The second is that this restricted set of θs suffices for us to characterize X_i and Z_i as σ_i^X and σ_i^Z. Intuitively, $\theta = 0$ is used to characterize $\{Z_1, \ldots, Z_{2N}\}$, $\theta \in [2N]$ is used to characterize X_θ, and $\theta = \diamond$ is used to characterize EPR pairs. We give a more precise correspondence in Table 1.

Then, we introduce new techniques to handle products of projectors corresponding to the X_i, Z_i observables. These techniques differ significantly from [39] because their techniques are not susceptible to generalization to arbitrary N (as we discuss after Proposition 15). These techniques also differ significantly from those used in nonlocal self-testing because we lack the perfect state-*independent* commutation relations between observables on two spatially-separated devices. More specifically, we introduce a "operator-state commutation" relation (Proposition 11) that, together with the computational indistinguishability of the σ^θs (which follows from the LWE hardness assumption), gives us the ability to "commute an observable past a state". We then use this ability to handle products of projectors. The usefulness of the ability to commute can be seen in the following simple example. Observe that $X_1 Z_2 X_3 \psi = Z_2 X_1 X_3 \psi$ (1) does not follow from the commutation relation $X_1 Z_2 \psi = Z_2 X_1 \psi$, where ψ is some density operator. However, (1) would follow if we could commute X_3 past ψ first because X_1 and Z_2 would then be directly next to ψ. Having all (1)-like relations involving products of up to N X_i and Z_i implies that these observables can be characterized as σ_i^X and σ_i^Z respectively, which follows from results in approximate representation theory [51, 26]. We remark that the preceding discussion is for intuition only: in fact, our proof directly shows that an explicit "swap" isometry (defined in Definition 12) approximately maps X_i and Z_i to σ_i^X and σ_i^Z respectively.

Applications. We present two applications of our result, the first is for device-independent (DI) quantum key distribution (QKD), and the second is for dimension testing. We stress that for both applications, we crucially rely on the characterization of *measurements* in Equation (3) of Theorem 1.

DIQKD. A DI protocol is one where the parties involved do not need to trust the inner working of the devices they use to be sure that the devices have successfully implemented the protocol. A QKD protocol is one for establishing information-theoretically secure keys between two parties. Previous DIQKD protocols rely on the nonlocal assumption. This assumption is usually justified experimentally by spatially separating two devices by a large distance, which is difficult to implement. Recently, Metger et. al. [38] proposed a different setting for DIQKD: they replace the nonlocal assumption with the assumption that the two devices are computationally bounded. However, since their protocol sequentially repeats the self-test in [39], their soundness proof relies on the IID assumption that the device behaves identically and independently at each repetition to argue that it has prepared and measured many EPR pairs.

Our DIQKD protocol consists of a random number of "test rounds" followed by a final "generation round", where both round types are based on our self-test. The N EPR pairs certified in the generation round are used to generate $\Omega(N)$ shared keys. Because of the

parallel nature of our self-test, our DIQKD protocol does not require the IID assumption. We sketch a soundness proof that uses a "cut-and-choose" argument from [23, Theorem 4.33] to upper bound the failure probability of the device in the generation round, conditioned on the protocol not aborting in the test rounds. This argument does not require an IID assumption *between* rounds. Then, we use Equation (3) of Theorem 1 to lower bound the key rate, which does not require an IID assumption *within* any round. Hence we remove the IID assumption overall. The application of our self-test to remove the IID assumption from DIQKD in the computational setting can be viewed as analogous to the application of the nonlocal self-test to remove the IID assumption from DIQKD in the usual nonlocal setting [45].

Dimension testing. Our dimension-test is a simplified version of our self-test and is inspired by the non-local dimension test in [11] and its exposition in [51, Section 2.5.2]. The protocol in [11] works as follows. The verifier chooses a random bit $\theta \in \{0,1\}$ and random bitstring $x \in \{0,1\}^n$ and sends n qubits to the device such that the qubits encode x in the computational basis ($\theta = 0$) or in the Hadamard basis ($\theta = 1$). After the device has received all n qubits, the verifier sends θ to the device and asks it to return a bitstring $x' \in \{0,1\}^n$. If $x' = x$, the verifier certifies that the device has a large quantum dimension. Our protocol can be viewed as a version of this protocol, where the verifier classically delegates the preparation of the appropriate n-qubit states to the prover in a secure manner. Although our protocol is inspired by [11], our security proof uses Theorem 1 and differs significantly from that in [11].

We prove that, under the same computational assumptions as in Theorem 1, if a quantum device runs in $\text{poly}(\lambda)$ time and passes our dimension-test with probability $\geq 1 - \epsilon$, then its quantum dimension is at least $(1 - O(N^2\epsilon^{1/32}))2^N$ $(*)$. To obtain a non-trivial bound, it suffices to estimate ϵ to precision $1/\text{poly}(N)$, which can be done by repeating the dimension-test $\text{poly}(N)$ times. Since a single run of the dimension test also only takes $\text{poly}(N)$ time, the total time taken is $\text{poly}(N)$. Intuitively, we prove $(*)$ by using Equation (3) of Theorem 1 to argue that the Hilbert space $\mathcal{H}$ of the device must be able to accommodate all possible post-measurement states that could result from performing a Hadamard basis measurement of N qubits in a computational basis state. Since there are 2^N such post-measurement states, and they are all orthogonal, we deduce a quantum dimension lower bound of 2^N. A formal proof is more challenging because Equation (3) of Theorem 1 gives an approximation and we need to prove that the rank of a quantum state is robust against the approximation error.

Compared to nonlocal dimension-tests [9, 10, 17], the advantage of ours is that we do not need to assume spatial separation between multiple devices. Compared to prepare-and-measure dimension-tests [22, 12, 13, 11], the advantage of ours is that the verifier does not need to be quantum – all computations and communications are classical. To the best of our knowledge, our dimension-test is the first[1] that can test for an arbitrary quantum dimension in the computational setting. In fact, whether this is possible was recently raised as an open question by Vidick in [51, pg. 84].

Discussion. One interesting direction is to further improve the efficiency and robustness of our protocol. When $N = \lambda$, one bottleneck in improving the efficiency is that sending (the public key of) one function pair already requires $\text{poly}(\lambda) = \text{poly}(N)$ bits of communication. In recent work, it has been shown that, instead of sending the public keys, the verifier can apply a *succinct batch key generation algorithm* to reduce the cost of sending public keys [3]. We expect that techniques in [3] can be used to shorten other messages of our protocol as

[1] More recently, [34] also claims a dimension test using completely different methods.

well. Turning to robustness, we note that there exists a nonlocal self-test [41] which uses poly(N) bits of communication and achieves robustness poly(ϵ). It might be possible to combine our techniques with those in [41] to achieve similar robustness in the computational setting. Another interesting question to ask is what MIP* protocols can be compiled into computation delegation protocols under computational assumptions. For comparison, it has been shown that classical MIP protocols sound against non-signalling provers can be turned into computation delegation protocols [49, 31]. It would also be interesting to see if a systematic way exists to translate nonlocal self-tests into computational ones. We note that [29] suggests that the two settings might not be too different at a conceptual level by presenting a test of quantumness in the computational setting that closely resembles the nonlocal CHSH test [16]. Recently, Kalai et. al. proposed a way to construct a proof-of-quantumness protocol from any nonlocal game with a classical and quantum separation using quantum homomorphic encryption [30]. However, it is unknown if the aforementioned protocols are quantumly sound. Going beyond quantum dimension testing, it would be interesting to see if our protocol can be combined with those that test quantum circuit depth [15, 2] to give a protocol that tests the quantum volume of a quantum computer.

2 Preliminaries

Notation. $\mathbb{N}$ is the set of positive integers. For $k \in \mathbb{N}$, we write $[k] \coloneqq \{1, 2, \ldots, k\}$. For a probability distribution μ on X, we use the notation $x \leftarrow_\mu X$ to mean that x is sampled from X according to μ. $\mathcal{H}$ denotes a finite-dimensional Hilbert space, $\mathcal{L}(\mathcal{H})$ denotes the set of linear operators on $\mathcal{H}$, and $\mathrm{Pos}(\mathcal{H})$ denotes the set of positive semi-definite operators on $\mathcal{H}$. We sometimes refer to operators in $\mathrm{Pos}(\mathcal{H})$ or vectors in $\mathcal{H}$, not necessarily normalized, as (quantum) states. For an operator $X \in \mathcal{L}(\mathcal{H})$, we write $\|X\|_p \coloneqq \mathrm{Tr}[|X|^p]^{1/p}$, where $|X| \coloneqq \sqrt{X^\dagger X}$, for the Schatten p-norm. For $\phi, \psi \in \mathcal{L}(\mathcal{H})$, we write $\phi \approx_\epsilon \psi$ to mean $\|\phi - \psi\|_1^2 \leq O(\epsilon)$. For $A, B \in \mathcal{L}(\mathcal{H})$ and $\psi \in \mathrm{Pos}(\mathcal{H})$, we write $\|A\|_\psi^2 \coloneqq \mathrm{Tr}[A^\dagger A \psi] = \|A\sqrt{\psi}\|_2^2$ and $A \approx_{\epsilon,\psi} B \iff \|A - B\|_\psi^2 \leq O(\epsilon)$. The single-qubit Z and X Pauli operators are denoted $\sigma_Z \coloneqq \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$ and $\sigma_X \coloneqq \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ which have eigenstates $\{|0\rangle \coloneqq \left(\begin{smallmatrix} 1 \\ 0 \end{smallmatrix}\right), |1\rangle \coloneqq \left(\begin{smallmatrix} 0 \\ 1 \end{smallmatrix}\right)\}$ and $\{|(-)^0\rangle \coloneqq \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle), |(-)^1\rangle \coloneqq \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)\}$, respectively.

We write $\lambda \in \mathbb{N}$ for the security parameter. Most quantities in this work are dependent on λ. Therefore, for convenience, we often make the dependence implicit. A function $f : \mathbb{N} \to \mathbb{R}$ is said to be negligible if for any polynomial $p \in \mathbb{R}[x]$, $\lim_{\lambda \to \infty} f(\lambda)p(\lambda) = 0$. We denote such functions by $\mathrm{negl}(\lambda)$.

ENTCFs. We informally summarize the properties that we employ of Extended Noisy Trapdoor Claw-free function Families (ENTCFs). For full details about the properties of ENTCFs, see the arXiv version of [33].

Let $\lambda \in \mathbb{N}$ be a security parameter. Let $\mathcal{X} \subseteq \{0,1\}^w$ and $\mathcal{Y}$ be finite sets that depend on λ, where $w = w(\lambda)$ is some integer that is a polynomially-bounded function of λ. An ENTCF consists of two families of function pairs, $\mathcal{F}$ and $\mathcal{G}$. Function pairs from these two families are labeled by public keys. The set of public keys for $\mathcal{F}$ is denoted by $\mathcal{K}_\mathcal{F}$, and the set of public keys for $\mathcal{G}$ is denoted by $\mathcal{K}_\mathcal{G}$. For $k \in \mathcal{K}_\mathcal{F}$, a function pair $(f_{k,0}, f_{k,1})$ from $\mathcal{F}$ is called a *claw-free* pair. For $k \in \mathcal{K}_\mathcal{G}$, a function pair $(f_{k,0}, f_{k,1})$ from $\mathcal{G}$ is called an *injective* pair. For any $k \in \mathcal{K}_\mathcal{F} \cup \mathcal{K}_\mathcal{G}$, the functions[2] $f_{k,0}$, $f_{k,1} \colon \mathcal{X} \to \mathcal{Y}$. Note that the keys and function pairs of an ENTCF are functions of λ. We use the terms "efficient" and "negligible" to refer to poly(λ)-time and negl(λ) respectively. We need the following properties of ENTCFs:

[2] This is a convenient simplification. These functions actually map to probability distributions on $\mathcal{Y}$. See Section 2.2 of the full version for details.

1. *Efficient function generation property* [33, Definitions 4.1 (1), 4.2 (1)]. There exist efficient classical probabilistic algorithms $\mathrm{Gen}_{\mathcal{F}}$ and $\mathrm{Gen}_{\mathcal{G}}$ for $\mathcal{F}$ and $\mathcal{G}$ respectively with $\mathrm{Gen}_{\mathcal{F}}(1^\lambda) \to (k \in \mathcal{K}_{\mathcal{F}}, t_k)$ and $\mathrm{Gen}_{\mathcal{G}}(1^\lambda) \to (k \in \mathcal{K}_{\mathcal{G}}, t_k)$, where t_k is known as a trapdoor.
2. *(Disjoint) injective pair property* [33, Definitions 4.1 (2), 4.2 (2)]. For all $k \in \mathcal{K}_{\mathcal{F}} \cup \mathcal{K}_{\mathcal{G}}$, $x, x' \in \mathcal{X}$ with $x \neq x'$, and $b \in \{0,1\}$, $f_{k,b}(x) \neq f_{k,b}(x')$. For all $k \in \mathcal{K}_{\mathcal{F}}$ and $x \in \mathcal{X}$, there exists an $x' \neq x$ such that $f_{k,0}(x) = f_{k,1}(x')$. We call any such pair of (x, x') a *claw*.
3. *Efficient range superposition property* [33, Definitions 4.1 (3.c), 4.2 (3.b), 4.3 (1)]. Given $k \in \mathcal{K}_{\mathcal{F}} \cup \mathcal{K}_{\mathcal{G}}$, there exists an efficient quantum algorithm that prepares a state that is negligibly close to $|\psi\rangle := \frac{1}{\sqrt{2\cdot|\mathcal{X}|}} \sum_{b\in\{0,1\}} \sum_{x\in\mathcal{X}} |b\rangle\,|x\rangle\,|f_{k,b}(x)\rangle$, in trace distance.
4. *Efficient decoding property* [33, Definitions 4.1 (2, 3.a, 3.b), 4.2 (2, 3.a), 4.3 (1)]. We define the following "decoding maps" that decode the output of functions from an ENTCF. For $k \in (\mathcal{K}_{\mathcal{F}} \cup \mathcal{K}_{\mathcal{G}})^m$ with $m = \mathrm{poly}(\lambda)$, $k_{\mathcal{G}} \in \mathcal{K}_{\mathcal{G}}$, $k_0 \in \mathcal{K}_{\mathcal{F}} \cup \mathcal{K}_{\mathcal{G}}$, and $k_{\mathcal{F}} \in \mathcal{K}_{\mathcal{F}}$

   $$\mathrm{CHK}(k, y, b, x) = 0 \text{ if } y_i = f_{k_i,b_i}(x_i) \text{ for all } i \in [m], \text{ else } = 1$$
   $$\hat{b}(k_{\mathcal{G}}, y) = b \text{ if } y \in \mathrm{Im}(f_{k_{\mathcal{G}},b}), \text{ else } = \perp$$
   $$\hat{x}(b, k_0, y) := x \text{ if } f_{k_0,b}(x) = y, \text{ else } = \perp$$
   $$\hat{h}(k_{\mathcal{F}}, y, d) := d \cdot (\hat{x}(0, k_{\mathcal{F}}, y) \oplus \hat{x}(1, k_{\mathcal{F}}, y)) \text{ if } y \in \mathrm{Im}(f_{k_{\mathcal{F}},0}) \text{ and } d \neq 0^w, \text{else } = \perp .$$

   The efficient decoding property states that $\hat{b}$, $\hat{x}$, and $\hat{h}$ can be computed efficiently given a trapdoor t_k for k by a classical deterministic algorithm and that CHK can be computed efficiently even without a trapdoor by a classical deterministic algorithm.
5. *Adaptive hardcore bit property* [33, Definition 4.1 (4)]. There does not exist an efficient quantum algorithm that, given $k \leftarrow \mathrm{Gen}_{\mathcal{F}}(1^\lambda)_{\mathrm{key}}$, can compute $b \in \{0,1\}$ and $x_b \in \mathcal{X}$ for some $b \in \{0,1\}$, $d \in \{0,1\}^w \backslash \{0^w\}$, and, with non-negligible advantage, a bit $d \cdot (x_0 \oplus x_1) \in \{0,1\}$ such that (x_0, x_1) is a claw.
6. *Injective invariance property* [33, Definition 4.3 (2)]. There does not exist an efficient quantum algorithm that can distinguish between the marginal key distributions of $\mathrm{Gen}_{\mathcal{F}}(1^\lambda)$ and of $\mathrm{Gen}_{\mathcal{G}}(1^\lambda)$ with non-negligible advantage.

3 Completeness of self-testing protocol

In this section, we present our self-testing protocol in Fig. 2. We sketch a proof of its completeness (Theorem 2), partly to establish some notation. For details, see Section 3 of the full version.

▶ **Theorem 2.** *There exists an efficient quantum device that is accepted by our self-testing protocol with probability* $\geq 1 - \mathrm{negl}(\lambda)$. *Moreover, the classical verifier is efficient.*

Proof sketch. In the first round, for each $i \in [2N]$, by the efficient range superposition property of ENTCFs (Item 3), the device uses k_i to efficiently prepare a state that is negligibly close to

$$|\psi_i\rangle := \frac{1}{\sqrt{2\cdot|\mathcal{X}|}} \sum_{b\in\{0,1\}} \sum_{x\in\mathcal{X}} |b\rangle\,|x\rangle\,|f_{k_i,b}(x)\rangle\,.$$

Then, the device measures the (image) y register of $|\psi_i\rangle$ and sends the outcome to the verifier. By the (disjoint) injective pair property of ENTCFs (Item 2), after the y measurement, the state $|\psi_i\rangle$ collapses to $|\phi_i\rangle\,|y_i\rangle$, where

$$|\phi_i\rangle := \begin{cases} |\hat{b}(k_i, y_i)\rangle\,|\hat{x}(k_i, y_i)\rangle & \text{if } k_i \in \mathcal{K}_{\mathcal{G}}, \\ \frac{1}{\sqrt{2}}(|0\rangle\,|\hat{x}_0(k_i, y_i)\rangle + |1\rangle\,|\hat{x}_1(k_i, y_i)\rangle) & \text{if } k_i \in \mathcal{K}_{\mathcal{F}}. \end{cases}$$

1. Input: $\lambda \in \mathbb{N}$. Set $N = \mathrm{poly}(\lambda)$. Given a distribution μ on $\{0,1\}^{2N}$. Sample $\theta \leftarrow_U [2N] \cup \{0, \diamond\}$ uniformly at random. Sample $2N$ key-trapdoor pairs $(k_1, t_{k_1}), \ldots, (k_{2N}, t_{k_{2N}})$ from an ENTCF according to θ as follows:

   $\theta \in [2N]$: the θ-th key-trapdoor pair is sampled from $\mathrm{Gen}_{\mathcal{F}}(1^\lambda)$ and the remaining $2N-1$ pairs are all sampled from $\mathrm{Gen}_{\mathcal{G}}(1^\lambda)$.

   $\theta = 0$: all the key-trapdoor pairs are sampled from $\mathrm{Gen}_{\mathcal{G}}(1^\lambda)$.

   $\theta = \diamond$: all the key-trapdoor pairs are sampled from $\mathrm{Gen}_{\mathcal{F}}(1^\lambda)$.

Send the keys $k = (k_1, \ldots, k_{2N})$ to the device.

2. Receive $y = (y_1, \ldots, y_{2N}) \in \mathcal{Y}^{2N}$ from the device.

3. Sample round type "preimage" or "Hadamard" uniformly at random and send to the device.

Case "preimage": receive

$$(b, x) = (b_1, \ldots, b_{2N}, x_1, \ldots, x_{2N})$$

from the device, where $b \in \{0,1\}^{2N}$ and $x \in \{0,1\}^{2Nw}$.
If $\mathrm{CHK}(k_i, y_i, b_i, x_i) = 0$ for all $i \in [2N]$, **accept**, else **reject**.

Case "Hadamard": receive

$$d = (d_1, \ldots, d_{2N}) \in \{0,1\}^{2Nw}$$

from the device.

4. With probability $1/2$, sample $q \leftarrow_U \{0^{2N}, 1^{2N}, 0^N 1^N, 1^N 0^N\}$ uniformly at random, and with probability $1/2$ sample $q \leftarrow_\mu \{0,1\}^{2N}$ according to the distribution μ. Send q to the device.

Receive $u \in \{0,1\}^{2N}$ from the device.

case A $\theta = 0$ and
if $q_i = 0$ and $\hat{b}(k_i, y_i) \neq u_i$ for some $i \in [2N]$, **reject**,
else **accept**.

case B $\theta \in [2N]$ and
if $q_i = 0$ and $\hat{b}(k_i, y_i) \neq u_i$ for some $i \neq \theta$, **reject**,
if $q_\theta = 1$ and $\hat{h}(k_\theta, y_\theta, d_\theta) \oplus \hat{b}(k_{\theta+N}, y_{\theta+N}) \neq u_\theta$, **reject**,
else **accept**.

case C $\theta = \diamond$ and
if $q_i = 0$, $q_{N+i} = 1$ and $u_i \oplus u_{N+i} \neq \hat{h}(k_{N+i}, y_{N+i}, d_{N+i})$ for some $i \in [N]$, **reject**,
if $q_i = 1$, $q_{N+i} = 0$ and $u_i \oplus u_{N+i} \neq \hat{h}(k_i, y_i, d_i)$ for some $i \in [N]$, **reject**,
else **accept**.

Figure 2 A protocol that self-tests EPRs of a computationally efficient device.

In the following, we use the shorthand $\hat{b}_i \coloneqq \hat{b}(k_i, y_i) \in \{0,1\}$ and, for $a \in \{0,1\}$, $\hat{x}_{a,i} \coloneqq \hat{x}(a, k_i, y_i) \in \mathcal{X}$.

In the second round, there are two cases, "preimage" or "Hadamard". In the "preimage" case, the device measures the b and x registers of each $|\phi_i\rangle$ in the computational basis and sends the outcome to the device. This will always be accepted by the device using the definition of CHK.

In the "Hadamard" case, the device measures the x register of each $|\phi_i\rangle$ in the Hadamard basis and sends the outcome $d = (d_1, d_2, \ldots, d_{2N})$ to the verifier. After this measurement, $|\phi_i\rangle$ collapses to $|\alpha_i\rangle\,|d_i\rangle$, where, if $\theta \in [2N]$, then

$$|\alpha_i\rangle = \begin{cases} |\hat{b}_i\rangle & \text{if } i \neq \theta, \\ (|0\rangle + (-1)^{d_\theta \cdot (\hat{x}_{0,\theta} \oplus \hat{x}_{1,\theta})}\,|1\rangle)/\sqrt{2} & \text{if } i = \theta; \end{cases}$$

if $\theta = 0$, then $|\alpha_i\rangle = |\hat{b}_i\rangle$; and if $\theta = \diamond$, then $|\alpha_i\rangle = (|0\rangle + (-1)^{d_i \cdot (\hat{x}_{0,i} \oplus \hat{x}_{1,i})}\,|1\rangle)/\sqrt{2}$.

In the following, we use the shorthand $\hat{h}_i \coloneqq d_i \cdot (\hat{x}_{0,i} \oplus \hat{x}_{1,i}) \in \{0,1\}$ and $\hat{h}' \coloneqq (\hat{h}_{N+1}, \ldots, \hat{h}_{2N}, \hat{h}_1, \hat{h}_2, \ldots, \hat{h}_N) \in \{0,1\}^{2N}$.

For $v \in \{0,1\}^{2N}$, we also define the state

$$|\psi^v\rangle := \frac{1}{\sqrt{2^N}} \bigotimes_{i=1}^{N} (\sigma^X)^{v_i} \otimes (\sigma^X)^{v_{N+i}} (|0\rangle_i |+\rangle_{N+i} + |1\rangle_i |-\rangle_{N+i}), \tag{4}$$

which consists of N (locally-rotated) EPR pairs.

Then, the device applies N controlled-σ^Z gates between the i-th and $(N+i)$-th qubits of $\bigotimes_{i=1}^{2N} |\alpha_i\rangle$ for all $i \in [N]$ (note that the controlled-σ^Z gate is independent of which qubit is the control and which qubit is the target). The device has now prepared the $2N$-qubit state

$$|\alpha\rangle := \begin{cases} |\hat{b}_1, \ldots, \hat{b}_{\theta-1}\rangle \, |(-)^{\hat{b}_{\theta+N} \oplus \hat{h}_\theta}\rangle \, |\hat{b}_{\theta+1}, \ldots, \hat{b}_{2N}\rangle & \text{if } \theta \in [2N],\ \theta \leq N, \\ |\hat{b}_1, \ldots, \hat{b}_{\theta-1}\rangle \, |(-)^{\hat{b}_{\theta-N} \oplus \hat{h}_\theta}\rangle \, |\hat{b}_{\theta+1}, \ldots, \hat{b}_{2N}\rangle & \text{if } \theta \in [2N],\ \theta > N, \\ |\hat{b}_1, \ldots, \hat{b}_{2N}\rangle & \text{if } \theta = 0, \\ |\psi^{\hat{h}'}\rangle & \text{if } \theta = \diamond. \end{cases} \tag{5}$$

In the "Hadamard" case, there is a third and final round where the verifier sends a bitstring $q \in \{0,1\}^{2N}$ to the device. The device performs the following q-dependent measurements. For $i \in [2N]$, if $q_i = 0$, measure the ith qubit of $|\alpha\rangle$ in the computational basis, otherwise, measure the ith qubit of $|\alpha\rangle$ in the Hadamard basis. The device finally sends the outcome $u \in \{0,1\}^{2N}$ of these measurements to the verifier. The right-hand side of Equation (5) implies that the device passes the last checks made by the verifier.

The "moreover" part of the theorem follows directly from the efficient function generation and the efficient decoding properties of ENTCFs (Items 1 and 4). ◀

4 Soundness of self-testing protocol

In this section, we show that our self-testing protocol achieves $\mathrm{poly}(N, \epsilon)$ soundness error. Unlike the proof of completeness in Section 3, we use the adaptive hardcore bit and injective invariance properties of ENTCFs to prove soundness in this section. Therefore, it is necessary for us to make the LWE hardness assumption throughout this section. All proofs can be found in Section 4 of the full version.

We start with a mathematical model of quantum devices.

▶ **Definition 3.** *A device $D = (S, M, \Pi, P)$ is specified by Hilbert spaces named $\mathcal{H}_D$, $\mathcal{H}_Y$, and $\mathcal{H}_R$, with $\dim(\mathcal{H}_Y) = |\mathcal{Y}|^{2N}$ and $\dim(\mathcal{H}_R) = 2^{2Nw}$, and the following.*

1. *A set $S := \{\psi^\theta \mid \theta \in [2N] \cup \{0, \diamond\}\} \subset \mathcal{D}(\mathcal{H}_D \otimes \mathcal{H}_Y)$ of states where each state ψ^θ is classical on $\mathcal{H}_Y$:*

$$\psi^\theta := \sum_{y \in \mathcal{Y}^{2N}} \psi_y^\theta \otimes |y\rangle\langle y|.$$

The state ψ_y^θ models the device's state immediately after returning $y \in \mathcal{Y}^{2N}$ to the verifier if the verifier initially sampled $\theta \in [2N] \cup \{0, \diamond\}$. More precisely, ψ_y^θ (and hence ψ^θ) is a function of the public keys $k \in (\mathcal{K}_\mathcal{F} \cup \mathcal{K}_\mathcal{G})^{2N}$ that the verifier sampled according to θ, as described in the protocol. We choose to make the k-dependence implicit for notational convenience.

2. *A projective measurement Π for the preimage test on $\mathcal{H}_D \otimes \mathcal{H}_Y$:*

$$\Pi := \left\{ \Pi^{b,x} := \sum_{y \in \mathcal{Y}^{2N}} \Pi_y^{b,x} \otimes |y\rangle\langle y| \;\middle|\; b \in \{0,1\}^{2N}, x \in \mathcal{X}^{2N} \right\}.$$

The measurement outcome b, x is the device's answer for the preimage test.

3. *A projective measurement M on $\mathcal{H}_D \otimes \mathcal{H}_Y$ for the device's first answer in the Hadamard test:*

$$M \coloneqq \left\{ M^d \coloneqq \sum_{y \in \mathcal{Y}^{2N}} M_y^d \otimes |y\rangle\langle y| \;\middle|\; d \in \{0,1\}^{2Nw} \right\}. \tag{6}$$

We write $\sigma^\theta(D)$ for the classical-quantum state that results from measuring M on ψ^θ followed by writing measurement outcome d into another classical register whose Hilbert space is denoted by $\mathcal{H}_R$. That is,

$$\sigma^\theta(D) \coloneqq \sum_{y \in \mathcal{Y}^{2N},\, d \in \{0,1\}^{2Nw}} \sigma^\theta_{y,d}(D) \otimes |y,d\rangle\langle y,d| \in \mathcal{H}_D \otimes \mathcal{H}_Y \otimes \mathcal{H}_R, \tag{7}$$

where $\sigma^\theta_{y,d}(D) \coloneqq M_y^d \psi_y^\theta M_y^d$.

4. *Projective measurements P_q on $\mathcal{H}_D \otimes \mathcal{H}_Y \otimes \mathcal{H}_R$ for the device's second answer in the Hadamard test when asked questions $q \in \{0,1\}^{2N}$:*

$$P_q \coloneqq \left\{ P_q^u = \sum_{y \in \mathcal{Y}^{2N}, d \in \{0,1\}^{2Nw}} P^u_{q,y,d} \otimes |y,d\rangle\langle y,d| \;\middle|\; u \in \{0,1\}^{2N} \right\}. \tag{8}$$

The measurement outcome v is the device's answer for the question q.

▶ **Definition 4.** *A device $D = (S, \Pi, M, P)$ is efficient if all the states in S can be efficiently prepared and all the measurements $\Pi, M,$ and P are efficient.*

We use P to define observables of the quantum device that we call X_i and Z_i, which should act as Pauli X and Z operators on the ith qubit respectively.

▶ **Definition 5** (Marginal observables)**.** *Let $D = (S, \Pi, M, P)$ be a device. For $i \in [2N]$ and $q \in \{0,1\}^{2N}$, we define the binary observables*

$$Z_{q,i}(D) \coloneqq \sum_{v \in \{0,1\}^{2N}} (-1)^{v_i} P_q^v \quad \text{if } q_i = 0 \quad \text{and} \quad X_{q,i}(D) \coloneqq \sum_{v \in \{0,1\}^{2N}} (-1)^{v_i} P_q^v \quad \text{if } q_i = 1.$$

Note that $Z_{q,j}(D)$ commutes with $X_{q,k}(D)$ for $j \neq k$ according to these definitions.

In the rest of the paper, we use the abbreviations $Z_i(D) \coloneqq Z_{0^{2N},i}(D)$ and $X_i(D) \coloneqq X_{1^{2N},i}(D)$ for all $i \in [2N]$; $\widetilde{Z}_i(D) \coloneqq Z_{0^N 1^N,i}(D)$ if $i \leq N$; $\widetilde{Z}_i(D) \coloneqq Z_{0^N 1^N,i}(D)$ if $i > N$; $\widetilde{X}_i(D) \coloneqq X_{1^N 0^N,i}(D)$ if $i \leq N$; and $\widetilde{X}_i(D) \coloneqq X_{0^N 1^N,i}(D)$ if $i > N$.

For different choices of θ, our goal is to characterize the actions of the observables X_i and Z_i on the state σ^θ, which is the post-M-measurement state defined below.

▶ **Definition 6** ($\sigma^{\theta,v}$)**.** *Let D be a device. For $\theta \in [2N] \cup \{0, \diamond\}$ and $v \in \{0,1\}^{2N}$, we define the state*

$$\sigma^{\theta,v}(D) \coloneqq \sum_{(y,d) \in \Sigma(\theta,v)} \sigma^\theta_{y,d}(D) \otimes |y,d\rangle\, \langle y,d| \in \mathcal{H}_D \otimes \mathcal{H}_Y \otimes \mathcal{H}_R, \tag{9}$$

where, $\Sigma(\theta, v)$ is set to

$$\begin{cases} \left\{(y,d) \;\middle|\; \hat{b}(k_i, y_i) = v_i \text{ for all } i \neq \theta \text{ and } \hat{h}(k_\theta, y_\theta, d_\theta) = v_\theta \oplus v_{\mathrm{mod}(\theta+N,2N)}\right\} & \text{if } \theta \in [2N], \\ \left\{(y,d) \;\middle|\; \hat{b}(k_i, y_i) = v_i \text{ for all } i\right\} & \text{if } \theta = 0, \\ \left\{(y,d) \;\middle|\; \hat{h}(k_i, y_i, d_i) = v_{\mathrm{mod}(i+N,2N)} \text{ for all } i\right\} & \text{if } \theta = \diamond. \end{cases}$$

In all cases, (y,d) ranges over $\mathcal{Y}^{2N} \times \{0,1\}^{2Nw}$, i ranges over $[2N]$, and the state $\sigma^{\theta,v}(D)$ implicitly depends on keys $k \in (\mathcal{K}_\mathcal{F} \cup \mathcal{K}_\mathcal{G})^{2N}$ chosen according to θ as described in the protocol.

Unlike the nonlocal self-testing case, where there is only one state, e.g. EPR pairs, to characterize, we have multiple states and multiple observables to characterize. Hence, we first decompose $\sigma^\theta \approx \sum_{v\in\{0,1\}^{2N}} \sigma^{\theta,v}$, where $\sigma^{\theta,v}$ are defined above. We then characterize the behavior of different observables on different $\sigma^{\theta,v}$ using the failure probabilities of different test cases:

▶ **Definition 7** (Failure probabilities). *Let D be a device. For $q \in \{0,1\}^{2N}$, we define $\epsilon_P(D)$ to be the probability that D fails the preimage test, $\epsilon_{H,q}(D)$ to be the probability that D fails question q of the Hadamard test, and $\epsilon_H(D)$ to be the maximum of $\epsilon_{H,q}(D)$ over $q \in \{0^{2N}, 1^{2N}, 0^N1^N, 1^N0^N\}$. Then, the average failure probability is*

$$\epsilon(D) \coloneqq \epsilon_P(D)/2 + \Big(\sum_{q\in\{0^{2N},1^{2N},0^N1^N,1^N0^N\}} \frac{1}{4}\epsilon_{H,q}(D) + \sum_{q\in\{0,1\}^{2N}} \mu(q)\epsilon_{H,q}(D)\Big)/4.$$

Henceforth, when D is clear from the context, we mostly omit the D dependence.

The probability that this device can pass the tests of our protocol allows us to say that the operator acts in the same way as the ideal operator acts on the ideal state. Therefore, we will use ϵ_P and $\epsilon_{H,q}$ to bound how far away the $Z_{q,i}, X_{q,i}$ observables and $\sigma^{\theta,v}$ states are from the ideal observables and states. How we characterize the states and observables using the passing probabilities of the four key questions: $q = 0^2N$, 1^{2N}, 0^N1^N and 1^N0^N is summarized in Table 1. Note that $q \in \{0^N1^N, 1^N0^N\}$ are for testing EPR pairs.

Table 1 Correspondence between the (θ, q) used in our protocol and the observables tested.

(q_i, q_{i+N}) with $i \le N$	$\theta = 0$	$\theta \in [2N]$	$\theta = \diamond$
$(0,0)$	$Z_{q,i}$ and $Z_{q,i+N}$	-	-
$(1,1)$	-	$X_{q,\theta}$ if $\theta \in \{i, i+N\}$	-
$(0,1)$	-	-	$Z_{q,i} \cdot X_{q,i+N}$
$(1,0)$	-	-	$X_{q,i} \cdot Z_{q,i+N}$

Our use of only $2N+2$ distinct θs allows us to bound the failure probability associated with each σ^θ by $O(N\epsilon)$. If we had naively used $\theta \in \{0,1\}^{2N}$, the robustness of our self-test would be $2^{\Omega(N)}\epsilon$. The fact that using only $2N+2$ distinct θs is *sufficient* for self-testing crucially relies on the following proposition, which can be proven using the injective invariance property of ENTCFs (Item 6).

▶ **Proposition 8.** *Any pair of states in $\{\sigma^\theta \mid \theta \in [2N] \cup \{0, \diamond\}\}$ of an efficient device D are computationally indistinguishable.*

In the next step, we use the computational indistinguishability of the σ^θs to argue that for all (q,i), the observables $Z_{q,i}$ and $X_{q,i}$ act like Z_i and X_i on any σ^θ.

▶ **Proposition 9.** *For all $q \in \{0,1\}^{2N}$, $\theta \in [2N] \cup \{0,\diamond\}$, and $i \in [2N]$, we have*

$$Z_{q,i} \approx_{N(\epsilon_{H,q}+\epsilon_H+\epsilon_P),\sigma^\theta} Z_i \text{ if } q_i = 0, \quad \text{and} \quad X_{q,i} \approx_{N(\epsilon_{H,q}+\epsilon_H+\epsilon_P),\sigma^\theta} X_i \text{ if } q_i = 1.$$

For self-testing, we not only need to characterize the action of a single operator on σ^θ as sketched above, we also need to characterize the actions of products of the operators. Next, we establish the commutation and anti-commutation relations of the observables with respect to σ^θ. Proving commutation is straightforward, while proving anti-commutation relies on the adaptive hardcore bit property. Our proof generalizes and refines techniques in [39, 24]: one difference is that we associate error parameters to each $\sigma^{\theta,v}$, where $v \in \{0,1\}^{2N}$, and use them collectively to bound the overall approximation error associated with σ^θ.

▶ **Proposition 10.** *Let D be an efficient perfect device. For all $i, j, \theta \in [2N]$, we have*

Commutation. $[Z_i, Z_j] = 0,\ [X_i, X_j] = 0,$ *and* $[Z_i, X_j] \approx_{N\epsilon_H + \mathrm{negl}(\lambda), \sigma^\theta} 0$ *if* $i \neq j$.
Anti-commutation. $\{Z_i, X_i\} \approx_{\sqrt{N\epsilon_H} + \mathrm{negl}(\lambda), \sigma^\theta} 0$.

The above relations allow us to handle products of two operators from $\{Z_i, X_i\}_{i \in [2N]}$. However, as mentioned in Section 1, we also want to show relations such as $Z_1 X_3 Z_2 \sigma^3 \approx X_3 Z_1 Z_2 \sigma^3$ $(\star)$, which does *not* directly follow because Z_1 and X_3 are not directly next to the state σ^3. We want to establish relations like $(\star)$ involving products of multiple observables Z_i and X_i in order to characterize Z_i and X_i as Pauli operators σ_i^Z and σ_i^X under the swap isometry defined later.

Our solution to this problem is the next proposition which shows observable-state commutation relations for certain pairs of observables and states. For example, we can now easily prove $(\star)$ by first using the proposition to commute Z_2 past σ^3. We view our use of observable-state commutation relations, which has no analog in prior work, as one of the main technical contributions of this work. These techniques should be useful in any future work that aims to efficiently self-test more than one qubit.

▶ **Proposition 11** (Operator-state commutation)**.** *Let D be an efficient perfect device. For all $i, \theta \in [2N]$ with $i \neq \theta$ and $q \in \{0,1\}^{2N}$, we have*

$$Z_{q,i}\, \sigma^\theta \approx_{N(\epsilon_H + \epsilon_{H,q}) + \mathrm{negl}(\lambda)} \sigma^\theta\, Z_{q,i} \text{ if } q_i = 0 \text{ and } X_{q,\theta}\, \sigma^\theta \approx_{N(\epsilon_H + \epsilon_{H,q}) + \mathrm{negl}(\lambda)} \sigma^\theta\, X_{q,\theta} \text{ if } q_\theta = 1.$$

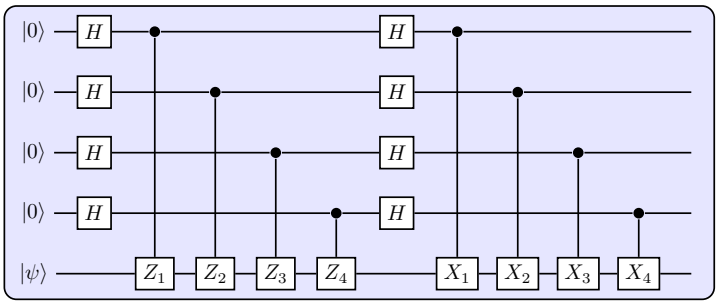
Observe that the proposition above does *not* say $Z_{q,i}$ and $X_{q,i}$ commute with σ^θ for all pairs (i, θ) as we would have desired to prove all $(\star)$-like relations. To get around this problem, we make use of the computational indistinguishability of the σ^θs to argue that efficient observables must act similarly on different σ^θs. For example, consider the following relation that looks similar to $(\star)$: $Z_1 X_3 Z_2 \sigma^2 \approx X_3 Z_1 Z_2 \sigma^2$ $(\star')$. In this case, we cannot directly apply Proposition 11, since Z_2 does not commute with σ^2. Nevertheless, by using the computational indistinguishability of σ^2 and σ^3, we can derive an "operational version" of $(\star')$ from $(\star)$. The operational version allows us to interchange the left-hand and right-hand sides of $(\star')$ when they appear inside traces (i.e., Tr). We can only derive such an operational version because the computational indistinguishability of σ^2 and σ^3 only allows us to interchange σ^2 and σ^3 inside traces; see the lifting lemmas in the full version. For an example of our using this technique, see the long aligned equation in the proof of Lemma 4.33 in the full version.

Next, we define our swap isometry $\mathcal{V}$. We will show that $\mathcal{V}$ maps the states, observables, and measurements of the device to their ideal counterparts. This swap isometry can be viewed as a special case of the swap isometry proposed in [54, Figure 2] in the nonlocal setting. It is not the obvious generalization of the swap isometry used in [39, Proof of Lemma 4.28] as that is more difficult to analyze.

▶ **Definition 12.** *Let D be a device and let $\mathcal{H} := \mathcal{H}_D \otimes \mathcal{H}_Y \otimes \mathcal{H}_R$. The swap isometry is the map $\mathcal{V} : \mathcal{H} \to \mathbb{C}^{2^{2N}} \otimes \mathcal{H}$ defined by*

$$\mathcal{V} = \sum_{u \in \{0,1\}^{2N}} |u\rangle \otimes \prod_{i \in [2N]} X_i^{u_i} \prod_{j \in [2N]} Z_j^{(u_j)}.$$

We illustrate $\mathcal{V}$ when $2N = 4$ below.



We proceed to analyze the effect of the swap isometry on the observables and states of the device. More specifically, in Proposition 13, we show that $\mathcal{V}$ maps the X_i and Z_i observables approximately to σ^X and σ^Z operators acting on the ith qubit of an auxiliary system.

▶ **Proposition 13.** *Let D be an efficient perfect device. For all $k \in [2N]$, $\theta \in [2N] \cup \{0, \diamond\}$, and $q \in \{0,1\}^{2N}$, we have*

$$\mathcal{V}^\dagger(\sigma_k^Z \otimes \mathbb{1})\mathcal{V} \approx_{N(\epsilon_H+\epsilon_{H,q})+\mathrm{negl}(\lambda),\sigma^\theta} Z_{q,k} \text{ if } q_k = 0, \text{ and}$$
$$\mathcal{V}^\dagger(\sigma_k^X \otimes \mathbb{1})\mathcal{V} \approx_{N^{3/2}\sqrt{\epsilon_H}+N\epsilon_{H,q},\sigma^\theta} X_{q,k} \text{ if } q_k = 1.$$

Moreover, for $k \in [N]$ and $\theta \in [2N] \cup \{0, \diamond\}$,

$$\mathcal{V}^\dagger(\sigma_k^X \otimes \sigma_{N+k}^Z \otimes \mathbb{1})\mathcal{V} \approx_{N^{3/8}\epsilon_H^{1/8},\sigma^\theta} \widetilde{X}_k\widetilde{Z}_{N+k} \quad \text{and} \quad \mathcal{V}^\dagger(\sigma_k^Z \otimes \sigma_{N+k}^X \otimes \mathbb{1})\mathcal{V} \approx_{N^{3/8}\epsilon_H^{1/8},\sigma^\theta} \widetilde{Z}_k\widetilde{X}_{N+k}.$$

In Proposition 15, we show that $\mathcal{V}$ maps the states of the device to states of the form $\tau^{\theta,v} \otimes \alpha^{\theta,v}$, where $\tau^{\theta,v}$ is the ideal state defined below and $\alpha^{\theta,v}$ is some junk state that is computationally indistinguishable to a fixed state α for all θ and v.

▶ **Definition 14** (density operators $\tau^{\theta,v}$)**.** *Let $v \in \{0,1\}^{2N}$. For $\theta \in [2N] \cup \{0, \diamond\}$, we define the $2N$-qubit density operator $\tau^{\theta,v} := |\tau^{\theta,v}\rangle\langle\tau^{\theta,v}|$, according to the following three cases.*

$$|\tau^{\theta,v}\rangle := \begin{cases} |v_1\rangle \otimes \cdots \otimes |v_{\theta-1}\rangle \otimes |(-)^{v_\theta}\rangle \otimes |v_{\theta+1}\rangle \otimes \cdots \otimes |v_{2N}\rangle & \text{if } \theta \in [2N], \\ |v\rangle := |v_1\rangle \otimes \cdots \otimes |v_{2N}\rangle & \text{if } \theta = 0, \\ |\psi^v\rangle & \text{if } \theta = \diamond, \end{cases} \tag{10}$$

where $|\psi^v\rangle$ is as defined in Equation (4).

▶ **Proposition 15.** *Let D be an efficient perfect device. For all $\theta \in [2N] \cup \{0, \diamond\}$ and $v \in \{0,1\}^{2N}$, there exists a state $\alpha^{\theta,v} \in \mathrm{Pos}(\mathcal{H})$ such that*

$$\sum_{v\in\{0,1\}^{2N}} \|\mathcal{V}\sigma^{\theta,v}\mathcal{V}^\dagger - \tau^{\theta,v} \otimes \alpha^{\theta,v}\|_1 \le O(N^{7/4}\epsilon_H^{1/4}), \text{ for } \theta \neq \diamond, \text{ and}$$
$$\sum_{v\in\{0,1\}^{2N}} \|\mathcal{V}\sigma^{\diamond,v}\mathcal{V}^\dagger - \tau^{\diamond,v} \otimes \alpha^{\diamond,v}\|_1 \le O(N^{35/32}\epsilon_H^{1/32}).$$

Moreover, there exists a state $\alpha \in \mathrm{Pos}(\mathcal{H})$ and numbers $\{\delta(v) \ge 0 \mid v \in \{0,1\}^{2N}\}$ such that any efficient device can distinguish between $\alpha^{\theta,v}$ and $\alpha/2^{2N}$ with advantage at most $O(\delta(v))$ for all $v \in \{0,1\}^{2N}$, with $\sum_{v\in\{0,1\}^{2N}} \delta(v) \le O(N^{49/32}\epsilon_H^{1/32})$.

The proofs of the two propositions above rely heavily on Propositions 10 and 11 which crucially allows us to bound the soundness error in Theorem 16 by $O(\mathrm{poly}(N, \epsilon))$. If we directly generalize the soundness analysis of [39], we would obtain an $O(2^N\epsilon^{1/2^N})$ bound on the soundness error which is extremely loose.[3]

[3] [23, End of Section 1.3] explains why the technique in [39] would lead to such a loose bound.

Lastly, we put everything together to give our main soundness result, Theorem 16. The main task is to characterize the measurement operator P^u_q, which is approximately a product of $2N$ binary projectors of the form $Z^{(u_i)}_{q,i}$ and $X^{(u_i)}_{q,i}$. We use the operator-state commutation relation to sequentially replace each projector in the product by its ideal counterpart.

▶ **Theorem 16.** *Let D be an efficient device. Let $\mathcal{H} \coloneqq \mathcal{H}_D \otimes \mathcal{H}_Y \otimes \mathcal{H}_R$ be the Hilbert space of D. Let $\mathcal{V} : \mathcal{H} \to \mathbb{C}^{2^{2N}} \otimes \mathcal{H}$ be the swap isometry defined in Definition 12. For $\theta \in [2N] \cup \{0, \diamond\}$ and $v \in \{0,1\}^{2N}$, let $\sigma^{\theta,v} \in \mathrm{Pos}(\mathcal{H})$ be the states that D prepares after returning the first answer in the Hadamard round, as defined in Definition 6. Let $\{\{P^u_q\}_{u\in\{0,1\}^{2N}} \mid q \in \{0,1\}^{2N}\}$ be the measurements defined in Equation (8) of Definition 3.*

Suppose that D fails the protocol in Fig. 2 (with an input distribution μ on $\{0,1\}^{2N}$ and $N = \mathrm{poly}(\lambda)$) with probability at most ϵ. Then, there exist states $\{\alpha^{\theta,v} \mid \theta \in [2N] \cup \{0,\diamond\}, v \in \{0,1\}^{2N}\}$, that are computationally indistinguishable from a single state $\alpha \in \mathrm{Pos}(\mathcal{H})$ in the way specified in Proposition 15, such that

$$\sum_{v\in\{0,1\}^{2N}} \|\mathcal{V}\sigma^{\theta,v}\mathcal{V}^\dagger - \tau^{\theta,v} \otimes \alpha^{\theta,v}\|_1 \leq O(N^{7/4}\epsilon^{1/32}),$$

$$\mathop{\mathbb{E}}_{q\leftarrow\mu}\left[\sum_{u,v\in\{0,1\}^{2N}} \|\mathcal{V}P^u_q\sigma^{\theta,v}P^u_q\mathcal{V}^\dagger - \langle B^u_q|\,\tau^{\theta,v}\,|B^u_q\rangle\,|B^u_q\rangle\langle B^u_q| \otimes \alpha^{\theta,v}\|_1\right] \leq O(N^2\epsilon^{1/32}),$$

and, for all $q \in \{0^{2N}, 1^{2N}, 0^N1^N, 1^N0^N\}$,

$$\sum_{u,v\in\{0,1\}^{2N}} \|\mathcal{V}P^u_q\sigma^{\theta,v}P^u_q\mathcal{V}^\dagger - \langle B^u_q|\,\tau^{\theta,v}\,|B^u_q\rangle\,|B^u_q\rangle\langle B^u_q| \otimes \alpha^{\theta,v}\|_1 \leq O(N^2\epsilon^{1/32}).$$

5 Applications

In this section, we briefly describe two applications of our self-test: DIQKD and dimension-testing. For details, see Section 5 of the full version.

DIQKD. We describe how to adapt the protocol for DIQKD under computational assumptions in [38] to use our self-testing protocol as its main component. The resulting DIQKD protocol operates under the same setting and assumptions as in [38] except we remove the IID assumption. In particular, we highlight the fact that we retain the advantage of the generated key being information-theoretically secure.

Recall that in our self-testing protocol, there is a single verifier interacting with a single device. On the other hand, in DIQKD, there are two verifiers, Alice and Bob, that each interact with their own (untrusted) device. In DIQKD *under computational assumptions*, the two devices are not assumed to be non-communicating and are modeled as a single device with two *components*, one on Alice's side, and one on Bob's. At a high level, to resolve the difference in the number of verifiers, we will let Alice play the role of the single verifier in our self-testing protocol while Bob will play a relaying role.

In Fig. 3, we describe a single test round of our DIQKD protocol. In Fig. 4, we describe how to modify the test round to give a single generation round of our DIQKD protocol. We construct our overall DIQKD protocol by using multiple test rounds followed by a single generation round. After the generation round, Alice and Bob proceed to key extraction, which is essentially the same as that in [38, Protocol 3].

1. Alice samples $\theta \leftarrow_U [2N] \cup \{0, \diamond\}$ uniformly at randomly, generates $2N$ key-trapdoor pairs $(k_1, t_1), \ldots, (k_{2N}, t_{2N})$ according to θ, and sends $k_{N+1}, \ldots, k_{2N}$ to Bob. Note that Alice has all the trapdoors $\{t_i\}_{i=1}^{2N}$. Then Alice sends $k_1, \ldots, k_N$ to her component. Bob sends $k_{N+1}, \ldots, k_{2N}$ to his component.
2. Alice receives back $(y_1, \ldots, y_N) \in \mathcal{Y}^N$ and Bob receives back images $(y_{N+1}, \ldots, y_{2N}) \in \mathcal{Y}^N$.
3. Alice samples $c \leftarrow_U \{\text{preimage}, \text{Hadamard}\}$ uniformly at random, sends it to Bob, and they both send c to their components.

   Case c = preimage. Alice receives $(b_1, \ldots b_N, x_1, \ldots, x_N) \in \{0,1\}^{N+Nw}$ from her component and Bob receives $(b_{N+1}, \ldots, b_{2N}, x_{N+1}, \ldots, x_{2N}) \in \{0,1\}^{N+Nw}$ from his component and sends it to Alice. Alice verifies $(b_1, \ldots, b_{2N}, x_1, \ldots, x_{2N})$ according to our self-testing protocol.

   Case c = Hadamard.

   a. Alice receives $(d_1, \ldots, d_N) \in \{0,1\}^{Nw}$ from her component and Bob receives $(d_{N+1}, \ldots, d_{2N}) \in \{0,1\}^{Nw}$ from his component.
   b. Alice samples $a \leftarrow_U \{0,1\}$ uniformly at random.
      - If $a = 0$, Alice samples $q \leftarrow_U \{0^{2N}, 1^{2N}, 0^N1^N, 1^N0^N\}$ uniformly at random.
      - If $a = 1$, Alice sets $q = 1^N0^N$.

      Note that the resulting distribution on $(q_1, \ldots, q_{2N}) \in \{0,1\}^{2N}$ is the same as in Step 4 of our self-testing protocol (Fig. 2) with μ chosen as the distribution that always outputs 1^N0^N.
      Alice sends q_{N+1} to Bob. Alice sends $q_1, \ldots, q_N$ to her component. Bob sends $q_{N+1}, \ldots, q_{N+1}$ $(= q_{N+1}, \ldots, q_{2N})$ to his component.
   c. Alice receives $(u_1, \ldots, u_N) \in \{0,1\}^N$ from her component and Bob receives $(u_{N+1}, \ldots, u_{2N}) \in \{0,1\}^N$ from his component. Alice sends "Test" to Bob. Bob sends $\{(y_i, d_i, u_i)\}_{i=N+1}^{2N}$ to Alice. Alice verifies $\{(y_i, d_i, u_i)\}_{i=1}^{2N}$ according to our self-testing protocol using the trapdoors that she holds, $(t_1, \ldots, t_{2N})$.

Figure 3 Test round for device-independent quantum key distribution (DIQKD) protocol.

Same as the test round (see Fig. 3) except with the following modifications.

- At Step 1, Alice chooses $\theta = \diamond$.
- At the start of Step 3, Alice chooses c = Hadamard.
- At the start of Step 3(b), instead of sampling q, Alice sets $q = 1^N0^N$.
- Replace Step 3 (c) by the following. Alice receives $(u_1, \ldots, u_N) \in \{0,1\}^N$ from her component and Bob receives $(u_{N+1}, \ldots, u_{2N}) \in \{0,1\}^N$ from his component. Alice sends "Generation" to Bob.

Figure 4 Generation round for device-independent quantum key distribution (DIQKD) protocol.

The completeness of this DIQKD protocol essentially follows from the completeness of our self-testing protocol. The soundness follows from the soundness of our self-testing protocol combined with the key rate analysis used to prove [38, Theorem 1] and the "cut-and-choose" argument used to prove [23, Theorem 4.33].

Dimension-testing. We simplify our self-testing protocol to give a protocol that tests if a quantum device can store N qubits. The simplifications are: 1. θ is sampled from $\{0, 1, \ldots, N\}$, 2. in the Hadamard case, there are only two questions $q = 0^N$ and $q = 1^N$. Details of this protocol can be found in Section 5.2 of the full version. The honest prover's behavior is similar to that of our self-test.

The intuition behind the soundness of this protocol is that, when it is passed with high probability, Theorem 16 guarantees the existence of a quantum state $\rho^\star$ on the quantum part of the device's memory that is close to the maximally mixed state up to some isometry. More specifically, $\rho^\star$ comes from using Theorem 16 to force the device to perform a Hadamard basis measurement on N qubits that are in the computational basis and discarding the measurement results. Then, the main proposition of this section, Proposition 17, shows that the guarantee on $\rho^\star$ is strong enough for us to lower bound the rank of $\rho^\star$, which is also a lower bound on the quantum dimension of the device's memory.

▶ **Proposition 17.** *Let $\rho, \alpha \in D(\mathcal{H})$ be density operators. If there exists a unitary $U \in \mathcal{L}(\mathbb{C}^{2^n} \otimes \mathcal{H})$ such that $\|U(|0\rangle\langle 0|^{\otimes n} \otimes \rho)U^\dagger - 2^{-n}\mathbb{1} \otimes \alpha\|_1 \leq \epsilon$, then $\mathrm{Rank}(\rho) \geq (1-\epsilon)2^n$.*

We now use Proposition 17 to prove the main theorem of this section. Much of the proof is devoted to bookkeeping to ensure that the (normalized) density operator condition in Proposition 17 is satisfied and that we are bounding the *quantum* dimension.

▶ **Theorem 18.** *Let D be an efficient device with Hilbert space $\mathcal{H} = \mathcal{H}_D \otimes \mathcal{H}_Y \otimes \mathcal{H}_R$. Let the classical-quantum decomposition of $\mathcal{H}$ be $\mathcal{H}_C \otimes \mathcal{H}_Q$, so that all states and observables of D on $\mathcal{H}$ are classical on $\mathcal{H}_C$, i.e., block-diagonal in a fixed basis $\{|c\rangle \mid c \in [\dim(\mathcal{H}_C)]\}$ of $\mathcal{H}_C$. If D can pass the dimension test protocol with probability $\geq 1-\epsilon$, then the quantum dimension of D, $\dim(H_Q)$, is at least $(1 - O(N^2\epsilon^{1/32}))2^N$.*

Matching Augmentation via Simultaneous Contractions

Mohit Garg[1]

Faculty of Mathematics and Computer Science, Universität Bremen, Germany

Nicole Megow
Faculty of Mathematics and Computer Science, Universität Bremen, Germany

Abstract

We consider the matching augmentation problem (MAP), where a matching of a graph needs to be extended into a 2-edge-connected spanning subgraph by adding the minimum number of edges to it. We present a polynomial-time algorithm with an approximation ratio of $13/8 = 1.625$ improving upon an earlier 5/3-approximation. The improvement builds on a new α-approximation preserving reduction for any $\alpha \geq 3/2$ from arbitrary MAP instances to well-structured instances that do not contain certain forbidden structures like parallel edges, small separators, and contractible subgraphs. We further introduce, as key ingredients, the technique of repeated simultaneous contractions and provide improved lower bounds for instances that cannot be contracted.

1 Introduction

In the `Matching Augmentation Problem (MAP)`, we are given an undirected graph G, where each edge $e \in E(G)$ has a weight in $\{0, 1\}$, and all the zero-weight edges form a matching. The task is to compute a minimum weight 2-edge-connected spanning subgraph (2-ECSS) of G, which is a connected graph $(V(G), F)$ with $F \subseteq E(G)$ that remains connected on deleting an arbitrary edge.

`MAP` is a fundamental problem in the field of *survivable network design* and is known to be MAX-SNP-hard with several better-than-2 approximation algorithms [3, 5, 6]. Prior to this work, the best-known approximation ratio for `MAP` was $\frac{5}{3}$, achieved by Cheriyan et al. [6].

Both [5, 6] provide combinatorial algorithms for `MAP`, where the approximation ratios are achieved by comparing the outputs against the minimum-cardinality 2-edge-cover (D_2). A 2-*edge-cover* of an undirected graph is a spanning subgraph in which each node has a degree of at least 2, but it may not be connected. Thus, computing a D_2 is a relaxation

[1] A part of this work was done while the author was affiliated with the University of Bremen and the University of Hamburg.

of MAP. In contrast to solving MAP, a D_2 can be computed exactly in polynomial time by extending Edmonds' matching algorithm [10]. A weaker approximation result for MAP by Bamas et al. [3] follows a very different approach: the output is compared against another lower bound on an optimal MAP solution, obtained by solving a linear programming relaxation, the so-called Cut LP. The integrality gap of the Cut LP is at least $\frac{4}{3}$ [3].

Our result. We present a polynomial-time algorithm for MAP with an approximation ratio of $\frac{13}{8} = 1.625$, improving the previous best ratio of 5/3.

▶ **Theorem 1.** *There is a polynomial-time $\frac{13}{8}$-approximation algorithm for MAP.*

This improvement builds on a new α-approximation preserving reduction for any $\alpha \geq 3/2$ from arbitrary MAP instances to well-structured instances that do not contain certain forbidden structures like parallel edges, small separators, and contractible subgraphs. We further introduce, as key ingredients, the technique of repeated simultaneous contractions and provide improved lower bounds for instances that cannot be contracted.

Further related work. MAP sits between the minimum unweighted 2-ECSS and the minimum weighted 2-ECSS problems. For the minimum weighted 2-ECSS problem, improving known 2-approximations [2, 18, 19, 27] is a major open problem. Whereas for the unweighted case, in a recent breakthrough, Garg et al. [13] provided a 1.326-approximation, improving the earlier $\frac{4}{3}$-approximations [17, 24].

Research on the minimum weighted 2-ECSS problem assuming that the set of zero-weight edges in the input graph has a certain structure such as forest, spanning tree, matching, or disjoint paths has received a lot of attention recently. A general variant is the Forest Augmentation Problem (FAP), where the edges in the input graph have 0/1 edge weights. For FAP, only recently, Grandoni et al. [15] obtained a 1.9973-approximation, breaking the approximation barrier of 2. A famous special case of FAP is the unweighted Tree Augmentation Problem (TAP) where the zero-weight edges in the input graph form a single connected component. In a long line of research, several better-than-2 approximations have been achieved for TAP [1, 4, 7–9, 11, 12, 16, 20–23, 25, 26], culminating in a 1.393-approximation by Cecchetto et al. [4].

Notice that MAP is somewhat orthogonal to TAP in terms of connectivity as it has many small connected components as input instead of a single big one. Understanding both the extreme cases well, TAP and MAP, seems promising for making further progress for FAP.

Organization of the rest of the paper. Section 2 contains preliminaries and a high-level overview of our work along with some important definitions. Section 3 and Section 4 consist of the description of our reduction and algorithm, respectively, along with the corresponding theorem and lemma statements which we prove in the appendix of the full version of this paper [14]. Using these theorems and lemmas, in Section 5 we prove Theorem 1. In Section 6, we conclude with final remarks, pointing out the bottleneck for improving our algorithm.

In the full version [14] we have included detailed proofs of various lemmas in Appendices A–F, which makes our write-up lengthy. A lot of material, especially in Appendices A, C, and F are standard, but formally necessary; the new innovations are mainly contained in Appendices B, D, and E. While some proofs admit a case analysis, no single proof has too many cases. We have tried to keep the exposition reader-friendly and make the proofs easily verifiable at the expense of making the write-up a bit lengthy; a terser style might have saved some pages.

2 Technical overview

2.1 Preliminaries

We use standard notation for graphs. We consider weighted undirected graphs where each edge has a weight of either 0 or 1. A *MAP instance* consists of a graph G such that the zero-weight edges of G form a matching, and the task is to compute a minimum weight 2-edge-connected spanning subgraph (2-ECSS) of G, which is a connected subgraph $(V(G), F)$ which remains connected on deletion of an arbitrary edge. Without loss of generality, we may assume that the input graph G is 2-edge-connected; this can be checked in polynomial time by testing for each edge whether its deletion results in a disconnected graph.

Given a set of edges $F \subseteq E(G)$, $||F||$ denotes the weight of F, i.e., the number of unit edges in F. With slight abuse of notation, we denote the weight of a subgraph H of G by $||H||$. Thus, $||H|| = ||E(H)||$. Given a MAP instance G, let $\mathsf{OPT}(G)$ represent a 2-edge-connected spanning subgraph of G of minimum total weight $\mathsf{opt}(G) := ||\mathsf{OPT}(G)||$. When G is clear from the context we sometimes omit G.

Whenever we speak of components of a graph we refer to its *connected* components.

2.2 Algorithmic template and the previous $\frac{5}{3}$-approximation

The algorithm and analysis of Cheriyan et al. [6], for obtaining a $\frac{5}{3}$-approximate solution for MAP, exemplifies the general template for obtaining combinatorial algorithms for 2-edge-connected spanning subgraphs used in several works [5, 11, 17, 20]. We first explain this template, by giving an overview of the algorithm of Cheriyan et al. [6], and then in the next subsection highlight our approach where we alter this template to achieve our improvement.

The algorithm consists of two parts. The first part is a preprocessing step which constitutes a $\frac{5}{3}$-approximation preserving reduction from arbitrary MAP instances to well-structured instances that do not contain certain forbidden structures. This is a key element of their work, which helps them to improve upon an earlier $\frac{7}{4}$-approximation by getting rid of certain hard instances.

In the second part, they handle instances that do not contain any of the forbidden structures through a *discharging scheme*. Their algorithm starts by computing a minimum 2-edge-cover, D_2 (in polynomial time). Additionally, all the zero-edges are added to the D_2, so that the edges not in the D_2 are all unit-edges. Now, since a 2-ECSS is a 2-edge-cover, $||D_2||$ lower bounds opt, the weight of the minimum weight 2-ECSS. To output a $(1+c)$-approximate solution (for $c = \frac{2}{3}$), one has $(1+c)||D_2||$ *charge* to work with. This charge is used to buy the edges of the D_2 and a charge of c is distributed to each of the unit edges of the D_2. Now, they incrementally transform this D_2 into a 2-ECSS by adding edges to it. For each edge that is added, a charge of 1 is used up from the available charge (which is taken from nearby edges), i.e., their D_2 incrementally evolves into a 2-ECSS at the expense of *discharging*. This is an oversimplified view of their actual algorithm. In reality, sometimes they even delete edges in the process which results in gaining charge.

We briefly describe the two steps involved in transforming the D_2 into a 2-ECSS, namely *bridge covering* and *gluing*. Note that a D_2 can have several connected components. Some of these components can be 2-edge-connected, whereas some might have bridges (i.e., deleting those edges will result in increasing the number of components). The first step is to *cover* all the bridges one by one. Given a bridge, they add edges so that the bridge becomes part of a cycle; as a side effect, multiple components might merge into one. At the end of the bridge-covering step, their graph has only 2-edge-connected components. They ensure that

after using up the charge for buying the edges in the process, each component with at least 3 unit-edges has at least a charge of 2 leftover. Components with exactly 2 unit-edges (cycles of lengths 3 and 4) keep the initial charge of $2c = \frac{4}{3}$.

Next, in the gluing step, the components are merged into a single component using the leftover charge in the components resulting in a feasible solution. To see how this might be done, momentarily assume that all components have at least 3 unit-edges, i.e., having a leftover charge of at least 2. Here, one can simply contract each component into a single node, find a cycle in the contracted graph, and buy all the edges in that cycle. This will result in merging all the components corresponding to the nodes in the cycle into a single component. To be able to repeat such merges, we need to ensure that we have a leftover charge of at least 2 in this newly formed component. For a cycle of length $k \geq 2$, initially there was a charge of at least $2k$ in the corresponding components, and we need to buy exactly k edges. Thus, after the merge, the leftover charge in the new component is at least $2k - k = k \geq 2$, maintaining the charge invariant. Repeating this process eventually leads to a feasible solution. Unfortunately, this idea is not guaranteed to work if there are components with 2 unit-edges; a cycle with 2 nodes corresponding to such components will have a total charge of $2 \times \frac{4}{3} = \frac{8}{3}$, and after buying the 2 edges in the cycle, we will be left with a charge of only $\frac{2}{3}$. On repeating such merges, the graph will run out of charge before the gluing finishes. To handle such small components one needs to delete edges to gain charge.

2.3 Highlights of our approach and innovations for the $\frac{13}{8}$-approximation

Our approach follows the same broad framework explained above with some key innovations. Formal definitions will be given in later sections.

Preprocessing

For all $\alpha \geq \frac{3}{2}$, we provide an α-approximation preserving reduction from arbitrary MAP instances to *structured graphs*. Our list of forbidden structures subsumes the one by Cheriyan et al. [6] and consists of parallel edges, cut vertices, small separators, and *contractible subgraphs*.

Contractible subgraphs are a general form of contractible cycles as considered in [17]. A 2-edge-connected subgraph H of a graph G is contractible if each 2-ECSS(G) includes at least $\frac{1}{\alpha}||H||$ unit-edges from $G[V(H)]$. Since we are interested in only an α-approximate solution, we may contract $V(H)$ into a single node, solve the problem on the contracted graph, and add the edges of H to the solution without any loss in the approximation ratio. As an example, suppose a 6-cycle in G of weight 6 has 2 antipodal vertices that have degree 2 in G. Then, $\mathsf{OPT}(G)$ must include the 4 edges incident on these two vertices. As the cycle costs 6, and $\mathsf{OPT}(G)$ is guaranteed to pick at least weight 4 from the subgraph induced on the vertices of the cycle, for a $\frac{3}{2}$-approximation, it suffices to buy all edges of this cycle, contract it and solve the reduced problem. We can detect all contractible subgraphs with constant-size vertex sets in polynomial time and remove them during preprocessing. Interestingly, some intricate structures considered in [6] are simply contractible subgraphs.

We further exclude several small separators, which is crucial for our bridge covering and gluing steps as we have less charge at our disposal. Given a separator, we split the graph into two or three parts, recursively solve the problem on the smaller parts, and then combine the solutions arguing that the approximation ratio is preserved. If each of these parts has at least 5 vertices, this step is relatively straightforward. But for parts containing at most 4 vertices, the argument becomes significantly more challenging, in particular, since we are

aiming for a better guarantee than previous work. Handling the small separators forms a substantial part of our work consisting of several innovations. In particular, given a separator that splits the graph into two parts, the structure of the interaction of the separator with the parts is exploited in carefully constructing the subproblems. Here, we sometimes introduce *pseudo-edges*, representing possible connections via the other part, and suitably remove them during the combining step. Our reduction, which works for any $\alpha \geq \frac{3}{2}$, might be useful for future works. We only need $\alpha = \frac{13}{8}$ for our main result.

Bridge covering

Empowered by a stronger preprocessing, we can rule out more structures in the input graph, which enables us to obtain a bridgeless 2-edge-cover of G, even for an approximation ratio of $(1 + c)$, for $c = \frac{5}{8}$. In fact, our bridge-covering works even for $c = \frac{3}{5}$, so it might also be useful for future works. At the end of the bridge-covering step, we have the following charges left in the 2-edge-connected components: 2 in the *large* components (containing 4 or more unit-edges), $3c = \frac{15}{8} < 2$ in the *medium* components (containing 3 unit-edges) and $2c = \frac{5}{4} \ll 2$ in the *small* components (containing 2 unit-edges).

Gluing

In the gluing step, we are able to merge all the medium components into large components even though medium components have strictly less than 2 charge. We are also able to handle some small components that have a particular configuration by deleting edges and gaining charge. Unfortunately, we were unable to handle all the small components as they have a minuscule charge. In the end, we are left with a *special* configuration that has only large (with charge ≥ 2) and small components (with charge $\frac{5}{4}$) which cannot be merged.

Two-edge-connecting special configurations

The small components of the special configuration originate in the initial D_2 and could not be merged. So we ask the following question. How *close* are these small components to OPT restricted to the vertices of the small components? Intuitively, if they are close, we should be able to do something algorithmically as we are roughly doing what OPT is doing on this part of the graph. Otherwise, if they are not close, we should be able to argue that OPT does much worse than what the D_2 does on this part of the graph, giving us an improved lower bound. Our main conceptual innovation is in articulating a notion of closeness and making this intuition work.

Method of simultaneous contractions

We now describe our measure of closeness. Let G be our input structured graph and let $H_1, \cdots, H_s$ be the small components of the special configuration obtained. We count the total number of unit-edges bought by OPT from the following subgraphs $G[V(H_1)], \cdots, G[V(H_s)]$. If this number is more than $\frac{8}{13}$ times the number of unit-edges in the small components of our special configuration, which is precisely $2s$, we say that the small components are close to OPT. Otherwise, they are not close.

Observe when the small components are indeed close, on average, each H_i is contractible, preserving an approximation ratio of $\frac{13}{8}$. Thus, algorithmically, we can simultaneously contract each $V(H_i)$ into a distinct single node, solve the problem on the reduced instance (which can be done recursively, as contracting vertices into nodes decreases the size of the graph), and add the edges of the small components to the solution, without incurring a loss in approximation.

When the small components are not close to OPT, i.e., the H_i's are not *simultaneously contractible*, we rely on the gluing step of Cheriyan et al. [6] using a charge of $\frac{4}{3}$ per small component instead of our original charge of $\frac{5}{4}$, increasing our cost. Our improvement, in this case, comes from improving the lower bound.

Note that it is not possible for us to check in polynomial time whether the small components are simultaneously contractible or not; so what should we do – contract, or use the gluing algorithm of Cheriyan et al. [6]? We do both and return the solution with a smaller weight and argue that in either scenario the algorithm performs well.

Improved lower bound

In the case when the small components are not simultaneously contractible, OPT picks at most $\frac{8}{13} \cdot 2s$ unit-edges from the $G[V(H_i)]$'s put together. Thus, at least $2s - \frac{16}{13}s = \frac{10}{13}s$ unit-edges are not picked from within the small components. We show that for each unit-edge not picked by OPT from this part, OPT buys on average at least $1 + \frac{1}{12}$ edges that go between different small components. To argue this, we crucially use the fact that the special configurations have a restricted structure, as certain merges are not possible in it. Thus, we show that in total the number of unit-edges used by OPT on the vertices of the small components is at least $\frac{8}{13} \cdot 2s + (1 + \frac{1}{12})\frac{10}{13}s = \frac{161}{78}s$, which is strictly more than $2s$, which is the number of unit-edges used by the D_2 on this part. Finally, through an elegant argument, we are able to use this improved lower bound on OPT restricted only to the vertices of the small components to show that it compensates for the increased cost incurred during gluing the small components.

2.4 Important definitions

We give some definitions that we need for the presentation of our algorithm.

▶ **Definition 2** ($f(\cdot)$). *Given a MAP instance G, let*

$$f(G) = \max\{\frac{13}{8} \cdot \mathsf{opt}(G) - 2, \mathsf{opt}(G)\}.$$

For a MAP instance G, we will compute a 2-ECSS of G with weight at most $f(G)$. Observe that the "-2" term gives us a slightly better bound than claimed, which we crucially exploit in our preprocessing.

▶ **Definition 3** (size of a graph $s(\cdot)$). *Given a graph G, its* **size** *is $s(G) = 10 \cdot |V(G)|^2 + |E(G)|$.*

We will show that the running time of our algorithm is upper bounded by a polynomial in the size of the input graph.

▶ **Definition 4** (notation graph contraction). *Given a graph G and a set of vertices $T \subseteq V(G)$, G/T denotes the graph obtained from G after contracting all the vertices in T into a single vertex. More generally, given disjoint vertex sets $T_1, \cdots T_k \subseteq V(G)$, $G/\{T_1, \cdots, T_k\}$ denotes the graph obtained from G after contracting vertices of each T_i into single vertices.*

Note that edges in G and $G/\{T_1, \cdots, T_k\}$ are in one-to-one correspondence. Given a subgraph H of the contracted graph, we use $\hat{H}$ to refer to the subgraph of G containing precisely those edges that correspond to the edges of H.

▶ **Definition 5** (contractible subgraphs). *Let $\alpha \geq 1$ and $t \geq 2$ be fixed constants. Given a 2-edge-connected graph G, a collection of vertex-disjoint 2-edge-connected subgraphs $H_1, H_2, ..., H_k$ of G is called* (α, t, k)-contractible *if $2 \leq |V(H_i)| \leq t$ for every $i \in [k]$ and every 2-ECSS of G contains at least $\frac{1}{\alpha}||\bigcup_{i\in[k]} E(H_i)||$ unit-edges from $\bigcup_{i\in[k]} E(G[V(H_i)])$.*

In our preprocessing, we will remove all $(\frac{13}{8}, 12, 1)$-contractible subgraphs, which we simply refer to as contractible subgraphs. Later, when considering a special configuration with n_s small components, we will work with a $(\frac{13}{8}, 4, n_s)$-contractible collection of small components; we will refer to the special configuration simply as $\frac{13}{8}$-simultaneously contractible.

2.5 Algorithm overview

Here, we give a brief overview of our main algorithm.

Step 1: Preprocessing: We apply our reduction to obtain a collection of subproblems of MAP on structured graphs (Section 3). We then assume that we are given some structured graph G.

Step 2: Bridge covering: We compute a D_2 in polynomial-time and apply bridge covering to obtain an *economical* bridgeless 2-edge-cover H – a bridgeless 2-edge-cover of low cost (Section 4.1).

Step 3: Special configuration: Given H, we compute a special configuration S of G (Section 4.2).

Step 4: Contract vs. glue: We compute two feasible solutions S_1 and S_2: S_2 is obtained by applying the algorithm of [6] to G and S (Section 4.3); S_1 is obtained by calling Step 1 for G_S, which arises from G by contracting each small component of S to a single vertex. Finally, we output $\arg\min\{||S_1||, ||S_2||\}$.

3 Preprocessing

We show that, for purposes of approximating MAP with any approximation ratio at least $\frac{3}{2}$, it suffices to consider MAP instances that do not contain certain forbidden configurations. These configurations are cut vertex, parallel edge, contractible subgraph, S_0, S_1, S_2, $S_{\{3,4\}}$, S_3, S_4, S_5, S_6, S'_3, S'_4, S'_5, and S'_6. The formal definitions of these structures are provided in Appendix B of the full version [14]. Each of these configurations is referred to as a **type** and is of constant size. A MAP instance with at least 20 vertices that does not contain any of these forbidden configurations is termed as **structured**.

We briefly describe some of the types that we forbid in a structured graph. Apart from cut vertex, parallel edge, and contractible subgraph, the other forbidden structures we consider can be broadly divided into two categories: (a) "Path-like"-separators and (b) "Component-like"-separators. Path-like separators are certain paths which when removed from the input graph disconnects it. Forbidding these structures in the structured graph is mostly used in the bridge-covering step. Roughly speaking, the absence of these structures helps us in finding sufficient credit while covering some path (consisting of bridges) between 2-edge connected blocks of the 2-edge-cover. Component-like structures, on the other hand, are certain 2-edge-connected subgraphs that when removed from the input graph disconnects it. Their absence from structured graphs is mainly exploited in the gluing step; it allows us to find certain cycles through some small components which help us gain credit that is needed for the gluing.

The reduction from MAP instances to structured graphs is given by the following algorithm where we assume ALG is an algorithm that works on structured graphs. Our reduction is essentially a divide-and-conquer algorithm. It searches for a forbidden configuration and if it detects one, it divides the problem into a few subproblems (at most 3) of smaller sizes, solves them recursively, and then combines the returned solutions into a solution for the original instance. In case there are no forbidden configurations in the input (the input is structured), it calls ALG to solve the problem.

Algorithm 1 Preprocessing.

function REDUCE(G)
  if G is simple and $|V(G)| \leq 20$ **then return** $\mathsf{opt}(G)$. ▷ by brute force

  Look for a forbidden configuration in G in the following type order:
  cut vertex, parallel edge, contractible subgraph, S_0, S_1, S_2, $S_{\{3,4\}}$, S_k, S'_k for $k \in \{3,4,5,6\}$.
  Stop immediately on detecting a forbidden configuration.

  if a forbidden configuration is detected **then**
    Call it F and let T be the type of F.
    $(H_1, H_2, H_3) = \mathsf{Divide}_T(G, F)$. ▷ H_2 and/or H_3 are always empty for certain types
    $H_i^* = \mathsf{Reduce}(H_i)$ for all $i \in \{1,2,3\}$.
    return $\mathsf{Combine}_T(G, H_1^*, H_2^*, H_3^*)$.
                                                ▷ G is now structured
  return $\mathsf{ALG}(G)$.

In the above algorithm, Divide_T and $\mathsf{Combine}_T$ are subroutines that are defined in Appendix B of the full version [14], which also contains proofs of the following lemmas.

▶ **Lemma 6.** *For all types T, Divide_T and $\mathsf{Combine}_T$ are polynomial time algorithms. Furthermore, given a MAP instance G and a type T, one can check in polynomial time whether G contains a forbidden configuration of type T.*

▶ **Lemma 7.** *Given a MAP instance G and a forbidden configuration F that appears in G of type T from the list L =(cut vertex, parallel edge, contractible subgraph, S_0, S_1, S_2, S_k, S'_k, $k \in \{3,4,5,6\}$) such that G does not contain any forbidden configuration of a type that precedes T in the list L and $\mathsf{Divide}_T(G, F) = (H_1, H_2, H_3)$, then the following statements hold:*

- **(i)** *for each $i \in \{1,2,3\}$ H_i is a MAP instance,*
- **(ii)** *$s(H_1) + s(H_2) + s(H_3) < s(G)$, and*
- **(iii)** *if for each $i \in \{1,2,3\}$, H_i^* is a 2-ECSS of H_i such that $||H_i^*|| \leq f(H_i)$, then $\mathsf{Combine}_T(G, H_1^*, H_2^*, H_3^*)$ is a 2-ECSS of G such that $||\mathsf{Combine}_T(G, H_1^*, H_2^*, H_3^*)|| \leq f(G)$.*

Using the above lemma, we can establish the following result: If for all structured graphs G, $\mathsf{ALG}(G)$ is a 2-ECSS of G such that $||\mathsf{ALG}(G)|| \leq f(G)$, then for all MAP instances G, $\mathsf{Reduce}(G)$ is a 2-ECSS of G such that $||\mathsf{Reduce}(G)|| \leq f(G)$.

We will produce an *admissible* ALG that calls Reduce on a smaller instance. Since Reduce and ALG call each other, we need a slightly stronger result, which is obtained using an induction argument. We first define an admissible algorithm.

▶ **Definition 8** (admissible)**.** *An algorithm* ALG *is* **admissible** *if the following holds. If for all MAP instances G with $s(G) \leq t$, $\mathsf{Reduce}(G)$ is a 2-ECSS of G such that $||\mathsf{Reduce}(G)|| \leq f(G)$, then for all structured graphs G such that $s(G) = t + 1$, $\mathsf{ALG}(G)$ is a 2-ECSS of G such that $||\mathsf{ALG}(G)|| \leq f(G)$. Furthermore, if $T(s)$ denotes the running time of* ALG *for structured graphs of size s, and $T'(s)$ denotes the running time of* Reduce *on MAP instances of size s', then $T(s) \leq T'(s-1) + poly(s)$.*

Our main results in this section are the following.

▶ **Theorem 9.** *If* ALG *is an admissible algorithm, then for all MAP instances* G, Reduce(G) *is a 2-ECSS of* G *such that* $||\text{Reduce}(G)|| \leq f(G)$.

▶ **Theorem 10.** *If* ALG *is an admissible algorithm, then* Reduce *runs in polynomial time.*

The proofs of the above two results follow from a straightforward application of Lemmas 6 and 7 and are included in Appendix A of the full version [14]. Now, if we can find an admissible ALG, Theorem 9 and Theorem 10 immediately imply Theorem 1. In the next subsections, we exhibit an admissible ALG.

4 Algorithm for structured graphs

We exhibit an admissible algorithm ALG that takes as input a structured graph G and outputs a 2-ECSS of G with weight at most $f(G)$. Our algorithm has three main steps. First, we compute an "economical" bridgeless 2-edge-cover of G. Then, with the aid of this 2-edge-cover, we compute a "special" configuration of G. We two-edge-connect the special configuration in two ways and return the solution with minimum weight. We define the relevant terms and explain these steps below.

Algorithm 2 Main algorithm for structured graphs.

function ALG(G) ▷ G is structured
  $H =$ economical bridgeless 2-edge-cover(G)
  $S =$ special configuration(G, H)
  $R =$ Contract-vs-Glue(G, S)
  return R

4.1 Computing an economical bridgeless 2-edge-cover

Given a structured graph G, we first compute an economical bridgeless 2-edge-cover of it. Before we define an economical bridgeless 2-edge-cover, we need to first define **small, medium,** and **large**, which is used to categorize a 2-edge-connected subgraph of G based on its weight.

▶ **Definition 11** (small, medium, large)**.** *For a weighted graph* G*, we call a 2-edge-connected subgraph* H *of* G **small** *if* $||H|| \leq 2$, **medium** *if* $||H|| = 3$, *and* **large** *if* $||H|| \geq 4$.

Note that for structured graphs, the only possible small components are cycles of length 3 or 4 with exactly 2 unit-edges, and medium components are cycles of length 3, 4, 5, or 6 with exactly 3 unit-edges.

▶ **Definition 12.** *A bridgeless 2-edge-cover* H *of a graph* G *is* **economical** *if all the zero-edges of* G *are in* H, $||H|| \leq \frac{13}{8} \cdot ||D_2(G)|| - 2n_\ell - \frac{15}{8}n_m - \frac{5}{4}n_s$, *where* n_ℓ, n_m, *and* n_s *are the number of large, medium, and small components of* H, *respectively. Furthermore, there exists a* D_2 *of* G *such that each small component of* H *is a small component of the* D_2.

Our main result for this subsection is as follows.

▶ **Theorem 13.** *Given a structured graph* G*, we can compute an economical bridgeless 2-edge-cover of* G *in polynomial time.*

To compute an economical bridgeless 2-edge-cover of G, we first find a D_2 of G and include all the zero-edges in it. Next, we transform this D_2 into a "canonical" D_2, which is defined in Appendix C of the full version [14]. Then, we cover the bridges of the canonical D_2 to get an "economical" bridgeless 2-edge-cover. All of this can be done in polynomial time. The details with the proof of Theorem 13 are in Appendix C of the full version [14].

4.2 Computing a special configuration

Next, given an economical bridgeless 2-edge cover H of a structured graph G, we compute a "special" configuration of G. A special configuration is a bridgeless 2-edge-cover that satisfies certain additional properties. In particular, it does not contain any medium components.

▶ **Definition 14** (Special configuration). *Given a structured graph G, we say H is a special configuration of G if*

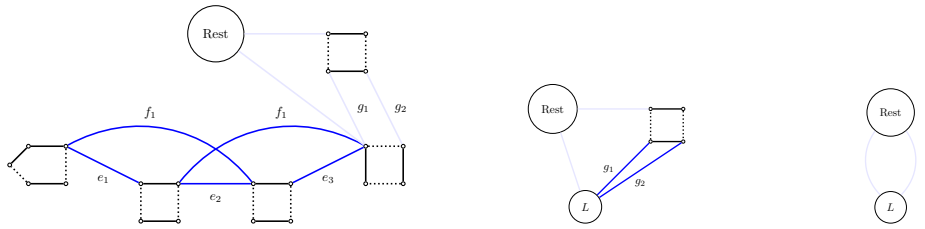
- **(i)** *H is an economical bridgeless 2-edge-cover of G,*
- **(ii)** *H does not contain medium-size components,*
- **(iii)** *G/H does not contain good cycles*
- **(iv)** *G/H does not contain open 3-augmenting paths, and*
- **(v)** *H does not contain a small to medium merge or small to large merge.*

The terms and notation used in conditions (iii)-(v) are formally defined in Appendix D of the full version [14]. Without going into details, we briefly describe the structures defined in (iii)-(v). A good cycle is a simple cycle C in G/H that contains either a) two large components, b) one large component and one small component containing a shortcut, or c) two small components each containing a shortcut. Here, we say a small component S is shortcut w.r.t. C if in $G[V(S)]$ there exists a Hamiltonian path from u to v of weight 1, where u and v are the vertices incident to C when S is expanded. Hence, there is a unit-edge in the small component S that is redundant for the 2-edge-connectivity of H after we add the edges of C to it. An open 3-augmenting path is a simple path P in G/H through 4 small components such that for each of the two interior small components there is a shortcut w.r.t. P. Finally, a small to medium merge (or small to large merge) is a set of 3 small components $S_1, S_2, S_3 \in H$ such that in $G' = G[V(S_1 \cup S_2 \cup S_3)]$ there exists a set of edges that form two medium components (or one large component) of weight precisely 6 spanning $V(G')$.

Essentially, these conditions restrict the structure of special configurations. For example, in the graph G/H (the graph obtained by contracting the various components of H into single nodes), there is no cycle that has 2 or more nodes corresponding to large components. In particular, a special configuration contains at least one small component or is already feasible. The restricted structure of special configurations will be crucially exploited while proving an improved lower bound on $\mathsf{OPT}(G)$.

From an economical bridgeless 2-edge-cover H, we obtain a special configuration by repeatedly searching for the four forbidden structures (properties (ii)-(v) above) and buying and selling certain edges such that we turn H into an economical bridgeless 2-edge cover H' with fewer components. One can show that searching for such structures can be done in polynomial time.

We briefly explain this process by an example: Figure 1a. The black edges correspond to the economical bridgeless 2-edge-cover H, where the dotted edges are of weight 0. The (bold and faint) blue edges are edges of G that are not in H. The 3 blue edges e_1, e_2, and e_3 form an open 3-augmenting path in G/H (as it can "shortcut" the two black unit edges adjacent to e_2). By the properties of structured graphs, one can show that the blue edges f_1 and f_2 must exist, and hence four components of H can be merged into one large component by



(a) open 3-augmenting path. **(b)** good cycle. **(c)** after merges.

Figure 1 An example of obtaining a special configuration.

buying all the 5 bold blue edges and selling the 2 black unit edges adjacent to e_2, which are "shortcut" by the open 3-augmenting path, to obtain Figure 1b; as initially the 4 components incident to the blue edges have a credit of $9 \times \frac{5}{8} \geq 5$, we buy 5 blue and sell 2 black edges to have a final credit of at least 2. One can show that this step is tight for our analysis with an approximation ratio of 13/8. Now, in Figure 1b the blue edges g_1 and g_2 form a good cycle in G/H (as it can be merged into a single large component). Initially, the credits in the large and small components that are part of this good cycle have a credit of $2 + 2 \times \frac{5}{8} \geq 3$. We buy the edges g_1 and g_2 and sell the unit edge adjacent to both g_1 and g_2 to form a single 2-edge-connected component having a credit of at least $3 - 2 + 1 = 2$, and thus the good cycle merges into a large component as shown in Figure 1c. In general, we show the following theorem, which is proved in Appendix D of the full version [14].

▶ **Theorem 15.** *Given a structured graph G and an economical bridgeless 2-edge-cover of it, we can compute a special configuration of G in polynomial time.*

4.3 Two-edge-connecting special configurations

Finally, we present the last part of our algorithm, which we call "Contract-vs-Glue", that converts a special configuration into a 2-edge-connected graph. Recall, a special configuration is an economical bridgeless 2-edge-cover of a structured graph that contains only small and large components and satisfies certain additional properties. Our algorithm computes two solutions and returns the one with a lower weight. The first solution is obtained by contracting the small components into single nodes and recursively computing the solution on the contracted graph (this is done by calling Reduce on the contracted graph) and then adding the edges in the small components to the solution after expanding it back. The second solution is obtained by following the "Gluing Algorithm" of Cheriyan et al. [6], which we call "Glue", and reproduce it below for completeness' sake.

Algorithm 3 Contract-vs-Glue.

function CONTRACT-VS-GLUE(G, S) ▷ G is structured, S is a special configuration of G
  if S is a 2-ECSS of G **then return** S
  Let $H_1, \cdots, H_k$ be the small components of S. ▷ now S must have small components
  $G_1^* = \mathsf{Reduce}(G/\{H_1, \cdots, H_k\})$
  $S_1 = (V(G), E(\hat{G}_1^*) \cup \bigcup_{i \in [k]} E(H_i))$
  $S_2 = \mathsf{Glue}(G, S)$
  return $\arg\min\{||S_1||, ||S_2||\}$

We will be using the following lemmas to prove our main result.

▶ **Lemma 16.** *Let G be a structured graph, S be a special configuration of G with small components $H_1, \cdots, H_k$, and let $G_1^* = \mathsf{Reduce}(G/\{H_1, \cdots, H_k\})$. If G_1^* is a 2-edge-connected spanning subgraph of $G/\{H_1, \cdots, H_k\}$, then $(V(G), E(\hat{G}_1^*) \cup \bigcup_{i\in[k]} E(H_i))$ is a 2-edge-connected spanning subgraph of G. Furthermore, if $H_1, \cdots, H_k$ is $(\frac{13}{8}, 4, k)$-contractible in G and $||G_1^*|| \leq f(G/\{H_1, \cdots, H_k\})$, then $||(V(G), E(\hat{G}_1^*) \cup \bigcup_{i\in[k]} E(H_i))|| \leq f(G)$.*

The first statement in the above lemma is straightforward to see. The second part is obtained by specializing Lemma 33 of Appendix B of the full version [14] to our parameters.

The following lemma is proved implicitly in [6]. For completeness, we give a full proof in Appendix F of the full version [14].

▶ **Lemma 17.** *Let G be a structured graph and S be a special configuration of G with n_ℓ large and n_s small components. Then, $\mathsf{Glue}(G, S)$ is a 2-edge-connected spanning subgraph of G with $||\mathsf{Glue}(G, S)|| \leq ||S|| + 2n_\ell + \frac{4}{3}n_s - 2$.*

Also, we prove the following lower bound result. Informally, if a 2-ECSS includes t fewer edges from within the small components of a special configuration, it must include $t(1 + \frac{1}{12})$ edges going between different small components. The proof is given in Appendix E of the full version [14]..

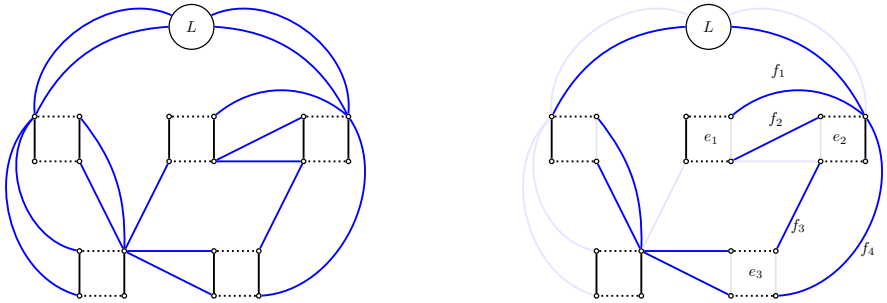
▶ **Lemma 18.** *Let G be a structured graph and S be a special configuration of G with k small components: $H_1, \cdots, H_k$. Let R be any 2-edge-connected spanning subgraph of G such that $2k - \sum_{i\in[k]} ||R[V(H_i)]|| = t$, then $\sum_{i<j\leq k} e_R(V(H_i), V(H_j)) \geq (1 + \frac{1}{12})t$, where $e_R(A, B)$ represents the number of unit-edges going between vertex sets A and B in R.*

Here, we give an intuition on how to prove Lemma 18. Fix a structured graph G together with a special configuration S and a 2-edge-connected spanning subgraph R as specified in Lemma 18. In order to simplify things, here we assume that each small component H_i of S is a cycle of length 4 such that G does not contain any of the diagonals of H_i. Furthermore, let $H_1, H_2, \ldots, H_\ell$ be the set of small components in S.

An edge between two small components is called **crossing**, whereas an edge inside a small component is called **inside**. Informally speaking, Lemma 18 states that, on average, for each inside edge $e \in E(S)$ of some small component of S that is not present in R, $E(R)$ has to contain at least $1 + \frac{1}{12}$ crossing edges. First, one can show that the vertices incident to an inside edge e that is not present in $E(R)$ cannot be adjacent to vertices of a large component of S, as otherwise this implies that S contains a good cycle, contradicting that S is special. Hence, each vertex incident to an inside edge e that is not present in $E(R)$ must be incident to at least one crossing edge in R.

In order to show that R contains sufficiently many crossing edges, we define an assignment ξ that distributes for each inside or crossing edge of R a total charge of one to the small components $H_1, \ldots, H_\ell$. The sum over all charges of edges incident to some component H_i then defines the *load* of the component H_i. Note that, by construction, the total load over all small components is equal to the number of inside and crossing edges in R.

Each inside edge contributes one to the charge of its component, while each crossing edge distributes a charge of one to the components incident to it: if only one of the two unit edges of $E(S)$ adjacent to a crossing edge is shortcut (absent) in R, then the component with the shortcut edge receives a charge of one from that crossing edge. Otherwise, both incident components receive a charge of $\frac{1}{2}$. Consider for example Figure 2b, where the bold edges represent R. By the above assignment, the components incident to f_3 receive a charge of $\frac{1}{2}$ each from f_3, while only the component containing e_3 receives a charge of 1 from f_4. The total load of the components (from left to right, top to bottom) then is $3, \frac{5}{2}, 2, 2$, and $\frac{7}{2}$, respectively.



(a) Special Configuration. **(b)** Optimal Solution.

Figure 2 Example: special configuration, optimal solution, and lower bound.

From our assignment, one can easily argue that the load of each small component is ≥ 2. Furthermore, if there are no two shortcut edges that are adjacent to a crossing edge, then it clearly follows that Lemma 18 holds. In fact, in this case, we could replace the $1 + \frac{1}{12}$ by 2 in the lemma – a much stronger result.

Hence, we may assume that there are some shortcuts that share crossing edges, e.g. edges e_1, e_2, and e_3 in Figure 2b. However, in this case, the edges f_2 and f_3 (which form an *open 2-augmenting path*) cannot be extended to an open 3-augmenting path (since S is special); the edges f_1 and f_4 have to go back to the component containing e_2. One can show that in this case (since there are also no good cycles or local merges), the average load of the components containing e_1, e_2, and e_3 is at least $\frac{5}{2}$. In the remaining case when there are no open 2-augmenting paths in R, using a similar argument we can also show that the average load of a component is at least $2 + \frac{1}{6}$. This load assignment then implies the statement of Lemma 18.

5 ALG is admissible

As noted earlier, from Theorems 9 and 10, it follows that if we can show ALG is admissible, Theorem 1 follows. Thus, we will now focus on proving that ALG is admissible.

▶ **Lemma 19.** ALG *is admissible.*

Before we proceed with the proof, we develop some key definitions and propositions that will be used in the proof. Throughout this subsection, G is a structured graph and S is a special configuration of G with small components $H_1, \cdots, H_{n_s}$.

▶ **Definition 20** (simultaneously-contractible)**.** *We say S is $\frac{13}{8}$-simultaneously contractible if the small components of S are $(\frac{13}{8}, 4, n_s)$-contractible in G.*

▶ **Definition 21** ($\mathsf{OPT}^L, \mathsf{OPT}^R, D_2^L, D_2^R$)**.** *We partition the vertex set of G in two sets: $V(G) = L \cup R$, where L consists of the vertices in the large components of the special configuration S and R is the set of remaining vertices, i.e., the set of vertices in the small components of S. Let OPT^L be the edges of $\mathsf{OPT}(G)$ that have at least one endpoint incident on a vertex in L, and OPT^R be the remaining edges of $\mathsf{OPT}(G)$, i.e., the edges whose both endpoints are in R. D_2^L and D_2^R are defined analogously: D_2^L is the set of edges of $D_2(G)$ that are incident on at least one vertex of L and $D_2^R = E(D_2(G)) \setminus D_2^L$. $\mathsf{opt}^L, \mathsf{opt}^R, d_2^L$, and d_2^R are defined to be $||\mathsf{OPT}^L||, ||\mathsf{OPT}^R||, ||D_2^L||$, and $||D_2^R||$, respectively.*

The following relationships are immediate.

▶ **Proposition 22.**

$||\mathsf{OPT}(G)|| := \mathsf{opt} = \mathsf{opt}^L + \mathsf{opt}^R$.

$||D_2(G)|| := d_2 = d_2^L + d_2^R$.

The following proposition is key to proving our bound.

▶ **Proposition 23.**

$\mathsf{opt}^L \geq d_2^L$

Proof. Assume for contradiction $\mathsf{opt}^L < d_2^L$. Observe $\mathsf{OPT}^L \cup D_2^R$ forms a 2-edge-cover of G, since each vertex of L has at least 2 edges incident on it from OPT^L (as OPT is a feasible 2-ECSS of G) and each vertex of D_2^R has 2 edges incident on it from D_2^R (as D_2^R are the edges of D_2 restricted to the small components of S, which were originally small in D_2). But

$$||\mathsf{OPT}^L \cup D_2^R|| = \mathsf{opt}^L + d_2^R < d_2^L + d_2^R = d_2,$$

which contradicts the fact that D_2 is a minimum 2-edge-cover of G. ◀

Now, we are ready to prove that ALG is admissible.

Proof of Lemma 19. Fix a structured graph G. To show ALG is admissible, we need to show two properties: (i) $\mathsf{ALG}(G)$ is a 2-edge-connected spanning subgraph of G with $||\mathsf{ALG}(G)|| \leq f(G)$ under the assumption that $\mathsf{Reduce}(G')$ is a 2-edge-connected spanning subgraph of G' with $||\mathsf{Reduce}(G')|| \leq f(G')$ for all MAP instances G' of size strictly smaller than the size of G, and (ii) $T(s(G)) \leq T'(s(G)-1) + poly(s)$, where T is the running time of ALG and T' is the running time of Reduce. Note that (ii) follows from the fact that each of the three steps in ALG takes polynomial time and in the final step, namely Contract-vs-Glue, ALG calls the subroutine Reduce only once on a smaller graph. Thus, we will focus on proving (i) below.

Note that ALG on input G first computes a special configuration S and then applies the algorithm Contract-vs-Glue on (G, S). If S is 2-ECSS, Contract-vs-Glue returns S, and $||S|| \leq \frac{13}{8}d_2 - 2n_\ell - \frac{5}{4}n_s$, where $n_\ell = 1$ is the number of large components and $n_s = 0$ is the number of small components in S (since S is an economical bridgeless 2-edge-cover of G). Thus, $||\mathsf{ALG}|| \leq f(G)$. Otherwise, S must contain at least one small component as observed in Section 4.2.

Let $H_1, \ldots, H_{n_s}$ be the small components of S. Contract-vs-Glue on (G, S) computes two solutions S_1 and S_2 and returns the one with lower weight. Recall S_1 is obtained by contracting the small components of S, calling Reduce on it, and then expanding the contracted nodes and adding back the edges of the small components. S_2 is computed by calling the $\mathsf{Glue}(G, S)$ subroutine. In either case, the output is guaranteed to be a 2-edge-connected spanning subgraph of G from Lemmas 16 and 17.

Now, to show $||\mathsf{ALG}(G)|| \leq f(G)$, we have two cases based on whether the special configuration S is $\frac{13}{8}$-simultaneously contractible in G. If S is a $\frac{13}{8}$-simultaneously contractible in G, then by invoking Lemma 16 (whose precondition holds since the contracted graph has size strictly smaller than G and then we have the guarantee that $||\mathsf{Reduce}(G')|| \leq f(G')$ for all MAP instances G'), we have $||\mathsf{ALG}(G)|| \leq ||S_1|| \leq f(G)$ and we are done.

In the case S is not $\frac{13}{8}$-simultaneously contractible in G, we will first lower bound opt and then upper bound $||S_2||$ to show $||\mathsf{ALG}(G)|| \leq f(G)$.

Lower bound on opt

From Propositions 22 and 23 we have

$$\mathsf{opt} = \mathsf{opt}^L + \mathsf{opt}^R \geq d_2^L + \mathsf{opt}^R.$$

We now focus on lower bounding opt^R. Recall OPT^R consists of edges whose both endpoints are contained in $\bigcup_{i\in[n_s]} V(H_i)$. We categorize the edges of OPT^R into two types.

- An edge of OPT^R is **inside** if both its endpoints belong to the same $V(H_i)$ for some i.
- An edge of OPT^R is **crossing** if its endpoints lie in distinct $V(H_i)$ and $V(H_j)$ for some $i \neq j$.

Since S is not $\frac{13}{8}$-simultaneously contractible in G, the number of unit-edges that are inside is at most $\frac{8}{13} \cdot 2n_s$. Let us say the number of inside edges is exactly t less than the number of unit-edges in the small components of S, i.e., $2n_s - t$, and this number is at most $\frac{8}{13} \cdot 2n_s$.

Now, to lower bound the number of unit-edges that are crossing, we invoke Lemma 18, which states that the number of unit-edges going between $V(H_i)$ and $V(H_j)$ for all $i \neq j$ is at least $(1 + \frac{1}{12})$t.

Thus, we have the following lower bound for opt.

$$\begin{aligned}\mathsf{opt} = \mathsf{opt}^L + \mathsf{opt}^R &\geq d_2^L + \mathsf{opt}^R = d_2^L + ||\text{inside}|| + ||\text{crossing}|| \\ &\geq d_2^L + (2n_s - t) + \left(1 + \frac{1}{12}\right) t,\end{aligned}$$

where $2n_s - t \leq \frac{8}{13} \cdot 2n_s$. The lower bound is minimized when t is kept as small as possible, i.e., when $2n_s - t = \frac{8}{13} \cdot 2n_s$, i.e., for $t = \frac{5}{13} \cdot 2n_s$. Thus,

$$\mathsf{opt} \geq d_2^L + \frac{8}{13} \cdot 2n_s + \left(1 + \frac{1}{12}\right) \frac{5}{13} \cdot 2n_s = d_2^L + \left(\frac{16}{13} + \frac{10}{12}\right) n_s = d_2^L + \frac{161}{78} \cdot n_s.$$

Upper bound on $||\mathsf{ALG}(G)||$

Since S is an economical bridgeless 2-edge-cover of G, we have

$$||S|| \leq \frac{13}{8} \cdot d_2 - 2n_\ell - \frac{5}{4} \cdot n_s,$$

where n_ℓ and n_s denote the number of large and small components of S, respectively. Also, from Lemma 17, we have

$$||S_2|| = ||\mathsf{Glue}(G, S)|| \leq ||S|| + 2n_\ell + \frac{4}{3} \cdot n_s - 2.$$

Combing the two bounds we obtain

$$||S_2|| \leq \frac{13}{8} \cdot d_2 + \frac{1}{12} \cdot n_s - 2.$$

Now we can split d_2 as $d_2^L + d_2^R$, and use the fact that $d_2^R = 2n_s$ to obtain our bound.

$$\begin{aligned}||\mathsf{ALG}(G)|| \leq ||S_2|| &\leq \frac{13}{8} \cdot d_2 + \frac{1}{12} \cdot n_s - 2 = \left(\frac{13}{8} \cdot d_2^L + \frac{13}{8} \cdot 2n_s\right) + \frac{1}{12} \cdot n_s - 2 \\ &= \frac{13}{8} \cdot d_2^L + \frac{10}{3} \cdot n_s - 2 \leq \frac{13}{8}\left(d_2^L + \frac{160}{78} \cdot n_s\right) - 2 \leq \frac{13}{8} \cdot \mathsf{opt} - 2 \leq f(G),\end{aligned}$$

where the second last inequality follows from the lower bound on opt obtained above. ◀

6 Conclusion

In this work, we presented a $\frac{13}{8}$-approximation for MAP, which is a fundamental problem in network design. While several of our steps also work for smaller approximation ratios, two of our steps are tight for $\frac{13}{8}$: First, constructing a special configuration is tight for $\frac{13}{8}$. In particular, the merge involving 3-augmenting paths, in the worst case, uses all the available credits. On the other hand, such a merge could not be avoided, as their absence from special configurations helps us improve the lower bound later. Furthermore, the lower bound is tight. Hence, simply obtaining a better construction of a special configuration is not enough as one has to improve upon the lower bound as well. Finally, even if one can resolve these two issues, our approximation ratio would still be tight for 1.6 at two places: First, constructing a bridgeless 2-edge-cover is tight for 1.6, even though we believe that this result can be strengthened. Second, in the construction of special configuration, handling the medium components is also tight for precisely 1.6. Hence, also here new ideas are needed in order to obtain an approximation ratio below 1.6.

Our result builds on a new $\frac{3}{2}$-approximation preserving reduction to instances not containing certain structures including small separators and contractible subgraphs. Furthermore, we introduced the method of simultaneous contractions and improved lower bounds to achieve our main result. These techniques seem general and applicable to other problems in network design.

Abstract

We study the problem of performing counting queries at different levels in hierarchical structures while preserving individuals' privacy. Motivated by applications, we propose a new error measure for this problem by considering a combination of multiplicative and additive approximation to the query results. We examine known mechanisms in differential privacy (DP) and prove their optimality, under this measure, in the pure-DP setting. In the approximate-DP setting, we design new algorithms achieving significant improvements over known ones.

1 Introduction

With the increasing need to preserve the privacy of users, differential privacy (DP) [18, 17] has emerged as a widely popular notion that provides strong guarantees on user privacy and satisfies compelling mathematical properties. There have been many deployments of DP in the field of data analytics both in industry [4, 14] and by government agencies [3].

We start by recalling the formal definition of DP, tailored to our setting.

▶ **Definition 1** (Differential Privacy). *Let $\mathcal{A}$ be a randomized algorithm taking an integer vector as input. We say $\mathcal{A}$ is* (ε, δ)-differentially private *(i.e., (ε, δ)-DP) if*

$$\mathbf{Pr}\left[\mathcal{A}(\boldsymbol{x}) \in S\right] \leq e^{\varepsilon} \cdot \mathbf{Pr}\left[\mathcal{A}(\boldsymbol{x}') \in S\right] + \delta,$$

holds for any measurable subset S of $\mathcal{A}$'s range and any two neighboring inputs $\boldsymbol{x}, \boldsymbol{x}'$, where $\boldsymbol{x}, \boldsymbol{x}'$ are considered neighbors *iff $\|\boldsymbol{x} - \boldsymbol{x}'\|_1 = 1$.*

When $\delta = 0$, we say $\mathcal{A}$ is ε-DP *(aka* pure-DP*); the case $\delta > 0$ is* approximate-DP.

Estimating Counts in Trees

A fundamental task in data analytics is to aggregate counts over hierarchical subsets (specifically, trees) of the input points. For example, the government might be interested in the number of households, aggregated at the state, country, and city levels. As another example, online advertisers might be interested in the number of user clicks on product ads, when there is a category hierarchy on the products. The tree aggregation problem has been the subject of several previous works in DP including in the context of range queries [13, 42, 21, 43], the continuous release model [20, 10], private machine learning [31, 30], and the US census top-down algorithms [2, 1, 12, 11], to name a few[1]. In this work, we revisit this basic problem and present new perspectives and results.

Let $\mathcal{T}$ be a rooted tree of depth[2] d and arity k; the structure of $\mathcal{T}$ is known a priori. Let $\mathsf{nodes}(\mathcal{T})$ be the set of *nodes* and $\mathsf{leaves}(\mathcal{T})$ be the set of *leaves* in $\mathcal{T}$. The problem of private aggregation in trees can be formalized as follows.

▶ **Problem 2** (Tree Aggregation). *Given a tree $\mathcal{T}$, the input to the problem is a vector $\boldsymbol{x} \in \mathbb{N}^{\mathsf{leaves}(\mathcal{T})}$, where $x_v \in \mathbb{N}$ is a value for $v \in \mathsf{leaves}(\mathcal{T})$. For each node $u \in \mathcal{T}$, define its weight w_u by*

$$w_u = \sum_{v \text{ is a leaf under } u} x_v.$$

The desired output is a DP estimate vector $\widetilde{\boldsymbol{w}} \in \mathbb{R}^{\mathsf{nodes}(\mathcal{T})}$ of $\boldsymbol{w}$.

In the above formulation, the input x_v represents the number of individuals that contribute to the leaf v, and the weight w_u counts all the number of individuals that contribute to any of its descendants (or itself). As before, $\boldsymbol{x}, \boldsymbol{x}'$ are neighbors iff $\|\boldsymbol{x} - \boldsymbol{x}'\|_1 = 1$.

Besides being a natural problem on its own, algorithms for tree aggregation also serve as subroutines for solving other problems such as range queries [13, 42, 21, 43].

Linear Queries and Error Measure

Tree aggregation in fact belongs to a class of problems called *linear queries* – one of the most widely studied problems in DP (see, e.g., [15, 19, 28, 5, 39, 9, 37, 6, 24, 38]). In its most general form, the problem can be stated as follows.

▶ **Problem 3** (Linear Queries). *For a given workload matrix $\boldsymbol{W} \in \mathbb{R}^{m \times n}$, the input to the $\boldsymbol{W}$-*linear query *problem is a vector $\boldsymbol{x} \in \mathbb{N}^n$ and the output is a DP estimate of $\boldsymbol{W}\boldsymbol{x}$.*

It is easy to see that the tree aggregation problem can be viewed as a linear query problem, where the binary workload matrix $\boldsymbol{W}^{\mathcal{T}} \in \{0,1\}^{\mathsf{nodes}(\mathcal{T}) \times \mathsf{leaves}(\mathcal{T})}$ encodes if each leaf (corresponding to a column index) is a descendant of (or itself) each node (corresponding to a row index).

Two error measures have been studied in the literature: the (expected) ℓ_2^2*-error*[3]

$$\ell_2^2\text{-}\mathsf{error}(\mathcal{M}; \boldsymbol{W}) := \max_{\boldsymbol{x} \in \mathbb{N}^n} \sqrt{\frac{1}{m} \mathbb{E}\left[\|\mathcal{M}(\boldsymbol{x}) - \boldsymbol{W}\boldsymbol{x}\|_2^2\right]},$$

[1] We remark that there is a reduction from our problem to that of releasing thresholds, which we discuss in more detail in Section 1.3.

[2] The *depth* is defined to be the maximum number of nodes along a root-to-leaf path of the tree.

[3] In some previous work, $\ell_2^2\text{-}\mathsf{error}(\mathcal{M}; \boldsymbol{W})$ is defined as $\max_{\boldsymbol{x} \in \mathbb{N}^n} \frac{1}{m} \mathbb{E}\left[\|\mathcal{M}(\boldsymbol{x}) - \boldsymbol{W}\boldsymbol{x}\|_2^2\right]$ (without the square root). We use the current version as it is more convenient to deal with in our error analysis. In any case, we can obviously convert a bound in one version to the other.

and the (expected) ℓ_∞-*error*

$$\ell_\infty\text{-error}(\mathcal{M}; \boldsymbol{W}) := \max_{\boldsymbol{x} \in \mathbb{N}^n} \mathbb{E}\left[\|\mathcal{M}(\boldsymbol{x}) - \boldsymbol{W}\boldsymbol{x}\|_\infty\right],$$

where $\mathcal{M}$ is a DP mechanism for the $\boldsymbol{W}$-linear query problem. Indeed, previous works have characterized the best possible errors in the approximate-DP case up to polylogarithmic factors for any given workload $\boldsymbol{W}$. (See the discussion in [24] for more details.)

It is worth noting that these measures focus only on the *additive error* of the query, i.e., $\mathcal{M}(\boldsymbol{x}) - \boldsymbol{W}\boldsymbol{x}$. In many scenarios, however, this is not the only possible measure of error. Specifically, in this work, we seek to expand the error measure by additionally incorporating *multiplicative error*. Intuitively, multiplicative errors are meaningful when the true answer (i.e., $(\boldsymbol{W}\boldsymbol{x})_i$) is quite large; e.g., if the true error is 10^6, then we should not be distinguishing whether the additive error is 10 or 100 as both of them are very small compared to 10^6. In addition to this intuition, multiplicative errors have also been used in other contexts such as in empirical evaluations of range queries (e.g., [13, 40, 43]).

With the above discussion in mind, we now proceed to define the error measure.

▶ **Definition 4** (Multiplicative Root Mean Squared Error). *Given parameter $\alpha > 0$, we define an* α-multiplicative root mean squared error (α-RMSE) *of an estimate $\widetilde{z}$ of the true answer $z \geq 0$ as*

$$\mathsf{RMSE}_\alpha(\widetilde{z}, z) := \sqrt{\mathop{\mathbb{E}}_{\widetilde{z}}\left[\left(\max\left\{|\widetilde{z} - z| - \alpha \cdot z, 0\right\}\right)^2\right]}.$$

For $\boldsymbol{W}$-linear query, we define an α-multiplicative maximum root mean squared error (α-mRMSE) *of a mechanism $\mathcal{M}$ to be*

$$\mathsf{mRMSE}_\alpha(\mathcal{M}; \boldsymbol{W}) := \max_{\boldsymbol{x} \in \mathbb{Z}^n} \max_{i \in [m]} \mathsf{RMSE}_\alpha\left(\mathcal{M}(\boldsymbol{x})_i, (\boldsymbol{W}\boldsymbol{x})_i\right).$$

Note that when $\alpha = 0$ (i.e., the error is only additive), our notion of α-RMSE coincides with that of the standard RMSE. By taking the maximum error across all queries when defining the error for linear queries, we mitigate the weakness of ℓ_2^2-error bound, which allows some queries to incur huge errors, while still avoiding the "union bound issue" faced in the ℓ_∞-error. The latter can be significant as the number of queries here can be exponential in the depth d.

We remark that our algorithms also achieve the usual with high probability guarantees, i.e., with probability at most η, $|\widetilde{z} - z| \leq \alpha \cdot \max\{z, \tau\}$ for some threshold τ. We defer such a statement to later sections for simplicity of comparing the bounds. Furthermore, our error notion implies upper bounds on "smoothed relative errors" used for empirical evaluations in previous works [40, 43]. We provide a formal statement in the full version.

When $\alpha = 0$, we drop the "α-multiplicative" or "α-" prefixes and refer to the errors simply as maximum RMSE or mRMSE. Similarly, we also drop α from the subscript and simply write mRMSE instead of mRMSE_0.

1.1 Our Results

Two known baselines for tree aggregation are the ε-DP Laplace mechanism and (ε, δ)-DP Gaussian mechanism, which achieve mRMSE of $O(d/\varepsilon)$ and $O(\sqrt{d\log(1/\delta)}/\varepsilon)$ respectively. We start by showing that these are already tight for the additive-only errors:

▶ **Theorem 5** (Informal; see Theorem 28). *There is no ε-DP algorithm for tree aggregation with* mRMSE $o(d/\varepsilon)$*, even for binary trees.*

Table 1 Overview of results; entries indicate upper/lower bounds on α-mRMSE. Upper bounds corresponding to Laplace and Gaussian mechanisms are formally stated in Corollary 15. For simplicity we omit the dependence on α in the additive-multiplicative bounds here.

Type of error	ε-DP	(ε, δ)-DP
Additive-only ($\alpha = 0$)	$O(d/\varepsilon)$: Laplace	$O_{\varepsilon,\delta}(\sqrt{d})$: Gaussian
	$\Omega(d/\varepsilon)$: Theorem 28	$\Omega_{\varepsilon,\delta}(\sqrt{d})$: Theorem 29
Additive-Multiplicative ($0 < \alpha < 1$)	$\Omega(d/\varepsilon)$: Theorem 28	$O_{\varepsilon,\delta}(\log d)$: Theorem 21

▶ **Theorem 6** (Informal; see Theorem 29). *There is no (ε, δ)-DP algorithm for tree aggregation with* mRMSE $o_{\varepsilon,\delta}(\sqrt{d})$*, even for binary trees.*

Given the above results, it is therefore natural to ask whether multiplicative errors can help reduce the error bound. For pure-DP, we show that this unfortunately is not the case.

▶ **Theorem 7** (Informal; see Theorem 28). *For any constant $\alpha < 1$, there is no ε-DP algorithm for tree aggregation with α-*mRMSE *$o(d/\varepsilon)$, even for binary trees.*

Our next – and perhaps the most surprising – result is that, unlike in the pure-DP case, allowing multiplicative approximation in approximate-DP allows us to reduce the upper bounds exponentially from $O_{\varepsilon,\delta}(\sqrt{d})$ to $O_{\varepsilon,\delta}(\log d)$:

▶ **Theorem 8** (Informal; see Theorem 21). *For any constant $\alpha > 0$, there is an efficient (ε, δ)-DP algorithm for tree aggregation with α-*mRMSE *$O(\log(d/\delta)/\varepsilon)$.*

We remark that Theorem 8 has worse dependency on δ than the (ε, δ)-DP Gaussian mechanism. Indeed, the former has $\log(1/\delta)$ whereas the latter only has $\sqrt{\log(1/\delta)}$. However this gap is somewhat unavoidable as we will discuss in Remark 33 when δ is small, say, $\delta = 2^{-\Omega(d)}$. Our results are summarized in Table 1.

Our bounds do *not* depend on the arity k of $\mathcal{T}$. This is immediate for the lower bounds (Theorems 5–7) since it suffices to prove it for binary trees $k = 2$. The reason for the upper bounds (Theorem 8) is less clear, relying on the fact that the weights of two nodes are correlated iff they are on the same root-to-leaf path, which is irrelevant of the arity.

1.2 Proof Overview

Probabilistic Utility Guarantee

Recall that we defined the error α-mRMSE as a variant of RMSE but with a multiplicative error subtracted out. While this gives us a nice scalar quantity (once α is fixed) to work with and state the results, it will be useful in the subsequent analyses to define a probabilistic version of the guarantee with additional fixed thresholds.

In this different utility guarantee (formalized in (1)), every node u is given an additional threshold τ_u, and a randomized output $\widetilde{\boldsymbol{w}}$ is accurate if for all $u \in \mathsf{nodes}(\mathcal{T})$ we have with probability at least $1 - \eta$ that

$$|\widetilde{w}_u - w_u| \leq \alpha \cdot \max\{w_u, \tau_u\}.$$

The smaller the thresholds τ_u's are, the better the accuracy will be.

The benefit of having τ_u is that it is independent of w_u and is explicitly available to the algorithms; this formulation may be of independent interest. On the other hand, this probabilistic guarantee is closely related to the original α-mRMSE in Definition 4:

1. Any algorithm with low α-mRMSE has good probabilistic guarantee (Lemma 19).
2. Any algorithm with good probabilistic guarantee can be converted into one with low α-mRMSE (Lemma 20).

Improved Approximate-DP Algorithm

Given Item 2, it suffices to design an algorithm with a good probabilistic guarantee, i.e., works for thresholds τ_u's as small as possible. Our algorithm can be decomposed into two parts: a reduction step and a classification algorithm.

Reduction. Since the error measure is multiplicative when w_u is large, we design a geometric sequence of thresholds and classify each w_u into the correct interval created by the thresholds. To do so, every time we use a classification algorithm to find nodes that are above the current threshold, and in the next round we only focus on the ones below the threshold. Assuming previous classifications are all correct, the weights of the nodes above the current threshold are actually below the previous threshold. Such a sandwiching relation provides a good approximation if the granularity of the thresholds is not too large compared with the ratio α (Lemma 26).

Moreover, we assign privacy and error parameters in the same geometric fashion, thus their telescoping sum (from composition theorems) converges.
