Contents

Track B: Automata, Logic, Semantics, and Theory of Programming

Preface

This volume contains the papers presented at the *50th EATCS International Conference on Automata, Languages and Programming (**ICALP 2023**)*, held in Paderborn, Germany, during July 10–14, 2023. ICALP is a series of annual conferences of the *European Association for Theoretical Computer Science (EATCS)*, which first took place in 1972.

This year, the ICALP program consisted of two tracks:

Track A: Algorithms, Complexity, and Games

Track B: Automata, Logic, Semantics, and Theory of Programming

In response to the call for papers, a total of 443 eligible, anonymous submissions were received: 346 for Track A and 97 for Track B. The committees decided to accept 132 papers for inclusion in the scientific program: 103 papers for Track A and 29 for Track B. The selection was made by the program committees based on originality, quality, and relevance to theoretical computer science. The quality of the submissions was very high, and many deserving papers could not be selected.

The EATCS sponsored awards for both a best paper and a best student paper in each of the two tracks, selected by the program committees.

The **best paper awards** were given to the following papers:

Track A: Tsun-Ming Cheung, Hamed Hatami, Pooya Hatami, and Kaave Hosseini. *Online Learning and Disambiguations of Partial Concept Classes.*

Track A: Miguel Bosch Calvo, Fabrizio Grandoni, and Afrouz Jabal Ameli. *A* 4/3 *Approximation for* 2*-Vertex-Connectivity.*

Track B: Marvin Künnemann, Filip Mazowiecki, Lia Schütze, Henry Sinclair-Banks, and Karol Węgrzycki. *Coverability in VASS Revisited: Improving Rackoff's Bound to Obtain Conditional Optimality.*

The **best student paper awards**, for papers that are solely authored by students, were given to the following papers:

Track A: Manuel Cáceres. *Minimum Chain Cover in Almost Linear Time.*

Track B: Ruiwen Dong. *The Identity Problem in* $\mathbb{Z} \wr \mathbb{Z}$ *is decidable.*

Apart from the contributed talks, ICALP 2023 included invited presentations by

- Anna Karlin, University of Washington, USA,
- Rasmus Kyng, ETH Zurich, Switzerland,
- Rupak Majumdar, Max Planck Institute for Software Systems, Germany,
- Thomas Vidick, California Institute of Technology, USA, and Weizmann Institute of Science, Israel,
- James Worrell, University of Oxford, UK.

This volume contains all the contributed papers presented at the conference, and an abstract or paper accompanying each of the invited talks by Anna Karlin, Rasmus Kyng, Rupak Majumdar, Thomas Vidick, and James Worrell.

For this special 50th anniversary of ICALP 2023, the conference program also included a special session with two invited talks by

- Kurt Mehlhorn, Max Planck Institute for Computer Science, Germany,
- Thomas A. Henzinger, Institute of Science and Technology, Austria.

50th International Colloquium on Automata, Languages, and Programming (ICALP 2023).
Editors: Kousha Etessami, Uriel Feige, and Gabriele Puppis
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Although they did not provide abstracts for the proceedings, we acknowledge their involvement and contribution.

The program of ICALP 2023 also included presentations of the EATCS Award 2023 to Amos Fiat (Tel Aviv University), the Presburger Award 2023 to Aaron Bernstein (Rutgers University) and to Thatchaphol Saranurak (University of Michigan), the Alonzo Church Award 2023 to the following group of papers:

- Ralf Jung, David Swasey, Filip Sieczkowski, Kasper Svendsen, Aaron Turon, Lars Birkedal, Derek Dreyer: "Iris: Monoids and Invariants as an Orthogonal Basis for Concurrent Reasoning". POPL 2015.
- Ralf Jung, Robbert Krebbers, Lars Birkedal, Derek Dreyer: "Higher-order ghost state". ICFP 2016.
- Robbert Krebbers, Ralf Jung, Aleš Bizjak, Jacques-Henri Jourdan, Derek Dreyer, Lars Birkedal: "The Essence of Higher-Order Concurrent Separation Logic". ESOP 2017.
- Ralf Jung, Robbert Krebbers, Jacques-Henri Jourdan, Aleš Bizjak, Lars Birkedal, Derek Dreyer: "Iris from the ground up: A modular foundation for higher-order concurrent separation logic". J. Funct. Program. 28 (2018).

The EATCS Distinguished Dissertation Award 2023 was awarded jointly to the following PhD dissertations:

- Kuikui Liu (University of Washington): "Spectral Independence: A New Tool to Analyze Markov Chains" (supervisor Shayan Oveis Gharan).
- Alex Lombardi (MIT, Department of Electrical Engineering and Computer Science): "Provable Instantiations of Correlation Intractability and the Fiat-Shamir Heuristic" (supervisor Vinod Vaikuntanathan).
- Lijie Chen (MIT, Department of Electrical Engineering and Computer Science): "Better Hardness via Algorithms, and New Forms of Hardness versus Randomness" (supervisor Ryan Williams).

There was also the announcement of the new EATCS Fellows for 2023, who are:

- Michael A. Bender (Stoney Brook University),
- Leslie Ann Goldberg (University of Oxford),
- Claire Mathieu (CNRS, IRIF, Université de Paris).

The following workshops were held as satellite events of ICALP 2023 on July 10, 2023:

- Combinatorial Reconfiguration
- Graph Width Parameters: from Structure to Algorithms (GWP 2023)
- Algorithmic Aspects of Temporal Graphs VI
- Adjoint Homomorphism Counting Workshop (ad hoc)
- Congestion Games
- Workshop On Reachability, Recurrences, and Loops '23 (WORReLL'23)
- Workshop on Recent Trends in Online Algorithms
- Quantum Computing with Qiskit, and why Classical Algorithms still matter!
- Algebraic Complexity Theory
- Computer Science for CONTINUOUS Data

We wish to thank all authors who submitted extended abstracts for consideration, the program committees for their scholarly effort, and all the reviewers who assisted the program committees in the evaluation process.

We are also grateful to the Conference General Chair, Sevag Gharibian, his colleagues from Paderborn University, and EATCS, for organizing ICALP 2023.

Finally, we would like to thank Anca Muscholl, the Chair of the ICALP Steering Committee, for her continuous support, Artur Czumaj, the president of EATCS, for his generous advice on the organization of the conference, as well as Michael Wagner, Michael Didas, and the entire editorial office of LIPIcs for their support in editing these proceedings.

Program Committees

Track A

Amir Abboud	Weizmann Institute, Israel
Mikkel Abrahamsen	University of Copenhagen, Denmark
Sepehr Assadi	Rutgers University, USA
Aditya Bhaskara	University of Utah, USA
Arnab Bhattacharyya	National University of Singapore, Singapore
Greg Bodwin	University of Michigan, USA
Karl Bringmann	Saarland University, Germany
Clément Canonne	University of Sydney, Australia
Vincent Cohen Addad	Google Research, Zurich
Amin Coja Oghlan	TU Dortmund, Germany
Michael Dinitz	Johns Hopkins University, USA
Uriel Feige (Chair)	Weizmann Institute, Israel
Moran Feldman	University of Haifa, Israel
Sebastian Forster	University of Salzburg, Austria
Sumegha Garg	Stanford University, USA
Parikshit Gopalan	Apple, USA
Karthik C.S.	Rutgers University, USA
Yin Tat Lee	University of Washington, USA
Stefano Leonardi	Sapienza Universita di Roma, Italy
Sepideh Mahabadi	MSR Redmond, USA
Giulio Malavolta	Max Planck Institute for Security and Privacy, Germany
Jesper Nederlof	Utrecht University, Netherlands
Vianney Perchet	Ensae and Criteo AI Lab, France
Will Perkins	Georgia Institute of Technology, USA
Marcin Pilipczuk	University of Warsaw, Poland, and IT University of Copenhagen, Denmark
Aviad Rubinstein	Stanford University, USA
Barna Saha	University of California San Diego, USA
Rahul Santhanam	University of Oxford, UK
Thatchaphol Saranurak	University of Michigan, USA
Igor Shinkar	Simon Fraser University, Canada
Mohit Singh	Georgia Institute of Technology, USA
David Steurer	ETH Zurich, Switzerland
Ola Svensson	EPFL, Switzerland
Inbal Talgam-Cohen	Technion, Israel
Kavitha Telikepalli	Tata Institute of Fundamental Research, Mumbai, India
Vera Traub	University of Bonn, Germany
Salil Vadhan	Harvard University, USA
David Wajc	Google Research, USA
Henry Yuen	Columbia University, USA
Meirav Zehavi	Ben-Gurion University, Israel

Track B

Shaull Almagor	Technion, Israel
Albert Atserias	Universitat Politecnica de Catalunya, Barcelona, Spain
Christel Baier	TU Dresden, Germany
Véronique Bruyère	University of Mons, Belgium
Thomas Colcombet	IRIF / CNRS / Université Paris Cité, France
Andrei Bulatov	Simon Fraser University, Canada
Wojciech Czerwiński	University of Warsaw, Poland
Kousha Etessami (Chair)	University of Edinburgh, UK
John Fearnley	University of Liverpool, UK
Dana Fisman	Ben-Gurion University, Israel
Rob van Glabbeek	University of New South Wales, Australia
Chris Heunen	University of Edinburgh, UK
Justin Hsu	Cornell University, USA
Stefan Kiefer	University of Oxford, UK
Kohei Kishida	University of Illinois Urbana-Champaign, USA
Jan Kretinsky	Technical University of Munich, Germany
Karoliina Lehtinen	CNRS, Université Aix Marseille et Université de Toulon, LIS, France
Anthony Widjaja Lin	TU Kaiserslautern & MPI-SWS, Germany
Wim Martens	University of Bayreuth, Germany
Joanna Ochremiak	CNRS, University of Bordeaux, France and University of Warsaw, Poland
Daniela Petrisan	Université Paris Cité, IRIF, France
Sam Staton	University of Oxford, UK
Ashutosh Trivedi	University of Colorado - Boulder, USA
Takeshi Tsukada	Chiba University, Japan
Mahesh Viswanathan	University of Illinois Urbana-Champaign, USA

Organizing Committee

Department of Information and Computing Sciences, Utrecht University, The Netherlands

50th International Colloquium on Automata, Languages, and Programming (ICALP 2023).
Editors: Kousha Etessami, Uriel Feige, and Gabriele Puppis
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Andrej Bogdanov (28)
University of Ottawa, Canada

Mikołaj Bojańczyk (117)
Institute of Informatics, University of Warsaw, Poland

Miguel Bosch-Calvo (29)
IDSIA, USI-SUPSI, Lugano, Switzerland

Patricia Bouyer (118)
Université Paris-Saclay, CNRS, ENS Paris-Saclay, Laboratoire Méthodes Formelles, 91190, Gif-sur-Yvette, France

Samuel Braunfeld (119)
Computer Science Institute of Charles University (IUUK), Prague, Czech Republic

Vladimir Braverman (30)
Rice University, Houston, TX, USA

Manuel Cáceres (31)
Department of Computer Science, University of Helsinki, Finland

Chris Cade (32)
QuSoft and University of Amsterdam (UvA), The Netherlands

Jin-Yi Cai (33)
Department of Computer Sciences, University of Wisconsin-Madison, WI, USA

Titouan Carette (120)
Centre for Quantum Computer Science, Faculty of Computing, University of Latvia, Riga, Latvia

Olivier Carton (121)
Université Paris Cité, CNRS, IRIF, F-75013, France; Institut Universitaire de France, Paris, France

Antonio Casares (122)
LaBRI, Université de Bordeaux, France

Diptarka Chakraborty (123)
National University of Singapore, Singapore

Sourav Chakraborty (123)
Indian Statistical Institute, Kolkata, India

Timothy M. Chan (34)
Department of Computer Science, University of Illinois at Urbana-Champaign, IL, USA

Yi-Jun Chang (35)
National University of Singapore, Singapore

Chandra Chekuri (36)
Department of Computer Science, University of Illinois, Urbana-Champaign, Urbana, IL, USA

Lijie Chen (39)
Miller Institute for Basic Research in Science at University of California at Berkeley, CA, USA

Yanlin Chen (38)
QuSoft and CWI, Amsterdam, The Netherlands

Yu Chen (37)
EPFL, Lausanne, Switzerland

Kuan Cheng (41)
Department of Computer Science, Peking University, Beijing, China

Pingan Cheng (7)
Aarhus University, Denmark

Siu-Wing Cheng (40)
Department of Computer Science and Engineering, Hong Kong University of Science and Technology, Hong Kong, China

Joseph Cheriyan (15)
Department of Combinatorics and Optimization, University of Waterloo, Canada

Tsun-Ming Cheung (42)
McGill University, Montreal, Canada

Dmitry Chistikov (112)
Centre for Discrete Mathematics and its Applications (DIMAP) & Department of Computer Science, University of Warwick, Coventry, UK

Keerti Choudhary (24)
Department of Computer Science and Engineering, Indian Institute of Technology Delhi, India

Omer Cohen Sidon (44)
Tel Aviv University, Israel

Ilan Reuven Cohen (43)
Faculty of Engineering, Bar-Ilan University, Ramat Gan, Israel

Sarel Cohen (24)
School of Computer Science, Tel-Aviv-Yaffo Academic College, Israel

Richard Cole (8)
New York University, NY, USA

Spencer Compton (45)
Stanford University, CA, USA

Sam Coy (46)
University of Warwick, Coventry, UK

Artur Czumaj (46)
University of Warwick, Coventry, UK

Peter Davies (46)
Durham University, UK

Anuj Dawar (119)
Department of Computer Science and Technology, University of Cambridge, UK

Ronald de Wolf (38)
QuSoft and CWI, Amsterdam, The Netherlands; University of Amsterdam, The Netherlands

Gregory Dexter (21)
Department of Computer Science, Purdue University, West Lafayette, IN, USA

Yann Disser (47)
TU Darmstadt, Germany

Magdalen Dobson (26)
Carnegie Mellon University, Pittsburgh, PA, USA

Ruiwen Dong (124)
Department of Computer Science, University of Oxford, UK

Dani Dorfman (9)
Tel Aviv University, Israel

Andrzej Dorobisz (48)
Theoretical Computer Science Department, Faculty of Mathematics and Computer Science, Jagiellonian University, Kraków, Poland

Ilan Doron-Arad (49)
Computer Science Department, Technion, Haifa, Israel

Gaëtan Douéneau-Tabot (121)
Université Paris Cité, CNRS, IRIF, F-75013, France; Direction générale de l'armement – Ingénierie des projets, Paris, France

Jan Dreier (125)
TU Wien, Austria

Lukas Drexler (50)
Heinrich-Heine Universität Düsseldorf, Germany

Petros Drineas (21)
Department of Computer Science, Purdue University, West Lafayette, IN, USA

Shaddin Dughmi (51)
University of Southern California, Los Angeles, CA, USA

Talya Eden (52)
Bar Ilan University, Ramat Gan, IL

Klim Efremenko (53)
Ben-Gurion University, Beer Sheva, Israel

Charilaos Efthymiou (54, 55)
Computer Science, University of Warwick, Coventry, UK

Ioannis Eleftheriadis (119)
Department of Computer Science and Technology, University of Cambridge, UK

David Eppstein (56)
Department of Computer Science, University of California, Irvine, CA, USA

Navid Eslami (10)
Aalto University, Espoo, Finland; Sharif University of Technology, Tehran, Iran

Javier Esparza (126)
Technische Universiät München, Germany

Louis Esperet (57)
Laboratoire G-SCOP, Grenoble, France

Jan Eube (50)
Universität Bonn, Germany

Austen Z. Fan (127)
Department of Computer Sciences, University of Wisconsin-Madison, WI, USA

Michal Feldman (58)
Blavatnik School of Computer Science, Tel Aviv University, Israel; Microsoft Research, Herzliya, Israel

Weiming Feng (54)
School of Informatics, University of Edinburgh, Edinburgh, UK

Robert Ferens (59)
University of Wrocław, Poland

Nathanaël Fijalkow (118)
CNRS, LaBRI and Université de Bordeaux, France; University of Warsaw, Poland

Emmanuel Filiot (121)
Université libre de Bruxelles & F.R.S.-FNRS, Brussels, Belgium

Marten Folkertsma (32)
QuSoft and CWI, Amsterdam, The Netherlands

Fedor V. Fomin (60, 61)
Department of Informatics,
University of Bergen, Norway

Tobias Friedrich (24, 62)
Hasso Plattner Institute,
Universität Potsdam, Germany

Zachary Friggstad (63)
Department of Computing Science,
University of Alberta, Canada

Daniel Frishberg (56)
Department of Computer Science,
University of California, Irvine, CA, USA

Honghao Fu (64)
CSAIL, Massachusetts Institute of Technology,
Cambridge, MA, USA

Federico Fusco (58)
Department of Computer, Control and
Management Engineering "Antonio Ruberti",
Sapienza University of Rome, Italy

Jakub Gajarský (128)
University of Warsaw, Poland

Moses Ganardi (3, 110)
Max Planck Institute for Software Systems
(MPI-SWS), Kaiserslautern, Germany

Ankit Garg (12)
Microsoft Research, Bangalore, India

Mohit Garg (65)
Department of Computer Science and
Automation, Indian Institute of Science,
Bengaluru, India

Sevag Gharibian (32)
Paderborn Universität, Germany

Badih Ghazi (66)
Google, Mountain View, CA, US

Alexandru Gheorghiu (67)
Department of Computer Science and
Engineering, Chalmers University of Technology,
Göteborg, Sweden;
Institute for Theoretical Studies, ETH Zürich,
Switzerland

Ashish Goel (70)
Stanford University, CA, USA

Leslie Ann Goldberg (68)
Department of Computer Science,
University of Oxford, UK

Ishay Golinsky (19)
Blavatnik School of Computer Science,
Tel Aviv University, Israel

Petr A. Golovach (60, 61)
Department of Informatics,
University of Bergen, Norway

Gramoz Goranci (69)
Faculty of Computer Science,
Universität Wien, Austria

Mohak Goyal (70)
Stanford University, CA, USA

Vincent P. Grande (126)
RWTH Aachen University, Germany

Fabrizio Grandoni (29)
IDSIA, USI-SUPSI, Lugano, Switzerland

Carla Groenland (27)
Mathematical Institute, Utrecht University,
The Netherlands

Research Institute for Mathematical Sciences,
Kyoto University, Japan

Shimon Kogan (85)
Weizmann Institute of Science, Rehovot, Israel

Daumantas Kojelis (111)
Department of Computer Science,
University of Manchester, UK

Gillat Kol (53)
Princeton University, NJ, USA

Vladimir Kolmogorov (72)
Institute of Science and Technology Austria,
Klosterneuburg, Austria

Niels Kornerup (17)
Computer Science, University of Texas,
Austin, TX, USA

Pravesh K. Kothari (77, 78)
Carnegie Mellon University,
Pittsburgh, PA, USA

Michal Koucký (22)
Computer Science Institute of Charles
University, Prague, Czech Republic

Paraschos Koutris (127)
Department of Computer Sciences,
University of Wisconsin-Madison, WI, USA

Dexter Kozen (136)
Department of Computer Science,
Cornell University, Ithaca, NY, USA

Jakub Kozik (48)
Theoretical Computer Science Department,
Faculty of Mathematics and Computer Science,
Jagiellonian University, Kraków, Poland

László Kozma (19)
Institut für Informatik, Freie Universität Berlin,
Germany

Robert Krauthgamer (30)
Weizmann Institute of Science, Rehovot, Israel

Aditya Krishnan (30)
Pinecone, San Francisco, CA, USA

Simon Krogmann (24)
Hasso Plattner Institute,
Universität Potsdam, Germany

Ariel Kulik (49)
CISPA Helmholtz Center for Information
Security, Saarbrücken, Germany

Pooja Kulkarni (16)
University of Illinois at Urbana-Champaign, IL,
USA

Gunjan Kumar (123)
National University of Singapore, Singapore

Ravi Kumar (66)
Google, Mountain View, CA, US

Orna Kupferman (109)
School of Computer Science and Engineering,
Hebrew University, Jerusalem, Israel

Rasmus Kyng (2)
ETH Zürich, Switzerland

Marvin Künnemann (131)
RPTU Kaiserslautern-Landau, Germany

François Ladouceur (115)
Department of Computer Science,
Université de Sherbrooke, Canada

Michael Lampis (132)
Université Paris-Dauphine, PSL University,
CNRS, LAMSADE, 75016, Paris, France

François Le Gall (32)
Nagoya University, Japan

Shi Li (86)
State Key Laboratory for Novel Software
Technology, Nanjing University, China;
Department of Computer Science and
Engineering, University at Buffalo, NY, USA

Xiantao Li (87)
Department of Mathematics, Pennsylvania State
University, University Park, PA, USA

Xin Li (41)
Department of Computer Science,
Johns Hopkins University, Baltimore, MD, USA

Moritz Lichter (133)
TU Darmstadt, Germany

Henrik Lievonen (10)
Aalto University, Espoo, Finland

Paul Liu (74)
Stanford University, CA, USA

Quanquan C. Liu (52)
Northwestern University, Evanston, IL, US

S. Cliff Liu (88)
Carnegie Mellon University,
Pittsburgh, PA, USA

Shu Liu (89)
The National Key Laboratory on Wireless Communications, University of Electronic Science and Technology of China, Chengdu, China

Markus Lohrey (134)
Universität Siegen, Germany

Daniel Lokshtanov (90)
University of California Santa Barbara, CA, USA

Kelin Luo (50)
Universität Bonn, Germany

Xin Lyu (39)
University of California at Berkeley, CA, USA

Shun-ichi Maezawa (81, 82)
Department of Mathematics,
Tokyo University of Science, Japan

Rupak Majumdar (3, 110)
Max Planck Institute for Software Systems (MPI-SWS), Kaiserslautern, Germany

Alessio Mansutti (112)
IMDEA Software Institute, Madrid, Spain

Pasin Manurangsi (66)
Google, Bangkok, Thailand

Claire Mathieu (91)
CNRS Paris, France

Simon Mauras (58)
Blavatnik School of Computer Science,
Tel Aviv University, Israel

Filip Mazowiecki (131)
University of Warsaw, Poland

Nicolas Mazzocchi (129)
Institute of Science and Technology Austria (ISTA), Klosterneuburg, Austria

A (Slightly) Improved Approximation Algorithm for the Metric Traveling Salesperson Problem

Anna R. Karlin ✉
Paul G. Allen School of Computer Science and Engineering,
University of Washington, Seattle, WA, USA

Abstract

We describe recent joint work with Nathan Klein and Shayan Oveis Gharan showing that for any metric TSP instance, the max entropy algorithm studied by [1] returns a solution of expected cost at most $\frac{3}{2} - \epsilon$ times the cost of the optimal solution to the subtour elimination LP and hence is a $\frac{3}{2} - \epsilon$ approximation for the metric TSP problem. The research discussed comes from [1], [2] and [3].

An Almost-Linear Time Algorithm for Maximum Flow and More

Rasmus Kyng
ETH Zürich, Switzerland

Abstract

In this talk, I will explain a new algorithm for computing exact maximum and minimum-cost flows in almost-linear time, settling the time complexity of these basic graph problems up to subpolynomial factors.

Our algorithm uses a novel interior point method that builds the optimal flow as a sequence of approximate minimum-ratio cycles, each of which is computed and processed very efficiently using a new dynamic data structure.

By well-known reductions, our result implies almost-linear time algorithms for several problems including bipartite matching, optimal transport, and undirected vertex connectivity. Our framework also extends to minimizing general edge-separable convex functions to high accuracy, yielding the first almost-linear time algorithms for many other problems including entropy-regularized optimal transport, matrix scaling, p-norm flows, and isotonic regression.

This talk is based on joint work with Li Chen, Yang P. Liu, Richard Peng, Maximilian Probst Gutenberg, and Sushant Sachdeva [1]. Our result appeared in FOCS'22 and won the FOCS best paper award.

Abstract

Context-bounded analysis of concurrent programs is a technique to compute a sequence of under-approximations of all behaviors of the program. For a fixed bound k, a context bounded analysis considers only those runs in which a single process is interrupted at most k times. As k grows, we capture more and more behaviors of the program. Practically, context-bounding has been very effective as a bug-finding tool: many bugs can be found even with small bounds. Theoretically, context-bounded analysis is decidable for a large number of programming models for which verification problems are undecidable. In this paper, we survey some recent work in context-bounded analysis of multithreaded programs.

In particular, we show a general decidability result. We study context-bounded reachability in a language-theoretic setup. We fix a class of languages (satisfying some mild conditions) from which each thread is chosen. We show context-bounded safety and termination verification problems are decidable iff emptiness is decidable for the underlying class of languages and context-bounded boundedness is decidable iff finiteness is decidable for the underlying class.

1 Introduction

Algorithmic verification of shared-state multithreaded programs is one of the main motivations for research in theoretical computer science. The general problem is undecidable, even when the class of programs is restricted in different ways. Thus, one direction of research has focused on finding decidable models that *over-approximate* the problem and another on finding *under-approximations*. An over-approximate model captures more behaviors than the original program; thus, if we find that the over-approximation has no bad behaviors, we

can be certain that neither does the original program. An under-approximation, conversely, captures fewer behaviors. In this case, if we find a bad behavior in the approximation, we know that the bad behavior is also possible in the original program.

We consider a particular type of under-approximation: *context bounding*. Context-bounding is a technique to construct a parameterized sequence of under-approximations [46, 37]. For a fixed parameter k, a k-context-bounded analysis considers only those behaviors of the program in which an individual thread is interrupted by the scheduler at most k times. As k increases, more and more behaviors of the original program fall into the purview of the analysis. In the limit, all behaviors are covered.

Context-bounding has become a popular technique because of two reasons. For a wide class of programming models and verification questions, context-bounded analyses become decidable, even though the unrestricted problems are undecidable. Moreover, in practice, context-bounded analysis has had success as a bug finding tool, since many bugs in practical instances can be discovered even with small values of k [46, 44, 36, 34].

We focus on decidability questions. In order to avoid "trivial" encodings of Turing machines, we restrict programs to be *finite data* – that is, we assume each program variable to take on finitely many values. Even with this restriction, depending on the model of programs, decidability can be non-immediate because the state space of a program can be infinite in other respects, such as the stack of an individual thread or the number of pending threads.

Properties of concurrent programs. For the moment, we focus on three decision problems: context-bounded *reachability* ("is there a k-bounded execution that reaches a specific global state?"), context-bounded *termination* ("all all k-bounded executions terminating?"), and context-bounded *boundedness* ("is there a bound on the number of pending threads along every k-bounded execution?"). We shall come back to other problems later.

Context-bounded analysis is a family of problems, depending on the model of concurrent programs as well as on the correctness properties considered. Qadeer and Rehof's original paper [46], that introduced context-bounding, stipulated that there is a fixed number of *recursive* threads that read or write shared variables but these threads do not spawn further threads. They showed that the reachability problem is NP-complete. Note that even with two threads, the reachability problem for finite-data programs is already undecidable: for example, we can encode the intersection non-emptiness problem for pushdown automata. On the other hand, if threads are not recursive, then the reachability problem is decidable without any context bounding restrictions, even if threads can spawn further threads: this can be shown by a reduction to the coverability problem for vector addition systems with states (VASS). Subsequently, Atig, Bouajjani, and Qadeer [11] extended decidability for context-bounded reachability when threads can spawn further threads. They showed an upper bound of 2EXPSPACE and a matching lower bound was shown by Baumann et al. [14]. Similar techniques show the same complexity for termination and boundedness.

A special case: Asynchronous programs. The special case of $k = 0$ of context-bounded analysis is important enough to have its own name: *asynchronous programs*. In an asynchronous program, threads are executed atomically to completion (that is, never interrupted by the scheduler). Many software systems based on cooperative scheduling implement this model. Sen and Viswanathan [47] studied the model and showed reachability is decidable by reducing to a well-structured transition system. Ganty and Majumdar [28] showed that reachability, termination, and boundedness are all EXPSPACE-complete, by again reducing to coverability problems for VASS.

Majumdar, Thinniyam, and Zetzsche [40] proved decidability results for asynchronous programs in a general language-theoretic setting. They fix a class of languages $\mathcal{C}$, and consider asynchronous programs in which each individual thread is a language from the class $\mathcal{C}$ over the alphabet of thread names as well as a transformer over the global states. That is, each thread is a language (from $\mathcal{C}$) of words of the form dwd', where d and d' are global states and w is a sequence of thread names. The intent is that an atomic execution of the thread takes the global state from d to d' and also spawns new instances of all the threads in w.

They show that for all classes $\mathcal{C}$ satisfying a mild language-theoretic assumption (the class $\mathcal{C}$ is a *full trio*), safety and termination are decidable if and only if the underlying language class $\mathcal{C}$ has a decidable emptiness problem. Similarly, boundedness is decidable if and only if finiteness is decidable for $\mathcal{C}$. As a consequence, they get decidability results for asynchronous programs over context-free languages, higher-order recursion schemes, as well as other language classes studied in infinite-state verification.

Contribution. Our starting point is the general approach of Majumdar, Thinniyam, and Zetzsche [40]. We show their general decidability results can be extended to context-bounded analysis (any $k \geq 0$). We define concurrent programs over a language class $\mathcal{C}$ and show analogous decidability results: (i) context-bounded reachability and context-bounded termination for programs are decidable if and only if $\mathcal{C}$ has a decidable emptiness problem, and (ii) context-bounded boundedness is decidable if and only if $\mathcal{C}$ has a decidable finiteness problem. As a consequence, we get a uniform proof for decidability for these problems for programs over context-free languages and for programs over higher-order recursion schemes.

The key argument in both settings is that of *downclosures* of languages under the subword ordering. Safety, termination, and boundedness are preserved if we "lose" some spawned threads, as long as the sequence of global state changes (and there are at most k of them for the fixed context bound k) is maintained. Since downclosures (even when maintaining a bounded number of distinguished letters) are always regular languages, this implies: If our concurrent program satisfies one of the above properties, then each thread can be over-approximated by a regular language so that the property is still satisfied. The decision procedure for reachability then runs two semi-decision procedures: one enumerates executions (to check for reachability) and the other enumerates regular languages and checks that (1) the thread languages are contained in the regular languages and (2) uses known decidability results for context-bounded reachability with regular thread languages.

The decision procedure does not, in particular, need to *construct* an explicit description of the downclosure. In fact, it even shows decidability for language classes for which downclosures cannot be constructed. On the flip side, we do not get complexity bounds.

Other properties. What about other properties? Ganty and Majumdar showed fair termination for context-free asynchronous programs is decidable (by reduction to Petri net reachability) [28]. Majumdar, Thinniyam, and Zetzsche generalized the result to show that fair termination is equivalent to configuration reachability in the general setting [40]. On the other hand, decidability of fair termination implies the decidability of checking the "equal letters problem": deciding if a language in $\mathcal{C}$ has an equal number of as and bs. Thus, fair termination is undecidable for indexed languages. The undecidability is inherited by context-bounded fair termination. On the other hand, somewhat surprisingly, fair termination is decidable for context-bounded runs of context-free multithreaded programs [15].

2 Preliminaries

An *alphabet* is a finite non-empty set of *symbols*. For an alphabet Σ, we write Σ^* for the set of finite sequences of symbols (also called *words*) over Σ. A set $L \subseteq \Sigma^*$ of words is a *language*. By $\mathsf{pref}(L) = \{u \in \Sigma^* \mid \exists v \in \Sigma^* \colon uv \in L\}$ we denote the set of prefixes of words in L.

The *subword* order $\sqsubseteq$ on Σ^* is defined as follows: for $u, v \in \Sigma^*$ we have $u \sqsubseteq v$ if and only if u can be obtained from v by deleting some of v's letters. For example, *abba* $\sqsubseteq$ *bababa*, but *abba* $\not\sqsubseteq$ *baaba*. The *downclosure* (or *downward closure*) $\downarrow w$ of a word $w \in \Sigma^*$ with respect to the subword order is defined as $\downarrow w := \{w' \in \Sigma^* \mid w' \sqsubseteq w\}$. The downclosure $\downarrow L$ of a language $L \subseteq \Sigma^*$ is given by $\downarrow L := \{w' \in \Sigma^* \mid \exists w \in L \colon w' \sqsubseteq w\}$. An important fact is that the subword ordering $\sqsubseteq$ is a *well-quasi ordering* (Higman's lemma). A consequence is that the downclosure $\downarrow L$ of *any* language L is a regular language [32]. However, a representation for the downclosure of a language may not be effectively constructible.

The projection of a word $w \in \Sigma^*$ onto some alphabet $\Gamma \subseteq \Sigma$, written $\mathrm{Proj}_\Gamma(w)$, is the word obtained by erasing from w each symbol which does not belong to Γ. For a language L, define $\mathrm{Proj}_\Gamma(L) = \{\mathrm{Proj}_\Gamma(w) \mid w \in L\}$. We write $|w|_\Gamma$ for the number of occurrences of letters $a \in \Gamma$ in w, and similarly $|w|_a$ if $\Gamma = \{a\}$.

A *multiset* $\mathbf{m} \colon X \to \mathbb{N}$ over a set X maps each symbol of X to a natural number. The size $|\mathbf{m}|$ of a multiset $\mathbf{m}$ is given by $|\mathbf{m}| = \sum_{x \in X} \mathbf{m}(x)$. The set of all multisets over X is denoted $\mathbb{M}[X]$. We identify subsets of X with multisets in $\mathbb{M}[X]$ where each element is mapped to 0 or 1. We write $\mathbf{m} = [\![a, a, c]\!]$ for the multiset $\mathbf{m} \in \mathbb{M}[\{a, b, c, d\}]$ such that $\mathbf{m}(a) = 2$, $\mathbf{m}(b) = \mathbf{m}(d) = 0$, and $\mathbf{m}(c) = 1$. The Parikh image $\mathsf{Parikh}(w) \in \mathbb{M}[\Sigma]$ of a word $w \in \Sigma^*$ is the multiset such that for each letter $a \in \Sigma$ we have $\mathsf{Parikh}(w)(a) = |w|_a$.

Given two multisets $\mathbf{m}, \mathbf{m}' \in \mathbb{M}[X]$ we define $\mathbf{m} \oplus \mathbf{m}' \in \mathbb{M}[X]$ to be the multiset such that for all $a \in X$, we have $(\mathbf{m} \oplus \mathbf{m}')(a) = \mathbf{m}(a) + \mathbf{m}'(a)$. If $\mathbf{m}(a) \geq \mathbf{m}'(a)$ for all $a \in X$, we also define $\mathbf{m}' \ominus \mathbf{m} \in \mathbb{M}[X]$: for all $a \in X$, we have $(\mathbf{m} \ominus \mathbf{m}')(a) = \mathbf{m}(a) - \mathbf{m}'(a)$. For $X \subseteq Y$ we regard $\mathbf{m} \in \mathbb{M}[X]$ as a multiset in $\mathbb{M}[Y]$ where undefined values are mapped to 0.

Language Classes and Full Trios. A *language class* is a collection of languages, together with some finite representation. Examples are the regular languages (e.g. represented by finite automata) or the context-free languages (e.g. represented by pushdown automata). A relatively weak and reasonable assumption on a language class is that it is a *full trio*, that is, it is closed under *rational transductions*. Equivalently, a language class is a full trio if it is closed under each of the following operations: taking intersection with a regular language, taking homomorphic images, and taking inverse homomorphic images [16].

We assume that all full trios $\mathcal{C}$ considered in this paper are *effective*: Given a language L from $\mathcal{C}$, a regular language R, and a homomorphism h, we can compute a representation of the languages $L \cap R$, $h(L)$, and $h^{-1}(L)$ in $\mathcal{C}$.

Many classes of languages studied in formal language theory form effective full trios. These include the regular and the context-free languages [33], the indexed languages [2, 25], the languages of higher-order pushdown automata [42], higher-order recursion schemes [31, 24, 40], Petri nets [29, 35], and lossy channel systems. However, the class of deterministic context-free languages is not a full trio: this class is not closed under rational transductions.

3 A Language-Theoretic Model of Concurrent Programs

Intuitively, a concurrent program consists of a shared global state and a finite number of thread names. Instances of thread names are called threads. A configuration of such a program consists of the current value of the global state and a multiset of partially-executed

threads. A non-deterministic scheduler picks a partially-executed thread and runs it for some number of steps. An executing thread can change the global state. It can also spawn new threads – these can be picked and executed by the scheduler (in any order) in the future. When a scheduler swaps a running thread for another one, we say that there is a context switch. In our formal model, we keep the global state explicit and we model the execution behavior of threads as languages. The language of a thread captures the new threads it can spawn, as well as the effect of the execution on the global state.

3.1 Model

Let $\mathcal{C}$ be an (effective) full trio. A *concurrent program* (CP) over $\mathcal{C}$ is a tuple $\mathfrak{P} = (D, \Sigma, (L_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$, where D is a finite set of *global states*, Σ is an alphabet of *thread names*, $(L_a)_{a\in\Sigma}$ is a family of languages from $\mathcal{C}$ over the alphabet $\Sigma_D = D \cup \Sigma \cup (D \times D)$, $d_0 \in D$ is an *initial state*, and $\mathbf{m}_0 \in \mathbb{M}[\Sigma]$ is a multiset of *initial pending thread instances*. We assume that each L_a, $a \in \Sigma$, satisfies the condition $L_a \subseteq aD\big(\Sigma \cup (D \times D)\big)^* D$ (we provide the intuition behind this condition below).

A *configuration* $c = (d, \mathbf{m}) \in D \times \mathbb{M}[\Sigma_D^*]$ consists of a global state $d \in D$ and a multiset $\mathbf{m}$ of strings representing pending threads instances and partially executed threads. Given a configuration $c = (d, \mathbf{m})$, we write $c.d$ and $c.\mathbf{m}$ to denote the elements d and $\mathbf{m}$, respectively. The size of a configuration c is $|c.\mathbf{m}|$, i.e. the number of threads in the task buffer. We distinguish between threads that have been spawned but not executed (*pending threads*) and threads that have been partially executed (but swapped out). The pending thread instances are represented by single letters $a \in \Sigma$ (which corresponds to the name of the thread) while the partially executed threads of "type" $a \in \Sigma$ are represented by strings in $\mathsf{pref}(L_a)$ which end in a letter from $D \times D$.

Before presenting the formal semantics, let us provide some intuition. Suppose the current configuration is $(d, \mathbf{m})$. A non-deterministic scheduler picks one of the outstanding threads (either a pending thread $a \in \mathbf{m}$ or a partially executed thread $w \in \mathbf{m}$) and executes it for some time, until it terminates or until the scheduler decides to interrupt it. The execution of a thread a is abstractly modeled by the language L_a. A word $ad_1w_1(d'_1, d_2)w_2(d'_2, d_3)\dots(d'_{k-1}, d_k)w_{k+1}d_{k+1} \in L_a$ represents a run of an instance of the thread a. The run starts executing in global state d_1. It spawns new threads $w_1 \in \Sigma^*$, then gets interrupted at global state d'_1 by the scheduler. At some future point, the scheduler starts executing it again at global state d_2, when new threads w_2 are spawned before it is interrupted again at d'_2. The execution continues in this way until the thread terminates in global state d_{k+1}. Thus, the jump from one global state to another (from the perspective of the thread) when a context switch is made is represented by a letter from $D \times D$. The part of a run starting at global state d_i, spawning threads w_i and interrupted at d'_i is called a *segment*. Each interruption is called a *context switch*; the above word has k context switches.

Formally, the semantics of $\mathfrak{P}$ are given as a labelled transition system over the set of configurations with the transition relation $\Rightarrow \subseteq (D \times \mathbb{M}[\Sigma_D^*]) \times (D \times \mathbb{M}[\Sigma_D^*])$. The initial configuration is given by $c_0 = (d_0, \mathbf{m}_0)$.

The transition relation is defined using rules of four different types shown below. All four types of rules are of the general form $d \xrightarrow{[\![w]\!], \mathbf{n}'} d'$. A rule of this form allows the program to move from a configuration $(d, \mathbf{m})$ to configuration $(d', \mathbf{m}')$, i.e., $(d, \mathbf{m}) \Rightarrow (d', \mathbf{m}')$, iff $d \xrightarrow{[\![w]\!].\mathbf{n}'} d'$ matches a rule and $(\mathbf{m} \ominus [\![w]\!]) \oplus \mathbf{n}' = \mathbf{m}'$. Note that due to the definition of $\ominus$, $\mathbf{m}$ has to contain w for the rule to be applicable. We also write $\overset{w}{\Longrightarrow}$ to specify the particular w used in the transition. As usual, the reflexive transitive closure of $\Rightarrow$ is denoted by $\Rightarrow^*$. A configuration c is said to be *reachable* if $c_0 \Rightarrow^* c$.

(R1) $d \xrightarrow{[\![a]\!],\mathsf{Parikh}(w)\oplus[\![adw(d',d'')]\!]} d'$ if $\exists w \in \Sigma^* : adw(d',d'') \in \mathsf{pref}(L_a)$.
Rule (R1) allows us to pick some thread a from $\mathbf{m}$ and atomically execute it until the point it is switched out by the scheduler. Note that the final letter (d', d'') of the thread indicates that it has been switched out at global d' and can be resumed when the global state is d''.

(R2) $d \xrightarrow{[\![a]\!],\mathsf{Parikh}(w)} d'$ if $\exists w \in \Sigma^* : adwd' \in L_a$.
Rule (R2) allows us to pick some thread a from $\mathbf{m}$ and atomically execute it to completion.

(R3) $d \xrightarrow{[\![aw'(d'',d)]\!],\mathsf{Parikh}(w)\oplus[\![aw'(d'',d)w(d',d''')]\!]} d'$ if $\exists w \in \Sigma^* : aw'(d'',d)w(d',d''') \in \mathsf{pref}(L_a)$
Rule (R3) allows us to pick some partially executed thread and execute it atomically until the point it is switched out by the scheduler.

(R4) $d \xrightarrow{[\![aw'(d'',d)]\!],\mathsf{Parikh}(w)} d'$ if $\exists w \in \Sigma^* : aw'(d'',d)wd' \in L_a$
Rule (R4) allows us to pick some partially executed thread and execute it to completion.

3.2 Runs and Context-bounded Runs

A *prerun* of a concurrent program $\mathfrak{P} = (D, \Sigma, (L_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$ is a finite or infinite sequence $\rho = (e_0, \mathbf{n}_0), w_1, (e_1, \mathbf{n}_1), w_2, \ldots$ of alternating elements of configurations $(e_i, \mathbf{n}'_i) \in D \times \mathbb{M}[\Sigma_D^*]$ and strings $w_i \in \Sigma^*$.

The set of preruns of $\mathfrak{P}$ will be denoted $\mathsf{Preruns}(\mathfrak{P})$. Note that if two concurrent programs $\mathfrak{P}$ and $\mathfrak{P}'$ have the same global states D and alphabet Σ, then $\mathsf{Preruns}(\mathfrak{P}) = \mathsf{Preruns}(\mathfrak{P}')$. The length $|\rho|$ of a finite prerun ρ is the number of configurations in ρ.

A *run* of a CP $\mathfrak{P} = (D, \Sigma, (L_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$ is a prerun $\rho = (d_0, \mathbf{m}_0), w_1, (d_1, \mathbf{m}_1), w_2, \ldots$ starting with the initial configuration $(d_0, \mathbf{m}_0)$, where for each $i \geq 0$, we have $(d_i, \mathbf{m}_i) \xrightarrow{w_{i+1}} (d_{i+1}, \mathbf{m}_{i+1})$. The set of runs of $\mathfrak{P}$ is denoted $\mathsf{Runs}(\mathfrak{P})$.

For a number k, the run ρ is said to be k-context-bounded (k-CB for short) if for each $c_i = (d_i, \mathbf{m}_i) \in \rho$ and for each $w \in \mathbf{m}_i$, we have $|w|_{D\times D} \leq k$. The set of k-context-bounded runs of $\mathfrak{P}$ is denoted by $\mathsf{Runs}_k(\mathfrak{P})$. In the case of finite runs which reach a certain configuration c, We say a configuration c is *k-reachable* if there is a finite k-CB run ρ ending in c.

3.3 Decision Problems

We study the following decision problems.

▶ **Definition 1.**

- **CB Safety (Global state reachability):**
  Instance: A concurrent program $\mathfrak{P}$, a context-bound k and a global state $d_f \in D$.
  Question: Is there a k-reachable configuration c such that $c.d = d_f$? If so, d_f is said to be k-reachable *(in $\mathfrak{P}$) and* k-unreachable *otherwise.*
- **CB Boundedness:**
  Instance: A concurrent program $\mathfrak{P}$ and a context-bound k.
  Question: Is there an $N \in \mathbb{N}$ such that for every k-reachable configuration c we have $|c.\mathbf{m}| \leq N$? If so, the concurrent program $\mathfrak{P}$ is k-bounded*; otherwise it is* k-unbounded*.*
- **CB Termination:**
  Instance: A concurrent program $\mathfrak{P}$, a context-bound k.
  Question: Is $\mathfrak{P}$ k-terminating, that is, is every k-CB run of $\mathfrak{P}$ finite?

3.4 Orders on Runs and Downclosures

Intuitively, k-safety, k-termination, and k-boundedness are preserved when the multiset of pending threads is "k-lossy": pending threads can get lost and we only consider runs where each thread makes at most k context switches. This loss corresponds to these pending threads never being scheduled by the scheduler. However, if a run demonstrates reachability of a global state, or non-termination, or unboundedness, in the k-lossy version, it corresponds also to a k-CB run in the original problem (and conversely). We make this intuition precise by introducing an ordering on runs and defining the downclosure.

Let $w, w' \in \Sigma D\big(\Sigma \cup (D \times D)\big)^* \big(D \cup (D \times D)\big)$ be words with $w = adw_1e_1w_2e_2 \dots w_le_l$ and $w' = a'd'w'_1e'_1w'_2e'_2 \dots w'_le'_l$, where $a, a' \in \Sigma$, $d, d' \in D$, $e_l, e'_l \in D \cup (D \times D)$, $w_i, w'_j \in \Sigma^*$ for $i, j \in [1, l]$, and $e_i, e'_j \in D \times D$ for $i, j \in [1, l-1]$. We define the state-preserving order $\sqsubseteq_D$ by $w \sqsubseteq_D w'$ iff $a = a'$, $d = d'$, $e_i = e'_i$ for each $i \in [1, l]$, and $w_i \sqsubseteq w'_i$, that is, w_i is a subword of w'_i, for each $i \in [1, l]$. We denote the corresponding notion of state-preserving downclosure under this order by $\Downarrow$. Intuitively, the $\sqsubseteq_D$ relation is a subword ordering on words that preserves the initial letter in Σ and all occurrences of $D \cup (D \times D)$, but potentially loses letters from each segment – that is, newly spawned threads can be lost.

We use the order $\sqsubseteq_D$ to naturally define the order $\preceq_D$ on $\mathbb{M}[\Sigma_D^*]$ by induction: for $\mathbf{m}, \mathbf{m}' \in \mathbb{M}[\Sigma_D^*]$ with $|\mathbf{m}|, |\mathbf{m}'| \geq 1$, we have $\mathbf{m} \preceq_D \mathbf{m}'$ iff there are $\mathbf{n}, \mathbf{n}' \in \mathbb{M}[\Sigma_D^*]$, $w, w' \in \Sigma_D^*$ with $\mathbf{m} = \mathbf{n} \oplus [\![w]\!]$ and $\mathbf{m}' = \mathbf{n}' \oplus [\![w']\!]$ such that $\mathbf{n} \preceq_D \mathbf{n}'$ and $w \sqsubseteq_D w'$. Furthermore, for all $\mathbf{m} \in \mathbb{M}[\Sigma_D^*]$, we have $\emptyset \preceq_D \mathbf{m}$.

We define an order $\trianglelefteq$ on preruns as follows: For preruns $\rho = (e_0, \mathbf{n}_0), w_1, (e_1, \mathbf{n}_1), w_2, \dots$ and $\rho' = (e'_0, \mathbf{n}'_0), w'_1, (e'_1, \mathbf{n}'_1), w'_2, \dots$, we have $\rho \trianglelefteq \rho'$ iff $|\rho| = |\rho'|$, $e_i = e'_i, w_i \sqsubseteq_D w'_i$ and $\mathbf{n}_i \preceq_D \mathbf{n}'_i$ for each $i \geq 0$. The downclosure $\downarrow R$ of a set R of preruns of $\mathfrak{P}$ is defined as $\downarrow R = \{\rho \in \mathsf{Preruns}(\mathfrak{P}) \mid \exists \rho' \in R.\ \rho \trianglelefteq \rho'\}$.

We write $\Downarrow\mathsf{Runs}(\mathfrak{P})$ for the downclosure with respect to $\trianglelefteq$ restricted to valid runs.

Some properties of a concurrent program $\mathfrak{P}$ only depend on the downclosure $\Downarrow\mathsf{Runs}_k(\mathfrak{P})$ of the set $\mathsf{Runs}_k(\mathfrak{P})$ of k-CB runs of the program $\mathfrak{P}$. For these properties, we may transform the program $\mathfrak{P}$ to a program $\Downarrow_k\mathfrak{P}$ such that the latter is easier to analyze but retains the properties of the former.

▶ **Definition 2.** *For a language L_a of a* CP*, let*

$$\Downarrow_k L_a = \left\Downarrow \left(L_a \cap \left(\bigcup_{i=0}^{k} \left(aD(\Sigma^* D \times D)^i \Sigma^* D \right) \right) \right) \right.$$

For any CP $\mathfrak{P} = (D, \Sigma, (L_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$ *and number k, we define the* CP $\Downarrow_k\mathfrak{P} = (D, \Sigma, (\Downarrow_k L_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$*. In other words, $\Downarrow_k\mathfrak{P}$ is the program obtained by taking the state-preserving downclosure of those words in L_a which contain at most k context switches.*

Note that, by well-quasi-ordering arguments, for any fixed k, the languages L_a of $\Downarrow_k\mathfrak{P}$ are all *regular*.

▶ **Proposition 3.** *Let $\mathfrak{P} = (D, \Sigma, (L_c)_{c\in\mathfrak{C}}, d_0, \mathbf{m}_0)$ be a concurrent program. Then $\Downarrow\mathsf{Runs}_k(\mathfrak{P}) = \Downarrow\mathsf{Runs}(\Downarrow_k\mathfrak{P})$. In particular,*

1. *For every $d \in D$, $\mathfrak{P}$ can k-reach d if and only if $\Downarrow_k\mathfrak{P}$ can k-reach d.*
2. *$\mathfrak{P}$ is k-terminating if and only if $\Downarrow_k\mathfrak{P}$ is k-terminating.*
3. *$\mathfrak{P}$ is k-bounded if and only if $\Downarrow_k\mathfrak{P}$ is k-bounded.*

Clearly, every run in $\mathsf{Runs}_k(\mathfrak{P})$ is also in $\mathsf{Runs}(\Downarrow_k\mathfrak{P})$. Conversely, we can show by induction on the length of the run that for every run $\rho \in \mathsf{Runs}(\Downarrow_k\mathfrak{P})$ there is a run $\rho' \in \mathsf{Runs}(\mathfrak{P})$ such that $\rho \trianglelefteq \rho'$. The result follows.

4 Decidability Results

We now characterize full trios $\mathcal{C}$ for which decision problems for concurrent programs over $\mathcal{C}$ are decidable. We shall make use of the following decidability results about regular languages.

▶ **Theorem 4.**
1. [28, 10] *CB Safety is decidable for concurrent programs over regular languages.*
2. [28, 15] *CB Boundedness and CB termination are decidable for concurrent programs over regular languages.*

In fact, the above problems are decidable even if there is no bound on the number of context switches. The result in [10] is stated for a model called *Dynamic networks of Concurrent Finite-state Systems* (DCFS), but it is easy to see that there is a polynomial time reduction for the problems of safety, termination and boundedness for CP over regular languages to the corresponding problems for DCFS. The paper [15] shows decidability of CB termination and CB boundedness for the model of dynamic networks of concurrent pushdown systems, of which DCFS is a special case. There is also a simple reduction of these problems to the corresponding results for the model of asynchronous programs [28].

Our first decidability result is the following.

▶ **Theorem 5.** *Let $\mathcal{C}$ be a full trio. The following are equivalent:*
- **(i)** *CB Safety is decidable for concurrent programs over $\mathcal{C}$.*
- **(ii)** *CB Termination is decidable for concurrent programs over $\mathcal{C}$.*
- **(iii)** *Emptiness is decidable for $\mathcal{C}$.*

The implications "(i)⇒(iii)" and The implications "(ii)⇒(iii)" are immediate from corrsponding results for asynchronous programs [40], since context bounded analysis problems generalize the corresponding analysis for asynchronous programs.

Before we prove the next implication, let us introduce a bit of notation. For each $i \in \mathbb{N}$, let R_i be the regular language $R_i = \Sigma D \Sigma^* ((D \times D)\Sigma^*)^i D$, $R'_i = \Sigma D \Sigma^* ((D \times D)\Sigma^*)^i (D \times D)$, for each $l \in \mathbb{N}$ we define $\mathcal{R}_l = \bigcup_{i=0}^{l} (R_i \cup R'_i)$. For any language L and $k \in \mathbb{N}$, the language $L \cap \mathcal{R}_k$ captures those words in L that contain at most k context switches.

For the implication "(iii)⇒(i)", we construct two semidecision procedures (Algorithm 1): the first one searches for regular over-approximations A_a of each language L_a such that the program $\mathfrak{P}'$ obtained by replacing each L_a by the corresponding A_a is safe. We can check whether our current guess for $\mathfrak{P}'$ is safe using Theorem 4. By Proposition 3, we know that in case $\mathfrak{P}$ is safe, then there must exist such a safe regular over-approximation. Concurrently, the second procedure searches for a k-CB run reaching the target global state d which witnesses the negation. Clearly, one of the two procedures must terminate. Note that we use an emptiness check to ensure that our current guess for A_a includes the set $L_a \cap \mathcal{R}_k$.

To show "(iii)⇒(ii)", we need an algorithm for termination of concurrent programs. As in the case of safety, it consists of two semi-decision procedures. The one for termination works just like the one for safety: It enumerates regular over-approximations and checks if one of them terminates. The procedure for non-termination requires some terminology:

Predictions. We will use a notion of *prediction*, which assigns to each configuration $(e, \mathbf{n})$ of a run a multiset of strings that encode not only the *past* of each thread (as is done in $\mathbf{n}$), but also its *future*. To do this, we define the alphabet $\Gamma_D = \Sigma_D \cup \{\#\}$ that extends Σ_D a fresh letter $\#$. We shall encode predictions using strings of the form $au\#v$, which encode a thread with name a, past execution au, and future execution v. Additionally, we extend the order $\preceq_D$ to strings of the form $au\#v$ by treating $\#$ as a letter from $D \times D$ which is to be preserved. Let us make this precise.

Algorithm 1 Checking CB Safety.

Input: Concurrent program $\mathfrak{P} = (D, \Sigma, (L_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$ over $\mathcal{C}$, context bound $k \in \mathbb{N}$, state $d \in D$

run concurrently

begin `/* find a safe over-approximation */`

foreach *tuple* $(A_a)_{a\in\Sigma}$ *of regular languages* $A_a \subseteq \Sigma^*$ **do**

if $(L_a \cap \mathcal{R}_k) \cap (\Sigma_D^* \setminus A_a) = \emptyset$ *for each* $a \in \Sigma$ **then**

if $\mathfrak{P}' = (D, \Sigma, (A_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$ *does not* k*-reach* d **then**

return d *is not reachable.*

begin `/* find a run reaching` d `*/`

foreach *prerun* ρ *of* $\mathfrak{P}$ **do**

if ρ *is a* k*-CB run that reaches* d **then**

return d *reachable.*

Suppose ρ is a (finite or infinite) prerun $(e_0, \mathbf{n}_0), w_1, (e_1, \mathbf{n}_1), \ldots$. An *annotation for* ρ is a sequence $\mathbf{f}_0, \mathbf{f}_1, \ldots \in \mathbb{M}[\Gamma_D^*]$ of multisets of strings such that the sequence has the same length as ρ. If ρ is a run, then we say that the annotation $\mathbf{f}_0, \mathbf{f}_1, \ldots$ is a *prediction* if

1. each string occurring in $\mathbf{f}_0, \mathbf{f}_1, \ldots$ is of the form $au\#v$ such that $auv \in \Sigma_D^*$ and $auv \in \mathsf{pref} L_a \cap \big(\Sigma \cup (D \times D)\big)^* \big(D \cup (D \times D)\big)$
2. for each $i \geq 0$, the multisets $\mathbf{n}_i$ and $\mathbf{f}_i$ have the same cardinality and there is a bijection between $\mathbf{n}_i$ and $\mathbf{f}_i$ so that (i) each word au in $\mathbf{n}_i$ is in bijection with some word $au\#v$ in $\mathbf{f}_i$ and (ii) if au is the active thread when going from $(e_i, \mathbf{n}_i)$ to $(e_{i+1}, \mathbf{n}_{i+1})$ and $au\#v$ is its corresponding string $au\#v$ in $\mathbf{f}_i$, then the system executes the next segment in v.

Note that then indeed, for each thread, its string in $\mathbf{n}_i$ records its past spawns, whereas the corresponding string in $\mathbf{f}_i$ contains all its future spawns (and possibly an additional suffix).

Of course, for each (finite or infinite) run, there exists a prediction: Just take the sequence of actions of each thread in the future. Moreover, taking a prefix of both a run and some accompanying prediction will yield a (shorter) run with a shorter prediction.

Self-covering runs. Recall that for each alphabet Θ, we have an embedding relation $\preceq_D$ on the set $\mathbb{M}[\Theta_D^*]$, and in particular on $\mathbb{M}[\Gamma_D^*]$. We say that a finite run $(e_0, \mathbf{n}_0), w_1, (e_1, \mathbf{n}_1), \ldots, w_m, (e_m, \mathbf{n}_m)$, together with a prediction $\mathbf{f}_0, \ldots, \mathbf{f}_m$ is *k-self-covering* if for some $i < m$, we have $e_i = e_m, \mathbf{f}_i \preceq_D \mathbf{f}_m$, and also, all words in $\mathbf{f}_0, \mathbf{f}_1, \ldots$ contain at most k context-switches. As the name suggests, self-covering runs are witnesses for non-termination:

▶ **Lemma 6.** *For every $k \in \mathbb{N}$, a concurrent program has an infinite k-CB run if and only if it has a k-self-covering run.*

Here, it is crucial that for each $k \in \mathbb{N}$, the ordering $\sqsubseteq_D$ is a WQO on the set of words with at most k context-switches (on all of Σ_D^*, $\sqsubseteq_D$ is not a WQO).

We can now decide termination (Algorithm 2): the algorithm either (i) exhibits a k-self-covering run, which shows the existence of a k-bounded infinite run by Lemma 6, or (ii) finds a regular over-approximation that terminates, which means the original program is terminating. We can check termination of the regular over-approximation using Theorem 4. The algorithm also terminates: If there is an infinite k-bounded run, then Lemma 6 yields the existence of a k-self-covering run. Moreover, if the concurrent program does terminate, then Proposition 3 ensures the existence of a terminating regular over-approximation. This concludes our proof of Theorem 5.

Algorithm 2 Checking CB Termination.

Input: Concurrent program $\mathfrak{P} = (D, \Sigma, (L_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$ over $\mathcal{C}$ and context bound $k \in \mathbb{N}$
run concurrently
  begin `/* find a terminating over-approximation */`
    foreach *tuple* $(A_a)_{a\in\Sigma}$ *of regular languages* $A_a \subseteq \Sigma_D^*$ **do**
      if $(L_a \cap \mathcal{R}_k) \cap (\Sigma^* \setminus A_a) = \emptyset$ *for each* $a \in \Sigma$ **then**
        if $\mathfrak{P}' = (D, \Sigma, (A_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$ *is k-terminating* **then**
          return $\mathfrak{P}$ *is k-terminating.*
  begin `/* find a self-covering run */`
    foreach *prerun* ρ *of* $\mathfrak{P}$ *and an annotation* σ **do**
      if ρ *with* σ *is a k-self-covering run* **then**
        return $\mathfrak{P}$ *is not k-terminating.*

Our second theorem is as follows.

▶ **Theorem 7.** *Let $\mathcal{C}$ be a full trio. The following are equivalent:*
(i) *CB Boundedness is decidable for concurrent programs over $\mathcal{C}$.*
(ii) *Finiteness is decidable for $\mathcal{C}$.*

The implication "(i)⇒(ii)" follows from the special case of asynchronous programs [40]. It was also observed in [40] that decidability of finiteness for $\mathcal{C}$ implies decidability of emptiness for $\mathcal{C}$. Further, by Theorem 5, we may assume that CB safety is decidable for CP over $\mathcal{C}$.

We now show the implication "(ii)⇒(i)". For a language $L \subseteq \Sigma_D^*$ and $n \in \mathbb{N}$, let $L|_n = L \cap \Sigma_D^{\leq n}$ be the language restricted to strings of length at most n and, in addition, for $k \in \mathbb{N}$, let $L'_a|_n = L_a|_n \cap \mathcal{R}_k$. Moreover, for an alphabet Θ, a language $L \subseteq \Theta^*$, and a word $w \in \Theta^*$, we define the left quotient of L by w as $w^{-1}L := \{u \in \Theta^* \mid wu \in L\}$. Our algorithm is based on the following characterization of unboundedness.

▶ **Lemma 8.** *The program $\mathfrak{P}$ is k-unbounded iff one of the two following conditions hold:*
(P1) *Either there exists some number n such that $\mathfrak{P}_n = (D, \Sigma, (L'_a|_n)_{a\in\Sigma}, d_0, \mathbf{m}_0)$ is unbounded, or*
(P2) *for some $a \in \Sigma$, there exists some word $w \in \mathsf{pref}(L_a)$ ending in a letter $(d, d') \in D \times D$ such that $\mathsf{pref}(w^{-1}L_a) \cap \Sigma^*$ is infinite and there exists a run ρ reaching a configuration c with $w \in c$ and $c.d = d'$.*

Essentially, (P1) captures the case where each thread spawns a finite number of other threads and (P2) the case that there is some reachable configuration at which a single thread can spawn an unbounded number of new threads. The above characterization allows us to implement Algorithm 3, which interleave three semidecision procedures: Checking properties (P1) and (P2) for positive certificates of unboundedness, as well as looking for certificates of boundedness by looking for bounded regular over-approximations. Here we can check boundedness for the latter by Theorem 4. Note that while checking for (P1), it is possible to compute each language $L'_a|_n$ explicitly since these languages are all finite. This is because, given any finite language $F \in \mathcal{C}$ and an explicitly given finite language A, we know $F = A$ iff $F \cap (\Sigma_D^* \setminus A) = \emptyset$ and for all $w \in A$, $F \cap \{w\} \neq \emptyset$, where the first condition checks if $F \subseteq A$ and the second if $A \subseteq F$. Therefore, by enumerating all strings w, we can build A iteratively.

A Remark on Complexity. Our procedures show decidability, but do not provide complexity results. For particular classes of languages, precise complexity bounds are known. For example, CB Safety, CB Termination, and CB Boundedness for concurrent programs over

Algorithm 3 Checking CB Boundedness.

Input: Concurrent program $\mathfrak{P} = (D, \Sigma, (L_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$ over $\mathcal{C}$ and context bound $k \in \mathbb{N}$
run concurrently
begin `/* (P1): Check if finite under-approximation is unbounded */`
foreach $n \in \mathbb{N}$ **do** `/* Explicitly find strings in` $L'_a|_n$ `*/`
foreach $a \in \Sigma$ **do**
$X_a \leftarrow \emptyset, L'_a|_n \leftarrow L_a \cap \Sigma_D^{\leq n} \cap \mathcal{R}_k$
foreach $w \in \Sigma_D^{\leq n}$ **do**
if $L'_a|_n \cap \{w\} \neq \emptyset$ **then**
$X_a \leftarrow X_a \cup \{w\}$
if $L'_a|_n \cap (\Sigma_D^* \setminus X_a) = \emptyset$ **then**
break
if $\mathfrak{P}_n = (D, \Sigma, (X_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$ *is unbounded* **then**
return $\mathfrak{P}$ *unbounded.*
begin `/* (P2): Check if unbounded segment can be reached */`
foreach *prerun* ρ *of* $\mathfrak{P}$, $a \in \Sigma$, $w \in aD\Sigma^*(D \times D\Sigma^*)^{\leq k-2}(D \times D) \cup \{a\}$ **do**
if ρ *is a* k*-run that reaches* c *with* $w \in c$, $w = w'(d, d')$ *where* $d' = c.d$, *and* $\mathsf{pref}(w^{-1}L_a) \cap \Sigma^*$ *is infinite* **then**
return $\mathfrak{P}$ *unbounded.*
if ρ *is a* k*-run that reaches* c *with* $w \in c$, $w = a$ *where* $d' = c.d$, *and* $\mathsf{pref}((wd')^{-1}L_a) \cap \Sigma^*$ *is infinite* **then**
return $\mathfrak{P}$ *unbounded.*
begin `/* Find a bounded over-approximation */`
foreach *tuple* $(A_a)_{a\in\Sigma}$ *of regular languages* $A_a \subseteq (a\Sigma_D^* \cap \mathcal{R}_k)$ **do**
if $(L_a \cap \mathcal{R}_k) \cap (\Sigma_D^* \setminus A_a) = \emptyset$ *for each* $a \in \Sigma$ **then**
if $\mathfrak{P}' = (D, \Sigma, (A_a)_{a\in\Sigma}, d_0, \mathbf{m}_0)$ *is bounded* **then**
return $\mathfrak{P}$ *bounded.*

regular languages are all EXPSPACE-complete [28], and over context-free languages are 2EXPSPACE-complete [11, 14]. These bounds use explicit constructions of the downclosure. In particular, our results show decidability of the same problems for concurrent programs over higher-order recursion schemes. However, we do not get an explicit complexity bound. While there is an explicit construction of the downclosure of these languages [53, 30, 20], a precise complexity bound for the construction remains open.

5 Further Results

Other Decision Problems. While we focus on safety, termination, and boundedness, there are decidability results for other properties and other classes of systems. The *fair termination* problem is a variant of termination, where we require that the scheduler is *fair*. Intuitively, a scheduler is fair if it schedules each partially executed thread that is infinitely often ready to execute. Context-bounded fair termination is decidable (but non-elementary) for context-free concurrent programs [15]. The problem is equivalent to Petri net reachability already for asynchronous programs [28]. It is undecidable for indexed languages.

Context-bounded analysis has also been studied for non-regular specifications. Lal et al. [38] showed decidability for context-bounded analysis for a subclass of weighted pushdown systems. Recently, Baumann et al. [13] studied the *context-bounded refinement problem* for

non-regular specifications. In their setting, there is a fixed number of recursive (context-free) threads which also generate a language over a set of events. The specification is given by a Dyck language. They show that checking containment in the specification is coNP-complete, the same complexity as that of context-bounded safety verification, albeit requiring very different techniques. An analogous result was shown for the setting of asynchronous programs, but the complexity is EXPSPACE-complete [12].

Tools and Sequentialization. A practical motivation for studying context-bounded reachability was that, empirically, many bugs in concurrent programs could be found with a small number of context switches. This led to the development of several academic and industrial tools, such as CHESS [44] and CSeq [27]. CHESS incorporated context bounding in an enumerative search. CSeq and several other tools implemented *sequentialization*: a preprocessing step that compiles the original concurrent program into a sequential program that preserves all k-context bounded runs, an idea going back to Lal and Reps [37]. Context-bounding was integrated with other exploration heuristics such as abstract interpretation and partial-order reduction [45, 21, 41].

Context-Bounded Analysis of Related Models. Context-bounding was studied for other models of concurrency, such as parameterized state machines communicating through message-passing over a given topology [18], concurrent queue systems [49], programs over weak memory models [9, 1], abstract models such as valence automata [43], etc. In each case, the notion of "context" has to be refined based on the model.

Similar Restrictions. The theory of context-bounding has inspired other natural bounds in the analysis of concurrent systems. For example, a well-studied restricion is *scope-bounding*: In a *k-scope-bounded* run, there can be an unbounded number of context-switches, but during the time span of a single function call (i.e. between a push and its corresponding pop), there can be at most k interruptions [52]. This covers more executions than context-bounding, which comes at the cost of PSPACE-completeness of safety verification [52]. Scope-boundedness has also been studied in terms of timed systems [4, 17], temporal-logic model-checking [6], resulting formal languages [51], and as an under-approximation for infinite-state systems beyond multi-pushdown systems [48].

Similarly, a *k-phase-bounded* run consists of k phases, in each of which at most one stack is popped [50, 8]. Another variant is *k-stage-bounded* runs: They consist of k stages, each of which allows only one thread to write to the shared memory, whereas the other threads can only read from it [7]. Further restrictions are *ordered multi-pushdown systems* [19, 5] and *delay-bounded scheduling* [26].

Powerful abstract notions of under-approximate analysis (which explain decidability of several concrete restrictions described above) are available in the concepts of *bounded tree-width* [39] and *bounded split-width* [3, 23, 22].

In conclusion, *context-bounding* is an elegant idea that has been very influential both in practice and in theory. In practice, it has been incorporated in several tools for automatic analysis of programs. Theoretically, it has led to a wealth of new models and analysis algorithms. At this point, the theory has marched ahead of implementations: it is an interesting open challenge to see how far the new algorithms can also lead to practical tools.

Quantum Codes, Local Testability and Interactive Proofs: State of the Art and Open Questions

Thomas Vidick ✉
Weizmann Institute of Science, Rehovot, Israel
California Institute of Technology, Pasadena, CA, USA

Abstract

The study of multiprover interactive proof systems, of locally testable codes, and of property testing are deeply linked, conceptually if not formally, through their role in the proof of the PCP theorem in complexity theory. Recently there has been substantial progress on an analogous research programme in quantum complexity theory. Two years ago we characterized the power of multiprover interactive proof systems with provers sharing entanglement, showing that MIP* =RE [4], a hugely surprising increase in power from the classical result MIP=NEXP of [2]. The following year Panteleev and Kalachev gave the first construction of quantum low-density parity-check codes (QLDPC) [5], thus marking a major step towards the possible realization of good quantum locally testable codes – the classical analogue of which was only constructed quite recently [3]. And finally, less than a year ago Anshu, Breuckmann and Nirkhe used facts evidenced in the construction of good decoders for the new QLDPC codes to resolve the NLTS conjecture [1], widely viewed as a crucial step on the way to a possible quantum PCP theorem.

In the talk I will survey these results, making an effort to motivate and present them to the non-expert. I will explain the connections between them and point to where, in my opinion, our understanding is currently lacking. Along the way I will highlight a number of open problems whose resolution could lead to further progress on one of the most important research programmes in quantum complexity theory.

The Skolem Landscape

James Worrell ✉
Department of Computer Science, University of Oxford, UK

Abstract

The Skolem Problem asks to determine whether a given integer linear recurrence sequence (LRS) has a zero term. This decision problem arises within a number of different topics in computer science, including loop termination, weighted automata, formal power series, and probabilistic model checking, among many other examples. Decidability of the problem is notoriously open, despite having been the subject of sustained interest over several decades [2]. More specifically, the problem is known to be decidable for recurrences of order at most 4 – a result obtained some 40 years ago [4, 5] – while decidability is open already for recurrences of order 5.

In this talk we take a wide-ranging view of the Skolem Problem. We survey its history and context, starting with the theorem of Skolem-Mahler-Lech characterising the set of zeros of a LRS over fields of characteristic zero. Here we explain the non-effective nature of the existing proofs of the theorem. Among modern developments, we overview versions of the Skolem-Mahler-Lech theorem for non-linear recurrences and for fields of non-zero characteristic. We also describe two recent directions of progress toward showing decidability of the Skolem Problem subject to classical number theoretic conjectures.

The first new development concerns a recent algorithm [1] that decides the problem on the class of simple LRS (those with simple characteristic roots) subject to two classical conjectures about the exponential function. The algorithm is self-certifying: its output comes with a certificate of correctness that can be checked unconditionally. The two conjectures alluded to above are required for the proof of termination of the algorithm.

A second new development concerns the notion of Universal Skolem Set [3]: a recursive set $\mathcal{S}$ of positive integers such that it is decidable whether a given non-degenerate linear recurrence sequence has a zero in $\mathcal{S}$. Decidability of the Skolem Problem is equivalent to the assertion that $\mathbb{N}$ is a Universal Skolem Set. In lieu of this one can ask whether there exists a Universal Skolem Set of density one. We will present a recent a construction of a Universal Skolem Set that has positive density unconditionally and has density one subject to the Bateman-Horn conjecture in number theory. The latter is a far-reaching generalisation of Hardy and Littlewood's twin primes conjecture.

Abstract

We present a dynamic algorithm for maintaining the connected and 2-edge-connected components in an undirected graph subject to edge deletions. The algorithm is Monte-Carlo randomized and processes any sequence of edge deletions in $O(m + n \operatorname{poly} \log n)$ total time. Interspersed with the deletions, it can answer queries whether any two given vertices currently belong to the same (2-edge-)connected component in constant time. Our result is based on a general Monte-Carlo randomized reduction from decremental c-edge-connectivity to a variant of fully-dynamic c-edge-connectivity on a sparse graph.

For non-sparse graphs with $\Omega(n \operatorname{poly} \log n)$ edges, our connectivity and 2-edge-connectivity algorithms handle all deletions in optimal linear total time, using existing algorithms for the respective fully-dynamic problems. This improves upon an $O(m \log(n^2/m) + n \operatorname{poly} \log n)$-time algorithm of Thorup [J.Alg. 1999], which runs in linear time only for graphs with $\Omega(n^2)$ edges.

Our constant amortized cost for edge deletions in decremental connectivity in non-sparse graphs should be contrasted with an $\Omega(\log n / \log \log n)$ worst-case time lower bound in the decremental setting [Alstrup, Husfeldt, and Rauhe FOCS'98] as well as an $\Omega(\log n)$ amortized time lower-bound in the fully-dynamic setting [Patrascu and Demaine STOC'04].

1 Introduction

In this paper, we present Monte Carlo randomized decremental dynamic algorithms for maintaining the connected and 2-edge-connected components in an undirected graph subject to edge deletions. Starting from a graph with n vertices and m edges, the algorithm can process any sequence of edge deletions in $O(m + n \operatorname{polylog} n)$ total time while answering queries whether a pair of vertices is currently in the same (2-edge-)connected component. Each query is answered in constant time. The algorithm for decremental 2-edge-connectivity additionally reports all bridges as they appear.

Putting our results in perspective, we say a graph is *non-sparse* if it has $n \log^{\omega(1)} n$ edges. Large areas of algorithmic research are devoted to non-sparse graphs, e.g., the generic goal of sparsifying graphs to $O(n \operatorname{polylog} n)$ edges [6], or semi-streaming algorithms that aim to sketch graphs using $O(n \operatorname{polylog} n)$ space [11]. Our result states that for dynamic connectivity and 2-edge-connectivity, we can get down to amortized constant time per edge deletion if the initial input graph is non-sparse. Prior to this work, such a result was only known in the case where the initial input graph is very dense with $\Omega(n^2)$ edges, and in the case of some special classes of sparse graphs.

Achieving constant update and query time is generally the ideal target in data structures. What makes amortized constant time for decremental connectivity particularly interesting is that the most closely related problems have near-logarithmic cell-probe lower bounds. This concerns the problem of getting worst-case time bounds or getting a fully-dynamic algorithm (supporting both insertions and deletions of edges). The decremental setting and the fact that we allow for amortization is therefore just enough assumptions to barely push us into the world of constant update and query time (removing any of these assumptions, the polylogarithmic lower bounds would kick in) and as such, our result draws a fine line between the possible and the impossible. We shall discuss this further with precise references in Section 1.1. It is worth noting that for some dynamic graph problems related to maintaining (approximate) maximum matchings and colorings, constant amortized update bounds have been shown, see, e.g., [7, 20, 21, 37].

Our algorithms are Monte Carlo randomized and answer all queries correctly with high probability[1]. We note that since the correct answer to each query is *uniquely* determined from the input, the algorithms work against adaptive adversaries, that is, each deleted edge may depend on previous answers to queries and (in the case of decremental 2-edge-connectivity) on the alleged bridges reported by the algorithm[2]

Furthermore, our algorithms offer a *self-check* capability. At the end, after all updates and queries have been processed online, each algorithm can deterministically check if it might have made a mistake. If the self-check passes, it is *guaranteed* that no incorrect answer was given. Otherwise, the algorithm *may have* made a mistake. Given the self-check is deterministic, the probability that the self-check passes following the execution of the algorithm only

[1] We define high probability as probability $1 - O(n^{-\gamma})$ for any given γ.

[2] To be precise, with unique correct answers, for any adaptive adversary $\mathcal{A}_{\text{ad}}$, there is a non-adaptive adversary $\mathcal{A}_{\text{non-ad}}$ which provides the same sequence of edge deletions up to the first point in time where the algorithm potentially reports an incorrect answer. $\mathcal{A}_{\text{non-ad}}$ is simply defined to provide the same edge-deletions as $\mathcal{A}_{\text{ad}}$ would conditioned on it receiving the *unique* correct answers to every query. Intuitively, the adaptivity of the adversary only becomes relevant once the algorithm has already made a mistake. Illustrating the issue of non-uniqueness in the case of decremental connectivity, suppose we augmented our algorithm to report a (non-unique) *path* between queried pairs of vertices in the same component. The choice of path could reveal information about the random bits employed by our algorithm and this could be very problematic if $\mathcal{A}_{\text{ad}}$ decided to delete the reported path edges.

depends on the correctness of the algorithm execution. However, as we show in the following, the self-check passes with high probability. This feature implies that we can obtain Las Vegas algorithms for certain *non-dynamic* problems whose solutions employ decremental (2-edge-)connectivity algorithms as subroutines: we simply repeat trying to solve the static problem from scratch, each time with new random bits, until the final self-check is passed. With high probability, we are done already after the first round. A nice concrete example is the algorithm of Gabow, Kaplan, and Tarjan [15] for the static problem of deciding if a graph has a unique perfect matching. The algorithm uses a decremental 2-edge-connectivity algorithm as a subroutine. With our decremental 2-edge-connectivity algorithm, repeating until the self-check is passed, we obtain a Las Vegas algorithm for the unique perfect matching problem that is always correct, and which terminates in $O(m + n \operatorname{polylog} n)$ time with high probability.

The tradition of looking for linear time algorithms for non-sparse graphs goes back at least to Fibonacci heaps, which can be used for solving single source shortest paths in $O(m + n \log n)$ time [14]. Our results show that another fundamental graph problem can be solved in linear time in the non-sparse case.

The previous best time bounds for the decremental connectivity and 2-edge-connectivity problems were provided by Thorup [39]. His algorithms run in $O(m \log(n^2/m) + n \operatorname{polylog} n)$ total time. This is amortized constant time per edge deletion only for very dense graphs starting with $\Omega(n^2)$ edges. For graphs with $O(n^{1.99})$ edges, this is $O(\log n)$ amortized time per edge deletion.

Both our algorithm and the previous one by Thorup are based on a general reduction from decremental c-edge-connectivity to fully-dynamic c-edge-connectivity on a sparse c-certificate graph with $\tilde{O}(cn)$ updates.

The contribution of this paper is a new type of sparse c-certificate that is much more efficient to maintain during edge deletions, reducing amortized time per deletion from $O(\log(n^2/m))$ to the optimal $O(1)$. We hope that this new sparse c-certificate will inspire other applications. We shall discuss it further in Section 2.

It should be noted that [39] used Las Vegas randomization, that is, correctness was guaranteed, but the running time bound only held with high probability. Our algorithms are Monte Carlo randomized, but offer the final self-check. Another difference is that our new algorithms need only a polylogarithmic number of random bits, whereas the ones from [39] used $\Theta(m)$ random bits.

We will now give a more detailed discussion of our results in the context of related work.

1.1 Connectivity

Dynamic connectivity is the most fundamental dynamic graph problem. The fully dynamic version has been extensively studied [8, 9, 12, 22, 23, 26, 28, 31, 34, 35, 36, 40, 42, 43] from both the lower and upper bound perspective, even though close to optimal amortized update bounds have been known since the 90s [22, 23, 40]. Currently, the best known amortized update time bounds are $O(\log^2 n / \log\log n)$ deterministic [43] and $O(\log n \cdot (\log\log n)^2)$ expected time [26].

Note that Thorup's $O(\log(n^2/m))$ bound for decremental connectivity is essentially only a $(\log\log n)^2$ factor better than the latter of these bounds for fully-dynamic connectivity, while our new bound brings the decremental cost down to a constant (for non-sparse graphs). Getting down to a constant is particularly interesting when we compare with related lower bounds as discussed below.

Connectivity Lower Bounds. Our result implies that decremental connectivity is provably easier than fully-dynamic connectivity for a wide range of graph densities. Specifically, let t_u be the update time of a fully dynamic connectivity algorithm and let t_q be its query time. Pătraşcu and Demaine [35] showed a lower bound of $\Omega(\log n)$ on $\max(t_u, t_q)$ in the cell-probe model. Pătraşcu and Thorup [36] also showed that $t_u = o(\log n)$ implies $t_q = \Omega(n^{1-o(1)})$. These lower bounds hold for all graph densities and allow for both amortization and randomization. As a result, no fully-dynamic connectivity algorithm can answer connectivity queries in constant time and have an amortized update time of $o(\log n)$.

In sharp contrast, assuming that $m = \Omega(n \operatorname{poly} \log n)$ edges are deleted, our algorithm shows that one can solve decremental connectivity handling both queries and updates in constant amortized time.

We note that such a result is possible only because we allow for amortization, as any decremental connectivity algorithm with *worst-case* update time $O(\operatorname{polylog} n)$ must have worst-case query time $\Omega\left(\frac{\log n}{\log \log n}\right)$ [3]. This lower bound holds even for trees supporting restricted connectivity queries of the form "are u and v connected?" for a fixed "root" u. This lower bound also holds for dense graphs, as we can always add a large static clique to the problem.

An optimal incremental connectivity algorithm has been known for over 40 years. Namely, to handle $m \geq n$ edge insertion and q connectivity queries, one can use the union-find data structure [38] with $n - 1$ unions and $2(m + q)$ finds. The total running time is $\Theta((m+q)\alpha((m+q), n))$, which is linear for all but very sparse graphs (since $\alpha(\Omega(n \log n), n) = O(1)$). It was later shown that this running time is optimal for incremental connectivity [13]. Interestingly, incremental connectivity can be solved in optimal linear time in the case of forests provided that the final shape of the forest is known in advance [16].

Similarly to the decremental case, one cannot hope to obtain an analogous result with a worst-case update time in the incremental setting: Pătraşcu and Thorup [36] showed that any incremental connectivity data structure with $o\left(\frac{\log n}{\log \log n}\right)$ worst-case update time must have worst-case $\Omega(n^{1-o(1)})$ query time in the cell-probe model.

Other cases of optimal decremental connectivity. There is much previous work on cases where decremental connectivity can be supported in $O(m)$ total time. Alstrup, Secher, and Spork [5] showed that decremental connectivity can be solved in optimal $O(m)$ total time on forests, answering queries in $O(1)$ time.[3] This was later extended to other classes of sparse graphs: planar graphs [32], and minor-free graphs [24]. All these special graph classes are sparse with $m = O(n)$ edges.

For general graphs, we only have the previously mentioned work by Thorup [39], yielding a total running time of $O(m)$ for very dense graphs with $m = \Omega(n^2)$ edges. We now obtain the same linear time bound for all non-sparse graphs with $m = \Omega(n \operatorname{poly} \log n)$ edges.

1.2 General reduction for c-edge-connectivity

Our algorithm for decremental connectivity is based on a general randomized reduction from decremental c-edge-connectivity (assuming all m edges are deleted) to fully-dynamic c-edge-connectivity on a sparse graph with $\tilde{O}(cn)$ updates. The reduction has a polylogarithmic cost per vertex as well as a constant cost per edge. The previous decremental connectivity

[3] The general *word encoding* trick behind [5, 16] that brings the update time to amortized constant has been even shown to have practical relevance [4].

algorithm of Thorup [39] was also based on such a general reduction, but the cost per edge was $O(\log(n^2/m))$ which is $O(1)$ only for very dense graphs with $m = \Omega(n^2)$. Below we will describe the format of the reductions in more detail.

Because there are different notions of c-edge-connectivity, we first need to clarify our definitions. We say that two vertices u, v are c-edge-connected iff there exist c edge-disjoint paths between u and v in G. It is known that c-edge-connectivity is an equivalence relation; we call its classes the *c-edge-connected classes*. However, for $c \geq 3$, a c-edge-connected class may induce a subgraph of G which is not connected, so it also makes sense to consider *c-edge-connected components*, i.e., the maximal c-edge-connected induced subgraphs of G.[4] It is important to note that the c-edge-connected components and the c-edge-connected classes are *uniquely defined* and both induce a natural partition of the vertices of the underlying graph. Moreover, each c-edge-connected component of G is a subset of some c-edge-connected class of G. For $c = 1, 2$, the c-edge-connected classes are c-edge-connected, so the two notions coincide. To illustrate the difference, let us fix $c \geq 3$ and consider a graph with $c + 2$ vertices $v_s, v_t, v_1, \ldots, v_c$ and edges $\{v_s, v_t\} \times \{v_1, \ldots, v_c\}$; while all c-edge-connected components in this graph are singletons, there is one c-edge-connected class, which is not a singleton, namely $\{v_s, v_t\}$.

We define a *c-certificate* of G to be a subgraph H of G that contains all edges not in c-edge-connected components, and also contains a c-edge-connected subgraph of each c-edge-connected component. Both Thorup's and our reduction maintains a c-certificate H of G. Then, for any $c' \leq c$, we have that the c'-edge-connected equivalence classes and the c'-edge-connected components are the same in G and H. As the edges from G are deleted, we maintain a c-certificate with $\widetilde{O}(cn)$ edges undergoing only $\widetilde{O}(cn)$ edge insertions and deletions in total.

The (uniquely defined) c-edge-connected components of a graph can be found using the following algorithm: while the graph contains a cut of size at most $c - 1$, remove all edges of this cut. For the reductions, we need algorithms that can help us in this process. We therefore define the *fully dynamic c-edge-cut problem* as follows. Suppose a graph G is subject to edge insertions and/or deletions. Then, a fully dynamic c-edge-cut data structure should report, after each update, some edge e that belongs to some cut of size less than c. A typical application of such a data structure is to repeatedly remove such edges e belonging to cuts of size less than c, which splits G into its c-edge-connected components. For each $c \geq 1$, denote by $T_c(n)$ the amortized time needed by the data structure to find an edge belonging to a cut of size less than c. For example, for $c = 1$ we have $T_1(n) = O(1)$ since we do not have to maintain anything. For $c = 2$, the data structure is required to maintain some *bridge* of G and it is known that $T_2(n) = O((\log n \cdot \log\log n)^2)$ [25]. For $c \geq 3$, in turn, we have $T_c(n) = O(n^{1/2} \operatorname{poly}(c))$ [41].

Given a fully dynamic c-edge-cut data structure, whose update time for a graph on n vertices is $T_c(n)$, Thorup's [39] reduction maintains, in $O(m \log(n^2/m)) + \widetilde{O}(c \cdot n \cdot T_c(n))$ total time, a c-certificate H of the decremental graph G starting with n vertices and m edges. The certificate undergoes only $\widetilde{O}(cn)$ edge insertions and deletions throughout any sequence of deletions issued to G. We reduce here the total time to $O(m) + \widetilde{O}(c \cdot n \cdot T_c(n))$.

Combining our reduction with the polylogarithmic fully-dynamic connectivity and 2-edge-connectivity algorithm of Holm, de Lichtenberg, and Thorup [23], we can now solve decremental connectivity and 2-edge-connectivity in $O(m) + \widetilde{O}(n)$ time.

[4] There is no consensus in the literature on the terminology relating to c-edge-connected components and classes. Some authors (e.g., [17, 18]) reserve the term c-edge-connected components for what we in this paper call c-edge-connected classes.

We can also apply the fully dynamic min-cut algorithm of Thorup [41] which identifies cuts of size $n^{o(1)}$ in $n^{1/2+o(1)}$ worst-case time. For $c = n^{o(1)}$, we then maintain a c-certificate H in $O(m + n^{3/2+o(1)})$ total time. This includes telling which vertices are in the same c-edge-connected component. If we further want to answer queries about c-edge-connectivity between pairs of vertices, we can apply the fully-dynamic data structure of Jin and Sun [27] to the c-certificate H. By definition, the answers to these queries are the same in H and G, and the algorithm takes $n^{o(1)}$ time per update or query. Hence the total time for the updates remains $O(m + n^{3/2+o(1)})$, and we can tell if two vertices are c-edge-connected in $n^{o(1)}$ time.

1.3 Results

We will now give a more precise description of our reduction, including the log-factors hidden in the $\widetilde{O}(cn)$ bound. Let the *decremental c-certificate* problem be that of maintaining a c-certificate of G when G is subject to edge deletions. Recall that $T_c(n)$ denotes the amortized update time of a fully-dynamic c-edge-cut data structure. Thorup [39] showed the following.

▶ **Theorem 1** (Thorup [39])**.** *There exists a Las Vegas randomized algorithm for the decremental c-certificate problem with expected total update time $O(m \log(n^2/m) + n(c + \log n) \cdot T_c(n) \log^2 n)$. The maintained certificate undergoes $O(n \cdot (c + \log n))$ expected edge insertions and deletions throughout, assuming $\Theta(m)$ random bits are provided. These bounds similarly hold with high probability.*

In particular the total update time is $O(m)$ for very dense graphs with $\Omega(n^2)$ edges. Our main result, which we state below, shows that amortized constant update time can be obtained as long as the initial graph has $\Omega(n \operatorname{polylog}(n))$ edges.

▶ **Theorem 2.** *There exists a Monte Carlo randomized algorithm for the decremental c-certificate problem with total update time $O(m + n(c + \log n) \cdot T_c(n) \log^3 n + nc \log^7 n)$. The maintained certificate undergoes $O(nc \log^4 n)$ edge insertions and deletions throughout. The algorithm is correct with high probability. Within this time bound, the algorithm offers a final self-check after processing all updates.*

In fact, our algorithm is itself a reduction to $O(\log n)$ instances of the decremental c-certificate problem on a subgraph of G with $m' = O(m/\log^2 n)$ edges. To handle each of these instances, we use the state-of-the-art data structure (Theorem 1) which costs only $O(m' \log m') = O(m/\log n)$ (for non-sparse graphs), yielding a combined cost of $O(m)$. As a result, our improved reduction (Theorem 2) requires $\Theta(m/\log n)$ random bits to hold.

We can reduce the need for random bits dramatically paying a little extra cost per vertex. Our new randomized c-certificate that is the key to obtaining the new reduction requires only pairwise independent sampling to work. This is in sharp contrast with the certificate of Karger [30], used in the construction of Thorup's data structure (Theorem 1), which requires full independence, i.e., $\Theta(m)$ random bits. We show that we may instead plug our new certificate into Thorup's data structure at the cost of a single additional logarithmic factor in the running time. Since Karger's certificate constitutes the only use of randomness in Thorup's data structure, and full independence in our construction is required only for invoking Theorem 1, we obtain the below low-randomness version of our main result.

▶ **Theorem 3.** *There exists a Monte Carlo randomized algorithm for the decremental c-certificate problem with total update time $O(m + nc \cdot T_c(n) \log^4 n + nc \log^7 n)$. The maintained certificate undergoes $O(nc \log^4 n)$ edge insertions and deletions throughout. The algorithm is correct with high probability if $O(\operatorname{polylog} n)$ random bits are provided. Within this time bound, the algorithm offers the final self-check after processing all updates.*

By using Theorem 3 with best known fully dynamic algorithms for different values of c [23, 27, 41], we obtain:

▶ **Theorem 4.** *There exists Monte Carlo randomized decremental connectivity and decremental 2-edge-connectivity algorithms with $O(m + n \log^7 n)$ total update time and $O(1)$ query time.*

▶ **Theorem 5.** *Let $c = (\log n)^{o(1)}$. There exists a Monte Carlo randomized decremental c-edge-connectivity data structure which can answer queries to whether two vertices are in the same c-edge connected class in $O(n^{o(1)})$ time, and which has $O(m) + \tilde{O}(n^{3/2})$ total update time.*

▶ **Theorem 6.** *Let $c = O(n^{o(1)})$. There exists a Monte Carlo randomized decremental c-edge-connected components data structure with $O(m + n^{3/2+o(1)})$ total update time and $O(1)$ query time.*

While Theorems 5 and 6 are only optimal for graphs with $m = \Omega(n^{3/2+o(1)})$ edges, we do note that the improvement in runtime from $O(mT_c(n))$ to $O(m + nT_c(n) \operatorname{polylog} n)$ is in general more impressive when $T_c(n)$ is large. E.g., if $T_c(n) = \sqrt{n}$, for dense graphs with $\Omega(n^2)$ edges, the former bound is $O(m^{5/4})$ while the later is $O(m)$ which is a polynomial improvement.

All the above applications of our main result work using only $O(\operatorname{polylog} n)$ random bits. They moreover each have the self-check property as well. As discussed before, our new 2-edge-connectivity data structure implies an optimal $O(m)$-time unique perfect matching algorithm for $m = \Omega(n \operatorname{polylog} n)$.

1.3.1 Adaptive updates and unique perfect matching

All our time bounds are amortized. Amortized time bounds are particularly relevant for dynamic data structures used inside algorithms solving problems for static graphs. In such contexts, future updates often depend on answers to previous queries, and therefore we need algorithms that work with adaptive updates.

Our reduction works against adaptive updates as long as all the information it provides is uniquely defined from the input graph and the update sequence, hence not revealing any information about the random choices in our c-certificate H. We assume some linear orderings of the vertices and the edges, and define the representative (or ID) of a c-edge connected component to be the smallest vertex in it. The reduction will safely maintain the following public information about the c-edge-connected components of G: between deletions, each vertex stores a pointer to the representative of its c-edge connected component, so two vertices are in the same c-edge-connected component if and only if they have they point to the same representative. With the representative, we store the size of the c-edge connected component, and list its vertices in sorted order. Finally, we have a sorted list of all edges that go between c-edge-connected components. After each update, we can also reveal the representatives of the new c-edge-connected components, and the edges between these components. For the case of 2-edge-connectivity, the above means that we can maintain the bridges of a decremental graph and we can also maintain the connected components and their sizes without revealing what the current randomized certificate looks like. All this is needed for the unique perfect matching algorithm of Gabow, Kaplan, and Tarjan [15]. The algorithm is an extremely simple recursion based on the fact that a graph with a unique

Algorithm 1 Algorithm computing Thorup's certificate in the static setting.

Input : A graph $G = (V, E)$, where $n = |V|$, sampling probability P, parameter c
Returns: A set of $\tilde{O}(c \cdot n/P)$ edges giving a c-certificate of G

```
1 Function ThorupCertificate(V, E, P, c):
2     if |E| ≤ c · n then
3         return E
4     S ← subset of E, in which each edge is included independently with prob. P;
5     D ← edges of E connecting distinct c-edge-connected components of (V, S);
6     return D ∪ ThorupCertificate(V, S, P, c)
```

perfect matching has a bridge and all components have even sizes. The algorithm first asks for a bridge (u, v) of some component. If there is none, there is no unique matching. Otherwise we remove (u, v) and check the sizes of the components of u and v. If they are odd, (u, v) is in the unique matching, and we remove all other incident edges. Otherwise (u, v) is not in the unique matching. The important thing here is that the bridges do not tell us anything about our random 2-certificate of the 2-edge-connected components.

Thus we solve the static problem of deciding if a graph has a unique perfect matching in $O(m) + \widetilde{O}(n)$ time. If the self-verification reports a possible mistake, we simply rerun. Consequently we get a Las Vegas algorithm that terminates in $O(m) + \widetilde{O}(n)$ time with high probability.

Outline. Due to space constraints, in the remaining part of this extended abstract we give a rather extensive technical overview of our data structure. All the details and proofs can be found in the full version of this paper.

2 Technical overview

Our main technical contribution is a new construction of a sparse randomized c-certificate that witnesses the c-edge-connected components of G and can be maintained in constant time per edge deletion in G (assuming that the initial graph is not too sparse). In the static case, deterministic certificates of this kind have been known for decades [33]. However, they are not very robust in the decremental setting, where an adversary can constantly remove its edges forcing it to update frequently. Consequently, Thorup [39] used a randomized sample-based certificate to obtain his reduction. The general idea behind this approach is to ensure that the certificate is sparse and undergoes few updates. Ideally, the sparse certificate will only have to be updated whenever an edge from the certificate is deleted. Using a fully dynamic data structure on the certificate, we may obtain efficient algorithms provided that we don't spend too much time on maintaining the certificate. Thorup's reduction had an additive overhead $O(m \log(n^2/m))$ for maintaining the certificate, which we will reduce to the optimal $O(m)$. We shall, in fact, use Thorup's reduction as a subroutine, called on $O(\log n)$ decremental subproblems each starting with $O(m/\log^2 n)$ edges.

2.1 Thorup's construction [39]

Let us first briefly describe how Thorup's algorithm operates on certificates and highlight difficulties in improving his reduction to linear time. First of all, the c-certificate is constructed as follows (see Algorithm 1 for pseudocode). Initially, sample edges of G uniformly with

probability $P \leq 1/2$, thus obtaining a subgraph S. Then, compute the c-edge-connected components of S and form a certificate H out of two parts: (1) A *recursive* certificate of S, and (2) the subgraph D consisting of edges of G connecting distinct c-edge-connected components of S.

As proved by Karger [30], D has size $\widetilde{O}(cn/P)$ with high probability. Thorup [39] generalizes this by proving that D undergoes only $\widetilde{O}(cn/P)$ insertions throughout any sequence of edge deletions to S. Since D depends only on the c-edge-connected components of S, it is enough to have a c-certificate of S in order to define D. Hence, a c-certificate of S (which is a graph a size $O(mP)$, i.e., a constant factor smaller) is maintained under edge deletions recursively. The recursion stops when the size of the input graph is $O(cn)$. To maintain D at each recursive level, we first need to maintain the c-edge-connected components of the (recursive) certificate of S under edge deletions. The certificate of S can be (inductively) seen to have $\widetilde{O}(cn/P)$ edges and undergo $\widetilde{O}(cn/P)$ updates. As a result, for $P = 1/2$ maintaining its c-edge-connected components costs $\widetilde{O}(cn \cdot T_c(n))$ total time using the fully-dynamic c-edge-cut data structure. Since at each recursion level the certificate size decreases geometrically, the expected cost of all the dynamic c-edge-cut data structures is $\widetilde{O}(cn \cdot T_c(n))$. For $c = 1, 2$, $\widetilde{O}(cn \cdot T_c(n)) = \widetilde{O}(n)$.

The bottle-neck in Thorup's reduction. For non-sparse graphs, the bottleneck in Thorup's reduction is the additional cost of $O(m \log(n^2/m))$ which comes from the fact that, at each level of the recursion, when a c-edge-connected component in S splits into two components as a result of an edge deletion, we need to find edges of G between these two components in order to update D. This takes $O(m \log(n^2/m))$ total time throughout using a standard technique of iterating through the edges incident to the vertices in the smaller component every time a split happens [10]. The $O(\log(n^2/m))$ (instead of $O(\log(n))$) cost comes by noticing that a vertex can at most have q neighbors in a component of order q, and that after we go through the edges of a vertex i times it is in a component of order $\leq n/2^i$; hence it is only the first $O(\log(n/\deg(v)))$ times that all neighbors of v have to be considered, so, by applying Jensen's inequality, the total time spent on this becomes $O\left(\sum_{v \in V} \deg(v) \log(n/\deg(v))\right) = O(m \log(n^2/m))$.

It turns out very challenging to get rid of the $O(m \log(n^2/m))$ term associated with finding cuts when components split in Thorup's reduction. If we knew that all of these cuts were *small*, say of size at most δ, then we could apply a whole bag of tricks for efficiently finding them in a total time of $\tilde{O}(n\delta)$, e.g., using invertible Bloom lookup tables [19], or the XOR-trick [1, 2, 29]. Unfortunately, the bound of $\tilde{O}(cn/P)$ only gives an average bound on the number of edges between pairs of components, and in fact there can be pairs of components having as many as $\Omega(n^{1/3})$ edges between them, as we will later show. In order to resolve this, we have to introduce a new type of sample based c-edge certificate obtained by only removing cuts of size at most $\delta = O(c \operatorname{polylog} n)$ from G. In the following three subsections, we describe the ideas behind this new certificate, the technical challenges encountered in efficiently maintaining it, and why such a certificate is relevant for decremental connectivity algorithms.

2.2 Our c-certificate based on small cut samples

In this section we describe the construction of our c-certificate. For simplicity, we assume $c = 1$ for now.

The (simplified) algorithm for computing the certificate in the static setting is given as Algorithm 2. In order to obtain a conceptually simpler picture of the certificate, Algorithm 2 is described recursively where each recursive call takes as input a *minor* G' of G, namely

Algorithm 2 Algorithm computing our new certificate in the static setting.

Input : A graph $G = (V, E)$ where $n = |V|$ and $m = |E|$, sampling probability P, parameter δ

Returns : A set of $O(mP \log n + n\delta \log n)$ edges giving a 1-certificate of G

```
1  Function NewCertificate(V, E, P, δ):
2      if E = ∅ then
3          return ∅
4      D = ∅;
5      while G has a non-isolated vertex v of degree ≤ δ do
6          Remove from E all edges incident to v and add them to D
7      S ← subset of E, in which each edge is included independently with prob. P;
8      H ← (V, S);
9      G' ← graph obtained from G by contracting connected components of H;
10     return S ∪ D ∪ NewCertificate(V(G'), E(G'), P, δ)
```

the graph obtained by contracting the connected components of $H = (V, S)$, where S is a subset of edges of G (after pruning G of small cuts in lines 5-6) sampled with probability P. Adding an edge e of G' to the certificate, simply means that we add the corresponding edge of G. While Algorithm 2 gives a precise description of the static certificate at any given point, maintaining these minors in the dynamic setting is too costly. Because of that, in the dynamic algorithm, instead of using minors we work with a sequence of subgraphs of the initial graph that are easier to maintain dynamically.

Denote by ℓ the depth of the recursion in Algorithm 2. For $i = 1, \ldots, \ell$, let S_i be the union of samples S on the recursive levels $1, \ldots, i$ of Algorithm 2, so that S_ℓ contains all the edges sampled in the process. When an edge is deleted from G, it is removed from all the sampled subsets S in the recursion, and thus also from all the relevant subsets S_i. This way, after any sequence of deletions the certificate that we maintain only depends on the initial samples $S_1, S_2 \setminus S_1, \ldots, S_\ell \setminus S_{\ell-1}$ and the current graph G, not on the sequence of edge updates made to G so far. We may therefore describe the certificate statically.

The critical idea behind our certificate is to introduce a small-cut-parameter δ. Our certificate is obtained by iteratively removing certain cuts from G where each cut is allowed to be of size at most δ. We denote by $D \subset G$ the graph whose edge set consists of the edges removed in this process. The overall goal is to define this cut removal process in a way so that (1) each connected component of $G \setminus D$ is connected in S_l, and (2) it is easy to detect new small cuts under edge deletions issued to G. We then use $S_\ell \cup D$ as our connectivity certificate of G. Importantly, we want δ to be *as small as possible*, ideally $\delta = O(\text{polylog}(n))$. This is because $\tilde{O}(\delta n)$ will show up as an additive cost in our algorithm for maintaining the certificate.

We will describe shortly how this type of certificate can be used in the design of efficient decremental connectivity algorithms, but let us first demonstrate that the existence of such a cut removal process (satisfying both (1) and (2)) for a small δ is non-trivial.

First of all, we could simply remove *all* cuts from G of size at most δ leaving us with the $(\delta + 1)$-connected components. Karger's result [30] implies that with $\delta = O((c + \log n)/P)$ sufficiently large, these components will remain c-edge connected in S. However, in order to maintain the small cuts, we would need a decremental δ-edge connectivity algorithm. As $\delta > c$, this approach simply reduces our problem to a much harder one.

Suppose on the other hand that we attempted to use Thorup's sampling certificate [39] described above. To simplify the exposition, let's assume that $P = 1/2$. If D is the set of edges between connected components of S, $D \cup S$ is a certificate. Thorup's algorithm recurses on S to find a final certificate of G. At first sight it may seem like D can be constructed by iteratively removing cuts of size at most $\delta = O(\log n)$ between the connected components of S. After all, isn't it unlikely that a connected component of S has more than, say, $100 \log n$ unsampled outgoing edges when the sampling probability is $P = 1/2$? As alluring as this logic may be, it is flawed. Indeed, there exist graphs of maximum degree $O(\log n)$ such that after sampling with $P = 1/2$, some two connected components of the sampled subgraph, C_1 and C_2, will have $\Omega(n^{1/3})$ unsampled edges between them. At some point in the iterative process, we are thus forced to remove a cut of size $\Omega(n^{1/3})$ splitting C_1 and C_2, and we would have to choose δ of at least this size (but it is possible that other examples could show that δ would have to be even larger). Our algorithms spend total time $\tilde{O}(n\delta)$ on finding these cuts, and if $\delta = \Omega(n^{1/3})$, this is not good enough for a linear time algorithm for non-sparse graphs.

We remark that in this example, each vertex of G has degree $O(\log n)$ with high probability. Therefore, an alternative approach yielding cuts of size $O(\log n)$ would be to cut out one vertex at a time moving all incident edges to D. In particular this would cut the large sampled components C_1 and C_2 into singletons, one vertex at a time. We cannot proceed like this for general graphs which may have many vertices of large degree. Nevertheless, this simple idea will be critically used in our construction which we will now discuss.

Our actual certificate uses $\delta = \Theta(\frac{\log n}{P})$ and $P = 1/\operatorname{polylog} n$. To construct our certificate, we start by iteratively pruning G of the edges incident to vertices of degree less than δ, moving these edges to D. The graph left after the pruning $G_1 = G \setminus D$ satisfies that each vertex of positive degree has degree at least δ. Next, S_1 defines a sample of G_1, $H_1 = S_1 \cap G_1$. The expected degree of each vertex in H_1 which is not isolated in G_1 is at least $\delta \cdot P = \Theta(\log n)$, and thus we get that with constant probability a fraction of $3/4$ of the vertices with positive degree in the sampled subgraph H_1 have degree ≥ 4.

Using this property we show that H_1 can have at most $5n/6$ connected components. As a result, if we contract the connected components of H_1 in the pruned graph G_1, the resulting graph G_1' has at most $5n/6$ vertices. Finally, we construct a certificate for G_1' recursively using the samples $S_2 \setminus S_1, S_3 \setminus S_2, \ldots$, stopping when the contracted graph has no edges between the contracted vertices (here G played the role of G_0'). The constant factor decay in the number of components ensures that we are done after $\ell = O(\log n)$ steps with high probability. All edges of D are obtained as the removed edges of cuts of G of size less than δ, so D will have size $O(n\delta)$. Our certificate will simply be $S_\ell \cup D$ which we prove is in fact a certificate.

With this, we have thus completed the goal of obtaining a small cut sample certificate with δ as small as $O(\frac{\log n}{P})$. Abstractly, our certificate has a quite simple description: we alternate between sampling, removing small cuts around connected components in the sample, and finally contracting these components. However, in our implementation, we cannot afford to perform the contractions as described above explicitly, as updating them dynamically would be costly. As a result we end up solving a more challenging problem in the dynamic setting. Given a graph G and its subgraph H undergoing edge deletions, determine if any connected components of H is incident to at most δ edges of $G \setminus D$, i.e., induces a cut of at most δ edges. It turns out that since we are only concerned with cuts of size at most δ, we can in fact identify these cuts in total time $O(m) + \tilde{O}(\delta n)$. We will describe this in the following section.

A final property of our new randomized decremental certificate algorithm is that it requires only $O(\log^2 n)$ random bits to yield high-probability correctness bounds. This is in sharp contrast with Thorup's algorithm [39] which requires $\Omega(m)$ random bits. On a high level, the reason we can do with few random bits is that in each step of the construction of our certificate, we only need the bounds on the number of contracted components to hold with constant probability. Indeed, we will still only have $O(\log n)$ recursive levels with high probability. This means that for the probability bounds within a single recursive level, it suffices to apply Chebyshev's inequality. While the reduction of the number of required random bits is nice, the main point, however, is that with our new certificate we can get down to constant amortized update time per edge-deletion for decremental (2-edge)-connectivity for all but the sparsest graphs.

2.3 Maintaining our certificate

As edges are deleted from G, the recursive structure of the c-certificate H changes. Indeed, a deletion of an edge may cause the following changes in one of the recursive layers of H: (1) introduce a cut of size less than δ surrounding a c-edge-connected component or (2) break a c-edge-connected component in two. In the first case, the edges of the cut have to be moved to D, and deleted from the current and later layers of H, causing further cascading. When a c-edge-connected component (in a recursive layer) of H breaks in two, we need to determine whether either of the new components has less than δ outgoing edges in $G \setminus D$. If we use the standard technique of iterating over all the edges incident to vertices of the smaller component, this again incurs an $O(\log(n^2/m))$ cost per edge which is insufficient. However, as we only care about components with at most δ outgoing edges, it turns out that we can do better. We define the *boundary* $\partial_G(C)$ of a component C of some graph $H \subset G$ to be the set of edges of G with one endpoint in C, and another in $V \setminus C$. To overcome the $O(\log(n^2/m))$ cost per edge, we prove that we can maintain boundaries of size at most δ under splits using a Monte Carlo randomized algorithm in $O(m + n\delta \operatorname{polylog} n)$ total time. We achieve this by developing a fully dynamic data structure summarized as follows, that we believe may be of independent interest.

▶ **Theorem 7.** *Let $G = (V, E)$ be an initially empty graph subject to edge insertions and deletions and let s, $1 \leq s \leq n$, be an integral parameter. There exists a data structure that can process up to $O(\operatorname{poly} n)$ queries of the form "given some $S \subseteq V$, compute $\partial_G(S)$", where $\partial_G(S) = E(S, V \setminus S)$, so that with high probability each query is answered correctly in $O\left(|S|s + |E(S,V)| \cdot \frac{|\partial_G(S)|}{s} + \log n\right)$ time. The data structure is initialized in $O(ns)$ time and can be updated in constant time.*

We realize this result by deploying the so-called XOR-trick [29][5] for deciding if a boundary of some subset of vertices is non-empty, albeit in a somewhat unusual manner. We now briefly describe the method. Suppose each $e \in E$ is assigned a random bit-string x_e of length $\Theta(\log n)$, which fits in $O(1)$ machine words. Let $x_v = \bigoplus_{vw=e\in E} x_e$ denote the XOR of the respective bit-strings of edges incident to v. Then, one can prove that, given $S \subseteq V$, with high probability the XOR $\bigoplus_{u\in S} x_u$ is non-zero if and only if $\partial_G(S) \neq \emptyset$. The underlying idea is that if an edge e incident to $v \in S$ has its other endpoint also contained in S, its corresponding bit string x_e appears exactly twice in $\bigoplus_{u\in S} x_u$, and thus cancels out. So, emptiness of $\partial_G(S)$ can be tested in $O(|S|)$ time.

[5] See also [1, 2] for uses of the same idea in other contexts.

The XOR trick can also be used with no change to retrieve a non-empty boundary $\partial_G(S)$, but only when that boundary has precisely one element. In order to retrieve *some* element of $\partial_G(S)$, existing applications of the XOR-trick consider a polylogarithmic number of independent edge set samples, chosen such that one of the samples intersects $\partial_G(S)$ precisely on one edge (with high probability). This unavoidably introduces a polylogarithmic dependence in the cost per edge of the graph, which is prohibitive in our scenario.

The main idea behind Theorem 7 which allows us to deal with this problem is as follows. We partition the edge set E into $E_1, \dots, E_s$. Each $e \in E$ is assigned to one of these sets uniformly at random. We apply the XOR-trick for each of the edge-disjoint subgraphs (V, E_i) separately. This takes $O(s|S|)$ time and computes a set I of all i such that $\partial_G(S) \cap E_i \neq \emptyset$ (with high probability). Clearly, in order to find $\partial_G(S)$, we only need to look for this boundary's elements in $\left(\bigcup_{i \in I} E_i\right) \cap E_G(S, V)$. Note that the expected size of this set is $(|I|/s) \cdot |E_G(S, V)| \leq (|\partial_G(S)|/s) \cdot |E_G(S, V)|$. If we set s to be larger than the maximum size of a boundary that we would like to retrieve (in the algorithm we ensure that the ratio is polylogarithmic), we significantly reduce the set of candidate edges to consider and can search through them exhaustively. In total, as we show, only $O(|\partial_G(S)| + |E_G(S, V)| \cdot |\partial_G(S)|/s + \log n)$ edges are explored with high probability.

In our application, we end up using the data structure of Theorem 7 storing the (dynamic) graph $G \setminus D$, and handling small boundary (of size no more than $\delta = \operatorname{polylog} n$) queries for smaller sides $C \subseteq V$ of decomposing components of $\ell = O(\log n)$ dynamic subgraphs of $G \setminus D$. Throughout, the total size of the queried subsets C is $O(n \log^2 n)$. Consequently, the sum of $|E(C, V)|$ over these sets is $O(m \log^2 n)$. By setting $s = \delta \log^2 n$ in Theorem 7, we obtain that the required queries for δ-bounded boundaries $\partial_{G \setminus D}(C)$ can be processed in $O(n \operatorname{polylog} n + m)$ total time.

2.4 Combining our certificate with Thorup's algorithm

With the certificate as above, the overall idea for a decremental connectivity algorithm is to maintain a c-certificate of (each recursive layer of) the *decremental* graph $H = S \setminus D$ using the algorithm by Thorup [39]. By choosing $P = 1/\log^2 n$, S has $m' = O(m/\log^2 n)$ edges with high probability, so employing the algorithm of Theorem 1 on each recursive layer takes total time $O(m' \log^2 n + ncT_c(n) \operatorname{polylog} n) = O(m + ncT_c(n) \operatorname{polylog} n)$ with high probability. Let H^* be the c-certificate thus obtained for H. Using a fully dynamic c-edge-connectivity algorithm on $H^* \cup D$ (which undergoes $O(cn \operatorname{polylog} n)$ updates), we maintain a c-edge certificate of G. As $H^* \cup D$ undergoes $O(cn \operatorname{polylog} n)$ updates, running the fully dynamic algorithm takes total time $O(cnT_c(n) \operatorname{polylog} n)$.

We remark that for $c = 1, 2$ we could instead use a fully dynamic c-edge connectivity algorithm on H with polylogaritmic update and query time at the price of a smaller P (which would incur more log-factors in our final time bound). For $c > 2$, however, we only know that $T_c(n) = O(n^{1/2} \operatorname{poly}(c))$. Since running a fully dynamic algorithm on H takes total time $\Omega(mT_c(n)/\operatorname{polylog} n)$, this is insufficient to obtain linear time algorithms for dense graphs.

2.5 Final self-check

Let us finally describe the ideas behind the final self-checks claimed in Theorem 2 and 3 in a more general context. In particular, we show that if a randomized Monte Carlo dynamic algorithm satisfies some generic conditions then it can be augmented to detect, at the end of its execution, whether there is any chance that it answered any query incorrectly. That is, if the self-check passes then it is guaranteed that all queries were answered correctly

throughout the execution of the algorithm. Otherwise, it indicates that some queries might have been answered incorrectly. The self-check property is particularly useful in applications of dynamic algorithms as subroutines in algorithms solving static problems, that is, it enables static algorithms to exhibit Las Vegas guarantees instead of the Monte Carlo guarantees provided by the dynamic algorithm, as they can simply re-run the static algorithm with fresh randomness until the self-check passes.

The properties of a dynamic algorithm amenable to a self-check behavior are as follows:

- Once an error is made by the dynamic algorithm it should be detectable and any subsequent updates of the algorithm should not correct the error before it is detected.
- If the dynamic algorithm is stopped at any point in time, it should be able to still perform the self-check within the guaranteed running time of the algorithm.

In our algorithm, as long as the c-certificate maintained by our algorithm is correct, the c-edge-connectivity queries answered by our algorithm exhibit the same guarantees as the fully dynamic c-edge-connectivity algorithm running on the c-certificate H. Hence, we only need to detect potential errors in the process of maintaining the c-certificate H. Such errors only happen with probability $n^{-\Omega(1)}$.

By definition, a c-certificate $H \subseteq G$ of G is correct if for every "non-witness" edge (u, v) from $G \setminus H$, we have that u and v are c-edge-connected in H. We use $H = S_\ell \cup D$ where S_ℓ is decremental, and we impose the stronger requirement that if $(u, v) \in G \setminus H$, then u and v are c-edge-connected in S_ℓ. If this is not the case, we consider it an error.

Suppose we have an error with (u, v). Since S_ℓ is decremental, u and v cannot later become c-edge connected in S_ℓ. Thus, the error can only disappear if (u, v) is deleted from G or (u, v) is added to H. Therefore, all our self-checker needs to do is this: Whenever an edge from $G \setminus H$ is about to be deleted from G or about to be added to H, we first check that u and v are c-edge-connected in S_ℓ; otherwise we found an error. Also, if the algorithm is terminated before all edges are deleted, we perform that above check on all remaining edges. If any check finds an error, we flag the execution as invalid.

If an execution of our algorithm has not been flagged, we know that all queries have been answered correctly. Moreover, the execution is only flagged with probability $n^{-\Omega(1)}$.

As a final note, every vertex will maintain an ID of its c-edge-connected component in S_ℓ. Then u and v are the c-edge-connected in S_ℓ if and only if they have the same ID. This is checked in constant time, so these extra checks do not affect our overall asymptotic time bounds.

Abstract

We study the query version of the approximate heavy hitter and quantile problems. In the former problem, the input is a parameter ε and a set P of n points in $\mathbb{R}^d$ where each point is assigned a color from a set C, and the goal is to build a structure such that given any geometric range γ, we can efficiently find a list of approximate heavy hitters in $\gamma \cap P$, i.e., colors that appear at least $\varepsilon|\gamma \cap P|$ times in $\gamma \cap P$, as well as their frequencies with an additive error of $\varepsilon|\gamma \cap P|$. In the latter problem, each point is assigned a weight from a totally ordered universe and the query must output a sequence S of $1 + 1/\varepsilon$ weights such that the i-th weight in S has approximate rank $i\varepsilon|\gamma \cap P|$, meaning, rank $i\varepsilon|\gamma \cap P|$ up to an additive error of $\varepsilon|\gamma \cap P|$. Previously, optimal results were only known in 1D [23] but a few sub-optimal methods were available in higher dimensions [4, 6].

We study the problems for two important classes of geometric ranges: 3D halfspace and 3D dominance queries. It is known that many other important queries can be reduced to these two, e.g., 1D interval stabbing or interval containment, 2D three-sided queries, 2D circular as well as 2D k-nearest neighbors queries. We consider the real RAM model of computation where integer registers of size w bits, $w = \Theta(\log n)$, are also available. For dominance queries, we show optimal solutions for both heavy hitter and quantile problems: using linear space, we can answer both queries in time $O(\log n + 1/\varepsilon)$. Note that as the output size is $\frac{1}{\varepsilon}$, after investing the initial $O(\log n)$ searching time, our structure takes on average $O(1)$ time to find a heavy hitter or a quantile! For more general halfspace heavy hitter queries, the same optimal query time can be achieved by increasing the space by an extra $\log_w \frac{1}{\varepsilon}$ (resp. $\log\log_w \frac{1}{\varepsilon}$) factor in 3D (resp. 2D). By spending extra $\log^{O(1)} \frac{1}{\varepsilon}$ factors in both time and space, we can also support quantile queries.

We remark that it is hopeless to achieve a similar query bound for dimensions 4 or higher unless significant advances are made in the data structure side of theory of geometric approximations.

1 Introduction

Range searching is an old and fundamental area of computational geometry that deals with storing an input set $P \subset \mathbb{R}^d$ of n (potentially weighted) points in a data structure such that given a query range γ, one can answer certain questions about the subset of points inside γ. Range searching is often introduced within a general framework that allows a very diverse set of questions to be answered. For instance, if the points in P have been assigned integer or real weights, then one can count the points in γ (range counting), sum the total weights of the points in γ (weighted range counting), or find the maximum or minimum weight in γ (range max or min queries).

However, there are some important questions that cannot be answered within this general framework. Consider the following motivating example: our data includes the locations of houses in a city as well as their estimated values and given a query range γ, we are interested in the distribution of the house values within γ, for example, we might be interested to see if there's a large inequality in house values or not. Through classical results, we can find the most expensive and the least expensive houses (max and min queries), and the average value of the houses (by dividing the weighted sum of the values by the total number of houses in γ). Unfortunately, this information does not tell us much about the distribution of the house values within γ, e.g., one cannot compute the Gini index which is a widely-used measure of inequality of the distribution. Ideally, to know the exact distribution of values within γ, one must have all the values inside γ, which in the literature is known as a *range reporting* query which reports all the points inside the query range γ. However, this could be an expensive operation, e.g., it can take $\Omega(n)$ time if the query contains a constant fraction of the input points. A reasonable alternative is to ask for a "summary" query, one that can summarize the distribution. In fact, the streaming literature is rich with many important notions of summary that are used to concisely represent a large stream of data approximately but with high precision. Computing ε-quantiles can be considered as one of the most important concepts for a succinct approximation of a distribution and it also generalizes many of the familiar concepts, e.g., 0-quantile, 0.5-quantile, and 1-quantile that are also known as the minimum, the median, and the maximum of S. We now give a formal definition below.

Quantile summaries. Given a sequence of values $w_1 \leq \cdots \leq w_k$, a δ-quantile, for $0 \leq \delta \leq 1$, is the value with rank $\lfloor \delta k \rfloor$. By convention, 0-quantile and 1-quantiles are set to be the minimum and the maximum, i.e., w_1 and w_k respectively. An ε-quantile summary is then defined as the list of $1 + \varepsilon^{-1}$ values where the i-th value is the $i\varepsilon$-quantile, for $i = 0, \cdots, \varepsilon^{-1}$. As we will review shortly, computing exact quantiles is often too expensive so instead we focus on approximations. We define an approximate ε-quantile summary (AQS) to be a sequence of $1 + \varepsilon^{-1}$ values where the i-th value is between the $(i-1)$-quantile and the $(i+1)$-quantile[1], for $i = 0, \cdots, \varepsilon^{-1}$. An approximate quantile summary with a reasonably small choice of ε can give a very good approximation of the distribution. It also has the benefit that the query needs to output only $O(\varepsilon^{-1})$ values, regardless of the number of points inside the query range.

To obtain a relatively precise approximation of the distribution, ε needs to be chosen sufficiently small, and thus we consider it an additional parameter (and thus not a constant). This is also similar to the literature on streaming where the dependency on ε is important.

[1] For $a \leq 0$ (resp. $a \geq k$), we define the a-quantile to be the 0-quantile (resp. k-quantile).

1.1 Problem Definition, Previous Work, and Related Results

One of our main problems is the problem of answering approximate quantile summary (AQS) queries which is defined as follows.

▶ **Problem 1** (Approximate quantile summaries). *Consider an input set P of n points in $\mathbb{R}^d$ where each point $p \in P$ is assigned a weight w_p from a totally ordered universe. Given a value ε, we are asked to build a structure such that given a query range γ, it can return an AQS of $P \cap \gamma$ efficiently.*

It turns out that another type of "range summary queries" is extremely useful for building data structures for AQS queries.

Heavy hitter summaries. Consider a set P of k points where each point in P is assigned a color from the set $[n]$. Let f_i be the frequency of color i in P, i.e., the number of times color i appears among the points in P. A *heavy hitter summary (HHS)* with parameter ε, is the list of all the colors i with $f_i \geq \varepsilon k$ together with the value f_i. As before, working with exact HHS will result in very inefficient data structures and thus once again we turn to approximations. An *approximate heavy hitter summary (AHHS)* with parameter ε is a list, L, of colors such that every color i with $f_i \geq \varepsilon k$ is included in L and furthermore, every color $i \in L$ is also accompanied with an approximation, f'_i, of its frequency such that $f_i - \varepsilon k \leq f'_i \leq f_i + \varepsilon k$.

▶ **Problem 2** (Approximate heavy hitters summaries). *Consider an input set P of n points in $\mathbb{R}^d$ where each point in P is assigned a color from the set $[n]$. Given a parameter ε, we are asked to build a structure such that given a query γ, it can return an AHHS of the set $P \cap \gamma$.*

Observe that in both problems, the output size of a query is $O(1/\varepsilon)$ in the worst-case. Our main focus is to obtain data structures with the optimal worst-case query time of $O(\log n + \varepsilon^{-1})$. Note that it makes sense to define an *output-sensitive* variant where the query time is $O(\log n + k)$ where k is the output size. E.g., it could be the case for a AHHS query that the numbrer of heavy hitters is much fewer than ε^{-1}. This makes less sense for AQS queries, since unless the distribution of weights inside the query range γ is almost constant, an AQS will have $\Omega(\varepsilon^{-1})$ distinct values. As our main focus is on AQS, we only consider AHHS data structures with the worst-case query time of $O(\log n + \varepsilon^{-1})$.

A note about the notation. To reduce the clutter in the expressions of query time and space, we adopt the convention that $\log(\cdot)$ function is at least one, e.g., we define $\log_a b$ to be $\max\{1, \frac{\ln b}{\ln a}\}$ for any positive values a, b.

Previous Results

As discussed, classical range searching solutions focus on rather simple queries that can return sum, weighted sum, minimum, maximum, or the full list of points contained in a given query range. This is an extensively researched area with numerous results to cite and so we refer the reader to an excellent survey by Agarwal [5] that covers such classical results.

However, classical range searching data structures cannot give detailed statistical information about the set of points contained inside the query region, unless one opts to report the entire subset of points inside the query range, which could be very expensive if the set is large. Because of this, there have been a number of attempts to answer more informative queries. For example, "range median" queries have received quite a bit of attention [20, 10, 18]. Note that the median is the same as 0.5-quantile and thus these can be considered the

first attempts at answering quantile queries. However, optimal solution (linear space and logarithmic query time) to exact range median queries has only be found in 1D [10]. For higher dimensions, to the best of our knowledge, the only known technique is to reduce the problem to several range counting instances [10, 13], and it is a major open problem in the range searching field to find efficient data structures for exact range counting. Due to this barrier, the approximate version of the problem [9] has been studied.

Data summary queries have also received some amount of attention, especially in the context of geometric queries. Agarwal et al. [6] showed that the heavy hitters summary (as well as a few other data summaries) are "mergeable" and this gives a baseline solution for a lot of different queries in higher dimensions, although a straightforward application of their techniques gives sub-optimal dependency on ε. In particular, for $d = 2$ and for halfspace (or simplex) queries it yields a linear-space data structure with $O(\frac{\sqrt{n}}{\varepsilon})$ query time. For $d = 3$ the query time will be $O(n^{2/3}/\varepsilon)$. In general, in the naive implementation, the query time will be $O(f(n)/\varepsilon)$ where $f(n)$ is the query time of the corresponding "baseline" range searching query (see Table 1 for more information). A more efficient approach towards merging of summaries was taken by [17] where they study the problem in a communication complexity setting, however, it seems possible to adopt their approach to a data structure as well, in combination with standard application of partition trees; after building an optimal partition tree, for any node v in the tree, consider it as a player in the communication problem with the subset of points in the subtree of v as its input. At the query time, after identifying $O(n^{2/3})$ subsets that cover the query range, the goal would be to merge all the summaries involved. By plugging the results in [17] this can result in a linear-space data structure with query time of $\tilde{O}(n^{2/3} + n^{1/6}\varepsilon^{-3/2})$.

The issue of building optimal data structures for range summary queries was only tackled in 1D by Wei and Yi [24]. They built a data structure for answering a number of summary queries, including heavy hitters queries, and showed it is possible to obtain an optimal data structure with $O(n)$ space and $O(\log n + 1/\varepsilon)$ query time. Beyond this, only sub-optimal solutions are available. Recently, there have been efforts to tackle "range sampling queries" where the goal is to extract k random samples from the set $|P \cap \gamma|$ [3, 4, 16]. In fact, one of the main motivations to consider range sampling queries was to gain information about the distribution of the point set inside the query [3]. In particular, range sampling provides a general solution for obtaining a "data summary" and for example, it is possible to solve the heavy hitters query problem. However, it has a number of issues, in particular, it requires sampling at least $1/\varepsilon^2$ points from the set $|P \cap \gamma|$, and even then it will only provide a Monte Carlo type approximation which means to boost the probabilistic guarantee, even more points need to be sampled. For example, to get a high probability guarantee, $\Omega(\varepsilon^{-2}\log n)$ samples are required.

Type-2 Color Counting. These queries were introduced in 1995 by Gupta et al. [15] within the area of "colored range counting". In this problem, given a set of colored points, we want to report the frequencies of all the colors that appeared in a given query range. This is a well-studied problem, but mostly in the orthogonal setting, see e.g., [11].

AHHS queries can be viewed as approximate type-2 color counting queries but with an additive error. Consider a query with k points. If we allow error εk in type-2 counting, then we can ignore colors with frequencies fewer than εk but otherwise we have to report frequencies with error εk, which is equivalent to answering an AHHS query.

Other Related Problems. Karpinski and Nekrich [19] studied the problem of finding the most frequent colors in a given (orthogonal) query range. This problem has received further attention in the community [8, 7, 14]. But the problem changes fundamentally when we introduce approximations.

The Model of Computation. Our model of computation is the real RAM where we have access to real registers that can perform the standard operations on real numbers in constant time, but we also have access to $w = \Theta(\log n)$ bits long integer registers that can perform the standard operations on integers and extra nonstandard operations which can be implemented by table lookups since we only need binary operations on fewer than $\frac{1}{2}\log n$ bits. Note that our data structure works when the input coordinates are real numbers, however, at some point, we will make use of the capabilities of our model of computation to manipulate the bits inside its integer registers.

1.2 Our Contributions

Our main results and a comparison with the previously known results are shown in Table 1.

Overall, we obtain a series of new results for 3D AHHS and AQS query problems which improve the current results via mergeability and independent range sampling [6, 4] by up to a huge multiplicative $n^{\Omega(1)}$ factor in query time with almost the same linear-space usage. This improvement is quite nontrivial and requires an innovative combination of known techniques like the shallow cutting lemma, the partition theorem, ε-approximations, as well as some new ideas like bit-packing for nonorthogonal queries, solving AQS query problem using AHHS instances, rank-preserving geometric sampling and so on.

For dominance queries, we obtain the first optimal results. When $\varepsilon^{-1} = O(\log n)$ our halfspace AHHS results are also optimal. Note that for small values of ε, our halfspace AHHS results yield significant improvements in the query time over the previous approaches. Along the way, we also show improved results of the above problems for 2D as well as a slightly improved exact type-2 simplex color counting result.

2 Preliminaries

In this section, we introduce the main tools we will use in our results. For a comprehensive introduction to the tools we use, see the full version.

2.1 Shallow Cuttings and Approximate Range Counting

Given a set H of n hyperplanes in $\mathbb{R}^3$, the level of a point $q \in \mathbb{R}^3$ is the number of hyperplanes in H that pass below q. We call the locus of all points of level at most k the $(\leq k)$-level and the boundary of the locus is the k-level. A shallow cutting $\mathscr{C}$ for the $(\leq k)$-level of H (or a k-shallow cutting for short) is a collection of disjoint cells (tetrahedra) that together cover the $(\leq k)$-level of H with the property that every cell $C \in \mathscr{C}$ in the cutting intersects a set H_C, called the conflict list of C , of $O(k)$ hyperplanes in H. The shallow cutting lemma is the following.

▶ **Lemma 1.** *For any set of n hyperplanes in $\mathbb{R}^3$ and a parameter k, there exists an $O(k/n)$-shallow cutting of size $O(n/k)$ that covers the $(\leq k)$-level. The cells in the cutting are all vertical prisms unbounded from below (tetrahedra with a vertex at $(0, 0, -\infty)$).*

Table 1 Our main results compared with Mergeability-based [6] and Independent Range Sampling (IRS)-based [4] solution. The IRS-based solutions are randomized with success probability $1-\delta$ for a parameter $0<\delta<1$. F is the number of colors of the input. $w=\Theta(\log n)$ is the word size of the machine. † indicates optimal solutions.

Summary Query Types	Space	Query Time	Remark
Type-2 Simplex Color Counting	$O(n)$	$O\left(n^{1-\frac{1}{d}}+\frac{n^{1-\frac{1}{d}}F^{\frac{1}{d}}}{w^{\alpha}}\right)$	New
3D AHHS Halfspace	$O(n)$ $O(n)$ $O(n)$ $\boldsymbol{O(n\log_w \frac{1}{\varepsilon})}$	$O(\log n+\frac{1}{\varepsilon}n^{2/3})$ $\tilde{O}(n^{2/3}+\frac{1}{\varepsilon^{3/2}}n^{1/6})$ $O(\log n+\frac{1}{\varepsilon^2}\log\frac{1}{\delta})$ $\boldsymbol{O(\log n+\frac{1}{\varepsilon})}$	Mergeability-based [6] Monte Carlo [17] IRS-based [4] **New**
3D AHHS Dominance	$O(n)$ $O(n)$ $\boldsymbol{O(n)}$	$O(\log n+\frac{1}{\varepsilon}\log^3 n)$ $O(\log n+\frac{1}{\varepsilon^2}\log\frac{1}{\delta})$ $\boldsymbol{O(\log n+\frac{1}{\varepsilon})}$	Mergeability-based [6] IRS-based [4] **New**†
3D AQS Halfspace	$O(n)$ $O(n)$ $\boldsymbol{O(n\log^2\frac{1}{\varepsilon}\log_w\frac{1}{\varepsilon})}$	$O(\log n+\frac{1}{\varepsilon}n^{2/3}\log(\varepsilon n))$ $O(\log n+\frac{1}{\varepsilon^2}\log\frac{1}{\delta})$ $\boldsymbol{O(\log n+\frac{1}{\varepsilon}\log^2\frac{1}{\varepsilon})}$	Mergeability-based [6] IRS-based [4] **New**
3D AQS Dominance	$O(n)$ $O(n)$ $\boldsymbol{O(n)}$	$O(\log n+\frac{1}{\varepsilon}\log^3 n\log(\varepsilon n))$ $O(\log n+\frac{1}{\varepsilon^2}\log\frac{1}{\delta})$ $\boldsymbol{O(\log n+\frac{1}{\varepsilon})}$	Mergeability-based [6] IRS-based [4] **New**†

Furthermore, we can construct these cuttings for all k of form a^i simultaneously in $O(n\log n)$ time for any $a>1$. Given any point $q\in\mathbb{R}^3$, we can find the smallest level k that is above q as well the cell containing q in $O(\log n)$ time.

The above can also be applied to dominance ranges, which are defined as below. Given two points p and q in $\mathbb{R}^d$, p dominates q if and only if every coordinate of p is larger or equal to that of q. The subset of $\mathbb{R}^d$ dominated by p is known as a *dominance range*. When the query range in a range searching problem is a dominance range, we refer to it as a *dominance query*. As observed by Chan et al. [12], dominance queries can be simulated by a halfspace queries and thus Lemma 1 applies to them. See the full version for details.

We obtain the approximate version of the range counting result using shallow cuttings.

▶ **Theorem 2** (Approximate Range Counting [2]). *Let P be a set of n points in $\mathbb{R}^3$. One can build a data structure of size $O(n)$ for halfspace or dominance ranges such that given a query range γ, one can report $|\gamma\cap P|$ in $O(\log n)$ time with error $\alpha|\gamma\cap P|$ for any constant $\alpha>0$.*

2.2 ε-approximation

Another tool we will use is ε-approximation, which is a useful sampling technique:

▶ **Definition 3.** *Let (P,Γ) be a finite set system. Given any $0<\varepsilon<1$, a set $A\subseteq P$ is called an ε-approximation for (P,Γ) if for any $\gamma\in\Gamma$, $\left|\frac{|\gamma\cap A|}{|A|}-\frac{|\gamma\cap P|}{|P|}\right|\leq\varepsilon$.*

The set A above allows us to approximate the number of points of $\gamma\cap P$ with additive error $\varepsilon|P|$ by computing $|\gamma\cap A|$ exactly; essentially, ε-approximations reduce the approximate counting problem on the (big) set P to the exact counting problem on the (small) set A.

It has been shown that small-sized ε-approximations for set systems formed by points and halfspaces/dominance ranges exist:

▶ **Theorem 4** (ε-approximation [21, 22]). *There exist ε-approximations of size $O(\varepsilon^{-\frac{2d}{d+1}})$ and $O(\varepsilon^{-1}\log^{d+1/2}\varepsilon^{-1})$ for halfspace and dominance ranges respectively.*

3 Approximate Heavy Hitter Summary Queries

We solve approximate quantile summary (AQS) queries using improved results for approximate heavy hitter summary (AHHS) queries. We sketch the main ideas of our new AHHS solutions in this section and refer the readers to the full version for details. For the clarity of description, we use ε_0 to denote the target error for the AHHS queries. We will reserve ε as a general error parameter. We show the following.

▶ **Theorem 5.** *For $d = 3$, the approximate halfspace heavy hitter summary queries can be answered using $O(n\log_w(1/\varepsilon_0))$ space and with the optimal $O(\log n + 1/\varepsilon_0)$ query time.*

▶ **Theorem 6.** *For $d = 2$, the approximate halfspace heavy hitter summary queries can be answered using $O(n\log\log_w(1/\varepsilon_0))$ space and with the optimal $O(\log n + 1/\varepsilon_0)$ query time.*

▶ **Theorem 7.** *For $d = 2, 3$, the approximate dominance heavy hitter summary queries can be answered using the optimal $O(n)$ space and with the optimal $O(\log n + 1/\varepsilon_0)$ query time.*

3.1 Base Solution

The above results are built from a *base solution*, which solves the following problem:

▶ **Problem 3** (Coarse-Grained AHHS Queries). *Let P be a set of points in $\mathbb{R}^d$, each associated with a color. The problem is to store P in a structure such that given a query range q, one can estimate the frequencies of colors in $q \cap P$ with an additive error up to $\varepsilon|P|$ efficiently for some parameter $0 < \varepsilon < 1$.*

Note that here we allow more error (since the error is defined in the entire point set). To solve Problem 3, one crucial component we need is a better (exact) type-2 color counting structure for halfspaces. We combine several known techniques in a novel way with bit-packing to get the following theorem. See the full version for details.

▶ **Theorem 8.** *Given an integer parameter F, a set P of n points in $\mathbb{R}^d$ where each point is assigned a color from the set $[F]$, one can build a linear-sized data structure, such that given a query simplex q, it can output the number of times each color appears in $P \cap q$ in total time $\max\{O(n^{(d-1)/d}), O(n^{(d-1)/d}F^{1/d}/w^{\alpha})\}$, for some appropriate constant α and word size w.*

The main idea for getting a base solution is relatively straightforward. We group colors according to their frequencies where each group contains colors of roughly equal frequencies. However, we have to be careful about the execution and the analysis is a bit tricky. For example, if we place all the points in one copy of the data structure of Theorem 8, then we will get a sub-optimal result. However, by grouping the points correctly, and being stringent about the analysis, we can obtain the following.

▶ **Theorem 9.** *For $d \geq 3$, Problem 3 for simplex queries (the intersection of $d+1$ halfspaces) can be solved with $O(X)$ space for $X = \min\{|P|, \varepsilon^{-\frac{2d}{d+1}}\}$ and a query time of*

$$O\left(\frac{|P|^{1-\frac{2}{d-1}}}{w^{\alpha}\varepsilon^{\frac{2}{d-1}}}\right) + O\left(X^{\frac{d-1}{d}}\right)$$

where w is the word-size of the machine and α is some positive constant.

The main challenge is that we have two cases for the size of an ε-approximation on n points since it is bounded by $\min\left\{n, O(\varepsilon^{-\frac{2d}{d+1}})\right\}$ and also two cases for the query time of Theorem 8. However, the main idea is that since the total error budget is $\varepsilon|P|$, we can afford to pick a larger error parameter $\varepsilon_i = \frac{\varepsilon|P|}{|P_i|}$, where P_i is the set of points with color i. The details are presented in the full version.

3.2 Solving AHHS Queries

We first transform the problem into the dual space. So the point set P becomes a set H of hyperplanes and any query halfspace becomes a point q. We want to find approximate heavy hitters of hyperplanes of H below q. Here, we remark that obtaining a data structure with $O(n \log \frac{1}{\varepsilon_0})$ space is not too difficult: build a hierarchy of shallow cuttings covering level $2^i/\varepsilon_0$ for $i = 0, 1, \cdots, \log(\varepsilon_0 n)$ of the arrangement of H. For each shallow cutting cell Δ, we build the previous base structure for the conflict list $\mathcal{S}_\Delta$ for a parameter $\varepsilon = \varepsilon_0/c$ for a big enough constant c. Then, observe that for queries below level ε_0^{-1}, we can spend $O(\log n + \frac{1}{\varepsilon_0})$ time to find all the hyperplanes passing below the query and answer the AHHS queries explicitly and also for shallow cutting levels above level $\varepsilon_0^{-3/2}$, the total amount of space used by the base solution is $O(n)$. Thus, it turns out that the main difficulty lies in handling the levels between ε_0^{-1} and $\varepsilon_0^{-3/2}$.

To reduce the space to $O(\log_w \frac{1}{\varepsilon_0})$, recall that in the query time of the base structure, we have two terms $O(1/(\varepsilon_0 w^\alpha))$ and $O(X^{2/3})$. Observe that we can afford to set ε to be roughly ε_0/w^α and the first term will still be $O(\varepsilon_0^{-1})$ because we are at level below $\varepsilon_0^{-3/2}$, we have $X < \varepsilon_0^{-3/2}$ and so the second term will always be $O(\varepsilon_0^{-1})$! The effect of setting $\varepsilon = \varepsilon_0/w^\alpha$ is that now the base structure we built for a cell can output frequencies with a factor of w^α more precision, meaning it can be used for a factor of w^α many more levels. So we only need to build the base structure for shallow cuttings built for a factor of w^α! This gives us the $O(n \log_w \frac{1}{\varepsilon_0})$ space bound. Of course, here the output has size $O(\varepsilon^{-1}) = O(w^\alpha \varepsilon_0^{-1})$ and we cannot afford to examine all these colors. The final ingredient here is that we can maintain a list of $O(\varepsilon_0^{-1})$ candidate colors using shallow cuttings built for a factor of 2.

We remark that although the tools are standard, the combination of the tools and the analysis are quite nontrivial. Also when we have $\Theta(1/\varepsilon_0)$ heavy hitters, our query time is optimal. It is an interesting open problem if the query time can be made output sensitive.

4 Approximate Quantile Summary Queries

In this section, we solve Problem 1. We first show a general technique that uses our solution to AHHS queries solution to obtain an efficient solution for AQS queries. We show that for 3D halfspace and dominance ranges we can convert the solution for AHHS queries to a solution for AQS queries with an $O(\log^2 \frac{1}{\varepsilon})$ blow up in space and time. Then in Section 4.2, we present an optimal solution for dominance ranges based on a different idea.

First, we show how to solve AQS queries using the AHHS query solution. We describe the data structure for halfspaces, since as we have mentioned before, the same can be applied to dominance ranges in 3D as well. The high level idea of our structure is as follows: We first transform the problem into the dual space. This yields the problem instance where we have n weighted hyperplanes and given a query point q, we would like to extract an approximate quantile summary for the hyperplanes that pass below q. To do this, we build hierarchical shallow cuttings. For each cell in each cutting, we collect the hyperplanes in its conflict list and then divide them into $O(\frac{1}{\varepsilon_0})$ groups according to the increasing order of their weights.

Given a query point in the dual space, we first find the cutting and the cell containing it, and then find an approximated rank of each group, within the subset below the query. This is done by generating an AHHS problem instance and applying Theorem 5. We construct the instance in a way such that the rank approximated will only have error small enough such that we can afford to scan through the groups and pick an arbitrary hyperplane in corresponding groups to form an approximate ε_0-quantile summary.

4.1 The Data Structure and the Query Algorithm

We dualize the set P of n input points which gives us a set $H = \overline{P}$ of n hyperplanes. We then build a hierarchy of shallow cuttings where the i-th shallow cutting, $\mathscr{C}_i$, is a k_i-shallow cutting where $k_i = \frac{2^i}{\varepsilon_0}$, for $i = 0, 1, 2, \cdots, \log(\varepsilon_0 n)$. Consider a cell Δ in the i-th shallow cutting and its conflict list $\mathcal{S}_\Delta$. Let $\epsilon = \frac{\varepsilon_0}{c}$ for a big enough constant c. We partition $\mathcal{S}_\Delta$ into $t = \frac{1}{\epsilon}$ groups $G_1, G_2, \cdots, G_t$ sorted by weight, meaning, the weight of any hyperplane in G_j is no larger than that of any hyperplane in G_{j+1} for $j = 1, 2, \cdots, t-1$.

For each group G_j, we store the smallest weight among the hyperplanes it contains, as its representative. To make the description shorter, we make the simplifying assumption that t is a power of 2 (if not, we can add some dummy groups). We arrange the groups G_j as the leaves of a balanced binary tree $\mathcal{T}$ and let $V(\mathcal{T})$ be the set of vertices of $\mathcal{T}$. Next, we build the following set A_Δ of colored hyperplanes, associated with Δ: Let $\varepsilon' = \frac{\epsilon}{\log^2 t}$. For every vertex $v \in V(\mathcal{T})$, let G_v to be the set of all the hyperplanes contained in the subtree of v; we add an ε'-approximation, E_v, of G_v to A_Δ with color v. Using Theorem 5, we store the points dual to hyperplanes in A_Δ in a data structure Ψ_Δ for AHHS queries with error parameter ε'. This completes the description of our data structure.

The query algorithm. A given query q is answered as follows. Let us quickly go over the standard parts: We consider the query in the dual space and thus q is considered to be a point. Let k be the number of hyperplanes passing below q. Observe that by Theorem 2, we can find a $(1+\alpha)$ factor approximation, k^*, of k in $O(\log n)$ time for any constant α, using a data structure that consumes linear space. This allows us to find the first k_i-shallow cutting $\mathscr{C}_i$ with $k_{i-1} < k \leq k_i$. The cell $\Delta \in \mathscr{C}_i$ containing q can also be found in $O(\log n)$ time using a standard point location data structure (e.g., see [1]).

The interesting part of the query is how to handle the query after finding the cell Δ. Let H_q be the subset of H that lies below q. Recall that $\mathcal{S}_\Delta$ is the subset of H that intersects Δ. The important property of Δ is that $H_q \subset \mathcal{S}_\Delta$ and also $|\mathcal{S}_\Delta| = O(|H_q|) = O(k)$.

We query the data structure Ψ_Δ built for Δ to obtain a list of colors and their approximate counts where the additive error in the approximation is at most $\varepsilon'|A_\Delta|$. To continue with the description of the query algorithm, let us use the notation g_j to denote the subset of G_j that lies below q, and let $g = \cup_{j=1}^{t} g_j$ and thus $|g| = k$.

Note that while the query algorithm does not have direct access to g, or k, we claim that using the output of the data structure Ψ_Δ, we can calculate the approximate rank of the elements of g_i within g up to an additive error of $\varepsilon_0 k$. Again, we can use tree $\mathcal{T}$ to visualize this process. Recall that in Ψ_Δ, every vertex $v \in V(\mathcal{T})$ represents a unique color in the data structure Ψ_Δ and the data structure returns an AHHS summary with error parameter ε'. This allows us to estimate the number of elements of E_v that pass below q with error $\varepsilon'|A_\Delta|$ and since E_v is an ε'-approximation of G_v, this allows us to estimate the number of elements of G_v that pass below q with error at most $2\varepsilon'|A_\Delta|$. Consider the leaf node that represents $g_j \subset G_j$ and the path π that connects it to the root of $\mathcal{T}$. The approximate rank, r_j, of g_j is calculated as follows. Consider a subtree with root u that hang to the left of the path π (as

shown in Figure 1). If color u does not appear in the output of the AHHS query, then we can conclude that at most $2\varepsilon'|A_\Delta|$ of its hyperplanes pass below q and in this case we do nothing. If it does appear in the output of the AHHS query, then we know the number of hyperplanes in its subtree that pass below q up to an additive error of $2\varepsilon'|A_\Delta|$ and in this case, we add this estimate to r_j. In both cases, we are off by an additive error of $2\varepsilon'|A_\Delta|$. We repeat this for every subtree that hangs to the left of π. The number of such subtree is at most $\log t$ and thus the total error is at most $2\varepsilon'|A_\Delta|\log t$. Now observe that

$$2\varepsilon'|A_\Delta|\log t = 2\frac{\epsilon}{\log^2 t}\cdot \log t|\mathcal{S}_\Delta|\cdot\log t = O(\varepsilon k) = O\left(\frac{\varepsilon_0 k}{c}\right) \leq \varepsilon_0 k$$

which follows by setting c large enough and observing the fact that $|A_\Delta| \leq \log t|\mathcal{S}_\Delta|$ since every hyperplane in $\mathcal{S}_\Delta$ is duplicated $\log t$ times.

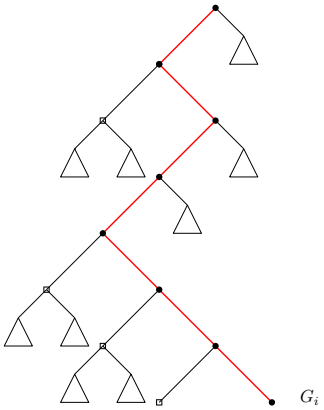

Figure 1 Compute the Approximate Rank of a Group: The approximated rank of G_i is calculated as the sum of all the approximate counts of square nodes.

We are now almost done. We just proved that in each g_i, we know the rank of its elements within g up to an additive error of $\varepsilon_0 k$. This means that picking one element from each G_i gives us a super-set of an AQS; in the last stage of the query algorithm we simply prune the unnecessary elements as follows: We scan all the leave in $\mathcal{T}$ from left to right, i.e., consider the group G_j for $j = 1$ to t and compute the quantile summary in a straightforward fashion. To be specific, we initialize a variable $j' = 0$ and then consider G_j, for $j = 1$ to t. The first time r_j exceeds a quantile boundary, i.e., $r_j \geq j'\varepsilon_0 k^*$, we add the hyperplane with the lowest weight in G_j to the approximate ε_0-quantile summary, and then increment j'.

Analysis

Based on the previous paragraph, the correctness is established. Thus, it remains to analyze the space and query complexities. We start with the former.

Space Usage. Consider the structure Ψ_Δ built for cell Δ from a k_i-shallow cutting $\mathscr{C}_i$. Observe that $\sum_{v\in V(\mathcal{T})}|G_v| = |\mathcal{S}_\Delta|\log t$ since in the sum every hyperplane will be counted $\log t$ times. E_v is an ε'-approximation of G_v and thus

$$|E_v| \leq \min\left\{\varepsilon'^{-3/2}, G_v\right\} \tag{1}$$

which implies

$$|A_\Delta| = \sum_{v \in V(\mathcal{T})} |E_v| \leq \min\left\{\varepsilon'^{-3/2} 2t, |\mathcal{S}_\Delta| \log t\right\} \tag{2}$$

where the first part follows as there are at most $2t$ vertices in $\mathcal{T}$ and the second part follows from (1). We build an instance of Theorem 5 on the set A_Δ which by Theorem 5 uses $O(|A_\Delta| \log_w \frac{1}{\varepsilon'})$ space. Assuming Δ belongs to a k_i-shallow cutting $\mathscr{C}_i$, we have $|\mathcal{S}_\Delta| = O(k_i)$ and there are $O(n/k_i)$ cells in $\mathscr{C}_i$. Observe that

$$\sum_{\Delta \in \mathscr{C}_i} |A_\Delta| = \sum_{\Delta \in \mathscr{C}_i} \min\left\{\varepsilon'^{-3/2} 2t, |\mathcal{S}_\Delta| \log t\right\} = \sum_{\Delta \in \mathscr{C}_i} O\left(\min\left\{\varepsilon'^{-3/2} t, k_i \log t\right\}\right) = O\left(\min\left\{\frac{n}{k_i}\varepsilon_0^{-3}, n \log \frac{1}{\varepsilon_0}\right\}\right). \tag{3}$$

Thus, the total space used for $\mathscr{C}_i$ is

$$O\left(\min\left\{\frac{n}{k_i}\varepsilon_0^{-3} \log_w \frac{1}{\varepsilon_0}, n \log_w \frac{1}{\varepsilon_0} \log \frac{1}{\varepsilon_0}\right\}\right).$$

Finally, observe that there can be at most $O(\log \frac{1}{\varepsilon_0})$ levels where the second term dominates; to be specific, at least when k_i exceeds ε_0^{-4}, the first term dominates and the total space used by those levels is $O(n)$ as k_i's form a geometric series. So the total space usage of our structure is $O(n \log^2 \frac{1}{\varepsilon_0} \log_w \frac{1}{\varepsilon_0})$.

Query Time. By Lemma 1, we can find the desired cutting cell in time $O(\log n)$. Next, we query the data structure Ψ_Δ which by Theorem 5 uses $O(\log n + \varepsilon'^{-1}) = O(\log n + \frac{\epsilon}{\log^2 t}) = O(\log n + \frac{1}{\varepsilon_0} \log^2 \frac{1}{\varepsilon_0})$ query time. Scanning the groups and pruning the output of the data structure Ψ_Δ takes asymptotically smaller time and thus it can be absorbed in the above expression. Therefore, we obtain the following result.

▶ **Theorem 10.** *Given an input consisting of an error parameter ε_0, and a set P of n points in $\mathbb{R}^3$ where each point $p \in P$ is associated with a weight w_p from a totally ordered universe, one can build a data structure that uses $O(n \log^2 \frac{1}{\varepsilon_0} \log_w \frac{1}{\varepsilon_0})$ space such that given any query halfspace h, it can answer an AQS query with parameter ε_0 in time $O(\log n + \frac{1}{\varepsilon_0} \log^2 \frac{1}{\varepsilon_0})$.*

For the case of 2D, we can just replace Ψ_Δ with the structure in Theorem 6, and we immediately get the following:

▶ **Theorem 11.** *Given an input consisting of an error parameter ε_0, and a set P of n points in $\mathbb{R}^2$ where each point $p \in P$ is associated with a weight w_p from a totally ordered universe, one can build a data structure that uses $O(n \log^2 \frac{1}{\varepsilon_0} \log \log_w \frac{1}{\varepsilon_0})$ space such that given any query halfspace h, it can answer an AQS query with parameter ε_0 in time $O(\log n + \frac{1}{\varepsilon_0} \log^2 \frac{1}{\varepsilon_0})$.*

4.2 Dominance Approximate Quantile Summary Queries

Now we turn our attention to dominance ranges. We will show a structure similar to that for halfspace queries. The main difference is that we now use exact type-2 color counting as an auxiliary structure to estimate the rank of each group. This saves us roughly $\log^2 \frac{1}{\varepsilon_0}$ factors for both space and query time and so we can answer quantile queries in the optimal $O(\log n + \frac{1}{\varepsilon_0})$ time. To reduce the space to linear, we need more ideas. We first present a suboptimal but simpler structure to demonstrate our main idea. Then we modify this structure to get the desired optimal structure. We use shallow cuttings in the primal space.

4.2.1 A Suboptimal $O(n \log\log \frac{1}{\varepsilon_0})$ Space Solution

We first describe a data structure that solves the dominance AQS problem with $O(n \log\log \frac{1}{\varepsilon_0})$ space and the optimal $O(\log n + \frac{1}{\varepsilon_0})$ query time.

Rank-Preserving Approximation for Weighted Points. Let S be a weighted point set where every point has been assigned a weight from a totally ordered universe. Let $r_S(p)$ be the rank of a point p in the set S. Consider a geometric set system $(P, \mathscr{D})$, where P is a set of weighted points in $\mathbb{R}^3$ and $\mathscr{D}$ is a family of subsets of P induced by 3D dominance ranges. We mention a way to construct a sample A for P and a parameter ϵ such that

$$\left| \frac{r_{P\cap\mathcal{D}}(p)}{|P|} - \frac{r_{A\cap\mathcal{D}}(p)}{|A|} \right| \leq \epsilon \tag{4}$$

for any point $p \in P$ and any range $\mathcal{D} \in \mathscr{D}$. First note that taking an ϵ-approximation for P does **not** work since it does not take the weights of P into consideration. Our simple but important observation is that we can lift the points P into 4D by adding their corresponding weights as the fourth coordinate. Let us call this new point set P' and let $(P', \mathscr{D}')$ be the set system in 4D induced by 4D dominance ranges. Consider an ϵ-approximation A' for P' and let A be the projection of A' into the first three dimensions (i.e., by removing the weights again). A will be our sample for P and to distinguish it from an unweighted approximation, we call it *rank-preserving ϵ-approximation*. Indeed, for any point $p \in P$ with weight w_p and any $\mathcal{D} \in \mathscr{D}$, $r_{P\cap\mathcal{D}}(p)$ (resp. $r_{A\cap\mathcal{D}}(p)$) is equal to the number of points in P' (resp. A') contained in 4D dominance range $\mathcal{D} \times (-\infty, w_p)$. By the definition of ϵ-approximation, property (4) holds.

We now turn our attention to the AQS for 3D dominance queries.

The Data Structure and The Query Algorithm. Similar to the structure we presented for halfspace queries, we build $\frac{2^i}{\varepsilon_0}$-shallow cuttings for $i = 0, 1, \cdots, \log(\varepsilon_0 n)$. Let $\kappa = O(1)$ be the constant such that $O(\frac{1}{\varepsilon_0}\log^\kappa \frac{1}{\varepsilon_0})$ is the size of the ε_0-approximation for dominance ranges in 4D. Consider one k-shallow cutting $\mathscr{C}$. We consider two cases:

- If $k \leq \frac{1}{\varepsilon_0}\log^\kappa \frac{1}{\varepsilon_0}$, for each cell Δ in the cutting $\mathscr{C}$, we collect the points in its conflict list $\mathcal{S}_\Delta$ and divide them into $t = \frac{1}{\epsilon}$ groups $G_1, G_2, \cdots, G_t$ according to their weights (meaning, the weights in G_i are no larger than weights in group G_{i+1}) where $\epsilon = \frac{\varepsilon_0}{c}$ for a big enough constant c as we did for halfspace queries.
- For $k > \frac{1}{\varepsilon_0}\log^\kappa \frac{1}{\varepsilon_0}$, we take a rank-preserving ϵ-approximation of $\mathcal{S}_\Delta$ first, and then divide the approximation into $t = \frac{1}{\epsilon}$ groups, just like the above case. Again, for each group, we store the smallest weight among the points it contains.

We build the following structure for each cell Δ.

Let N be the number of points in all the t groups we generated for a cell Δ. We collect groups $G_{i\cdot\alpha+1}, G_{i\cdot\alpha+2}, \cdots, G_{(i+1)\cdot\alpha}$ into a cluster $\mathcal{C}_i$ for each $i = 0, 1, \cdots, t/\alpha - 1$ where $\alpha = (\log\log \frac{1}{\varepsilon_0})^3$. For each group j in cluster $\mathcal{C}_i$ for $j = 1, 2, \cdots, \alpha$, we color the points in the group with color j. Then we build the following type-2 color counting structure Ψ_i for $\mathcal{C}_i$. Let N_i be the total number of points in $\mathcal{C}_i$:

- First, we store three predecessor search data structures, one for each coordinate. This allows us to map the input coordinates as well as the query coordinates to rank space.
- Next, we build a grid of size $\sqrt[3]{N_i} \times \sqrt[3]{N_i} \times \sqrt[3]{N_i}$ such that each slice contains $\sqrt[3]{N_i^2}$ points. For each grid point, we store the points it dominates in a frequency vector using the compact representation.

- Finally, we recurse on each grid slab (i.e., three recursions, one for each dimension). The recursion stops when the number of points in the subproblem becomes smaller than $N_* = N_i^{\eta}$ for some small enough constant η.
- For these "leaf" subproblems, note that the total number of different answers to queries is bounded by $O(N_i^{3\eta})$. We build a lookup table which records the corresponding frequency vectors for these answers. Note that since at every step we do a rank space reduction, the look up can be simply done in $O(1)$ time, after reducing the coordinates of the query to rank space.

The query algorithm. Given a query q, we first locate the grid cell C containing q and this gives us three ranks. Using the ranks for x and y, we obtain an entry and using the rank of z, we find the corresponding word and the corresponding frequency vector stored in the lower corner of C. We get three more frequency vectors by recursing to three subproblems. We merge the three frequency vectors to generate the final answer. This completes the description of the structure we build for each family $\mathcal{C}_i$.

To answer a query q, we first find the first shallow cutting level above q and the corresponding cutting cell Δ. We then query the data structure described above to get the count the number of points dominated by q in each of the t groups. Then by maintaining a running counter, we scan through the t groups from left to right to construct the approximate ε_0-quantile summary.

Space Usage. For the space usage, note that there are N_i grid points in each recursive level and the recursive depth is $O(1)$. There are α colors and the frequency of a color is no more than N_i. So the total number of words needed to store frequency vectors is $O(N_i \frac{\alpha \log N_i}{w})$. When the problem size is below N_i^{η}, for each subproblem, we store a lookup table using $O(N_i^{3\eta} \frac{\alpha \log N_i}{w})$ words. So the total number of words used for the bottom level is $O(\frac{N_i}{N_i^{\eta}}) \cdot O(N_i^{3\eta} \frac{\alpha \log N_i}{w}) = O(N_i \frac{N_i^{2\eta} \alpha \log N_i}{w})$. Note that by our construction and $\varepsilon_0 \geq \frac{1}{n}$, $N = O(\frac{1}{\varepsilon_0} \log^{\kappa} \frac{1}{\varepsilon_0})$, $\alpha = (\log\log \frac{1}{\varepsilon_0})^3 \leq (\log\log n)^3$ and $N_i = O(\alpha \frac{N}{1/\varepsilon_0}) = O(\alpha \log^{\kappa} \frac{1}{\varepsilon_0}) = O(\alpha \log^{\kappa} n)$. Since by assumption, $w = \Omega(\log n)$, by picking η in $N_* = N_i^{\eta}$ to be a small enough constant, the space usage for frequency vectors satisfy

$$f(N_i) = \begin{cases} 3\sqrt[3]{N_i} f(\sqrt[3]{N_i^2}) + O(\frac{N_i}{w^{1-o(1)}}), \text{for } N_i \geq N_* \\ O(\frac{N_i}{w^{1-\beta}}), \text{otherwise} \end{cases},$$

for some constant $0 < \beta < 1$, which solves to $O(\frac{N_i (\log N_i)^3}{w^{1-\beta}}) = O(\frac{N_i}{w^{1-\tau}})$ for some constant $0 < \tau < 1$. Since the recursive depth is $O(1)$, the space usage for all the predecessor searching structures is $O(N_i)$. Therefore the space usage of Ψ_i is $O(N)$. So the total space for each shallow cutting cell Δ is bounded by $\frac{N}{N_i} \cdot O(N_i) = O(N)$.

For $k_i \geq \frac{1}{\varepsilon_0} \log^{\kappa} \frac{1}{\varepsilon_0}$, $N = O(\frac{1}{\varepsilon_0} \log^{\kappa} \frac{1}{\varepsilon_0})$. So the total space usage for them is bounded by

$$\sum_{i=\kappa \log\log \frac{1}{\varepsilon_0}}^{\varepsilon_0 n} O\left(\frac{n}{k_i}\right) \cdot O(N) = \sum_{i=\kappa \log\log \frac{1}{\varepsilon_0}}^{\varepsilon_0 n} O\left(\frac{n\varepsilon_0}{2^i}\right) \cdot O\left(\frac{1}{\varepsilon_0} \log^{\kappa} \frac{1}{\varepsilon_0}\right) = O(n).$$

For $k_i < \frac{1}{\varepsilon_0} \log^{\kappa} \frac{1}{\varepsilon_0}$, $N = k_i$ and so we have space bound

$$\sum_{i=0}^{\kappa \log\log \frac{1}{\varepsilon_0}} O\left(\frac{n}{k_i}\right) \cdot O(N) = \sum_{i=0}^{\kappa \log\log \frac{1}{\varepsilon_0}} O\left(\frac{n}{k_i}\right) \cdot O(k_i) = O\left(n \log\log \frac{1}{\varepsilon_0}\right).$$

This completes our space bound proof.

Query Time. For the query time, we first spend $O(\log n)$ time to find an appropriate shallow cutting level and the corresponding cell by the property of shallow cuttings. Then we query Ψ_i for $i = 0, 1, \cdots, t/\alpha - 1$ to estimate the count for each group in the cell. For each Ψ_i, note that each predecessor searching takes $O(\log N_i)$ time. Also each frequency vector can fit in one word and so we can merge two frequency vectors in time $O(1)$. This gives us the following recurrence relation for the query time

$$g(N_i) = \begin{cases} 3g(\sqrt[3]{N_i^2}) + O(\log N_i), \text{for } N_i \geq N_* \\ O(\log N_i), \text{otherwise} \end{cases},$$

which solves to $O((\log N_i)^3) = O((\log\log \frac{1}{\varepsilon_0})^3) = O(\alpha)$. Since we need to query t/α such data structures to get the count for all groups, the total query time for count estimation is $O(t) = O(1/\varepsilon_0)$. Then we scan through the groups and report the approximate quantiles which takes again $O(1/\varepsilon_0)$ time. So the total query time is $O(\log n + \frac{1}{\varepsilon_0})$.

Correctness. Given a query q, let k be the actual number of points dominated by q. By the property of shallow cuttings, we find a cell Δ containing q in the shallow cutting level k_i above it such that $k \leq k_i \leq 2k$. When $k_i < \frac{1}{\varepsilon_0}\log^\kappa \frac{1}{\varepsilon_0}$, after we estimate the count in each group, since the estimation is exact and each group has size $\frac{|\mathcal{S}_\Delta|}{t} = \frac{\varepsilon_0|\mathcal{S}_\Delta|}{c}$, each quantile we output will have error at most $\frac{\varepsilon_0|\mathcal{S}_\Delta|}{c}$. For $k_i \geq \frac{1}{\varepsilon_0}\log^\kappa \frac{1}{\varepsilon_0}$, we introduce error $\epsilon|\mathcal{S}_\Delta|$ in the ϵ-approximation, but since we use exact counting for each group, the total error will not increase as we add up ranks of groups. So the total error is at most $\frac{2\varepsilon_0|\mathcal{S}_\Delta|}{c}$. In both cases, the total error is at most $\varepsilon_0 k$ for a big enough c.

4.2.2 An Optimal Solution for 3D Dominance AQS

In this section, we modify the data structure in the previous section to reduce the space usage to linear. It can be seen from the space analysis that the bottleneck is shallow cuttings with $k_i \leq \frac{1}{\varepsilon_0}\log^\kappa \frac{1}{\varepsilon_0}$. For the structures built for these levels, the predecessor searching structures take linear space at each level which leads to a super linear space usage in total. To address this issue, we do a rank space reduction for points in the cells of these levels before constructing Ψ_i's so that we can use the integer register to spend sublinear space for the predecessor searching structures.

Rank Space Reduction Structure. We consider the cells in the $\frac{1}{\varepsilon_0}\log^\kappa \frac{1}{\varepsilon_0}$-shallow cutting. Let $A = \log^{\kappa+1} \frac{1}{\varepsilon_0}$. For the points in the conflict list $\mathcal{S}_\Delta$ of a shallow cutting cell $\Delta \in \mathscr{C}$, we build a grid of size $A \times A \times A$ such that each slice of the grid contains $O(1/(\varepsilon_0 \log \frac{1}{\varepsilon_0}))$ points. The coordinate of each grid point consists of the ranks of its three coordinates in the corresponding dimensions. For each of the $O(\frac{A}{\varepsilon_0 \log(1/\varepsilon_0)})$ points in $\mathcal{S}_\Delta$, we round it down to the closest grid point dominated by it. This reduces the coordinates of the points down to $O(\log\log \frac{1}{\varepsilon_0})$ bits and now we can apply the sub-optimal solution from the previous subsection which leads to an $O(n)$ space solution. To be more specific, we build the hierarchical shallow cuttings for $k_i \leq \frac{1}{\varepsilon_0}\log^\kappa \frac{1}{\varepsilon_0}$ locally for hyperplanes in $\mathcal{S}_\Delta$ and apply the previous solution with a value $\varepsilon' = \varepsilon/c$ for a large enough constant c.

Query Algorithm and the query time. The query algorithm is similar to that for the previous suboptimal solution. The only difference is that when the query q is in a shallow cutting level smaller than $\frac{1}{\varepsilon_0}\log^\kappa \frac{1}{\varepsilon_0}$, we use the rank space reduction structure to reduce q

to the rank space. Let q' be the grid point obtained after reducing q to rank space. Observe that the set of points dominated by q can be written as the union of the points dominated by q' and the subset of points dominated by q in three grid slabs of A that contain q. We get an ε'-quantile for the former set using the data structure implemented on the grid points. The crucial observation is that there are $O(\varepsilon_0^{-1}/\log\frac{1}{\varepsilon_0})$ points in the slabs containing q and thus we can afford to build an approximate ε'-quantile summary of these points in $O(\frac{1}{\varepsilon_0})$ time. We can then merge these two quantiles and return the answer as the result. By setting c in the definition of ε' small enough, we make sure that the result is a valid ε_0 quantile summary. This also yields a query time (after locating the correct cell Δ in the shallow cutting) of $O(\frac{1}{\varepsilon_0})$.

Correctness. Since we build shallow cutting $k_i \leq \frac{1}{\varepsilon_0}\log^{\kappa}\frac{1}{\varepsilon_0}$ inside each cell in $\frac{1}{\varepsilon_0}\log^{\kappa}\frac{1}{\varepsilon_0}$-shallow cutting, the transformed coordinates are consistent. As we described above, this introduces error to the counts Ψ_i's outputs, but since we correct the error explicitly afterwards, the counts we get are still exact. The remaining is the same as the suboptimal solution and so our structure finds ε_0-quantile properly.

Space Usage. For the rank space reduction structure, we need to store a predecessor searching structure for the query, which takes space linear in the number of slices which is $O(A)$. We build this structure for each cell in the A/ε_0-shallow cutting level and there are $O(n\varepsilon_0/A)$ cells in total, and so the space usage is $O(n\varepsilon_0)$. Building shallow cuttings inside each cell will only increase the space by a constant factor by the property of shallow cuttings.

For each Ψ_i, by our analysis in the suboptimal solution, the frequency vectors will take $O(\frac{N}{w^{1-\tau}})$ space. Now since the coordinates of the points and queries are integers of size at most A, it takes $O(\log A) = O(\log\log\frac{1}{\varepsilon_0})$ bits to encode a coordinate. Since the word size is $w = \Omega(\log n)$, we need only $O(\frac{N_i \log A}{w})$ space to build the predecessor searching structures for Ψ_i. In total, we spend $O(\frac{N}{w^{1-o(1)}})$ space for each shallow cutting level less than A/ε_0. So, the total space usage is $O(n)$. We conclusion this section by the following theorem.

▶ **Theorem 12.** *Given an input consisting of a parameter $\varepsilon_0 > 0$, and a set P of n points in $\mathbb{R}^3$ where each point $p \in P$ is associated with a weight w_p from a totally ordered universe, one can build a data structure that uses the optimal $O(n)$ space such that given any dominance query γ, the data structure can answer an AQS query with parameter ε_0 in the optimal query time of $O(\log n + \frac{1}{\varepsilon_0})$.*

5 Open Problems

Our results bring many interesting open problems. First, for type-2 color counting problems, we showed a linear-sized structure for simplex queries. It is not clear if the query time can be reduced with more space. It is an intriguing open problem to figure out the correct space-time tradeoff for the problem. Note that our query time in Theorem 8 depends on the number of colors in total. It is unclear if the query time can be made output-sensitive. This seems difficult and unfortunately there seems to be no suitable lower bound techniques to settle the problem. Furthermore, since improving exact simplex range counting results is already very challenging, it makes sense to consider the approximate version of the problem with multiplicative errors.

Second, for heavy-hitter queries, there are two open problems. In our solution, the space usage is optimal with up to some extra polylogarithmic factor (in $\frac{1}{\varepsilon}$). An interesting challenging open problem is if the space usage can be made linear. On the other hand, our

query time is not output-sensitive. Technically speaking, there can be less than $1/\varepsilon$ heavy hitters, and in this case, it would be interesting to see if $O(\log n + k)$ query time can be obtained for k output heavy hitters with (close to) linear space[2].

Third, for AQS queries, our data structure for halfspace ranges is suboptimal. The main reason is that we need a type-2 range counting solution as a subroutine. For halfspace ranges, our exact type-2 solution is too costly, and so we have to switch to an approximate version. This introduces some error and as a result, we need to use a smaller error parameter, which leads to extra polylogarithmic factors in both time and space. In comparison, we obtain an optimal solution for dominance AQS queries through exact type-2 counting. Currently, it seems quite challenging to improve the exact type-2 result for halfspace queries and some different ideas probably are needed to improve our results.

Finally, it is also interesting to investigate approximate quantile summaries, or heavy hitter summaries (or other data summaries or data sketches used in the streaming literature) for a broader category of geometric ranges. In this paper, our focus has been on very fast data structures, preferably those with optimal $O(\log n + \frac{1}{\varepsilon})$ query time, but we know such data structures do not exist for many important geometric ranges. For example, with linear space, simplex queries require $O(n^{(d-1)/d})$ time and there are some matching lower bounds. Nonetheless, it is an interesting open question whether approximate quantile or heavy hitter summary can be built for simplex queries in time $O(n^{(d-1)/d} + \frac{1}{\varepsilon})$ using linear or near-linear space; as we review in the introduction, the general approaches result in sub-optimal query times of $O(n^{(d-1)/d} \cdot \frac{1}{\varepsilon})$ or $O(n^{(d-1)/d} + \frac{1}{\varepsilon^2})$.

Stable Matching: Choosing Which Proposals to Make

Ishan Agarwal

New York University, NY, USA

Abstract

To guarantee all agents are matched in general, the classic Deferred Acceptance algorithm needs complete preference lists. In practice, preference lists are short, yet stable matching still works well. This raises two questions:

- Why does it work well?
- Which proposals should agents include in their preference lists?

We study these questions in a model, introduced by Lee [17], with preferences based on correlated cardinal utilities: these utilities are based on common public ratings of each agent together with individual private adjustments. Lee showed that for suitable utility functions, in large markets, with high probability, for most agents, all stable matchings yield similar valued utilities. By means of a new analysis, we strengthen Lee's result, showing that in large markets, with high probability, for *all* but the agents with the lowest public ratings, all stable matchings yield similar valued utilities. We can then deduce that for *all* but the agents with the lowest public ratings, each agent has an easily identified length $O(\log n)$ preference list that includes all of its stable matches, addressing the second question above. We note that this identification uses an initial communication phase.

We extend these results to settings where the two sides have unequal numbers of agents, to many-to-one settings, e.g. employers and workers, and we also show the existence of an ϵ-Bayes-Nash equilibrium in which every agent makes relatively few proposals. These results all rely on a new technique for sidestepping the conditioning between the tentative matching events that occur over the course of a run of the Deferred Acceptance algorithm. We complement these theoretical results with an experimental study.

1 Introduction

Consider a doctor applying for residency positions. Where should she apply? To the very top programs for her specialty? Or to those where she believes she has a reasonable chance of success (if these differ)? And if the latter, how does she identify them? We study these questions in the context of Gale and Shapley's deferred acceptance (DA) algorithm [5]. It is well-known that in DA the optimal strategy for the proposing side is to list their choices in order of preference. However, this does not address which choices to list.

The DA algorithm is widely used to compute matchings in real-world applications: the National Residency Matching Program (NRMP), which matches future residents to hospital programs [25]; university admissions programs which match students to programs, e.g. in Chile [24], school choice programs, e.g. for placement in New York City's high schools [1], the Israeli psychology Masters match [9], and no doubt many others (e.g. [7]).

Recall that each agent provides the mechanism a list of its possible matches in preference order, including the possibility of "no match" as one of its preferences. These mechanisms promise that the output will be a stable matching with respect to the submitted preference lists. In practice, preference lists are relatively short. This may be directly imposed by the mechanism or could be a reflection of the costs – for example, in time or money – of determining these preferences. Note that a short preference list is implicitly stating that the next preference after the listed ones is "no match".

Thus it is important to understand the impact of short preference lists. Roth and Peranson observed that the NRMP data showed that preference lists were short compared to the number of programs and that these preferences yielded a single stable partner for most participants; we note that this single stable partner could be the "no match" choice, and in fact this is the outcome for a constant fraction of the participants. They also confirmed this theoretically for the simplest model of uncorrelated random preferences; namely that with the preference lists truncated to the top O(1) preferences, almost all agents have a unique stable partner. Subsequently, in [10] the same result was obtained in the more general popularity model which allows for correlations among different agents' preferences; in their model, the first side – men – can have arbitrary preferences; on the second side – women – preferences are selected by weighted random choices, the weights representing the "popularity" of the different choices. These results were further extended by Kojima and Parthak in [15].

The popularity model does not capture behavior in settings where bounds on the number of proposals lead to proposals being made to plausible partners, i.e. partners with whom one has a realistic chance of matching. One way to capture such settings is by way of tiers [2], also known as block correlation [4]. Here agents on each side are partitioned into tiers, with all agents in a higher tier preferred to agents in a lower tier, and with uniformly random preferences within a tier. Tiers on the two sides may have different sizes. If we assign tiers successive intervals of ranks equal to their size, then, in any stable matching, the only matches will be between agents in tiers whose rank intervals overlap.

A more nuanced way of achieving these types of preferences bases agent preferences on cardinal utilities; for each side, these utilities are functions of an underlying common assessment of the other side, together with idiosyncratic individual adjustments for the agents on the other side. These include the separable utilities defined by Ashlagi, Braverman, Kanoria and Shi in [2], and another class of utilities introduced by Lee in [17]. This last model will be the focus of our study.

To make this more concrete, we review a simple special case of Lee's model, the *linear separable model*. Suppose that there are n men and n women seeking to match with each other. Each man m has a public rating r_m, a uniform random draw from $[0, 1]$. These ratings can be viewed as the women's joint common assessment of the men. In addition, each woman w has an individual adjustment, which we call a score, $s_w(m)$ for man m, again a uniform random draw from $[0, 1]$. All the draws are independent. Woman w's utility for man m is given by $\frac{1}{2}[r_m + s_w(m)]$; her full preference list has the men in decreasing utility order. The men's utilities are defined similarly.

Lee stated that rather than being assumed, short preference lists should arise from the model; this appears to have been a motivation for the model he introduced. A natural first step would be to show that for some or all stable matchings, the utility of each agent can

be well-predicted, for this would then allow the agents to limit themselves to the proposals achieving such a utility. Lee proved an approximate version of this statement, namely that with high probability (w.h.p., for short) most agents obtain utility within a small ϵ of an easily-computed individual benchmark. However, this does not imply that agents can restrict their proposals to a reduced utility range. (See the paragraph preceding Definition 5 for the specification of the benchmarks.)

Our work seeks to resolve this issue. We obtain the following results. Note that in these results, when we refer to the bottommost agents, we mean when ordered by decreasing public rating. Also, we let the term loss mean the difference between an agent's benchmark utility and their achieved utility.

1. We show that in the linearly separable model, for any constant $c > 0$, with probability $1 - 1/n^c$, in every stable matching, apart from a sub-constant σ fraction of the bottommost agents, *all* the other agents obtain utility equal to an easily-computed individual benchmark $\pm\epsilon$, where ϵ is also sub-constant.
   We show that both $\sigma, \epsilon = \widetilde{\Theta}(n^{-1/3})$.[1] As we will see, this implies, w.h.p., that for all the agents other than the bottommost σ fraction, each agent has $\Theta(\ln n)$ possible edges (proposals) that could be in any stable matching, namely the proposals that provide both agents utility within ϵ of their benchmark. Furthermore, we show our bound is tight: with fairly high probability, there is no matching, let alone stable matching, providing every agent a partner if the values of ϵ and σ are reduced by a suitable constant factor.
   An interesting consequence of this lower bound on the agents' utilities is that the agents can readily identify a moderate sized subset of the edge set to which they can safely restrict their applications. More precisely, any woman w outside the bottommost σ fraction, knowing only her own public rating, the public ratings of the men, and her own private score for each man, can determine a preference list of length $\widetilde{\Theta}(n^{1/3})$ which, w.h.p, will yield the same result as her true full-length list. Our analysis also shows that if w obtained the men's private scores for these proposals, then w.h.p. she could safely limit herself to a length $O(\ln n)$ preference list.
2. The above bounds apply not only to the linearly separable model, but to a significantly more general bounded derivative model (in which derivatives of the utility functions are bounded).
3. The result also immediately extends to settings with unequal numbers of men and women. Essentially, our analysis shows that the loss for an agent is small if there is a σ fraction of agents of lower rank on the opposite side. Thus even on the longer side, w.h.p., the topmost $n(1-\sigma)$ agents all obtain utility close to their benchmark, where n is the size of the shorter side. This limits the "stark effect of competition" [3] – namely that the agents on the longer side are significantly worse off – to a lower portion of the agents on the longer side.
4. The result extends to the many-to-one setting, in which agents on one side seek multiple matches. Our results are given w.r.t. a parameter d, the number of matches that each agent on the "many" side desires. For simplicity, we assume this parameter is the same for all these agents. In fact, we analyze a more general many-to-many setting.
5. A weaker result with arbitrarily small $\sigma, \epsilon = \Theta(1)$ holds when there is no restriction on the derivatives of the utility functions, which we call the general values model. Again, we show this bound cannot be improved in general. This setting is essentially the general

[1] The $\widetilde{\Theta}(\cdot)$ notation means up to a poly-logarithmic term; here $\sigma, \epsilon = \Theta((n/\ln n)^{-1/3})$.

setting considered by Lee [17]. He had shown there was a σ fraction of agents who might suffer larger losses; our bound identifies this σ fraction of agents as the bottommost agents.

6. In the bounded derivative model, with slightly stronger constraints on the derivatives, we also show the existence of an ϵ-Bayes-Nash equilibrium in which no agent proposes more than $O(\ln^2 n)$ times and all but the bottommost $O((\ln n/n)^{1/3})$ fraction of the agents make only the $O(\ln n)$ proposals identified in (1) above. Here $\epsilon = \Theta(\ln n/n^{1/3})$.

These results all follow from a lemma showing that, w.h.p., each non-bottommost agent has at most a small loss. In turn, the proof of this lemma relies on a new technique which sidesteps the conditioning inherent to runs of DA in these settings.

Experimental results

Much prior work has been concerned with preference lists that have a constant bound on their length. For moderate values of n, say $n \in [10^3, 10^6]$, $\ln n$ is quite small, so our $\Theta(\ln n)$ bound may or may not be sufficiently small in practice for this range of n. What matters are the actual constants hidden by the Θ notation, which our analysis does not fully determine. To help resolve this, we conducted a variety of simulation experiments.

We have also considered how to select the agents to include in the preference lists, when seeking to maintain a constant bound on their lengths, namely a bound that, for the values of n we considered, was smaller than the $\Theta(\ln n)$ bound determined by the above simulations; again, our investigation was experimental.

Other Related work

The random preference model was introduced by Knuth [12] (for a version in English see [13]), and subsequently extensively analyzed [20, 14, 21, 18, 23, 22, 16]. In this model, each agent's preferences are an independent uniform random permutation of the agents on the other side. An important observation was that when running the DA algorithm, the proposing side obtained a match of rank $\Theta(\ln n)$ on the average, while on the other side the matches had rank $\Theta(n/\ln n)$.

A recent and unexpected observation in [3] was the "stark effect of competition": that in the random preferences model the short side, whether it was the proposing side or not, was the one to enjoy the $\Theta(\ln n)$ rank matches. Subsequent work showed that this effect disappeared with short preference lists in a natural modification of the random preferences model [11]. Our work suggests yet another explanation for why this effect may not be present: it does not require that short preference lists be imposed as an external constraint, but rather that the preference model generates few edges that might ever be in a stable matching.

The number of edges present in any stable matching has also been examined for a variety of settings. When preference lists are uniform the expected number of stable pairs is $\Theta(n \ln n)$ [21]; when they are arbitrary on one side and uniform on the other side, the expected number is $O(n \ln n)$ [14]. This result continues to hold when preference lists are arbitrary on the men's side and are generated from general popularities on the women's side [6]. Our analysis shows that in the linear separable model (and more generally in the bounded derivative setting) the expected number of stable pairs is also $O(n \ln n)$.

Another important issue is the amount of communication needed to identify who to place on one's preference lists when they have bounded length. In general, the cost is $\Omega(n)$ per agent (in an n agent market) [8], but in the already-mentioned separable model of Ashlagi et al. [2] this improves to $\widetilde{O}(\sqrt{n})$ given some additional constraints, and further improves to

$O(\ln^4 n)$ in a tiered separable market [2]. We note that for the bounded derivatives setting, with high probability, the communication cost will be $O(n^{1/3}\ln^{2/3} n)$ for all agents except the bottommost $\Theta(n^{2/3}\ln^{1/3} n)$, for whom the cost can reach $O(n^{2/3}\ln^{1/3} n)$.

Another approach to selecting which universities to apply to was considered by Shorrer who devised a dynamic program to compute the optimal choices for students assuming universities had a common ranking of students [26].

Roadmap

In Section 2 we review some standard material. In Section 3 we state our main result in two parts: Theorem 6, which bounds the losses in the setting of the linear model, and Theorem 8, which shows it suffices to limit preference lists to a small set of edges. We prove these theorems in Sections 4 and 5, respectively. We also present some numerical simulations for the linear separable model in Section 6 We conclude with a brief discussion of open problems in Section 7.

In the appendices of the full version of the paper, we formally state and prove all the other results alluded to in the introduction and we also present further numerical simulations for the linear separable model. For the reader's convenience, in the text that follows, we provide pointers to these appendices, as appropriate. We note that Appendix A provides a complete summary of the content in these appendices.

2 Preliminaries

2.1 Stable Matching and the Deferred Acceptance (DA) Algorithm

Let M be a set of n men and W a set of n women. Each man m has an ordered list of women that represents his preferences, i.e. if a woman w comes before a woman w' in m's list, then m would prefer matching with w rather than w'. The position of a woman w in this list is called m's ranking of w. Similarly each woman w has a ranking of her preferred men[2]. The stable matching task is to pair (match) the men and women in such a way that no two people prefer each other to their assigned partners. More formally:

▶ **Definition 1** (Matching). *A matching is a pairing of the agents in M with the agents in W. It comprises a bijective function μ from M to W, and its inverse $\nu = \mu^{-1}$, which is a bijective function from W to M.*

▶ **Definition 2** (Blocking pair). *A matching μ has a blocking pair (m, w) if and only if:*

1. *m and w are not matched: $\mu(m) \neq w$.*
2. *m prefers w to his current match $\mu(m)$.*
3. *w prefers m to her current match $\nu(w)$.*

▶ **Definition 3** (Stable matching). *A matching μ is stable if it has no blocking pair.*

Gale and Shapley [5] proposed the seminal deferred acceptance (DA) algorithm for the stable matching problem. We present the woman-proposing DA algorithm (Algorithm 1); the man-proposing DA is symmetric. The following facts about the DA algorithm are well known. We state them here without proof and we shall use them freely in our analysis.

[2] Throughout this paper, we assume that each man m (woman w) ranks all the possible women (men), i.e. m's (w's) preference list is complete.

Algorithm 1 Woman Proposing Deferred Acceptance (DA) Algorithm.

Initially, all the men and women are unmatched.
while *some woman w with a non-empty preference list is unmatched* **do**
  let m be the first man on her preference list;
  if *m is currently unmatched* **then**
    tentatively match w to m.
  end
  if *m is currently matched to w', and m prefers w to w'* **then**
    make w' unmatched and tentatively match w to m.
  else
    remove m from w's preference list.
  end
end

▶ **Observation 4.**

1. *DA terminates and outputs a stable matching.*
2. *The stable matching generated by DA is independent of the order in which the unmatched agents on the proposing side are processed.*
3. *Woman-proposing DA is woman-optimal, i.e. each woman is matched with the best partner she could be matched with in any stable matching.*
4. *Woman-proposing DA is man-pessimal, i.e. each man is matched with the worst partner he could be matched with in any stable matching.*

2.2 Useful notation and definitions

There are n men and n women. In all of our models, each man m has a utility $U_{m,w}$ for the woman w, and each woman w has a utility $V_{m,w}$ for the man m. These utilities are defined as

$$U_{m,w} = U(r_w, s_m(w)), \text{ and}$$
$$V_{m,w} = V(r_m, s_w(m)),$$

where r_m and r_w are common public ratings, $s_m(w)$ and $s_w(m)$ are private scores specific to the pair (m, w), and $U(\cdot,\cdot)$ and $V(\cdot,\cdot)$ are continuous and strictly increasing functions from $\mathbb{R}_+^2$ to $\mathbb{R}_+$. The ratings are independent uniform draws from $[0, 1]$ as are the scores.

In the *Linear Separable Model*, each man m assigns each woman w a utility of $U_{m,w} = \lambda \cdot r_w + (1-\lambda) \cdot s_m(w)$, where $0 < \lambda < 1$ is a constant. The women's utilities for the men are defined analogously as $V_{m,w} = \lambda \cdot r_m + (1-\lambda) \cdot s_w(m)$. All our experiments are for this model.

We let $\{m_1, m_2, \ldots, m_n\}$ be the men in descending order of their public ratings and $\{w_1, w_2, \ldots, w_n\}$ be a similar ordering of the women. We say that m_i has public rank i, or rank i for short, and similarly for w_i. We also say that m_i and w_i are *aligned*. In addition, we often want to identify the men or women in an interval of public ratings. Accordingly, we define $M(r, r')$ to be the set of men with public ratings in the range (r, r'), and $M[r, r']$ to be the set with public ratings in the range $[r, r']$; we also use the notation $M(r, r']$ and $M[r, r')$ to identify the men with ratings in the corresponding semi-open intervals. We use an analogous notation, with W replacing M, to refer to the corresponding sets of women.

We will be comparing the achieved utilities in stable matchings to the following benchmarks: the rank i man has as benchmark $U(r_{w_i}, 1)$, the utility he would obtain from the combination of the rank i woman's public rating and the highest possible private score; and similarly for the women. Based on this we define the loss an agent faces as follows.

▶ **Definition 5** (Loss). *Suppose man m and woman w both have rank i. The* loss *m sustains from a match of utility u is defined to be $U(r_w, 1) - u$. The loss for women is defined analogously.*

In our analysis we will consider a complete bipartite graph whose two sets of vertices correspond to the men and women, respectively. For each man m and woman w, we view the possible matched pair (m, w) as an edge in this graph. Thus, throughout this work, we will often refer to edges being proposed, as well as edges satisfying various conditions.

3 Upper Bound in The Linear Separable Model

To illustrate our proof technique for deriving upper bounds, we begin by stating and proving our upper bound result for the special case of the linear separable model with $\lambda = \frac{1}{2}$.

▶ **Theorem 6.** *In the linear separable model with $\lambda = 1/2$, when there are n men and n women, for any given constant $c > 0$, for large enough n, with probability at least $1 - n^{-c}$, in every stable matching, for every i, with $r_{w_i} \geq \overline{\sigma} \triangleq 3\overline{L}/2$, agent m_i suffers a loss of at most $\overline{L}$, where $\overline{L} = (16(c+2)\ln n/n)^{1/3}$, and similarly for the agents w_i.*

In words, w.h.p., all but the bottommost agents (those whose aligned agents have public rating less than $\overline{\sigma}$) suffer a loss of no more than $\overline{L}$. This is a special case of our basic upper bound for the bounded utilities model (Theorem 12).

One of our goals is to be able to limit the number of proposals the proposing side needs to make. We identify the edges that could be in some stable matching, calling them acceptable edges. Our definition is stated generally so that it covers all our results; accordingly we replace the terms $\overline{L}$ and $\overline{\sigma}$ in Theorem 6 with parameters L and σ.

▶ **Definition 7** (Acceptable edges). *Let $0 < \sigma < 1$ and $0 < L < 1$ be two parameters. An edge (m_i, w_j) is* (L, σ)-man-acceptable *either if it provides m_i utility at least $U(r_{w_i}, 1) - L$, or if $m_i \in M[0, \sigma)$. The definition of (L, σ)-woman-acceptable is symmetric. Finally, (m_i, w_j) is* (L, σ)-acceptable *if it is both (L, σ)-man and (L, σ)-woman-acceptable.*

To prove our various results, we choose L and σ so that w.h.p. the edges in every stable matching are (L, σ)-*acceptable*. We call this high probability event $\mathcal{E}$. We will show that if $\mathcal{E}$ occurs, then running DA on the set of acceptable edges, or any superset of the acceptable edges obtained via loss thresholds, produces the same stable matching as running DA on the full set of edges.

▶ **Theorem 8.** *If $\mathcal{E}$ occurs, then running woman-proposing DA with the edge set restricted to the acceptable edges or to any superset of the acceptable edges obtained via loss thresholds (including the full edge set) result in the same stable matching.*

The implication is that w.h.p. a woman can safely restrict her proposals to her acceptable edges, or to any overestimate of this set of edges obtained by her setting an upper bound on the loss she is willing to accept. There is a small probability – at most n^{-c} – that this may result in a less good outcome, which can happen only if $\mathcal{E}$ does not occur. Note that Theorem 8 applies to every utility model we consider. Then, w.h.p., every stable matching gives each woman w, whose aligned agent m has public rating $r_m \geq \overline{\sigma} = \Omega((\ln n/n)^{1/3})$, a partner with public rating in the range $[r_m - 2\overline{L}, r_m + \frac{5}{2}\overline{L}]$ (see Theorem 25 in Appendix F.1). The bound $r_m - 2\overline{L}$ is a consequence of the bound on the woman's loss; the bound $r_m + \frac{5}{2}\overline{L}$ is a consequence of the bound on the men's losses. An analogous statement applies to the men.

This means that if we are running woman-proposing DA, each of these women might as well limit her proposals to her woman-acceptable edges, which is at most the men with public ratings in the range $r_m \pm \Theta(\overline{L})$ for whom she has private scores of at least $1 - \Theta(\overline{L})$. In expectation, this yields $\Theta(n^{1/3}(\ln n)^{2/3})$ men to whom it might be worth proposing. It also implies that a woman can have a gain of at most $\Theta(\overline{L})$ compared to her target utility.

If, in addition, each man can inexpensively signal the women who are man-acceptable to him, then the women can further limit their proposals to just those men providing them with a signal; this reduces the expected number of proposals these women can usefully make to just $\Theta(\ln n)$.

4 Sketch of the Proof of Theorem 6

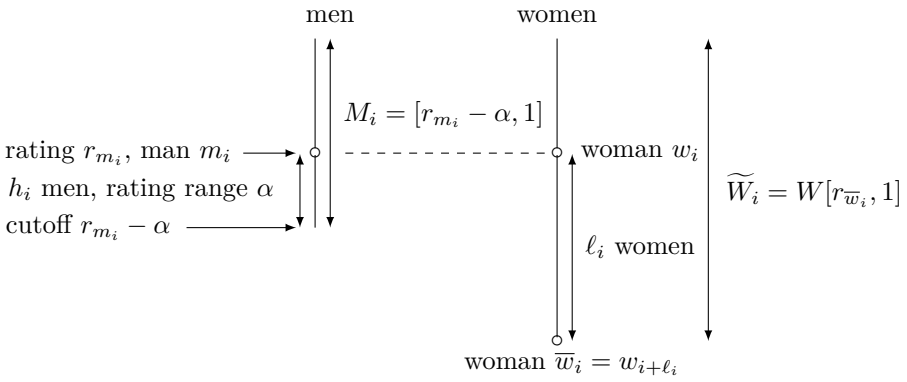

Figure 1 Illustrating Lemma 11.

We begin by outlining the main ideas used in our analysis. Our goal is to show that when we run woman proposing DA, w.h.p. each man receives a proposal that gives him a loss of at most L (except possibly for men among the bottommost $\Theta(nL)$). As the outcome is the man-pessimal stable matching, this means that w.h.p., in all stable matchings, these men have a loss of at most L. By symmetry, the same bound holds for the women.

Next, we provide some intuition for the proof of this result. See Fig. 1. Our analysis uses 3 parameters $\alpha, \beta, \gamma = \Theta(L)$. Let m_i be a non-bottommost man. We consider the set of men with public rank at least $r_{m_i} - \alpha$: $M_i = M[r_{m_i} - \alpha, 1]$. We consider a similar, slightly larger set of women: $\widetilde{W}_i = W[r_{w_i} - 3\alpha, 1]$. Now we look at the best proposals by the women in $\widetilde{W}_i$, i.e. the ones they make first. Specifically, we consider the proposals that give these women utility at least $V(r_{m_i} - \alpha, 1)$, proposals that are therefore guaranteed to be to the men in M_i. Let $\left|M_i\right| = i + h_i$ and $\left|W_i\right| = i + \ell_i$. In expectation, $\ell_i - h_i = 2\alpha n$. Necessarily, at least $\ell_i - h_i + 1$ women in M_i cannot match with men in $M_i \setminus \{m_i\}$. But, as we will see, these women all have probability at least β of having a proposal to m_i which gives them utility at least $V(r_{m_i} - \alpha, 1)$. These are proposals these women must make before they make any proposals to men with public rating less than $r_{m_i} - \alpha$. Furthermore, for each of these proposals, m_i has probability at least γ of having a loss of L or less. Thus, in expectation, m_i receives at least $2\alpha\beta\gamma n$ proposals which give him a loss of L or less.

We actually want a high-probability bound. So we choose α, β, γ so that $\alpha\beta\gamma n \geq c \log n$ for a suitable constant $c > 0$, and then apply a series of Chernoff bounds. There is one difficulty. The Chernoff bounds requires the various proposals to be independent. Unfortunately, in

general, this does not appear to be the case. However, we are able to show that the failure probability for our setting is at most the failure probability in an artificial setting in which the events are independent, which yields the desired bound.

We now embark on the actual proof.

We formalize the men's rating cutoff with the notion of DA stopping at public rating r.

▶ **Definition 9** (DA stops). *The women* stop at public rating r *if, in each woman's preference list, all the edges with utility less than $V(r, 1)$ are removed. The women* stop at man m *if, in each woman's preference list, all the edges following her edge to m are removed. The women* double cut at man m and public rating r*, if they each stop at m or r, whichever comes first. Men stopping and double cutting are defined similarly. Finally, an edge is said to* survive *the cutoff if it is not removed by the stopping.*

To obtain our bounds for man m_i, we will have the women double cut at rating $r_{m_i} - \alpha$ and at man m_i, where $\alpha > 0$ is a parameter we will specify later.

Our upper bounds in all of the utility models depend on a parameterized key lemma (Lemma 11) stated shortly. This lemma concerns the losses the men face in the woman-proposing DA; a symmetric result applies to the women. The individual theorems follow by setting the parameters appropriately. Our key lemma uses three parameters: $\alpha, \beta, \gamma > 0$. To avoid rounding issues, we will choose α so that αn is an integer. The other parameters need to satisfy the following constraints.

$$\text{for } r \geq \alpha: \qquad V(r - \alpha, 1) \leq V(r, 1 - \beta) \tag{1}$$

$$\text{for } r \geq 3\alpha: \qquad U(r, 1) - U(r - 3\alpha, 1 - \gamma) \leq L \tag{2}$$

Equation (1) relates the range of private values that will yield a woman an edge to m_i that survives the cut at $r_{m_i} - \alpha$, or equivalently the probability of having such an edge. Observation 10 below, shows that Equation (2) identifies the range of m_i's private values for proposals from $\widetilde{W}_i$ that yield him a loss of at most L (for we will ensure the women in $\widetilde{W}_i$ have public rating at least $r_{w_i} - 3\alpha$).

▶ **Observation 10.** *Consider the proposal from woman w to the rank i man m_i. Suppose the rank i woman w_i has rating $r_{w_i} \geq 3\alpha$. If w has public rating $r \geq r_{w_i} - 3\alpha$ and m_i's private score for w is at least $1-\gamma$, then m_i's utility for w is at least $U(r_{w_i} - 3\alpha, 1-\gamma) \geq U(r_{w_i}, 1) - L$.*

In the linear separable model with $\lambda = \frac{1}{2}$, we set $\alpha = \beta = \gamma$ and $L = 2\alpha$.

The next lemma determines the probability that man m_i receives a proposal causing him a loss of at most L. The lemma calculates this probability in terms of the parameters we just defined. Note that the result does not depend on the utility functions $U(\cdot, \cdot)$ and $V(\cdot, \cdot)$ being linear. In fact, the same lemma applies to much more general utility models which we also study (see Appendix C) and it is the crucial tool we use in all our upper bound proofs.

In what follows, to avoid heavy-handed notation, by $r_{m_i} - \alpha$ we will mean $\max\{0, r_{m_i} - \alpha\}$.

In order to state our next result crisply, we define the following Event $\mathcal{E}_i$. It concerns a run of woman-proposing DA with double cut at the rank i man m_i and at public rating $r_{m_i} - \alpha$. Let $h_i = \left|M[r_{m_i} - \alpha, r_{m_i})\right|$, $\ell_i = \left|W[r_{w_i} - 3\alpha, r_{w_i})\right|$, and $\overline{w}_i$ be the woman with rank $i + \ell_i$. See Figure 1 for an illustration of these definitions. Event $\mathcal{E}_i$ occurs if $r_{w_i} \geq 3\alpha$ and between them the $i + \ell_i$ women in $W[r_{w_i} - 3\alpha, 1]$ make at least one proposal to m_i that causes him a loss of at most L.

Finally we define Event $\mathcal{E}$: it happens if $\mathcal{E}_i$ occurs for all i such that $r_{w_i} \geq 3\alpha$.

▶ **Lemma 11.** *Let $\alpha > 0$ and $L > 0$ be given, and suppose that β and γ satisfy* (1) *and* (2)*, respectively. Then, Event $\mathcal{E}$ occurs with probability at least $1 - p_f$, where the failure probability*

$$p_f = n \cdot \exp(-\alpha(n-1)/12) + n \cdot \exp(-\alpha(n-1)/24) + n \exp(-\alpha\beta n/8) + n \cdot \exp(-\alpha\beta\gamma n/2).$$

The following simple claim notes that the men's loss when running the full DA is no larger than when running double-cut DA.

▷ Claim 12. Suppose a woman-proposing double-cut DA at man m_i and rating $r_{m_i} - \alpha$ is run, and suppose m_i incurs a loss of L. Then in the full run of woman-proposing DA, m_i will incur a loss of at most L.

Proof. Recall that when running the women-proposing DA the order in which unmatched women are processed does not affect the outcome. Also note that as the run proceeds, whenever a man's match is updated, the man obtains an improved utility. Thus, in the run with the full edge set we can first use the edges used in the double-cut DA and then proceed with the remaining edges. Therefore if in the double-cut DA m_i has a loss of L, in the full run m_i will also have a loss of at most L. ◁

To illustrate how this lemma is applied, we now prove Theorem 6. Note that $\overline{L}$ is the value of L used in this theorem. Our other results use other values of L.

Proof of Theorem 6. By Lemma 11, in the double-cut DA, for all i with $r_{w_i} \geq 3\alpha$, m_i obtains a match giving him loss at most $\overline{L}$, with probability at least $1 - n \cdot \exp(-\alpha(n-1)/12) - n \cdot \exp(-\alpha n/24) - n \exp\big(-\alpha^2 n/8\big) - n \cdot \exp\big(-\alpha^3 n/2\big)$.

By Claim 12, m_i will incur a loss of at most $\overline{L}$ in the full run of woman-proposing DA with at least as large a probability. But this is the man-pessimal match. Consequently, in every stable match, m_i has a loss of at most $\overline{L}$. By symmetry, the same bound applies to each woman w_i such that $r_{m_i} \geq 3\alpha$.

We choose $\overline{L} = [16(c+2)\ln n/n]^{1/3}$. Recalling that $\alpha = \overline{L}/2$, we see that for large enough n the probability bound, over all the men and women, is at most $1 - n^{-c}$. The bounds $r_{w_i} \geq 3\alpha$ and $r_{m_i} \geq 3\alpha$ imply we can set $\overline{\sigma} = 3\alpha = \frac{3}{2}\overline{L}$. ◀

Proof of Lemma 11. We run the double-cut DA in two phases, defined as follows. Recall that $h_i = \big|M[r_{m_i} - \alpha, r_{m_i})\big|$ and $\ell_i = \big|W[r_{w_i} - 3\alpha, r_{w_i})\big|$. Note that women with rank at most $i + \ell_i$ have public rating at least $r_{w_i} - 3\alpha$.

Phase 1. Every unmatched woman with rank at most $i + \ell_i$ keeps proposing until her next proposal is to m_i, or she runs out of proposals.

Phase 2. Each unmatched women makes her next proposal, if any, which will be a proposal to m_i.

Our analysis is based on the following four claims. The first two are simply observations that w.h.p. the number of agents with public ratings in a given interval is close to the expected number. We defer the proofs to the appendix.

A critical issue in this analysis is to make sure the conditioning induced by the successive steps of the analysis does not affect the independence needed for subsequent steps. To achieve this, we use the Principle of Deferred Decisions, only instantiating random values as they are used. Since each successive bound uses a different collection of random variables this does not present a problem.

▷ Claim 13. Let $\mathcal{B}_1$ be the event that for some i, $h_i \geq \frac{3}{2}\alpha(n-1)$. $\mathcal{B}_1$ occurs with probability at most $n \cdot \exp(-\alpha(n-1)/12)$. The only randomness used in the proof are the choices of the men's public ratings. The same bound applies to the women.

Proof (Sketch). As $\mathrm{E}[h_i] = \alpha(n-1)$, w.h.p., $h_i < \frac{3}{2}\alpha(n-1)$. This claim uses a Chernoff bound with the randomness coming from the public ratings of the men. ◁

▷ Claim 14. Let $\mathcal{B}_2$ be the event that for some i, $\ell_i \leq \frac{5}{2}\alpha(n-1)$. $\mathcal{B}_2$ occurs with probability at most $n \cdot \exp(-\alpha(n-1)/24)$. The only randomness used in the proof are the choices of the women's public ratings. The same bound applies to the men.

Proof. This is very similar to the proof of Claim 13. ◁

▷ Claim 15. Let $\mathcal{B}_3$ be the event that between them, the women with rank at most $i + \ell_i$ make fewer than $\frac{1}{2}\alpha\beta n$ Step 2 proposals to m_i. If events $\mathcal{B}_1$ and $\mathcal{B}_2$ do not occur, then $\mathcal{B}_3$ occurs with probability at most $\exp(-\alpha\beta n/8)$. The only randomness used in the proof are the choices of the women's private scores.

This bound uses the private scores of the women and employs a novel argument given below to sidestep the conditioning among these proposals.

▷ Claim 16. If none of the events $\mathcal{B}_1$, $\mathcal{B}_2$, or $\mathcal{B}_3$ occur, then at least one of the Step 2 proposals to m_i will cause him a loss of at most L with probability at least $1-(1-\gamma)^{\alpha\beta n/2} \geq 1 - \exp(-\alpha\beta\gamma n/2)$. The only randomness used in the proof are the choices of the men's private scores.

Proof. Note that each Phase 2 proposal is from a woman w with rank at most $i + \ell_i$. As already observed, her public rating is at least $r_{w_i} - 3\alpha$. Recall that man m_i's utility for w equals $U(r_w, s_{m_i}(w)) \geq U(r_{w_i} - 3\alpha, s_{m_i}(w))$. To achieve utility at least $U(r_{w_i}, 1) - L \leq U(r_{w_i} - 3\alpha, 1-\gamma)$ (using (2)) it suffices to have $s_{m_i}(w) \geq 1-\gamma$, which happens with probability γ. Consequently, utility at least $U(r_{w_i}, 1) - L$ is achieved with probability at least γ.

For each Phase 2 proposal these probabilities are independent as they reflect m_i's private scores for each of these proposals. Therefore the probability that there is no proposal providing m_i a loss of at most L is at most

$$\big(1-\gamma\big)^{\alpha\beta n/2} \leq \exp(\alpha\beta\gamma n/2).$$ ◁

Concluding the proof of Lemma 11: The overall failure probability summed over all n choices of i is

$$n \cdot \exp(-\alpha(n-1)/12) + n \cdot \exp(-\alpha(n-1)/24) + n\exp(-\alpha\beta n/8) + n \cdot \exp(-\alpha\beta\gamma n/2).$$ ◀

Proof of Claim 15. First, we simplify the action space by viewing the decisions as being made on a discrete utility space, as specified in the next claim, proved in the appendix.

▷ Claim 17. For any $\delta > 0$, there is a discrete utility space in which for each woman the probability of selecting m_i is only increased, and the probability of having any differences in the sequence of actions in the original continuous setting and the discrete setting is at most δ.

We represent the possible computations of the double-cut DA in this discrete setting using a tree T. Each woman will be going through her possible utility values in decreasing order, with the possible actions of the various women being interleaved in the order given by the DA processing. Each node u corresponds to a woman w processing her next utility value. The possible choices at this utility are each represented by an edge descending from u. These choices are:

i. Proposing to some man (among those men w has not yet proposed to); or

ii. "no action". This corresponds to w making no proposal achieving the current utility.

We observe the following important structural feature of tree T. Let S be the subtree descending from the edge corresponding to woman w proposing to m_i; in S there are no further actions of w, i.e. no nodes at which w makes a choice, because the double cut DA cuts at the proposal to m_i.

The assumption that $\mathcal{B}_1$ and $\mathcal{B}_2$ do not occur means that for all i, $h_i < \frac{3}{2}\alpha(n-1)$ and $\ell_i > \frac{5}{2}\alpha(n-1)$, and therefore $\ell_i - h_i > \alpha(n-1)$.

At each leaf of T, up to $i + h_i - 1$ women will have been matched with someone other than m_i. The other women either finished with a proposal to m_i or both failed to match and did not propose to m_i. Let w be a woman in the latter category. Then, on the path to this leaf, w will have traversed edges corresponding to a choice at each discrete utility in the range $[V(r_{m_i} - \alpha, 1), V(1,1)]$.

We now create an extended tree, T_x, by adding a subtree at each leaf; this subtree will correspond to pretending there were no matches; the effect is that each women will take an action at all their remaining utility values in the range $[V(r_{m_i} - \alpha, 1), V(1,1)]$, except that in the sub-subtrees descending from edges that correspond to some woman w selecting m_i, w has no further actions. For each leaf in the unextended tree, the probability of the path to that leaf is left unchanged. The probabilities of the paths in the extended tree are then calculated by multiplying the path probability in the unextended tree with the probabilities of each woman's choices in the extended portion of the tree.

Next, we create an artificial mechanism $\mathcal{M}$ that acts on tree T_x. The mechanism $\mathcal{M}$ is allowed to put $i + h_i - 1$ "blocks" on each path; blocks can be placed at internal nodes. A block names a woman w and corresponds to her matching (but we no longer think of the matches as corresponding to the outcome of the edge selection; they have no meaning beyond making all subsequent choices by this woman be the "no action" choice).

DA can be seen as choosing to place up to $i + h_i - 1$ blocks at each of the nodes corresponding to a leaf of T. $\mathcal{M}$ will place its blocks so as to minimize the probability p of paths with at least $\frac{1}{2}\alpha\beta n$ women choosing edges to m_i. Clearly p is a lower bound on the probability that the double-cut DA makes at least $\frac{1}{2}\alpha\beta n$ proposals in Step 2. Given a choice of blocks we call the resulting probability of having fewer than $\frac{1}{2}\alpha\beta n$ women choosing edges to m_i the *blocking probability.*

▷ Claim 18. The probability that $\mathcal{M}$ makes at least $\frac{1}{2}\alpha\beta n$ proposals to m_i is at least $1 - \exp(-\alpha\beta n/8)$.

▶ **Corollary 19.** *The probability that the double-cut DA makes at least $\frac{1}{2}\alpha\beta n$ proposals to m_i is at least $1 - \exp(-\alpha\beta n/8)$.*

Proof. For any fixed δ, by Claim 18, the probability that $\mathcal{M}$ makes at least $\frac{1}{2}\alpha\beta n$ proposals to m_i is at least $1 - \exp(-\alpha\beta n/8)$. By construction, the probability is only larger for the double-cut DA in the discrete space.

Therefore, by Claim 12, the probability that the double-cut DA makes at least $\frac{1}{2}\alpha\beta n$ proposals to m_i in the actual continuous space is at least $1-\exp(-\alpha\beta n/8)-\delta$, and this holds for any $\delta > 0$, however small. Consequently, this probability is at least $1-\exp(-\alpha\beta n/8)$. ◀

Proof of Claim 18. We will show that the most effective blocking strategy is to block as many women as possible before they have made any choices. This leaves at least $(i+\ell_i)-(i-1+h_i) \geq 1+\alpha(n-1) \geq \alpha n$ women unmatched. Then, as we argue next, each of these remaining at least αn women w has independent probability at least β that their proposal to m_i is cutoff-surviving. To be cutoff-surviving, it suffices that $V(r_{m_i}, s_w(m_i)) \geq V(r_{m_i}-\alpha, 1)$. But we know by (1) that $V(r_{m_i}-\alpha, 1) \leq V(r_{m_i}, 1-\beta)$, and therefore it suffices that $s_w(m_i) \geq 1-\beta$, which occurs with probability β.

Consequently, in expectation, there are at least $\alpha\beta n$ proposals to m_i, and therefore, by a Chernoff bound, at least $\frac{1}{2}\alpha\beta n$ proposals with probability at least $\exp(-\alpha\beta n/8)$.

We consider the actual blocking choices made by $\mathcal{M}$ and modify them bottom-up in a way that only reduces the probability of there being $\frac{1}{2}\alpha\beta n$ or more proposals to m_i.

Clearly, $\mathcal{M}$ can choose to block the same maximum number of women on every path as it never hurts to block more women (we allow the blocking of women who have already proposed to m_i even though it does not affect the number of proposals to m_i).

Consider a deepest block at some node u in the tree, and suppose b women are blocked at u. Let v be a sibling of u. As this is a deepest block, there will be no blocks at proper descendants of u, and furthermore as there are the same number of blocks on every path, v will also have b blocked women.

Observe that if there is no blocking in a subtree, then the probability that a woman makes a proposal to m_i is independent of the outcomes for the other women. Therefore the correct blocking decision at node u is to block the b women with the highest probabilities of otherwise making a proposal to m_i, which we call their *proposing probabilities*; the same is true at each of its siblings v.

Let x be u's parent. Suppose the action at node x concerns woman $\widetilde{w}_x$. Note that the proposing probability for any woman $w \neq \widetilde{w}_x$ is the same at u and v because the remaining sequence of actions for woman w is the same at nodes u and v, and as they are independent of the actions of the other women, they yield the same probability of selecting m_i at some point.

We need to consider a number of cases.

Case 1. w is blocked at every child of x.

Then we could equally well block w at node x.

Case 2. At least one woman other than $\widetilde{w}_x$ is blocked at some child of x.

Each such blocked woman w has the same proposing probability at each child of x. Therefore by choosing to block the women with the highest proposing probabilities, we can ensure that at each node either $\widetilde{w}_x$ plus the same $b-1$ other women are blocked, or these $b-1$ woman plus the same additional woman $w' \neq \widetilde{w}_x$ are blocked. In any event, the blocking of the first $b-1$ women can be moved to x.

Case 2.1. $\widetilde{w}_x$ is not blocked at any child of x.

Then the remaining identical blocked woman at each child of x can be moved to x.

Case 2.2. $\widetilde{w}_x$ is blocked at some child of x but not at all the children of x.

Notice that we can avoid blocking $\widetilde{w}_x$ at the child u of x corresponding to selecting m_i, as the proposing probability for $\widetilde{w}_x$ after it has selected m_i is 0, so blocking any other women would be at least as good. Suppose that $w \neq \widetilde{w}_x$ is blocked at node u.

Let v be another child of x at which $\widetilde{w}_x$ is blocked. Necessarily, $p_{v,\widetilde{w}_x}$, the proposing probability for $\widetilde{w}_x$ at node v, is at least the proposing probability $p_{v,w}$ for w at node v (for

otherwise w would be blocked at node v); also, $p_{v,w}$ equals the proposing probability for w at every child of x including u; in addition, $p_{v,\widetilde{w}_x}$ equals the proposing probability for $\widetilde{w}_x$ at every child of x other than u. It follows that w is blocked at u and $\widetilde{w}_x$ can be blocked at every other child of x. But then blocking $\widetilde{w}_x$ at x only reduces the proposing probability.

Thus in every case one should move the bottommost blocking decisions at a collection of sibling nodes to a single blocking decision at their parent. ◁

◁

5 Making Fewer Proposals

We identify a sufficient set of edges that contains all stable matchings, and on which the DA algorithm produces the same outcome as when it runs on the full edge set.

▶ **Definition 20** (Viable edges). *An edge (m, w) is* man-viable *if, according to m's preferences, w is at least as good as the woman he is matched to in the man-pessimal stable match. Woman-viable is defined symmetrically. An edge is* viable *if it is both man and woman-viable. E_v is the set of all viable edges.*

▶ **Lemma 21.** *Running woman-proposing DA with the edge set restricted to E_v and with any superset obtained via loss thresholds, including the full edge set, results in the same stable matching.*

Proof. Suppose a new stable matching, S, now exists in the restricted edge set: it could not be present when using the full edge set, therefore there must be a blocking edge (m, w) in the full edge set. But neither m nor w would have removed this edge when forming their restricted edge set since for both of them it is better than an edge they did not remove (the edge they are matched with in S).

It follows that w.h.p. the set of stable matchings is the same when using E_v (or any super set of it generated by truncation with larger loss thresholds) and the whole set. Thus woman-proposing DA run on the restricted edge set will yield the same stable matching as on the full edge set. ◀

Proof of Theorem 8. If $\mathcal{E}$ occurs, the set of acceptable edges contains all the viable edges. Furthermore, the acceptable edges are defined by means of loss thresholds. The result now follows from Lemma 21. ◀

For some of the very bottommost agents, almost all edges may be acceptable. However, in the bounded derivatives model, with slightly stronger constraints on the derivatives, we also show (see Appendix H) the existence of an ϵ-Bayes-Nash equilibrium in which all but a bottom $\Theta((\ln n/n)^{1/3})$ fraction of agents use only $\Theta(\ln n)$ edges, and all agents propose using at most $\Theta(\ln^2 n)$ edges, with $\epsilon = O(\ln n/n^{1/3})$.

6 Numerical Simulations

We present several simulation results which are complementary to our theoretical results. Throughout this section, we focus on the linear separable model.

6.1 NRMP Data

We used NRMP data to motivate some of our choices of parameters for our simulations. The NRMP provides extensive summary data [19]. We begin by discussing this data.

Over time, the number of positions and applicants has been growing. We mention some numbers for 2021. There were over 38,000 positions available and a little over 42,000 applicants. The main match using the DA algorithm (modified to allow for couples, who comprise a little over 5% of the applicants) filled about 95% of the available positions. The NRMP also ran an aftermarket, called SOAP, after which about 0.5% of the positions remained unfilled.

The positions cover many different specialities. These specialities vary hugely in the number of positions available, with the top 11, all of size at least 1,000, accounting for 75% of the positions. In addition, about 75% of the doctors apply to only one speciality. We think that as a first approximation, w.r.t. the model we are using, it is reasonable to view each speciality as a separate market. Accordingly, we have focused our simulations on markets with 1,000–2,000 positions (though the largest speciality in the NRMP data had over 9,000 positions).

On average, doctors listed 12.5 programs in their preference lists, hospital programs listed 88 doctors, and the average program size was 6.5 (all numbers are approximate). While there is no detailed breakdown of the first two numbers, it is clear they vary considerably over the individual doctors and hospitals. For our many-to-one simulations we chose to use a fixed size for the hospital programs. Our simulations cause the other two numbers to vary over the individual doctors and programs because the public ratings and private scores are chosen by a random process.

6.2 Numbers of Available Edges

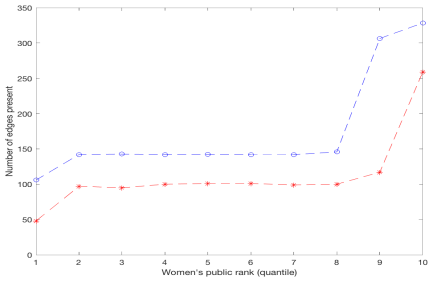
The first question we want to answer is how long do the preference lists need to be in order to have a high probability of including all acceptable edges, for all but the bottommost agents?

We chose bottommost to mean the bottom 20% of the agents, based on where the needed length of the preference lists started to increase in our experiments for $n = 1{,}000$–$2{,}000$.

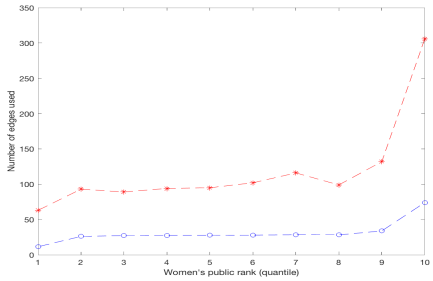
We ran experiments with $\lambda = 0.5, 0.67, 0.8$, corresponding to the public rating having respectively equal, twice, and four times the weight of the private scores in their contribution to the utility. We report the results for $\lambda = 0.8$. The edge sets were larger for smaller values of λ, but the results were qualitatively the same. We generated 100 random markets and determined the smallest value of L that ensured all agents were matched in all 100 markets. $L = 0.12$ sufficed. In Figure 2, we show results by decile of women's rank (top 10%, second 10%, etc.), specifically the average length of the preference list and the average number of edges proposed by a woman in woman-proposing DA, over these 100 randomly generated markets. We also show the max and min values over the 100 runs; these can be quite far from the average value. Note that the min values in Figure 2(a) are close to the max values in Figure 2(b), which suggests that being on the proposing side does not significantly reduce the value of L that the women could use compared to the value the men use. We also show data for a typical single run in Figure 3.

We repeated the simulation for the many-to-one setting. In Figure 4, we show the results for 2000 workers and 250 companies, each with 8 positions. Now, on average, a typical worker (i.e. among the top 80%) has an average preference list length of 55 and makes 7 proposals.

The one-to-one results show that for non-bottommost agents, the preference lists have length 150 on the average, while women make 30 proposals on the average (these numbers

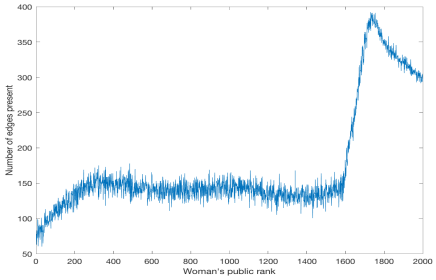


(a) Number of edges in the acceptable edge set, per woman, by decile; average in blue with circles, minimum in red with stars. ($n = 2{,}000$, $\lambda = 0.8$, $L = 0.12$.)

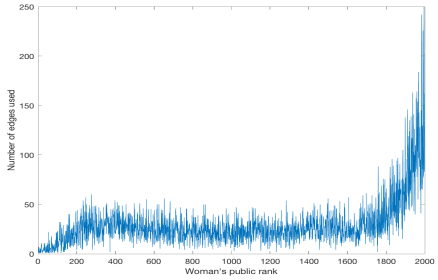


(b) Number of edges in the acceptable edge set proposed during the run of DA, per women, by decile; average in blue with circles, maximum in red with stars.

Figure 2 One-to-one case: summary statistics.



(a) Number of edges in the acceptable edge set for each woman.



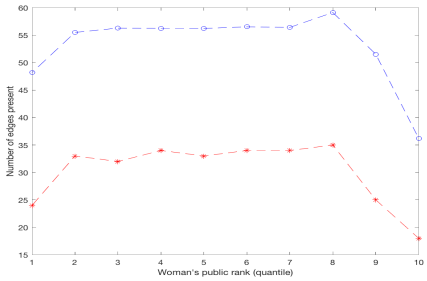
(b) Number of edges in the acceptable edge set proposed by each woman.

Figure 3 One-to-one case: a typical run.

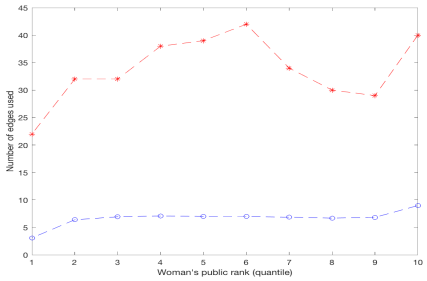
are slightly approximate). What is going on? We believe that the most common matches provide a small loss or gain ($\Theta(n^{-1/3})$ in our theoretical bounds) as opposed to the maximum loss possible ($\Theta(n^{-1/3} \ln^{1/3} n)$ in our theoretical bounds), as is indicated by our distribution bound on the losses (see item 4 in Appendix E.1). The question then is where do these edges occur in the preference list, and the answer is about one fifth of the way through (for one first has the edges providing a gain, which only go to higher up agents on the opposite side, and then one has the edges providing a loss, and these go both up and down). However, a few of the women will need to go through most of their list, as indicated by the fact that the max and min lines (for example in Figure 4) roughly coincide.

This effect can also be seen in the many-to-one experiment but it is even more stark on the worker's side. The reason is that the number of companies with whom a worker w might match which are above w, based on their public ratings alone, is $\Theta(L_c n_c)$, while the number below w is $\Theta(L_w n_c)$, a noticeably larger number. (See Appendix F.1 for a proof of these bounds.) The net effect is that there are few edges that provide w a gain, and so the low-loss edges, which are the typical matches, are reached even sooner in this setting.

Now we turn to why the number of edges in the available edge set per woman changes at the ends of the range. There are two factors at work. The first factor is due to an increasing loss bound as we move toward the bottommost women, which increases the sizes of their available edge sets. The second factor is due to public ratings. For a woman w the range of men's public ratings for its acceptable edges is $[r_m - \Theta(\overline{L}), r_m + \Theta(\overline{L})]$, where m is aligned with w. But at the ends a portion of this range will be cut off, reducing the number of



(a) Many to One Setting: Number of edges in the acceptable edge set per worker, by decile; average in blue with circles, minimum in red with stars. (n_w = 2,000, $d = 8$, $\lambda = 0.8$, $L_c = 0.14$, $L_w = 0.24$.)



(b) Number of edges in the acceptable edge set proposed during the run of DA, per worker, by decile; average in blue with circles, maximum in red with stars.

Figure 4 Many to One Setting.

acceptable edges, with the effect more pronounced for low public ratings. Because $\lambda = 0.8$, initially, as we move to lower ranked women, the gain due to increasing the loss bound dominates the loss due to a reduced public rating range, but eventually this reverses. Both effects can be clearly seen in Figure 3(a), for example.

6.3 Unique Stable Partners

Another interesting aspect of our simulations is that they showed that most agents have a unique stable partner. This is similar to the situation in the popularity model when there are short preference lists, but here this result appears to hold with full length preference lists. In Figure 5, we show the outcome on a typical run and averaged over 100 runs, for $n = 2{,}000$ in the one-to-one setting. We report the results for the men, but as the setting is symmetric they will be similar for the women. On the average, among the top 90% of agents by rank, 0.5% (10 of 1,800) had more than one stable partner, and among the remainder another 2% had multiple stable partners (40 of 200).

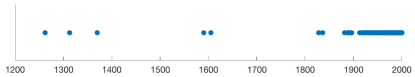
Also, as suggested by the single run illustrated in Figure 5(a), the pair around public rank 1,600 and the triple between 1,200 and 1,400 have multiple stable partners which they can swap (or exchange via a small cycle of swaps) to switch between different stable matchings. This pattern is typical for the very few men with multiple stable partners outside the bottommost region.

6.4 Constant Number of Proposals

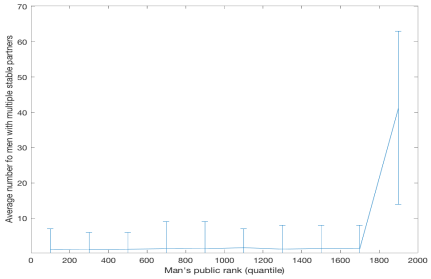
Our many-to-one experiments suggest that the length of the preference lists needed by our model are larger than those observed in the NRMP data. In addition, even though there is a simple rule for identifying these edges, in practice the communication that would be needed to identify these edges may well be excessive. In light of this it is interesting to investigate what can be done when the agents have shorter preference lists.

We simulated a strategy where the workers' preference lists contain only a constant number of edges. We construct an *Interview Edge Set* which contains the edges (w, c) satisfying the following conditions:

1. Let r_w and r_c be the public ratings of w and c respectively. Then $|r_w - r_c| \leq p$.



(a) Public ranks of men with multiple stable partners in a typical run.



(b) Average numbers of men with multiple stable partners, by decile.

Figure 5 Unique stable partners, one-to-one setting.

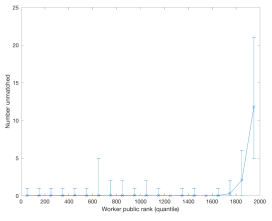
2. The private score w has for c as well as the private score of c for w are both greater than q.

We choose the parameters p and q so as to have 15 edges per agent on average. Many combinations of p and q would work. We chose a pair that caused relatively few mismatches. We then ran worker proposing DA on the Interview Edge Set.

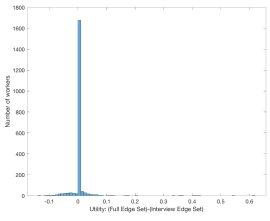
One way of identifying these edges is with the following communication protocol: the workers signal the companies which meet their criteria (the workers' criteria); the companies then reply to those workers who meet their criteria. In practice this would be a lot of communication on the workers's side, and therefore it may be that an unbalanced protocol where the workers use a larger q_w as their private score cutoff and the companies a correspondingly smaller q_c is more plausible. Clearly this will affect the losses each side incurs when there is a match, but we think it will have no effect on the non-match probability, and as non-matches are the main source of losses, we believe our simulation is indicative. We ran the above experiment with $p = 0.19$ and $q = 0.60$, with the company capacity being 8. Figure 6(a) shows the locations of unmatched workers in a typical run of this experiment while 6(b) shows the average numbers of unmatched workers per quantile (of public ratings) over 100 runs. We observe that the number of unmatched workers is very low (about 1.5% of the workers) and most of these are at the bottom of the public rating range.

Figure 6(c) compares the utility obtained by the workers in the match obtained by running worker-proposing DA on the Interview Edge Set to the utility they obtain in the worker-optimal stable match. We observe that only a small number of workers have a significantly worse outcome when restricted to the Interview Edge Set.

(a) Public ranks of unmatched workers in a typical run.



(b) Average numbers of unmatched workers by public rating decile.



(c) Distribution of workers' utilities with worker-proposing DA: (full edge set result) – (Interview edge set result).

Figure 6 Constant number of proposals.

7 Discussion and Open Problems

Our work shows that in the bounded derivatives model, apart from a sub-constant fraction of the agents, each of the other agents has $O(\ln n)$ easily identified edges on their preference list which cover all their stable matches w.h.p.

As described in Section 6, our experiments for the one-to-one setting yield a need for what appear to be impractically large preference lists. While the results in the many-to-one setting are more promising, even here the preference lists appear to be on the large side. Also, while our rule for identifying the edges to include is simple, in practice it may well require too much communication to identify these edges. At the same time, our outcome is better than what is achieved in practice: we obtain a complete match with high probability, whereas in the NRMP setting a small but significant percentage of positions are left unfilled. Our conclusion is that it remains important to understand how to effectively select smaller sets of edges.

In the popularity model, it is reasonable for each agent to simply select their favorite partners. But in the current setting, which we consider to be more realistic, it would be an ineffective strategy, as it would result in most agents remaining unmatched. Consequently, we believe the main open issue is to characterize what happens when the number of edges k that an agent can list is smaller than the size of the allowable edge set. We conjecture that following a simple protocol for selecting edges to list, such as the one we use in our experiments (see Section 6.4), will lead to an ϵ-Bayes-Nash equilibrium, where ϵ is a decreasing function of k. Strictly speaking, as the identification of allowable edges requires communication, we need to consider the possibility of strategic communication, and so one would need to define a notion of ϵ-equilibrium akin to a Subgame Perfect equilibrium. We conjecture that even with this, it would still be an ϵ-equilibrium.

Finally, it would be interesting to resolve whether the experimentally observed near uniqueness of the stable matching for non-bottom agents is a property of the linear separable model. We conjecture that in fact it also holds in the bounded derivatives model.

Expander Decomposition with Fewer Inter-Cluster Edges Using a Spectral Cut Player

Daniel Agassy

Abstract

A (ϕ, ϵ)-expander decomposition of a graph G (with n vertices and m edges) is a partition of V into clusters $V_1, \ldots, V_k$ with conductance $\Phi(G[V_i]) \geq \phi$, such that there are at most ϵm inter-cluster edges. Such a decomposition plays a crucial role in many graph algorithms. We give a randomized $\tilde{O}(m/\phi)$ time algorithm for computing a $(\phi, \phi \log^2 n)$-expander decomposition. This improves upon the $(\phi, \phi \log^3 n)$-expander decomposition also obtained in $\tilde{O}(m/\phi)$ time by [Saranurak and Wang, SODA 2019] (SW) and brings the number of inter-cluster edges within logarithmic factor of optimal.

One crucial component of SW's algorithm is a non-stop version of the cut-matching game of [Khandekar, Rao, Vazirani, JACM 2009] (KRV): The cut player does not stop when it gets from the matching player an unbalanced sparse cut, but continues to play on a trimmed part of the large side. The crux of our improvement is the design of a non-stop version of the cleverer cut player of [Orecchia, Schulman, Vazirani, Vishnoi, STOC 2008] (OSVV). The cut player of OSSV uses a more sophisticated random walk, a subtle potential function, and spectral arguments. Designing and analysing a non-stop version of this game was an explicit open question asked by SW.

1 Introduction

The *conductance* of a cut $(S, V \setminus S)$ is $\Phi_G(S, V \setminus S) = \frac{|E(S, V \setminus S)|}{\min(\mathbf{vol}(S), \mathbf{vol}(V \setminus S))}$, where $\mathbf{vol}(S)$ is the sum of the degrees of the vertices of S. The conductance of a graph G is the smallest conductance of a cut in G.

A (ϕ, ϵ)-*expander decomposition* of a graph G is a partition of the vertices of G into clusters $V_1, \ldots, V_k$ with conductance $\Phi(G[V_i]) \geq \phi$ such that there are at most ϵm inter-cluster edges, where $\phi, \epsilon \geq 0$. We consider the problem of computing in almost linear time ($\tilde{O}(m)$ time) a (ϕ, ϵ)-expander decomposition for a given graph G and $\phi > 0$, while minimizing ϵ as a function of ϕ. It is known that a (ϕ, ϵ)-expander decomposition, with $\epsilon = O(\phi \log n)$, always exists and that $\epsilon = \Theta(\phi \log n)$ is optimal [23, 2].

Expander decomposition algorithms have been used in many cutting edge results, such as directed/undirected Laplacian solvers [27, 11], graph sparsification [9, 10], distributed algorithms [6], and maximum flow algorithms [15]. Expander decomposition was also used [10]

(in the deterministic case) in order to break the $O(\sqrt{n})$ dynamic connectivity bound and achieve an improved running time of $O(n^{o(1)})$ per operation. It was also used in the recent breakthrough result by Chen et al. [8], who showed algorithms for maximum flow and minimum cost flow in almost linear time.

Given an $f(n)$-approximation algorithm for the problem of finding a minimum conductance cut, one can get a $(\phi, O(f(n) \cdot \phi \log n))$-expander decomposition algorithm by recursively computing approximate cuts (and thus splitting V) until all components are certified as expanders. In particular, using an exact minimum conductance cut algorithm ensures the existence of an expander decomposition with $\epsilon = O(\phi \log n)$ as mentioned above. Using the polynomial algorithms of [20, 4] which provide the best approximation ratios of $O\left(\sqrt{\phi}\right)$ and $O\left(\sqrt{\log n}\right)$, respectively, for conductance, gives polynomial time expander decomposition algorithms with $\epsilon = O\left(\phi^{3/2} \log n\right)$ and $\epsilon = O\left(\phi \log^{\frac{3}{2}} n\right)$. However, these decomposition algorithms might lead to a linear recursion depth, and therefore have superlinear time complexity.

To get a near linear time algorithm using this recursive approach, one must be able to efficiently compute low conductance cuts with additional guarantees. We get such cuts using the cut-matching framework of [16] (abbreviated as KRV). In order to present our results in the appropriate context we now give a brief background on the cut-matching framework.

Cut-matching. Edge-expansion is a connectivity measure related to conductance. The *edge-expansion* of a cut $(S, V \setminus S)$ is $h_G(S, V \setminus S) = \frac{|E(S, V \setminus S)|}{\min(|S|, |V \setminus S|)}$ and the *edge-expansion* of a graph G is the smallest edge-expansion of a cut in G.

The cut-matching game is a technique that reduces the approximation task for sparsest cut (in terms of edge-expansion) to a polylogarithmic number of maximum flow problems. The resulting approximation algorithm for sparsest cut is remarkably simple and robust.

The cut-matching game is played between a *cut player* and a *matching player*, as follows. We start with an empty graph G_0 on n vertices. At round t, the cut player chooses a bisection $(S_t, \overline{S_t})$ of the vertices (we assume n is even). In response, the matching player presents a perfect matching M_t between the vertices of S_t and $\overline{S_t}$ and the game graph is updated to $G_t = G_{t-1} \cup M_t$. Note that this graph may contain parallel edges. The game ends when G_t is a sufficiently good edge-expander. The goal of this game is to devise a strategy for the cut player that maximizes the ratio $r(n) := \phi/T$, where T is the number of rounds and $\phi = h(G_T)$ is the edge-expansion of G_T. KRV showed that one can translate a cut strategy of quality $r(n)$ into a sparsest cut algorithm of approximation ratio $1/r(n)$ by applying a binary search on a sparsity parameter ϕ until we certify that $h(G) \geq \phi$ and $h(G) = O(\phi/r(n))$.

KRV devised a randomized cut-player strategy that finds the bisection using a stochastic matrix that corresponds to a random walk on all previously discovered matchings. Their walk traverses the previous matchings in order and with probability half takes a step according to each matching. They showed that the matrix corresponding to this random walk can actually be embedded (as a flow matrix) into G_t with constant congestion. They terminate when the random walk matrix is close to uniform (i.e. having constant edge-expansion), resulting in G_T for $T = O\left(\log^2 n\right)$, having constant edge-expansion.

Orecchia et al. [21] (abbreviated as OSVV) took the same approach but devised a more sophisticated random walk and used Cheeger's inequality [7] in order to show that G_T, for $T = O\left(\log^2 n\right)$, has $\Omega(\log n)$ edge-expansion. That is, they got a ratio of $r(n) = \Omega\left(\frac{1}{\log n}\right)$.

Equipped with this background we now get back to expander decomposition, and focus on the $\tilde{O}(m/\phi)$ time algorithm by Saranurak and Wang [23] (abbreviated as SW). Their algorithm is randomized, follows the recursive scheme described above, and computes a

$(\phi, \phi \log^3 n)$-expander decomposition in $O\left(\frac{m \log^4 n}{\phi}\right)$ time. Its number of inter-cluster edges is off by a factor of $O\left(\log^2 n\right)$ from optimal and off by a factor of $O\left(\log^{\frac{3}{2}} n\right)$ from the aforementioned best achievable polynomial time construction.

One core component of this algorithm is a variation of the cut-matching game (inspired by Räcke et al. [22]). In this variation, the game graph $G_t = (V_t, E_t)$ may lose vertices (*i.e.*, $V_{t+1} \subseteq V_t$) throughout the game and the objective of the cut player is to make V_T a *near expander* in G_T (see Definition 9). The result of each round does not consist of a perfect matching in V_t, but rather a subset to remove from V_t and a matching of the remaining vertices. The game ends either with a balanced cut of low conductance, or with an unbalanced cut of low conductance, such that the larger side is a *near expander*. This allows SW to avoid recurring on the large side of the cut. Indeed, if the cut is balanced, they run recursively on both sides, and if it is unbalanced, they use the fact that the large side is a *near expander* and "trim" it by finding a large subset of this side which is an expander. Then, they run recursively on the smaller side combined with the "trimmed" vertices. SW's analysis of the new cut-matching game is based on the ideas and the potential function of KRV while carefully taking into account of the shrinkage of the game graph.

An open question, raised by SW, was whether one can adapt the technique of the cut-matching strategy of OSVV to improve their decomposition. A major obstacle is how to perform an OSVV-like spectral analysis when we lose vertices throughout the process and need to bound the near-expansion of the final piece. This is challenging as the analysis of OSVV is already somewhat more complicated than that of KRV: It uses a different lazy random walk and a subtle potential to measure progress towards near expansion. Moreover Cheeger's inequality is suitable to show high expansion and the object we are targeting is a near expander.

Our contribution. In this paper we answer this question of SW affirmatively. We present and analyze an expander decomposition algorithm with a new cut-player inspired by OSVV. This improves the result of SW and gives a randomized $\tilde{O}(m/\phi)$ time algorithm for computing an $(\phi, \phi \log^2 n)$-expander decomposition (Theorem 18). This brings the number of inter-cluster edges to be off only by $O(\log n)$ factor from the best possible.

To achieve this we overcome two main technical challenges: (1) We generalize the lazy random walk of the cut player of OSVV and the subtle potential tracking its progress, to the setting in which the vertex set shrinks (by ripping off of it small cuts as in SW). (2) We show that when the generalized potential is small the remaining part of the game graph is a near expander. This required a generalization of Cheeger's inequality appropriate for our purpose (see Lemma 33).

Our techniques may be applied in similar contexts. One concrete such context is the construction of tree-cut sparsifiers. Specifically, one could try to use our technique to improve the $O\left(\log^4 n\right)$-approximate tree-cut sparsifier construction of [22] by a factor of $\log n$. (Note that [22] in fact construct a tree-flow sparsifier, which is a stronger notion.)

The cut-matching framework [16] is formalized for edge-expansion rather than conductance. Consequently, SW and others whose primary objective is conductance had to transform the graph into a *subdivision-graph* in order to use this framework. The subdivision graph is obtained by adding a new vertex (called a *split-node*) in the middle of each edge e, splitting e into a path of length two. Consequently, the analysis has to translate cuts of low expansion in the modified graph (the *subdivision graph*) to cuts of low conductance in the original graph. This transformation complicates the algorithms and their analysis.

To avoid this transformation we revisit the seminal results of KRV and OSVV and redo them directly for conductance. This is not trivial and requires subtle changes to the cut players, and the matching players, and the potentials measuring progress towards a graph with small conductance. In particular the matching player does not produce a matching anymore but rather what we call a d_G-matching, which is a graph with the same degrees as G.

Our new cut-matching algorithm is then described using this natural reformulation of the cut-matching framework directly for conductance, removing the complications that would have followed from using the split graph.

We believe that our clean presentations of the cut-matching framework for conductance would prove useful for other applications of cut-matching that require optimization for conductance rather than expansion.

Further related work. Computing the expansion and the conductance of a graph G is NP-hard [18, 25], and there is a long line of research on approximating these connectivity measures. The best known polynomial algorithms for approximating the minimum conductance cut have either $O\left(\sqrt{\log n}\right)$ [4, 24] or $O\left(\sqrt{\Phi(G)}\right)$ approximation ratios [20]. Approximation algorithms for expansion and conductance play a crucial role in algorithms for expander decomposition [23, 5, 10], expander hierarchies [12, 14], and tree flow sparsifiers [22].

In his thesis, Orecchia [19] elaborates on the two cut-matching strategies described in OSVV, one based on a lazy random walk, called C_{NAT}, and a more sophisticated one based on the *heat-kernel* random walk, called C_{EXP}. Orecchia proves (Theorem 4.1.5 of [19]) that using C_{NAT} or C_{EXP}, after $T = \Theta(\log^2 n)$ iterations, the graph G_T has expansion $\Omega(\log n)$ (and thereby conductance $\Omega\left(\frac{1}{\log n}\right)$, since it is regular with degrees $\Theta(\log^2 n)$). Orecchia also bounds the second largest eigenvalue of the normalized Laplacian of G_T. However, Orecchia does not show how to use cut-matching to get approximation algorithms for the conductance of G.

In a recent paper [3] Ameranis *et al.* use a generalized notion of expansion, also mentioned in [19], where we normalize the number of edges crossing the cut by a general measure (μ) of the smaller side of the cut. They define a corresponding generalized version of the cut-matching game, and show how to use a cut strategy for this game to get an approximation algorithm for two generalized cut problems. They claim that one can construct a cut strategy for this measure using ideas from [19].[1]

Both SW and our result can be implemented in $\tilde{O}(m)$ time using the recent result of [17], by replacing Bounded-Distance-Flow (Lemma 21) and the "Trimming Step" of [23] with the algorithm of [17, Section 8]. This $\tilde{O}(m)$ hides many log factors and requires more complicated machinery.

The structure of this paper is as follows. Section 2 contains additional definitions. In order to provide the appropriate context for our work, Section 3 gives an overview of the cut-matching games in [16] and [21] and highlights the differences between them. In the full version of this paper, we give a complete and self-contained description of these approximation algorithms directly **for conductance**. A reader knowledgeable in the Cut-Matching game can skip directly to Section 4. In Section 4 we present our new non-stop spectral cut player and expander decomposition algorithm. Section 5 contains the analysis of our algorithm. Due to the space constraints some of the proofs are omitted, and are available in the full version of this paper [1].

[1] The details of such a cut player do not appear in [3] or [19].

To be consistent with common terminology we refer to a graph with conductance at least ϕ as a ϕ-expander (rather than ϕ-conductor.) No confusion should arise since in the rest of this paper we focus on conductance and do not use the notion of edge-expansion anymore. In this paper we only focus on unweighted graphs, although our algorithm can be adapted to the case of integral, polynomially bounded weights.

2 Preliminaries

We denote the transpose of a vector or a matrix x by x'. That is, if v is a column vector then v' is the corresponding row vector. For a vector $v \in \mathbb{R}^n_{\geq 0}$, define $\sqrt{v}$ to be vector whose coordinates are the square roots of those of v. Given $A \in \mathbb{R}^{n\times n}$, we denote by $A(i,j)$ the element at the i'th row and j'th column of A. We denote by $A(i,), A(,i)$ the i'th row and column of A, respectively. We define both $A(i,)$ and $A(,i)$ as column vectors. We use the abbreviation $A(i) := A(i,)$ only with respect to the rows of A. Given a vector $v \in \mathbb{R}^n$, we denote its i'th element by $v(i)$. For disjoint $A, B \subseteq V$, we denote by $E_G(A,B)$ the set of edges connecting A and B. We sometimes omit the subscript when the graph is clear from the context. If $A = V \setminus B$, then we call (A,B) a *cut*.

▶ **Fact 1.** *Let $X, Y \in \mathbb{R}^{n\times n}, m \in \mathbb{N}$, then $\mathrm{Tr}(XY) = \mathrm{Tr}(YX)$.*

▶ **Fact 2.** *Let $X, Y \in \mathbb{R}^{n\times n}$ be symmetric matrices and let $k \in \mathbb{N}$. Then*

$$\mathrm{Tr}\left((XYX)^{2^k}\right) \leq \mathrm{Tr}\left(X^{2^k}Y^{2^k}X^{2^k}\right).$$

▶ **Definition 3** (d_G,$\mathbf{vol}_G(S)$)**.** *Given a graph G, the vector $d_G \in \mathbb{R}^n$ is defined as $d_G(v) = \deg_G(v)$. To simplify the notation, we denote $d := d_G$ whenever the graph G is clear from the context. For $S \subseteq V$, we denote by $\mathbf{vol}_G(S) := \sum_{v\in S} d_G(v)$ the* volume *of S.*

▶ **Definition 4** ($G\{A\}$)**.** *Let $G = (V,E)$ be a graph, and let $A \subseteq V$ be a set of vertices. We define the graph $G\{A\} = (V', E')$ as the graph induced by A with self-loops added to preserve the degrees: $V' = A, E' = \{\{u,v\} \in E : u,v \in A\} \cup \{\{u,u\} : u \in A, v \in V \setminus A, \{u,v\} \in E\}$.*

▶ **Definition 5** (d-Matching)**.** *Given a vector $d \in \mathbb{N}^n$ and a collection of pairs $M = \{(u_i,v_i)\}_{i=1}^m$. We say that M is a* d-matching *if the graph defined by M (i.e., the graph whose edges are M) satisfies $d_M(v) = d(v)$, for every v.*

▶ **Definition 6** (d_G-stochastic)**.** *A matrix $F \in \mathbb{R}^{n\times n}$ is* d_G-stochastic *with respect to a graph G if the following two conditions hold: (1) $F \cdot \mathbb{1}_n = d_G$ and (2) $\mathbb{1}'_n \cdot F = d'_G$.*

▶ **Definition 7** (Laplacian, Normalized Laplacian)**.** *Let $A \in \mathbb{R}^{n\times n}$ be a symmetric matrix and let $d = A \cdot \mathbb{1}_n$, $D = \mathbf{diag}(d)$. The* Laplacian of A *is defined as $\mathcal{L}(A) = D - A$. The* normalized-Laplacian of A *is defined as $\mathcal{N}(A) = D^{-\frac{1}{2}}\mathcal{L}(A)D^{-\frac{1}{2}} = I - D^{-\frac{1}{2}}AD^{-\frac{1}{2}}$. The (normalized) Laplacian of an undirected graph is defined analogously using its adjacency matrix.*

▶ **Definition 8** (Conductance)**.** *Let $G = (V,E)$ and $S \subset V$, $S \neq \emptyset$. The* conductance *of the cut $(S, V \setminus S)$, denoted by $\Phi_G(S, V \setminus S)$, is*

$$\Phi_G(S, V \setminus S) = \frac{|E(S, V \setminus S)|}{\min(\mathbf{vol}(S), \mathbf{vol}(V \setminus S))}.$$

The conductance of G is defined to be $\Phi(G) = \min_{S\subseteq V} \Phi_G(S, V \setminus S)$.

▶ **Definition 9** (Expander, Near-Expander). *Let $G = (V, E)$. We say that G is a ϕ-*expander *if $\Phi(G) \geq \phi$. Let $A \subseteq V$. We say that A is a* near ϕ-expander *in G if*

$$\min_{S \subseteq A} \frac{|E(S, V \setminus S)|}{\min(\mathbf{vol}(S), \mathbf{vol}(A \setminus S))} \geq \phi.$$

That is, a near expander is allowed to use cut edges that go outside of A. Note that the above definition applies to both directed and undirected graphs.

▶ **Definition 10** (Embedding). *Let $G = (V, E)$ be an undirected graph. Let $F \in \mathbb{R}_{\geq 0}^{V \times V}$ be a matrix (not necessarily symmetric). We say that F is* embeddable in G with congestion c, *if there exists a multi-commodity flow f in G, with $|V|$ commodities, one for each vertex (vertex v is the source of its commodity), such that, simultaneously for each $(u, v) \in V \times V$, f routes $F(u, v)$ units of u's commodity from u to v, and the total flow on each edge is at most c.* [2]

If F is the weighted adjacency matrix of a graph H on the same vertex set V, we say that H is embeddable in G with congestion c if F is embeddable in G with congestion c.

▶ **Lemma 11.** *Let G, H be two graphs on the same vertex set V. Let $A \subseteq V$. Let $\alpha > 0$ be a constant such that for each $v \in V$, $d_G(v) = \alpha \cdot d_H(v)$. Assume that H is embeddable in G with congestion c, and that A is a near ϕ-expander in H. Then, A is a near $\frac{\phi}{c\alpha}$-expander in G.*

▶ **Corollary 12.** *Let G, H be two graphs on the same vertex set V. Let $\alpha > 0$ be a constant such that for each $v \in V$, $d_G(v) = \alpha \cdot d_H(v)$. Assume that H is embeddable in G with congestion c, and that H is a ϕ-expander. Then, G is a $\frac{\phi}{c\alpha}$-expander.*

Proof. This follows from Lemma 11 by choosing $A = V$. ◀

3 Approximating conductance via cut-matching

In preparation for our expander decomposition algorithm we give a high level overview of the conductance approximation algorithms of [16] and [21]. [16] and [21] described their results for edge-expansion rather than conductance. In the full version of this paper, we give a complete description and analysis of these algorithms for conductance. This translation from edge-expansion to conductance is not trivial as both the cut player, the matching player, and the analysis have to be carefully modified to take the degrees into account. Here we give a high level overview of the key components of these algorithms and the differences between them so one can better absorb our main algorithm in Section 4.2.

The cut-matching game of [16] (in the conductance setting) works as follows.

The Cut-Matching game for conductance, with parameters T and a degree vector d:

- The game is played on a series of graphs G_i. Initially, $G_0 = \emptyset$.
- In iteration t, the cut player produces two multisets of size m, $L_t, R_t \subseteq V$, such that each $v \in V$ appears in $L_t \cup R_t$ exactly $d(v)$ times.
- The matching player responds with a d-matching M_t that only matches vertices in L_t to vertices in R_t.
- We set $G_{t+1} = G_t \cup M_t$.
- The game ends at iteration T, and the *quality* of the game is $r := \Phi(G_T)$. Note that the volume of G_t increases from one iteration to the next.

[2] This definition requires to route $F(u, v) = F(v, u)$ both from u to v and from v to u if F is symmetric.

Given a strategy for the cut player of quality r, one can create a $\frac{1}{r}$ approximation algorithm for the conductance of a given graph G. To this end, the matching player has to provide matchings that can be embedded in G.

The difference between the results of [16] and [21] is mainly in the cut player. They both run the game for $T = \Theta(\log^2 n)$ iterations but [16]'s cut player achieves quality of $r = \Omega\left(\frac{1}{\log^2 n}\right)$ whereas [21]'s achieves quality of $r = \Omega\left(\frac{1}{\log n}\right)$. Notice that the cut player produces the stated expansion result in G_T regardless of the matchings given by the matching player.

3.1 KRV's Cut-Matching Game for Conductance

The cut player implicitly maintains a d_G-stochastic flow matrix (*i.e.*, representing flow demands) $F_t \in \mathbb{R}^{n\times n}$, and the graph G_t which is the union of the matchings that it obtained so far from the matching player (t is the index of the round). The flow F_t and the graph G_t have two crucial properties. First, we can embed F_t in G_t with $O(1)$ congestion (See Definition 10). Second, after $T = \Theta(\log^2 n)$ rounds, with high probability, F_T will have constant conductance.[3] Since the degrees in G_T are factor of $O(\log^2 n)$ larger than the degrees in F_T (when we think of F_T as a weighted graph) then it follows by Corollary 12 that G_T is $\Omega(1/\log^2 n)$ expander. Note that the cut player is unrelated to the input graph G in which we would like to approximate the conductance. Its goal is to produce the expander G_T.

At the beginning, $F_0 = D = \mathbf{diag}(d)$, and G_0 is the empty graph on $V = [n]$. The cut player updates F_t as follows. It draws a random unit vector $r \in \mathbb{R}^n$ orthogonal to $\sqrt{d}$ and computes the projections $u_i = \frac{1}{d(i)}\langle D^{-\frac{1}{2}} F_t(i), r\rangle$.[4] The cut player computes these projections in $O(m\log^2 n)$ time since the vector of all projections is $u := D^{-1}F_t D^{-\frac{1}{2}} \cdot r$ and F_t is defined (see below) as a multiplication of $\Theta(\log^2 n)$ sparse matrices, each having $O(m)$ non-zero entries. The cut player sorts the projections as $u_{i_1} \le \ldots \le u_{i_n}$. Consider the sequence $Q = (u_{i_1}, u_{i_1}, \ldots, u_{i_1}, u_{i_2}, u_{i_2}, \ldots, u_{i_2}, \ldots, u_{i_n}, \ldots, u_{i_n})$, where each u_{i_j} appears $d(i_j)$ times. Then, $|Q| = 2m$. Take $L_t \subseteq Q$ to be the multi-set containing the first m elements, and $R_t = Q \setminus L_t$ to be the multi-set containing the last m elements. Define $\eta \in \mathbb{R}$ such that $L_t \subseteq \{i_k : u_{i_k} \le \eta\}$ and $R_t \subseteq \{i_k : u_{i_k} \ge \eta\}$. Note that a vertex can appear both in L_t and in R_t, if $u_{i_j} = \eta$. For a vertex $v \in V$, denote by m_v the number of times v appears in L_t, and by $\bar{m}_v$ the number of times v appears in R_t. That is, except for (maybe) one vertex, for any $v \in V$, either $m_v = 0$ and $\bar{m}_v = d(v)$ or $m_v = d(v)$ and $\bar{m}_v = 0$.

The cut player hands out the partition L_t, R_t to the matching player who sends back a d_G-matching M_t (we think of M_t as an $n \times n$ matrix with at most m non-zero entries that encodes the matching) between L_t and R_t. The cut player updates its flow matrix using M_t and sets $F_{t+1}(v) = \frac{1}{2}F_t(v) + \sum_{(v,u)\in M_t} \frac{1}{2d(u)} F_t(u)$ (in matrix form $F_{t+1} = \frac{1}{2}\left(I + M_t \cdot D^{-1}\right) F_t$).[5] This update keeps F_t a d_G-stochastic matrix for all t. The cut player also defines the graph G_{t+1} as $G_{t+1} = G_t \cup M_t$. This completes the description of the cut player of [16] adapted for conductance.

[3] We think about F_t as a weighted graph on $V = [n]$. The definitions of conductance, expander and near-expander for weighted graphs are the same as Definitions 8-9 where $|E(S, V \setminus S)|$ is the sum of the weights of the edges crossing the cut.

[4] Recall that $F_t(i)$ is a column vector.

[5] Note that it is possible that some $u \in V$ appears in the sum $\sum_{(v,u)\in M_t} \frac{1}{2d(u)} F_t(u)$ multiple times, if v is matched to u multiple times in M_t.

The matching player constructs an auxiliary flow problem on $G' := G \cup \{s, t\}$, where s is a new vertex which would be the source and t is a new vertex which would be the sink. We add an arc (s, v) for each $v \in L_t$ of capacity m_v and we add an arc (v, t) of capacity $\bar{m}_v$ for each $v \in R_t$. The capacity of each edge $e \in G$ is set to be $c = \Theta\left(\frac{1}{\phi \log^2 n}\right)$, where c is an integer. The matching player computes a maximum flow g from s to t in this network.

If the value of g is less than m, then the matching player uses the minimum cut in G' separating the source from the sink to find a cut in G of conductance $O(\phi \log^2 n)$. Otherwise, it decomposes g to a set of paths, each carrying exactly one unit of flow from a vertex $u \in L_t$ to a vertex $v \in R_t$.[6] Then it defines the d_G-matching M_t as $M_t = ((v_j, u_j))_{j=1}^{m}$, where v_j and u_j are the endpoints of path j. We view M_t as a symmetric $n \times n$ matrix, such that $M_t(v, u)$ is the number of paths between v and u. The matching player connects the game to the input graph G. Indeed, by solving the maximum flow problems in G it guarantees that the expander G_T is embeddable in G with congestion $O(cT) = O(1/\phi)$. Since the degrees of G_T are a factor of $O(\log^2 n)$ larger than the degrees of G and G_T is $\Omega(1/\log^2 n)$ expander, we get that G is a $\Omega(\phi)$-expander (see Corollary 12). The following theorem summarizes the properties of this algorithm.

▶ **Theorem 13** ([16]'s cut-matching game for conductance). *Given a graph G and a parameter $\phi > 0$, there exists a randomized algorithm, whose running time is dominated by computing a polylogarithmic number of maximum flow problems, that either*

1. *Certifies that $\Phi(G) = \Omega(\phi)$ with high probability; or*
2. *Finds a cut $(S, V \setminus S)$ in G whose conductance is $\Phi_G(S, V \setminus S) = O(\phi \log^2 n)$.*

If the matching player finds a sparse cut in any iteration then we terminate with Case (2). On the other hand, if the game continues for $T = O(\log^2 n)$ rounds then since the cut player can embed F_T in G_T and the matching player can embed G_T in G, and since F_t is an expander, then we get Case (1).

The running time of the cut player is $O(m \log^4 n)$. The matching player solves $O(\log^2 n)$ maximum flow problems. By using the most recent maximum flow algorithm of [8], we get the matching player to run in $O\left(m^{1+o(1)}\right)$ time. Alternatively, we can adapt the cut-matching game, and use a version of the Bounded-Distance-Flow algorithm (which was called *Unit-Flow* in [23]; see Lemma 21), to get a running time of $\tilde{O}(\frac{m}{\phi})$ for the matching player. We can also get $\tilde{O}(m)$ running time using the recent result [17].

The key part of the analysis is to show that F_T is indeed an $\Omega(1)$-expander for any choice of d_G-matchings of the matching player. To this end, we keep track of the progress of the cut player using the potential function

$$\psi(t) = \sum_{i \in V} \sum_{j \in V} \frac{1}{d(i) \cdot d(j)} \left(F_t(i,j) - \frac{d(i)d(j)}{2m} \right)^2 = \left\| D^{-\frac{1}{2}} F_t D^{-\frac{1}{2}} - \frac{1}{2m} \sqrt{d} \sqrt{d'} \right\|_F^2$$

where the matrix norm which we use here is the Frobenius norm (sum of the squares of the entries). This potential represents the distance between the normalized flow matrix $\bar{F}_t = D^{-\frac{1}{2}} F_t D^{-\frac{1}{2}}$ and the (normalized) uniform random walk distribution $d_G d'_G / 2m$. Let $P = I - \frac{1}{2m} \sqrt{d} \sqrt{d'}$ be the projection matrix on the orthogonal complement of the span of the vector $\sqrt{d}$, then we can also write this potential as

[6] Note that there can be multiple flow paths between a pair of vertices $u \in L_t$ and $v \in R_t$. Furthermore, if $u \in L_t \cap R_t$ then it is possible that a path starts and ends at u.

$$\psi(t) = \left\|\bar{F}_t P\right\|_F^2 = \mathrm{Tr}\left((\bar{F}_t P)(\bar{F}_t P)'\right) = \mathrm{Tr}(\bar{F}_t P^2 \bar{F}_t') = \mathrm{Tr}(P\bar{F}_t'\bar{F}_t).$$

The first equality holds since F_t is d-stochastic and the last equality is due to Fact 1 (and that $P^2 = P$ as a projection matrix).

The crux of the proof is to show that after T rounds this potential is smaller than $1/(16m^2)$ which implies that for every pair of vertices u and v, $F_T(u,v) \geq d(v)d(u)/(4m)$. From this we get a lower bound of $1/4$ on the conductance of every cut.

3.2 OSVV's Cut-Matching Game for Conductance

The cut player of [21] also maintains (implicitly) a flow matrix F_t and the union G_t of the d_G-matchings it got from the matching player. Let $P = I - \frac{1}{2m}\sqrt{d}\sqrt{d'}$ be the projection to the subspace orthogonal to $\sqrt{d}$ as before (hence $P^2 = P$). Let $\delta = \Theta(\log n)$ be a power of 2. Here the matrix $W_t = (PD^{-\frac{1}{2}}F_tD^{-\frac{1}{2}}P)^\delta$ takes the role of $D^{-\frac{1}{2}}F_tD^{-\frac{1}{2}}$ from the cut player of Section 3.1.

In round t the cut player computes the projections $u_i = \frac{1}{\sqrt{d(i)}}\langle W_t(i), r\rangle$, and defines L_t and R_t based on these projections as in the previous section.[7] Then it gets a d_G-matching M_t between L_t and R_t from the matching player. It defines $N_t = \frac{\delta-1}{\delta}D + \frac{1}{\delta}M_t$ and updates the flow to be $F_{t+1} = N_t \cdot D^{-1}F_tD^{-1}N_t$. If we think of F_t as a random walk then $D^{-1}N_t$ is a lazy step that we add before and after the walk F_t to get F_{t+1}. It holds that F_{t+1} is d_G-stochastic and moreover that for all rounds t, F_t is embeddable in G_t with congestion $\frac{4}{\delta} = O(1/\log n)$. Note that here we embed F_t in G_t with smaller congestion than in Section 3.1. We can still prove, however, that F_T for $T = O(\log^2 n)$ is a $\Omega(1)$ expander and therefore, G_T is a $\Omega(1/\log n)$ expander.

The matching player solves the same flow problem as in Section 3.1 but with an integer capacity value of $c = \Theta(\frac{1}{\phi \log n})$ on the edges of G. If the value of maximum flow is less than m then it finds a cut of conductance $O(\phi \log n)$, and otherwise it returns the matching that it derives from a decomposition of the flow into paths. The matching player guarantees that the expander G_T is embeddable in G with congestion $O(cT) = O(\log n/\phi)$. Since the degrees of G_T are larger by a factor of $O(\log^2 n)$ than the degrees of G and G_T is $\Omega(1/\log n)$-expander, we get that G is a $\Omega(\phi)$-expander (see Lemma 11). The following theorem summarizes the properties of this algorithm.

▶ **Theorem 14** ([21]'s cut-matching game for conductance). *Given a graph G and a parameter $\phi > 0$, there exists a randomized algorithm, whose running time is dominated by computing a polylogarithmic number of maximum flow problems, that either*

1. *Certifies that $\Phi(G) = \Omega(\phi)$ with high probability; or*
2. *Finds a cut $(S, V \setminus S)$ in G whose conductance is $\Phi_G(S, V \setminus S) = O(\phi \log n)$.*

The running time of the cut player is dominated by computing the projections in $O(m \log^3 n)$ time per iteration for a total of $O(m \log^5 n)$ time. The matching player solves $O(\log^2 n)$ maximum flow problems. Again, we can modify the algorithm so that its running time is $\tilde{O}(\frac{m}{\phi})$ or $\tilde{O}(m)$, similarly to the previous subsection.

[7] Computing these projections takes $O(m \log^3 n)$ time since F_t is a multiplication of $\Theta(\log^2 n)$ sparse matrices, each with $O(m)$ non-zero entries. Therefore W_t is a multiplication of $\Theta(\log^3 n)$ matrices, each of which is either P or a sparse matrix.

As in Section 3.1, the key part of the analysis is to show that F_T is indeed an $\Omega(1)$-expander for any choice of d_G-matchings of the matching player. Here we keep track of the progress of the cut player using the potential function

$$\psi(t) = \left\| (D^{-\frac{1}{2}} F_t D^{-\frac{1}{2}})^\delta - \frac{1}{2m}\sqrt{d}\sqrt{d'} \right\|_F^2 .$$

Recall that $W_t = (PD^{-\frac{1}{2}} F_t D^{-\frac{1}{2}} P)^\delta$, so we can rewrite the potential function as

$$\psi(t) = \left\| (D^{-\frac{1}{2}} F_t D^{-\frac{1}{2}})^\delta P \right\|_F^2 = \mathrm{Tr}(P(D^{-\frac{1}{2}} F_t D^{-\frac{1}{2}})^{2\delta} P) \overset{(4)}{=} \mathrm{Tr}((PD^{-\frac{1}{2}} F_t D^{-\frac{1}{2}} P)^{2\delta}) = \mathrm{Tr}(W_t^2) ,$$

where equality (4) follows since F_t is d-stochastic and the fact that $P^2 = P$. A careful argument shows that after $T = O(\log^2 n)$ iterations, $\psi(T) \leq 1/n$. From this we deduce that the second smallest eigenvalue of the normalized Laplacian of F_T is at least $1/2$ and then by Cheeger's inequality [7] we get that $\Phi(F_T) = \Omega(1)$.

4 Expander decomposition via spectral Cut-Matching

To put our main result in context we first show how SW [23] modified the cut-matching game of KRV [16] for their expander decomposition algorithm.

4.1 SW's Cut-Matching for expander decomposition

SW [23] take a recursive approach to find an expander decomposition. One can use the cut-matching game to find a sparse cut, but if the cut is unbalanced, we want to avoid recursing on the large side.

In order to refrain from recursing on the large side of the cut, SW changed the cut-matching game as follows. The cut player now maintains a partition of V into a small set R and a large set $A = V \setminus R$, where initially $R = \emptyset$ and $A = V$. In each iteration the cut and the matching player interact as follows.

- The cut player computes two disjoint sets $A^l, A^r \subseteq A$ such that $|A^l| \leq n/8$ and $|A^r| \geq n/2$.
- The matching player returns a partition $(S, A \setminus S)$ of A, which may be empty ($S = \emptyset$), and a matching of $A^l \setminus S$ to a subset of $A^r \setminus S$.

The cut player computes the sets A^l and A^r by projecting the rows of a *flow-matrix* F that it maintains (as in KRV [16]) onto a random unit vector r, and applying a result by [22] to generate the sets A^l and A^r from the values of the projections. For the matching player, SW use a flow-based algorithm which simultaneously gives a cut $(S, A \setminus S)$ of conductance $O(\phi \log^2 n)$ of $G[A]$, and a matching of the vertices left in $A^l \setminus S$ to vertices of $A^r \setminus S$ (S may be empty when $G[A]$ has conductance $\geq \phi$). If the matching player found a sparse cut $(S, A \setminus S)$ then the cut player updates the partition (R, A) of V by moving S from A to R.

The game terminates either when the volume of R gets larger than $\Omega(m/\log^2 n)$ or after $O(\log^2 n)$ rounds. In the latter case, SW proved that the remaining set A (which is large) is a near ϕ-expander in G (see Definition 9).

To prove that after $T = \Theta(\log^2 n)$ iterations, the remaining set A is a near ϕ-expander, SW essentially followed the footsteps of KRV and used a similar potential. The argument is more complicated since they have to take the shrinkage of A into account. SW did not use a version of KRV suitable to conductance as we give in the full version. Therefore, they had to modify the graph by adding a split node for each edge, essentially reducing conductance to edge-expansion, a reduction that made their algorithm and analysis somewhat more complicated. The following theorem summarized the properties of the cut-matching game of [23].

▶ **Theorem 15** (Theorem 2.2 of [23]). *Given a graph $G = (V, E)$ of m edges and a parameter $0 < \phi < 1/\log^2 n$,[8] there exists a randomized algorithm, called "the cut-matching step", which takes $O((m \log n)/\phi)$ time and terminates in one of the following three cases:*

1. *We certify that G has conductance $\Phi(G) = \Omega(\phi)$ with high probability.*
2. *We find a cut (R, A) of G of conductance $\Phi_G(R, A) = O(\phi \log^2 n)$, and $\mathbf{vol}(R), \mathbf{vol}(A)$ are both $\Omega(\frac{m}{\log^2 n})$, i.e., we find a relatively balanced low conductance cut.*
3. *We find a cut (R, A) of G with $\Phi_G(R, A) \leq c_0 \phi \log^2 n$ for some constant c_0, and $\mathbf{vol}(R) \leq \frac{m}{10c_0 \log^2 n}$, and with high probability A is a near ϕ-expander in G.*

SW derived an expander decomposition algorithm from this modified cut-matching game by recursing on both sides of the cut only if Case (2) occurs. In Case (3) they find a large subset $B \subseteq A$ which is an expander (in what they called the *trimming step*), add $A \setminus B$ to R and recur only on R. The main result of [23] is as follows.

▶ **Theorem 16** (Theorem 1.2 of [23]). *Given a graph $G = (V, E)$ of m edges and a parameter ϕ, there is a randomized algorithm that with high probability finds a partitioning of V into clusters $V_1, \ldots, V_k$ such that $\forall i : \Phi_{G\{V_i\}} = \Omega(\phi)$ and there are at most $O(\phi m \log^3 n)$ inter cluster edges.[9] The running time of the algorithm is $O(m \log^4 n/\phi)$.*

4.2 Our contribution: Spectral cut player for expander decomposition

SW [23] left open the question if one can improve their expander decomposition algorithm using tools similar to the ones that allowed OSVV [21] to improve the conductance approximation algorithm of KRV [16]. We give a positive answer to this question. Specifically we improve the cut-matching game of SW and derive the following improved version of Theorem 15.

▶ **Theorem 17.** *Given a graph $G = (V, E)$ of m edges and a parameter $0 < \phi < \frac{1}{\log n}$,[10] there exists a randomized algorithm which takes $O\left(m \log^5 n + \frac{m \log^2 n}{\phi}\right)$ time and must end in one of the following three cases:*

1. *We certify that G has conductance $\Phi(G) = \Omega(\phi)$ with high probability.*
2. *We find a cut (R, A) in G of conductance $\Phi_G(R, A) = O(\phi \log n)$, and $\mathbf{vol}(R), \mathbf{vol}(A)$ are both $\Omega(\frac{m}{\log n})$, i.e, we find a relatively balanced low conductance cut.*
3. *We find a cut (R, A) with $\Phi_G(R, A) \leq c_0 \phi \log n$ for some constant c_0, and $\mathbf{vol}(R) \leq \frac{m}{10c_0 \log n}$, and with high probability A is a near $\Omega(\phi)$-expander in G.*

The proof of Theorem 17 is given in Section 5. Theorem 17 implies the following theorem

▶ **Theorem 18.** *Given a graph $G = (V, E)$ of m edges and a parameter ϕ, there is a randomized algorithm that with high probability finds a partition of V into clusters $V_1, ..., V_k$ such that $\forall i : \Phi_{G\{V_i\}} = \Omega(\phi)$ and $\sum_i |E(V_i, V \setminus V_i)| = O(\phi m \log^2 n)$. The running time of the algorithm is $O(m \log^7 n + \frac{m \log^4 n}{\phi})$.*[11]

To get Theorem 17 we use the following cut player and matching player.

[8] The theorem is trivial if $\phi \geq \frac{1}{\log^2 n}$, because any cut $(A, V \setminus A)$ has conductance $\Phi_G(A, V \setminus A) \leq 1$. We can therefore assume that $\phi < \frac{1}{\log^2 n}$.

[9] $G\{V_i\}$ is defined in Definition 4.

[10] The theorem is trivial if $\phi \geq \frac{1}{\log n}$, because any cut $(A, V \setminus A)$ has conductance $\Phi_G(A, V \setminus A) \leq 1$. We can therefore assume that $\phi < \frac{1}{\log n}$.

[11] Note that if $\phi \leq \frac{1}{\log^3 n}$, then the running time matches the running time of [23] in Theorem 16. In case that $\phi \geq \frac{1}{\log^3 n}$, we get a slightly worse running time of $O(m \log^7 n)$ instead of $O(\frac{m \log^4 n}{\phi})$.

4.3 Cut player

Like in Section 3, we consider a d-stochastic flow matrix $F_t \in \mathbb{R}^{n\times n}$, and a series of graphs G_t. F_0 is initialized as $F_0 = D := \mathbf{diag}(d)$, and G_0 is initialized as the empty graph on $V = [n]$. Here the cut player also maintains a low conductance cut $A_t \subseteq V, R_t = V \setminus A_t$, such that after $T = \Theta(\log^2 n)$ rounds, with high probability, A_T is a near expander in G_T. At the beginning, $A_0 = V$, $R_0 = \emptyset$,

Since the new cut-matching game consists of iteratively shrinking the domain $A_t \subseteq V$, we start by generalizing our matrices from Section 3 to this context of shrinking domain.

▶ **Definition 19** ($I_t, d_t, D_t, P_t, \mathbf{vol}_t$). *We define the following variables*[12]

1. $I_t \in \mathbb{R}^{n\times n}$ *is the diagonal* $0/1$ *matrix that have* 1*'s on the diagonal entries corresponding to* A_t*.*
2. $d_t = I_t \cdot d \in \mathbb{R}^n$*, i.e the projection of* d *onto* A_t*.*
3. $D_t = I_t \cdot D = \mathbf{diag}(d_t) \in \mathbb{R}^{n\times n}$*.*
4. $\mathbf{vol}_t = \mathbf{vol}_G(A_t)$*.*
5. $P_t = I_t - \frac{1}{\mathbf{vol}_t}\sqrt{d_t}\sqrt{d_t'} \in \mathbb{R}^{n\times n}$*.*

We define the matrix $W_t = (P_t D^{-\frac{1}{2}} F_t D^{-\frac{1}{2}} P_t)^\delta$, where $\delta = \Theta(\log n)$ is set in Lemma 33, that plays a crucial role in this section. This definition is similar to the definition of W_t in Section 3.2, but with P_t instead of P. This makes us "focus" only on the remaining vertices A_t, as any row/column of W_t corresponding to a vertex $v \in R_t$ is zero. The matrix W_t is used in this section to define the projections that our algorithm uses to update F_t. It is also used in Section 5.3 to define the potential that measures how far is the remaining part of the graph from a near expander. In particular, we show in Lemma 33 and Corollary 34 that if W_T^2 has small eigenvalues (which will be the case when the potential is small) then A_T is near-expander in G_T.

Let $r \in \mathbb{R}^n$ be a random unit vector. Consider the projections $u_i = \frac{1}{\sqrt{d(i)}}\langle W_t(i), r\rangle$, for $i \in A_t$. Note that because $P_t\sqrt{d_t} = 0$, and W_t is symmetric:

$$\sum_{i\in A_t} d(i)u_i = \sum_{i\in A_t}\sqrt{d(i)}\,\langle W_t(i), r\rangle = \left\langle \sum_{i\in A_t}\sqrt{d(i)}W_t(i), r\right\rangle = \left\langle W_t\sqrt{d_t}, r\right\rangle = 0$$

We use the following lemma to partition (some of) the remaining vertices into two multisets A_t^l and A_t^r.[13] The lemma follows by applying Lemma 3.3 in [22] on the multiset of the u_i's, where each u_i appears with multiplicity of $d(i)$.

▶ **Lemma 20** (Lemma 3.3 in [22]). *Given* $u_i \in \mathbb{R}$ *for all* $i \in A_t$*, such that* $\sum_{i\in A_t} d(i)u_i = 0$*, we can find in time* $O(|A_t|\cdot\log(|A_t|))$ *a multiset of source nodes* $A_t^l \subseteq A_t$*, a multiset of target nodes* $A_t^r \subseteq A_t$*, and a separation value* η *such that each* $i \in A_t$ *appears in* $A_t^l \cup A_t^r$ *at most* $d(i)$ *times, and additionally:*

1. η *separates the sets* A_t^l, A_t^r*, i.e., either* $\max_{i\in A_t^l} u_i \le \eta \le \min_{j\in A_t^r} u_j$*, or* $\min_{i\in A_t^l} u_i \ge \eta \ge \max_{j\in A_t^r} u_j$*,*
2. $|A_t^r| \ge \frac{\mathbf{vol}_t}{2}$*,* $|A_t^l| \le \frac{\mathbf{vol}_t}{8}$*,*
3. $\forall i \in A_t^l : (u_i - \eta)^2 \ge \frac{1}{9}u_i^2$*,*
4. $\sum_{i\in A_t^l} m_i u_i^2 \ge \frac{1}{80}\sum_{i\in A_t} d(i)u_i^2$*, where* m_i *is the number of times* i *appears in* A_t^l*.*

[12] These variables are the analogs of $I, d, D, \mathbf{vol}(G)$ and P (respectively) from Section 3.2 in $G[A_t]$.
[13] Note that this does not produce a bisection of V.

Note that a vertex could appear both in A_t^l and in A_t^r, if $u_{i_j} = \eta$. The cut player sends A_t^l, A_t^r and A_t to the matching player.

In turn, the matching player (see Subsection 4.4) returns a cut $(S_t, A_t \setminus S_t)$ and a matching M_t of $A_t^l \setminus S_t$ to $A_t^r \setminus S_t$ (each vertex of A_t^l is matched to a vertex of A_t^r). We add self-loops to M_t to preserve the degrees (that is, M_t is d-stochastic). Define $N_t = \frac{\delta-1}{\delta} D + \frac{1}{\delta} M_t$. The cut player then updates F_t similarly to Section 3.2: $F_{t+1} = N_t \cdot D^{-1} F_t D^{-1} N_t$. Like in the previous sections, we also define the graph G_{t+1} as $G_{t+1} = G_t \cup M_t$.[14]. We define $A_{t+1} = A_t \setminus S_t$.

4.4 Matching player

The matching player receives A_t^l and A_t^r and the current A_t. For a vertex $v \in V$, denote by m_v the number times v appears in A_t^l, and by $\bar{m}_v$ the number of times v appears in A_t^r. The matching player solves the flow problem on $G[A_t]$, specified by Lemma 21 below. This lemma is similar to Lemma B.6 in [23] and is proved using the *Bounded-Distance-Flow* algorithm (called *Unit-Flow* by [13, 23]). The details are provided in the full version of this paper [1]. Note that we can get running time of $\tilde{O}(m)$ mentioned in the introduction by replacing this subroutine is with a fair-cut computation as shown in [17, Section 8].

▶ **Lemma 21.** *Let $G = (V, E)$ be a graph with n vertices and m edges, let $A^l, A^r \subseteq V$ be multisets such that $|A^r| \geq \frac{1}{2}m, |A^l| \leq \frac{1}{8}m$, and let $0 < \phi < \frac{1}{\log n}$ be a parameter. For a vertex $v \in V$, denote by m_v the number times v appears in A^l, and by $\bar{m}_v$ the number of times v appears in A^r. Assume that $m_v + \bar{m}_v \leq d(v)$. We define the flow problem $\Pi(G)$, as the problem in which a source s is connected to each vertex $v \in A^l$ with an edge of capacity m_v and each vertex $v \in A^r$ is connected to a sink t with an edge of capacity $\bar{m}_v$. Every edge of G has the same capacity $c = \Theta\left(\frac{1}{\phi \log n}\right)$, which is an integer. A feasible flow for $\Pi(G)$ is a maximum flow that saturates all the edges outgoing from s. Then, in time $O(\frac{m}{\phi})$, we can find either*

1. *A feasible flow f for $\Pi(G)$; or*
2. *A cut S where $\Phi_G(S, V \setminus S) \leq \frac{7}{c} = O(\phi \log n)$, $\mathbf{vol}(V \setminus S) \geq \frac{1}{3}m$ and a feasible flow for the problem $\Pi(G - S)$, where we only consider the sub-graph $G[V \setminus S \cup \{s, t\}]$ (that is, vertices $v \in A^l \setminus S$ are sources of m_v units, and vertices $v \in A^r \setminus S$ are sinks of $\bar{m}_v$ units).*

▶ Remark 22. It is possible that $A^l \subseteq S$, in which case the feasible flow for $\Pi(G - S)$ is trivial (the total source mass is 0).

Let S_t be the cut returned by the lemma. If the lemma terminates with the first case, we denote $S_t = \emptyset$. Since c is an integer, we can decompose the returned flow into a set of paths (using *e.g.* dynamic trees [26]), each carrying exactly one unit of flow from a vertex $u \in A_t^l \setminus S_t$ to a vertex $v \in A_t^r \setminus S_t$. Note that multiple paths can route flow between the same pair of vertices. If $u \in A_t^l \cap A_t^r$ then it is possible that a path starts and ends at u. Each $u \in A_t^l \setminus S_t$ is the endpoint of exactly $m_u \leq d(u)$ paths, and each $v \in A_t^r \setminus S_t$ is the endpoint of *at most* $\bar{m}_v \leq d(v)$ paths. Define the "matching"[15] $\tilde{M}_t$ as $\tilde{M}_t = ((u_i, v_i))_{i=1}^{|A_t^l \setminus S_t|}$, where u_i and v_i are the endpoints of path i. We can view $\tilde{M}_t$ as a symmetric $n \times n$ matrix, such that $\tilde{M}_t(u, v)$ is the number of paths from u to v. We turn $\tilde{M}_t$ into a d-stochastic matrix by increasing its diagonal entries by $d - \tilde{M}_t \mathbb{1}_n$. Formally, we set $M_t := \tilde{M}_t + \mathbf{diag}(d - \tilde{M}_t \mathbb{1}_n)$.

[14] G_{t+1} may have self-loops.

[15] Note that this is **not** a matching or a d-matching, but rather a graph that connects vertices of A_t^ℓ to vertices of A_t^r, whose degrees are bounded by d.

Notice that $d - \tilde{M}_t \mathbb{1}_n$ has only non-negative entries, so M_t also has non-negative entries. Intuitively, we can think of M_t as the response of the matching player to the subsets A_t^l and A_t^r given by the cut player.

5 Analysis

This section is organized as follows. Subsection 5.1 presents in detail the algorithm for Theorem 17. Subsection 5.2 shows that F_t is embeddable in G_t with congestion $\frac{4}{\delta}$ and that G_t is embeddable in G with congestion $c \cdot t$. Subsection 5.3 shows that if we reach round T, then with high probability, A_T is a near $\Omega(\phi)$-expander in G. Finally, in Subsection 5.4 we prove Theorem 17.

5.1 The Algorithm

Similarly to Section 3.2, let $\delta = \Theta(\log n)$ be a power of 2, let $T = \Theta(\log^2 n)$ and $c = \Theta(\frac{1}{\phi \log n})$. We choose c to be an integer. The algorithm follows along the same lines as the algorithm of SW in Section 4.1. The only modifications are the usage of our new cut player and that the algorithm stops if $\mathbf{vol}(R_t) > \frac{m \cdot c \cdot \phi}{70} = \Omega(\frac{m}{\log n})$. In each round t, we implicitly update F_t (see Section 4.3). Like SW, in order to keep the running time near linear, we use the flow routine *Bounded-Distance-Flow* [13, 23] which is mentioned in Subsection 4.4. This routine may also return a cut $S_t \subseteq A_t$ with $\Phi_{G[A]}(S_t, A_t \setminus S_t) \leq \frac{1}{c}$, in which case we "move" S_t to R_{t+1}. After T rounds, F_T certifies that the remaining part of A_T is a near ϕ-expander.

5.2 F_t is embeddable in G

To begin the analysis of the algorithm, we first define a blocked matrix. This notion will be useful when our matrices "operate" only on vertices of A_t.

▶ **Definition 23.** *Let $A \subseteq V$. A matrix $B \in \mathbb{R}^{n \times n}$ is* A-blocked *if $B(i,j) = 0$ for all $i \neq j$ such that $(i,j) \notin A \times A$.*

▶ **Lemma 24.** *The following holds for all t:*
1. *M_t, N_t, F_t and W_t are symmetric.*
2. *M_t, N_t and F_t are d-stochastic.*
3. *M_t and N_t are A_{t+1}-blocked.*

▶ **Lemma 25.** *For all rounds t, F_t is embeddable in G_t with congestion $\frac{4}{\delta}$.*

▶ **Lemma 26.** *For all rounds t, G_t is embeddable in G with congestion ct.*

5.3 A_T is a near expander in F_T

In this section we prove that after $T = \Theta(\log^2 n)$ rounds, with high probability, A_T is a near $\Omega(1)$-expander in F_T, which will imply that it is a near $\Omega(\phi)$-expander in G.

The section is organized as follows. Lemma 27 contains matrix identities and Lemma 28 specifies a spectral property that our proof requires. We then define a potential function and lower bound the decrease in potential in Lemmas 29-32. Finally, in Lemma 33 and Corollary 34 we use the lower bound on the potential at round T, to show that with high probability A_T is a near $\Omega(1)$-expander in F_T and a near $\Omega(\phi)$-expander in G.

▶ **Lemma 27.** *The following relations hold for all t:*
1. *For any A_t-blocked d-stochastic matrix $B \in \mathbb{R}^{n \times n}$ we have $I_t D^{-\frac{1}{2}} B D^{-\frac{1}{2}} = D^{-\frac{1}{2}} B D^{-\frac{1}{2}} I_t$ and $P_t \cdot D^{-\frac{1}{2}} B D^{-\frac{1}{2}} = D^{-\frac{1}{2}} B D^{-\frac{1}{2}} \cdot P_t$.*

2. $I_t P_t = P_t$, $I_t^2 = I_t$ *and* $P_t^2 = P_t$.
3. $P_t P_{t+1} = P_{t+1} P_t = P_{t+1}$.
4. $P_t = D^{-\frac{1}{2}} \mathcal{L}(\frac{1}{\mathbf{vol}_t} d_t d_t') D^{-\frac{1}{2}}$ *(recall the Laplacian defined in Definition 7).*
5. *for any* $v \in \mathbb{R}^n$*, it holds that* $v' \mathcal{L} \left(\frac{1}{\mathbf{vol}_t} d_t d_t' \right) v = \left\| D_t^{\frac{1}{2}} v \right\|_2^2 - \frac{1}{\mathbf{vol}_t} \langle v, d_t \rangle^2$.
6. *For any* $B \in \mathbb{R}^{n \times n}$, $\mathrm{Tr}(I_t B B') = \sum_{i \in A_t} \|B(i)\|_2^2$.

We define the potential $\psi(t) = \mathrm{Tr}[W_t^2] = \sum_{i \in A_t} \|W_t(i)\|_2^2$, where W_t was defined as $W_t = (P_t D^{-\frac{1}{2}} F_t D^{-\frac{1}{2}} P_t)^\delta$. This is the same potential from Section 3.2 with the new definition of W_t. Intuitively, by projecting using P_t instead of P, the potential only "cares" about the vertices of A_t. As show in Lemma 33, having small potential will certify that A_T is a near expander in F_t.

Before we bound the decrease in potential, we recall Definition 7 of a normalized Laplacian $\mathcal{N}(A) = D^{-\frac{1}{2}} \mathcal{L}(A) D^{-\frac{1}{2}} = I - D^{-\frac{1}{2}} A D^{-\frac{1}{2}}$, where A is a symmetric d-stochastic matrix.

▶ **Lemma 28.** *For any matrix* $A \in \mathbb{R}^{n \times n}$, $\mathrm{Tr}(A'(I - (D^{-\frac{1}{2}} N_t D^{-\frac{1}{2}})^{4\delta}) A) \geq \frac{1}{3} \mathrm{Tr}(A' \mathcal{N}(M_t) A)$.

The following lemma bounds the decrease in potential. The bound takes into account both the contribution of the matched vertices and the removal of S_t from A_t.

▶ **Lemma 29.** *For each round* t*,*

$$\psi(t) - \psi(t+1) \geq \frac{1}{3} \sum_{\{i,k\} \in M_t} \left\| \left(\frac{W_t(i)}{\sqrt{d(i)}} - \frac{W_t(k)}{\sqrt{d(k)}} \right) \right\|_2^2 + \sum_{j \in S_t} d(j) \left\| \frac{W_t(j)}{\sqrt{d(j)}} \right\|_2^2$$

Proof. To simplify the notation, we denote $\bar{N}_t := D^{-\frac{1}{2}} N_t D^{-\frac{1}{2}}$ and $\bar{F}_t := D^{-\frac{1}{2}} F_t D^{-\frac{1}{2}}$. We rewrite the potential in the next iteration as follows:

$$\begin{aligned}
\psi(t+1) &= \mathrm{Tr}(W_{t+1}^2) = \mathrm{Tr}\left(\left(P_{t+1} D^{-\frac{1}{2}} F_{t+1} D^{-\frac{1}{2}} P_{t+1} \right)^{2\delta} \right) \\
&= \mathrm{Tr}\left(\left(P_{t+1} D^{-\frac{1}{2}} (N_t D^{-1} F_t D^{-1} N_t) D^{-\frac{1}{2}} P_{t+1} \right)^{2\delta} \right) \\
&= \mathrm{Tr}\left(\left(P_{t+1} D^{-\frac{1}{2}} (N_t D^{-\frac{1}{2}} D^{-\frac{1}{2}} F_t D^{-\frac{1}{2}} D^{-\frac{1}{2}} N_t) D^{-\frac{1}{2}} P_{t+1} \right)^{2\delta} \right) \\
&= \mathrm{Tr}\left(\left(P_{t+1} \bar{N}_t \bar{F}_t \bar{N}_t P_{t+1} \right)^{2\delta} \right) \overset{(6)}{=} \mathrm{Tr}\left(\left(\bar{N}_t P_{t+1} \bar{F}_t P_{t+1} \bar{N}_t \right)^{2\delta} \right) \\
&\overset{(7)}{=} \mathrm{Tr}\left(\left(\bar{N}_t P_{t+1} P_t \bar{F}_t P_t P_{t+1} \bar{N}_t \right)^{2\delta} \right) = \mathrm{Tr}\left(\left(\bar{N}_t P_{t+1} (P_t \bar{F}_t P_t) P_{t+1} \bar{N}_t \right)^{2\delta} \right) ,
\end{aligned}$$

where equality (6) follows from Lemma 27 (1) for N_t (which is A_{t+1}-blocked d-stochastic by Lemma 24), and equality (7) follows from Lemma 27 (3).

By Properties (1) and (2) of Lemma 27 it holds that $\bar{N}_{t+1} P_{t+1} = P_{t+1} \bar{N}_{t+1} = P_{t+1} \bar{N}_{t+1} P_{t+1}$. Therefore, the potential can be written in terms of symmetric matrices:

$$\begin{aligned}
\psi(t+1) &= \mathrm{Tr}\left(\left((P_{t+1} \bar{N}_t P_{t+1})(P_t \bar{F}_t P_t)(P_{t+1} \bar{N}_t P_{t+1}) \right)^{2\delta} \right) \\
&\leq \mathrm{Tr}((P_{t+1} \bar{N}_t P_{t+1})^{2\delta} (P_t \bar{F}_t P_t)^{2\delta} (P_{t+1} \bar{N}_t P_{t+1})^{2\delta}) \\
&\overset{(2)}{=} \mathrm{Tr}((P_{t+1} \bar{N}_t P_{t+1})^{4\delta} (P_t \bar{F}_t P_t)^{2\delta}) = \mathrm{Tr}((\bar{N}_t P_{t+1})^{4\delta} W_t^2) \\
&\overset{(4)}{=} \mathrm{Tr}(\bar{N}_t^{4\delta} P_{t+1} W_t^2) \overset{(5)}{=} \mathrm{Tr}(\bar{N}_t^{2\delta} P_{t+1} \bar{N}_t^{2\delta} W_t^2) \overset{(6)}{=} \mathrm{Tr}(W_t \bar{N}_t^{2\delta} P_{t+1} \bar{N}_t^{2\delta} W_t) \\
&\overset{(7)}{=} \mathrm{Tr}(W_t \bar{N}_t^{2\delta} D^{-\frac{1}{2}} \mathcal{L}\left(\frac{1}{\mathbf{vol}_{t+1}} d_{t+1} d_{t+1}' \right) D^{-\frac{1}{2}} \bar{N}_t^{2\delta} W_t) \\
&= \mathrm{Tr}\left(\left(D^{-\frac{1}{2}} \cdot \bar{N}_t^{2\delta} W_t \right)' \cdot \mathcal{L}\left(\frac{1}{\mathbf{vol}_{t+1}} d_{t+1} d_{t+1}' \right) \cdot \left(D^{-\frac{1}{2}} \cdot \bar{N}_t^{2\delta} W_t \right) \right) ,
\end{aligned}$$

where the inequality follows from Fact 2, equality (2) follows from Fact 1. Equalities (4) and (5) follow from Properties (1) and (2) of Lemma 27 (and from the fact that N_t is A_{t+1}-blocked d-stochastic, by Lemma 24). Equality (6) again uses Fact 1, and equality (7) follows from Lemma 27 (4).

Let $Z_t = D^{-\frac{1}{2}} \cdot \bar{N}_t^{2\delta} W_t$. By applying Lemma 27 (5) we get

$$\begin{aligned}
\psi(t+1) &\leq \operatorname{Tr}\left(Z_t' \mathcal{L}\left(\frac{1}{\mathbf{vol}_{t+1}} d_{t+1} d_{t+1}'\right) Z_t\right) = \sum_{i=1}^{n} (Z_t(,i))' \mathcal{L}\left(\frac{1}{\mathbf{vol}_{t+1}} d_{t+1} d_{t+1}'\right) Z_t(,i) \\
&\overset{(2)}{=} \sum_{i=1}^{n} \left(\left\| D_{t+1}^{\frac{1}{2}} Z_t(,i) \right\|_2^2 - \frac{1}{\mathbf{vol}_{t+1}} \langle Z_t(,i), d_{t+1} \rangle^2\right) \leq \sum_{i=1}^{n} \left\| D_{t+1}^{\frac{1}{2}} Z_t(,i) \right\|_2^2 \\
&= \sum_{i=1}^{n} \sum_{j \in A_{t+1}} \left(\sqrt{d(j)} Z_t(j,i)\right)^2 = \sum_{j \in A_{t+1}} \left\| \left(D_{t+1}^{\frac{1}{2}} Z_t\right)(j) \right\|_2^2 \overset{(5)}{=} \sum_{j \in A_{t+1}} \left\| \left(\bar{N}_t^{2\delta} W_t\right)(j) \right\|_2^2 \\
&= \sum_{j \in A_t} \left\| \left(\bar{N}_t^{2\delta} W_t\right)(j) \right\|_2^2 - \sum_{j \in S_t} \left\| \left(\bar{N}_t^{2\delta} W_t\right)(j) \right\|_2^2, \qquad (1)
\end{aligned}$$

where equality (2) holds by Property (5) of Lemma 27 and equality (5) holds since we only sum rows in A_{t+1}. Since $\bar{N}_t$ is diagonal outside A_{t+1} (by the definition of M_t), we have that $\left(\bar{N}_t^{2\delta} W_t\right)(j) = W_t(j)$, for every $j \in S_t$. Thus,

$$\sum_{j \in S_t} \left\| \left(\bar{N}_t^{2\delta} W_t\right)(j) \right\|_2^2 = \sum_{j \in S_t} \|W_t(j)\|_2^2 . \qquad (2)$$

By Lemma 27 (6), we get

$$\begin{aligned}
\sum_{j \in A_t} \left\| \left(\bar{N}_t^{2\delta} W_t\right)(j) \right\|_2^2 &= \operatorname{Tr}(I_t \cdot \bar{N}_t^{2\delta} \cdot W_t^2 \cdot \bar{N}_t^{2\delta}) = \operatorname{Tr}(\bar{N}_t^{2\delta} \cdot I_t \cdot W_t^2 \cdot \bar{N}_t^{2\delta}) \\
&= \operatorname{Tr}(\bar{N}_t^{2\delta} \cdot W_t^2 \cdot \bar{N}_t^{2\delta}) = \operatorname{Tr}(\bar{N}_t^{4\delta} W_t^2) \qquad (3)
\end{aligned}$$

where second equality holds since N_t is A_{t+1}-blocked d-stochastic (by Lemma 24), so in particular it is A_t-blocked d-stochastic, and we can use Lemma 27 (1). The third equality holds because $I_t W_t = I_t (P_t \bar{F}_t P_t)^\delta$ and $I_t P_t = P_t$ (by Lemma 27 (2)), and the last equality follows from Fact 1. Plugging Equations (2) and (3) into (1) we get the following bound on the decrease in potential:

$$\begin{aligned}
\psi(t) - \psi(t+1) &\geq \operatorname{Tr}((I - \bar{N}_t^{4\delta}) W_t^2) + \sum_{j \in S_t} \|W_t(j)\|_2^2 \\
&= \operatorname{Tr}(W_t (I - \bar{N}_t^{4\delta}) W_t) + \sum_{j \in S_t} \|W_t(j)\|_2^2 \geq \frac{1}{3} \operatorname{Tr}(W_t \mathcal{N}(M_t) W_t) + \sum_{j \in S_t} \|W_t(j)\|_2^2 \\
&= \frac{1}{3} \operatorname{Tr}((D^{-\frac{1}{2}} W_t)' \mathcal{L}(M_t)(D^{-\frac{1}{2}} W_t)) + \sum_{j \in S_t} d(j) \left\| \frac{W_t(j)}{\sqrt{d(j)}} \right\|_2^2 \\
&= \frac{1}{3} \sum_{\{i,k\} \in M_t} \left\| \frac{W_t(i)}{\sqrt{d(i)}} - \frac{W_t(k)}{\sqrt{d(k)}} \right\|_2^2 + \sum_{j \in S_t} d(j) \left\| \frac{W_t(j)}{\sqrt{d(j)}} \right\|_2^2
\end{aligned}$$

where the second inequality follows Lemma 28, and the last equality follows from by Laplacian matrix properties. ◀

The following lemma states that the potential is expected to drop by a factor of $1 - \Omega(1/\log n)$.

▶ **Lemma 30.** *For each round t,*

$$\mathbb{E}\left[\frac{1}{3}\sum_{\{i,k\}\in M_t}\left\|\frac{W_t(i)}{\sqrt{d(i)}}-\frac{W_t(k)}{\sqrt{d(k)}}\right\|_2^2+\sum_{j\in S_t}d(j)\left\|\frac{W_t(j)}{\sqrt{d(j)}}\right\|_2^2\right]\geq\frac{1}{3000\alpha\log n}\psi(t)-\frac{3}{n^{\alpha/16}}$$

for every $\alpha > 48$, where the expectation is over the unit vector $r \in \mathbb{R}^n$.

The following two corollaries follow by Lemmas 29 and 30.

▶ **Corollary 31.** *For each round t, $\mathbb{E}[\psi(t+1)] \leq \left(1-\frac{1}{3000\alpha\log n}\right)\psi(t)+\frac{3}{n^{\alpha/16}}$, where the expectation is over the unit vector $r \in \mathbb{R}^n$.*

▶ **Corollary 32** (Total Decrease in Potential)**.** *With high probability over the choices of r, $\psi(T) \leq \frac{1}{n}$.*

The following lemma uses the low potential to derive the near-expansion of A_T in F_T.

▶ **Lemma 33** (Variation of Cheeger's inequality)**.** *Let $H = (V, \bar{E})$ be a graph on n vertices, such that F_T is its weighted adjacency matrix. Assume that $\psi(T) \leq \frac{1}{n}$. Then, A_T is a near $\frac{1}{5}$-expander in H.*

Proof. Recall that F_T is symmetric and d-stochastic. Let $k = \mathbf{vol}(A_T)$. Let $S \subseteq A_T$ be a cut, and denote $d_S \in \mathbb{R}^n$ to be the vector where $d_S(u) = \begin{cases} d(u) & \text{if } u \in S, \\ 0 & \text{otherwise.} \end{cases}$ Additionally, denote $\ell = \mathbf{vol}(S) \leq \frac{1}{2}k$. Note that $\left\|\sqrt{d_S}\right\|_2^2 = \ell$.

Denote by $\bar{\lambda} \geq 0$ the largest singular value of $X_T := P_T D^{-\frac{1}{2}} F_T D^{-\frac{1}{2}} P_T$ (square root of the largest eigenvalue of $(P_T D^{-\frac{1}{2}} F_T D^{-\frac{1}{2}} P_T)^2$). Because $\mathrm{Tr}(X_T^{2\delta}) = \psi(T) \leq \frac{1}{n}$, we have in particular that the largest eigenvalue of $X_T^{2\delta}$ is at most $\frac{1}{n}$, so we have $\bar{\lambda} \leq \frac{1}{n^{\frac{1}{\delta}}}$. We choose $\delta = \Theta(\log n)$ such that $\frac{1}{n^{\frac{1}{\delta}}} \leq \frac{1}{20}$, so $\bar{\lambda} \leq \frac{1}{20}$.

In order to prove near-expansion we need to lower bound $|E_{F_T}(S, V \setminus S)|$. We do so by upper bounding $|E_{F_T}(S, S)| = \mathbb{1}_S' F_T \mathbb{1}_S$. Note that $\mathbb{1}_S' F_T \mathbb{1}_S = \mathbb{1}_S'(I_T F_T I_T)\mathbb{1}_S$. Observe the following relation between X_T and $I_T F_T I_T$:

$$\begin{aligned}
D^{\frac{1}{2}} X_T D^{\frac{1}{2}} &= D^{\frac{1}{2}}(P_T D^{-\frac{1}{2}} F_T D^{-\frac{1}{2}} P_T) D^{\frac{1}{2}} \\
&= D^{\frac{1}{2}}(I_T - \frac{1}{k}\sqrt{d_T}\sqrt{d_T'}) D^{-\frac{1}{2}} F_T D^{-\frac{1}{2}} (I_T - \frac{1}{k}\sqrt{d_T}\sqrt{d_T'}) D^{\frac{1}{2}} \\
&= (I_T - \frac{1}{k} d_T \mathbb{1}_T') F_T (I_T - \frac{1}{k}\mathbb{1}_T d_T') \\
&= I_T F_T I_T - \frac{1}{k} d_T \mathbb{1}_T' F_T I_T - \frac{1}{k} I_T F_T \mathbb{1}_T d_T' + \frac{1}{k^2} d_T \mathbb{1}_T' F_T \mathbb{1}_T d_T'.
\end{aligned}$$

Rearranging the terms, we get

$$I_T F_T I_T = D^{\frac{1}{2}} X_T D^{\frac{1}{2}} + \frac{1}{k} d_T \mathbb{1}_T' F_T I_T + \frac{1}{k} I_T F_T \mathbb{1}_T d_T' - \frac{1}{k^2} d_T \mathbb{1}_T' F_T \mathbb{1}_T d_T' \ .$$

Therefore

$$\begin{aligned}
|E_{F_T}(S, S)| &= \mathbb{1}_S' F_T \mathbb{1}_S \\
&= \mathbb{1}_S' \left(D^{\frac{1}{2}} X_T D^{\frac{1}{2}} + \frac{1}{k} d_T \mathbb{1}_T' F_T I_T + \frac{1}{k} I_T F_T \mathbb{1}_T d_T' - \frac{1}{k^2} d_T \mathbb{1}_T' F_T \mathbb{1}_T d_T' \right) \mathbb{1}_S.
\end{aligned}$$

We analyze the summands separately. The first summand can be bounded using $\bar{\lambda}$, the largest singular value of X_T:

$$\mathbb{1}'_S D^{\frac{1}{2}} X_T D^{\frac{1}{2}} \mathbb{1}_S = \sqrt{d'_S} X \sqrt{d_S} = \left\langle \sqrt{d_S}, X\sqrt{d_S} \right\rangle \leq \left\| \sqrt{d_S} \right\|_2 \left\| X_T \sqrt{d_S} \right\|_2 \leq \left\| \sqrt{d_S} \right\|_2^2 \bar{\lambda} \leq \frac{\ell}{20},$$

where the first inequality is the Cauchy-Schwartz inequality. Observe that the second and third summands are equal:

$$\frac{1}{k}\mathbb{1}'_S d_T \mathbb{1}'_T F_T I_T \mathbb{1}_S = \frac{\ell}{k}\mathbb{1}'_T F_T \mathbb{1}_S = \frac{\ell}{k}\mathbb{1}'_S F_T \mathbb{1}_T = \frac{1}{k}\mathbb{1}'_S I_T F_T \mathbb{1}_T d'_T \mathbb{1}_S,$$

where the second equality follows by transposing and since F_T is symmetric. We now bound the sum of the second, third and fourth summands:

$$\mathbb{1}'_S \left(\frac{1}{k} d_T \mathbb{1}'_T F_T I_T + \frac{1}{k} I_T F_T \mathbb{1}_T d'_T - \frac{1}{k^2} d_T \mathbb{1}'_T F_T \mathbb{1}_T d'_T \right) \mathbb{1}_S = \frac{2\ell}{k}\mathbb{1}'_T F_T \mathbb{1}_S - \frac{\ell^2}{k^2}\mathbb{1}'_T F_T \mathbb{1}_T$$
$$\leq \left(\frac{2\ell}{k} - \frac{\ell^2}{k^2} \right) \mathbb{1}'_T F_T \mathbb{1}_S \leq \left(\frac{2\ell}{k} - \frac{\ell^2}{k^2} \right) \mathbb{1}' F_T \mathbb{1}_S = \left(\frac{2\ell}{k} - \frac{\ell^2}{k^2} \right) d' \mathbb{1}_S = \frac{\ell}{k}\left(2 - \frac{\ell}{k}\right)\ell,$$

where the first inequality follows since $S \subseteq A_t$. Note that $\frac{\ell}{k} \in [0, \frac{1}{2}]$. The last inequality is true because for $\frac{\ell}{k}$ in this range, $\left(\frac{2\ell}{k} - \frac{\ell^2}{k^2} \right) \geq 0$. Moreover, because $\frac{\ell}{k} \in \left[0, \frac{1}{2}\right]$, we have $\frac{\ell}{k}\left(2 - \frac{\ell}{k}\right) \leq \frac{3}{4}$. Therefore, $|E_{F_T}(S, S)| \leq \frac{1}{20}\ell + \frac{3}{4}\ell = \frac{4}{5}\ell$, and

$$|E(S, V \setminus S)| = \sum_{u \in S} \sum_{v \in V \setminus S} F_T(u, v) = \sum_{u \in S} \sum_{v \in V} F_T(u, v) - \sum_{u \in S} \sum_{v \in S} F_T(u, v)$$
$$= \sum_{u \in S} d(u) - \sum_{u \in S} \sum_{v \in S} F_T(u, v) \geq \ell - \frac{4}{5}\ell = \frac{\ell}{5}\ .$$

So $\Phi_G(S, V \setminus S) = \frac{|E(S, V \setminus S)|}{\mathbf{vol}(S)} \geq \frac{1}{5}$, and this is true for all cuts $S \subseteq A$ with $\frac{\mathbf{vol}(S)}{\mathbf{vol}(A)} \leq \frac{1}{2}$. ◀

▶ **Corollary 34.** *If we reach round T, then with high probability, A_T is a near $\Omega(\phi)$-expander in G.*

Proof. Assume we reach round T. By Corollary 32 and Lemma 33, with high probability, A_T is a near $\Omega(1)$-expander in F_T. By Lemma 25, F_T is embeddable in G_T with congestion $O(\frac{1}{\delta})$. Note that G_T is a union of T d_G-matchings $\{M_t\}_{t=1}^T$, each having $d_{M_t} = d_G = d_{F_T}$. Therefore, $d_{G_T} = T \cdot d_{F_T}$. So by Lemma 11, A_T is a near $\Omega(\frac{\delta}{T})$-expander in G_T. By Lemma 26, G_T is embeddable in G with congestion cT. Together with the fact that $d_G = \frac{1}{T} \cdot d_{G_T}$, we get by Lemma 11 again, that A is a near $\Omega(\frac{\delta}{cT})$-expander in G. Recall that $c = O\left(\frac{1}{\phi \log n}\right)$, $\delta = \Theta(\log n)$, and $T = O(\log^2 n)$. Therefore, A is an near $\Omega(\phi)$-expander in G. ◀

5.4 Proof of Theorem 17

We are now ready to prove Theorem 17.

Proof of Theorem 17. Recall that S_t denotes the cut returned by Lemma 21 at iteration t, so that $A_{t+1} = A_t \setminus S_t$.

Observe first that in any round t, we have $\Phi_G(A_t, R_t) \leq \frac{7}{c} = O(\phi \log n)$. This is because $R_t = \bigcup_{0 \leq t' < t} S_{t'}$ and by Lemma 21, for each t', $\Phi_{G[A_{t'}]}(S_{t'}, V \setminus S_{t'}) \leq \frac{7}{c} = O(\phi \log n)$.

Assume the algorithm terminates because $\mathbf{vol}(R_t) > \frac{m \cdot c \cdot \phi}{70} = \Omega(\frac{m}{\log n})$. We also have, by Lemma 21, that $\mathbf{vol}(A_t) = \Omega(m) = \Omega(\frac{m}{\log n})$. Then (A_t, R_t) is a balanced cut where $\Phi_G(A_t, R_t) = O(\phi \log n)$. We end in Case (2) of Theorem 17.

Otherwise, the algorithm reached round T and we apply Corollary 34. If $R = \emptyset$, then we obtain the first case of Theorem 17 because the whole vertex set V is, with high probability, a near $\Omega(\phi)$-expander, which means that G is an $\Omega(\phi)$-expander. Otherwise, we write $c = \frac{c_1}{\phi \log n}$ for some constant c_1, and let $c_0 := \frac{7}{c_1}$. We have $\Phi_G(A_T, R_T) \leq \frac{7}{c} = \frac{7}{c_1}\phi \log n = c_0 \phi \log n$. Additionally, $\mathbf{vol}(R_T) \leq \frac{m \cdot c \cdot \phi}{70} = \frac{m \cdot c_1}{70 \log n} = \frac{m}{10 c_0 \log n}$, and, with high probability, A_T is a near $\Omega(\phi)$-expander in G, which means we obtain the third case of Theorem 17.

To bound the running time, note that the algorithm performs at most $T = \Theta(\log^2 n)$ iterations and each iteration's running time is dominated by computing $W_t \cdot r$ in $O(t \cdot \delta \cdot m)$ and by running the matching player (Lemma 21) in $O(\frac{m}{\phi})$. ◀

Abstract

In this work, we give a unifying view of locality in four settings: distributed algorithms, sequential greedy algorithms, dynamic algorithms, and online algorithms. We introduce a new model of computing, called the online-LOCAL model: the adversary presents the nodes of the input graph one by one, in the same way as in classical online algorithms, but for each node we get to see its radius-T neighborhood before choosing the output. Instead of *looking ahead* in time, we have the power of *looking around* in space.

We compare the online-LOCAL model with three other models: the LOCAL model of distributed computing, where each node produces its output based on its radius-T neighborhood, the SLOCAL model, which is the sequential counterpart of LOCAL, and the dynamic-LOCAL model, where changes in the dynamic input graph only influence the radius-T neighborhood of the point of change.

The SLOCAL and dynamic-LOCAL models are sandwiched between the LOCAL and online-LOCAL models. In general, all four models are distinct, but we study in particular *locally checkable labeling problems* (LCLs), which is a family of graph problems extensively studied in the context of distributed graph algorithms. We prove that for LCL problems in paths, cycles, and rooted trees, all four models are roughly equivalent: the locality of any LCL problem falls in the same broad class – $O(\log^* n)$, $\Theta(\log n)$, or $n^{\Theta(1)}$ – in all four models. In particular, this result enables one to generalize prior lower-bound results from the LOCAL model to all four models, and it also allows one to simulate e.g. dynamic-LOCAL algorithms efficiently in the LOCAL model.

We also show that this equivalence does not hold in two-dimensional grids or general bipartite graphs. We provide an online-LOCAL algorithm with locality $O(\log n)$ for the 3-coloring problem in bipartite graphs – this is a problem with locality $\Omega(n^{1/2})$ in the LOCAL model and $\Omega(n^{1/10})$ in the SLOCAL model.

1 Introduction

In *online graph algorithms*, the adversary reveals the input graph one node at a time: In step i, the adversary presents some node v_i. The algorithm gets to see the subgraph induced by the nodes $v_1, \ldots, v_i$, and the algorithm has to respond by labeling node v_i. For example, in *online graph coloring*, the algorithm has to pick a color for node v_i in such a way that the end result is a proper coloring of the input graph.

In this work, we consider a more general setting, which we call the online-LOCAL model: in step i, the algorithm gets to see the subgraph induced by all nodes that are within distance T from $v_1, \ldots, v_i$. That is, the algorithm can look T hops further in the input graph around the nodes presented by the adversary. For $T = 0$, this corresponds to the usual online model. For $T = n$, on the other hand, any graph problem (in connected graphs) is solvable in this setting. The key question is what value of T is sufficient for a given graph problem. Put otherwise, what is the *locality* of a given online problem?

It turns out that this question is very closely connected to questions studied in the context of *distributed* graph algorithms, and we can identify problem classes in which the online setting coincides with the distributed setting. However, we also see surprising differences, the prime example being the problem of 3-coloring bipartite graphs, which is a fundamentally *global* problem in the distributed setting, while we show that we can do much better in the online setting.

1.1 Contribution 1: landscape of models

In Section 2, we define the online-LOCAL model, and we also recall the definitions of three models familiar from the fields of distributed and dynamic graph algorithms:

- The LOCAL model [37, 44]: the nodes are processed *simultaneously* in parallel; each node looks at its radius-T neighborhood and picks its own output.
- The SLOCAL model [26]: the nodes are processed *sequentially* in an adversarial order; each node in its turn looks at its radius-T neighborhood and picks its own output (note that here the output of a node may depend on the outputs of other nodes that were previously processed).
- The dynamic-LOCAL model: the adversary *constructs* the graph by adding nodes and edges one by one; after each modification, the algorithm can only update the solution within the radius-T neighborhood of the point of change. While this is not one of the standard models, there is a number of papers [3, 9, 11, 21, 28, 34, 43] that implicitly make use of this model. We also occasionally consider the dynamic-LOCAL$^{\pm}$ model, in which we can have both additions and deletions.

In Section 3, we show that we can sandwich SLOCAL and both versions of dynamic-LOCAL between LOCAL and online-LOCAL, as shown in Figure 1. In particular, this implies that if we can prove that LOCAL and online-LOCAL are equally expressive for some family of graph problems, we immediately get the same result also for SLOCAL and dynamic-LOCAL. This is indeed what we achieve in our next contribution.

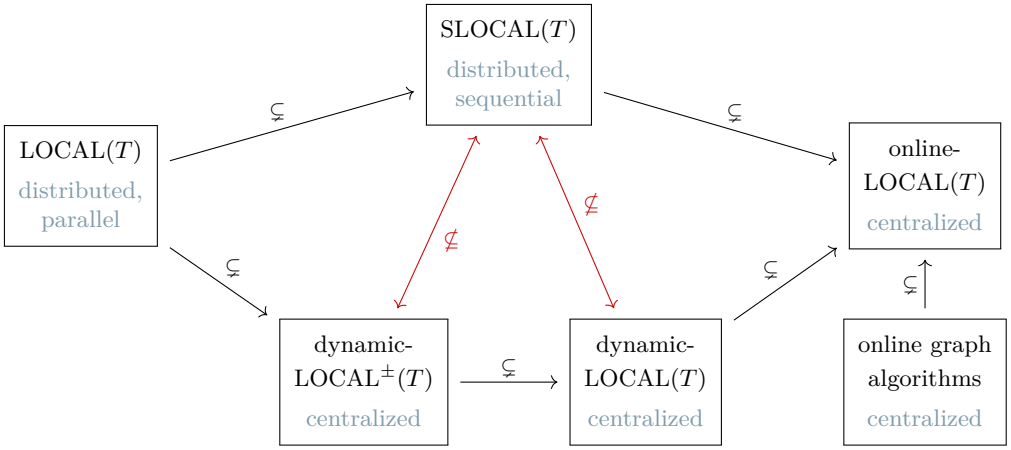

Figure 1 The landscape of models – see Section 2 for the definitions. Each box represents the set of problems solvable with locality $O(T)$ in the given model of computation (except for online graph algorithms, which do not have a notion of locality). For example, any problem with locality $O(T)$ in the LOCAL model can also be solved with locality $O(T)$ in both the SLOCAL and the online-LOCAL models. On the other hand, the SLOCAL and the dynamic-LOCAL models are incomparable, as there exist problems that are solvable with locality $O(T)$ in one of the models but that require $\omega(T)$ locality in the other model.

1.2 Contribution 2: collapse for LCLs in rooted regular trees

A lot of focus in the study of distributed graph algorithms and the LOCAL model has been on understanding *locally checkable labeling problems* (in brief, LCLs) [4,5,7,8,13,15,17,18,42]. These are problems where feasible solutions are defined with local constraints – a solution is feasible if it looks good in all constant-radius neighborhoods (see Definition 3). Coloring graphs of maximum degree Δ with k colors (for some constants Δ and k) is an example of an LCL problem.

In Section 5, we study LCL problems in *paths*, *cycles*, and *rooted regular trees*, and we show that all four models are approximately equally strong in these settings – see Table 1. For example, we show that if the locality of an LCL problem in rooted trees is $n^{\Theta(1)}$ in the LOCAL model, it is also $n^{\Theta(1)}$ in the dynamic-LOCAL, SLOCAL, and online-LOCAL models.

Table 1 In all four models, LCL problems have got the same locality classes in paths, cycles, and rooted trees. Here $n^{\Theta(1)}$ refers to locality $\Theta(n^\alpha)$ for some constant $\alpha > 0$. See Section 5 for more details.

	LOCAL		SLOCAL		dynamic-LOCAL		online-LOCAL
LCLs in paths and cycles	$O(\log^* n)$	$\Leftrightarrow$	$O(1)$	$\Leftrightarrow$	$O(1)$	$\Leftrightarrow$	$O(1)$
	$\Theta(n)$	$\Leftrightarrow$	$\Theta(n)$	$\Leftrightarrow$	$\Theta(n)$	$\Leftrightarrow$	$\Theta(n)$
LCLs in rooted regular trees	$O(\log^* n)$	$\Leftrightarrow$	$O(1)$	$\Leftrightarrow$	$O(1)$	$\Leftrightarrow$	$O(1)$
	$\Theta(\log n)$	$\Leftrightarrow$	$\Theta(\log n)$	$\Leftrightarrow$	$\Theta(\log n)$	$\Leftrightarrow$	$\Theta(\log n)$
	$n^{\Theta(1)}$	$\Leftrightarrow$	$n^{\Theta(1)}$	$\Leftrightarrow$	$n^{\Theta(1)}$	$\Leftrightarrow$	$n^{\Theta(1)}$

By previous work, we know that LCL complexities in paths, cycles, and rooted regular trees are *decidable* in the LOCAL model [4, 7, 18]. Our equivalence result allows us to extend this decidability to the SLOCAL, dynamic-LOCAL, and online-LOCAL models. For example, there is an algorithm that gets as input the description of an LCL problem in rooted trees and produces as output in which of the classes of Table 1 it is, for any of the four models.

1.3 Contribution 3: 3-coloring bipartite graphs in online-LOCAL

Given the equivalence results for LCLs in paths, cycles, and rooted regular trees, it would be tempting to conjecture that the models are approximately equal for LCLs in any graph class. In Section 4, we show that this is not the case: we provide an exponential separation between the SLOCAL and online-LOCAL models for the problem of 3-coloring bipartite graphs. By prior work it is known that in the LOCAL model, the locality of 3-coloring is $\Omega(n^{1/2})$ in two-dimensional grids [13], which are a special case of bipartite graphs; using this result we can derive a lower bound of $\Omega(n^{1/10})$ also for the SLOCAL model (see the full version). In Section 4, we prove the following:

▶ **Theorem 1.** *There is an online-LOCAL algorithm that finds a* 3*-coloring in bipartite graphs with locality* $O(\log n)$*.*

That is, in bipartite graphs, there is an LCL problem that requires locality $n^{\Omega(1)}$ in the LOCAL and SLOCAL models and is solvable with locality $O(\log n)$ in the online-LOCAL model.

The algorithm that we present for coloring bipartite graphs is also interesting from the perspective of competitive analysis of online algorithms. With locality $O(\log n)$, the online-LOCAL algorithm can compute a 3-coloring. Since bipartite graphs are 2-colorable, this gives us a 1.5-competitive online-LOCAL algorithm. On the other hand, it has been shown that any online algorithm for coloring bipartite graphs is at least $\Omega(\log n)$-competitive [10], with a matching algorithm presented in [38]. This result shows how much the competitive ratio of an algorithm can be improved by increasing the view of each node.

1.4 Contribution 4: locality of online coloring

As a corollary of our work, together with results on distributed graph coloring from prior work [13, 19, 37], we now have a near-complete understanding of the locality of graph coloring in paths, cycles, rooted trees, and grids in both distributed and online settings. Table 2 summarizes our key results. For the proofs of the localities in the online-LOCAL model, see Sections 4 and 5.

1.5 Motivation

Before we discuss the key technical ideas, we briefly explain the practical motivation for the study of online-LOCAL and dynamic-LOCAL models. As a running example, consider the challenge of providing public services (e.g. local schools) in a rapidly growing city. The future is unknown, depending on future political decisions, yet the residents need services every day.

The offline solution would result in a city-wide redesign of e.g. the entire school network every time the city plan is revised; this is not only costly but also disruptive. On the other hand, a strict online solution without any consideration of the future would commit to a solution that is far from optimal. The models that we study in this work capture the essence of two natural strategies for coping with such a situation:

Table 2 The locality of the vertex coloring problem in distributed vs. online settings, for two graph families: rooted trees and paths (with n nodes) and 2-dimensional grids (with $\sqrt{n} \times \sqrt{n}$ nodes). Note that most results for the online-LOCAL model follow from the equivalence results discussed in Section 1.2. See Sections 4 and 5 and the full version for more details.

	colors	competitive ratio	LOCAL	SLOCAL	online-LOCAL	references
Rooted trees and paths	2	1	$\Theta(n)$	$\Theta(n)$	$\Theta(n)$	trivial
	3	1.5	$\Theta(\log^* n)$	$O(1)$	$O(1)$	[19, 37]
	4	2	$\Theta(\log^* n)$	$O(1)$	$O(1)$	[19, 37]
	...					
Grids	2	1	$\Theta(n^{1/2})$	$\Theta(n^{1/2})$	$\Theta(n^{1/2})$	trivial
	3	1.5	$\Theta(n^{1/2})$	$\boldsymbol{\Omega(n^{1/10})}$	$\boldsymbol{O(\log n)}$	Section 4, [13]
	4	2	$\Theta(\log^* n)$	$O(1)$	$O(1)$	[13]
	5	2.5	$\Theta(\log^* n)$	$O(1)$	0	[13]
	...					

- Redesign the public service network only in the local neighborhoods in which there are new developments. This corresponds to the dynamic-LOCAL model, and the locality parameter T captures the redesign cost and the disruption it causes.
- Wait until new developments in a neighborhood are completed before providing permanent public services in the area. This corresponds to the online-LOCAL model, and the locality parameter T captures the inconvenience for the residents (the width of the "buffer zone" without permanent public services around areas in which the city plan is not yet finalized).

These two models make it possible to formally explore trade-offs between the quality of the solution in the long term vs. the inconvenience of those living close to the areas where the city is changing. In these kinds of scenarios, the key challenge is not related to the computational cost of finding an optimal solution (which is traditionally considered in the context of dynamic graph algorithms) but to the quality of the solution (which is typically the focus in online algorithms). The key constraint is not the availability of information on the current state of the world (which is traditionally considered in distributed graph algorithms), but the cost of changing the solution.

1.6 Techniques and key ideas

For the equivalence in paths and cycles (Section 5.1), we first make use of *pumping-style arguments* that were introduced by Chang and Pettie [17] in the context of distributed algorithms. We show that such ideas can be used to also analyze locality in the context of online algorithms: we start by showing that we can "speed up" (or "further localize") online-LOCAL algorithms with a *sublinear* locality to online-LOCAL algorithms with a *constant* locality in paths and cycles. Then, once we have reached constant locality in the online-LOCAL model, we show how to turn it into a LOCAL-model algorithm with locality $O(\log^* n)$. In this part, the key insight is that *we cannot directly simulate* online-LOCAL in LOCAL. Instead, we can use an online-LOCAL algorithm with a constant locality to find a *canonical labeling* for each possible input-labeled fragment, and use this information to design a LOCAL-model algorithm. The main trick is that we first present only disconnected path fragments to an online-LOCAL algorithm, and force it to commit to some output labeling in each fragment without knowing how the fragments are connected to each other.

In the case of rooted regular trees (Section 5.2), we face the same fundamental challenge: we cannot directly simulate black-box online-LOCAL algorithms in the LOCAL model. Instead, we need to look at the combinatorial properties of a given LCL problem Π. We proceed in two steps: (1) Assume that the locality of Π is $n^{\Theta(1)}$ in the LOCAL model; we need to show that the locality is $n^{\Theta(1)}$ also in the online-LOCAL model. Using the result of [7], high LOCAL-model locality implies that the structure of Π has to have certain "inflexibilities", and we use this property to present a strategy that the adversary can use to force any online-LOCAL algorithm with locality $n^{o(1)}$ to fail. (2) Assume that we have an online-LOCAL algorithm A for Π with locality $o(\log n)$; we need to show that the locality is $O(\log^* n)$ in the LOCAL model. Here we design a family of inputs and a strategy of the adversary that forces algorithm A to construct a "certificate" (in the sense of [7]) that shows that Π is efficiently solvable in the LOCAL model.

For 3-coloring bipartite graphs in online-LOCAL (Section 4), we make use of the following ideas. We maintain a collection of graph fragments such that each of the fragments has got a boundary that is properly 2-colored. Each such fragment has got one of two possible parities (let us call them here "odd" and "even") with respect to the underlying bipartition. We do not know the global parity of a given graph fragment until we have seen almost the entire graph. Nevertheless, it is possible to merge two fragments and maintain the invariant: if two fragments A and B have parities that are not compatible with each other, we can surround either A or B with a *barrier* that uses the third color, and thus change parities. Now we can merge A and B into one fragment that has got a properly 2-colored boundary. The key observation here is that we can make a *choice* between surrounding A vs. B, and if we always pick the one with the smallest number of nested barriers, we never need to use more than a logarithmic number of nested barriers. It turns out that this is enough to ensure that seeing up to distance $O(\log n)$ suffices to color any node chosen by the adversary.

1.7 Open questions

Our work gives rise to a number of open questions. First, we can take a more fine-grained view of the results in Tables 1 and 2:

1. Is there any problem in rooted trees with locality $\Theta(n^\alpha)$ in the online-LOCAL model and locality $\Theta(n^\beta)$ in the LOCAL model, for some $\alpha < \beta$?
2. Is it possible to find a 3-coloring in 2-dimensional grids in the dynamic-LOCAL model with locality $O(\log n)$?
3. Is it possible to find a 3-coloring in bipartite graphs in the online-LOCAL model with locality $o(\log n)$?

Perhaps even more interesting is what happens if we consider *unrooted* trees instead of rooted trees. In unrooted trees we can separate *randomized* and *deterministic* versions of the LOCAL model [16], and SLOCAL is strong enough to derandomize randomized LOCAL-model algorithms [25]; hence the key question is:

4. Does randomized-LOCAL $\approx$ SLOCAL $\approx$ dynamic-LOCAL $\approx$ online-LOCAL hold for LCL problems in unrooted trees?

Finally, our work shows a trade-off between the competitive ratio and the locality of coloring: With locality $O(\log n)$, one can achieve $O(1)$-coloring of a bipartite graph, and to achieve locality 0, one needs to use $\Omega(\log n)$ colors. This raises the following question:

5. What trade-offs exist between the locality and number of colors needed to color a (bipartite) graph in the online-LOCAL model?

2 Definitions and related work

Throughout this work, graphs are simple, undirected, and finite, unless otherwise stated. We write $G = (V, E)$ for a graph G with the set of nodes V and the set of edges E, and we use n to denote the number of nodes in the graph. For a node v and a natural number T, we use $B(v, T)$ to denote the set of all nodes in the radius-T neighborhood of node v. For a set of nodes U, we write $G[U]$ for the subgraph of G induced by U. By radius-T neighborhood of v we refer to the induced subgraph $G[B(v, T)]$, together with possible input and output labelings.

We use the following notation for graph problems. We write $\mathcal{G}$ for the family of graphs, Σ for the set of input labels, and Γ for the set of output labels. For a graph $G = (V, E)$, we write $I\colon V \to \Sigma$ for the input labeling and $L\colon V \to \Gamma$ for the output labeling. We consider here node labelings, but edge labelings can be defined in an analogous manner. A *graph problem* Π associates with each possible *input* (G, I) a set of feasible *solutions* L; this assignment must be invariant under graph isomorphism.

Locality. In what follows, we define five models of computing: LOCAL, SLOCAL, two versions of dynamic-LOCAL, and online-LOCAL. In all of these models, an algorithm is characterized by a *locality* T (a.k.a. locality radius, local horizon, time complexity, or round complexity, depending on the context). In general, T can be a function of n. We assume that the algorithm knows the value of n.

In each of these models $\mathcal{M}$, we say that algorithm $\mathcal{A}$ solves problem Π if, for each possible input (G, I) and for each possible adversarial choice, the labeling L produced by $\mathcal{A}$ is a feasible solution. We say that problem Π has locality T in model $\mathcal{M}$ if T is the pointwise smallest function such that there exists an $\mathcal{M}$-model algorithm $\mathcal{A}$ that solves Π with locality at most T.

LOCAL model. In the LOCAL model of distributed computing [37, 44], the adversary labels the nodes with unique identifiers from $\{1, 2, \ldots, \mathrm{poly}(n)\}$. In a LOCAL model algorithm, each node in parallel chooses its local output based on its radius-T neighborhood (the output may depend on the graph structure, input labels, and the unique identifiers).

Naor and Stockmeyer [42] initiated the study of the locality of LCL problems (see Definition 3) in the LOCAL model. Today, LCL problems are well classified with respect to their locality for the special cases of paths [4, 5, 13, 18, 42], grids [13], directed and undirected trees [5, 7, 8, 15, 17] as well as general graphs [13, 42], with only a few unknown gaps [7].

SLOCAL model. In the SLOCAL model [26], we have got adversarial unique identifiers similar to the LOCAL model, but the nodes are processed sequentially with respect to an adversarial input sequence $\sigma = v_1, v_2, v_3, \ldots, v_n$. Each node v is equipped with an unbounded local memory; initially, all local memories are empty. When a node v is processed, it can query the local memories of the nodes in its radius-T neighborhood, and based on this information, it has to decide what is its own final output and what to store in its own local memory.

The SLOCAL model has been used as a tool to e.g. better understand the role of randomness in the LOCAL model [25, 26]. It is also well-known that SLOCAL is strictly stronger than LOCAL. For example, it is trivial to find a maximal independent set greedily in the SLOCAL model, while this is a nontrivial problem in the general case in the LOCAL model [6, 36]. There are many LCL problems with LOCAL-locality $\Theta(\log^* n)$ [19, 37], and

all of them have SLOCAL-locality $O(1)$. There are also LCL problems (e.g. the so-called *sinkless orientation* problem), where the locality in the (deterministic) LOCAL model is $\Theta(\log n)$, while the locality in the (deterministic) SLOCAL model is $\Theta(\log \log n)$ [16, 25].

Dynamic-LOCAL model. To our knowledge, there is no standard definition or name for what we call dynamic-LOCAL here; however, the idea has appeared implicitly in a wide range of work. For example, many efficient dynamic algorithms for graph problems, such as vertex or edge coloring, maximal independent set, and maximal matching, also satisfy the property that the solution is only modified in the (immediate) local neighborhood of a point of change [3, 9, 11, 21, 28, 34, 43], and hence all of them fall in the class dynamic-LOCAL.

We use the following definition for dynamic-LOCAL: Computation starts with an empty graph G_0. In step i, the adversary constructs a supergraph G_i of G_{i-1} such that G_i and G_{i-1} differ in only one edge or one node; let C_i denote the set of nodes v in G_i with $G_i[B(v,T)] \neq G_{i-1}[B(v,T)]$, i.e., nodes that are within distance at most T from the point of change. In each step, the algorithm has to produce a feasible labeling L_i for problem Π in graph G_i, and the labeling can only be modified in the local neighborhood of a point of change, i.e., $L_i(v) = L_{i-1}(v)$ for all $v \notin C_i$.

Note that we defined the dynamic-LOCAL model for the *incremental* case, where nodes and edges are only added. If we do not require that G_i is a supergraph of G_{i-1}, we arrive at what we call the dynamic-LOCAL$^{\pm}$ model with both additions and deletions.

Online graph algorithms. In online graph algorithms, nodes are processed sequentially with respect to an adversarial input sequence $\sigma = v_1, v_2, \ldots, v_n$. Let $\sigma_i = v_1, v_2, \ldots, v_i$ denote the first i nodes of the sequence, and let $G_i = G[\{v_1, v_2, \ldots, v_i\}]$ be the subgraph induced by these nodes. When the adversary presents a node v_i, the algorithm has to label v_i based on σ_i and G_i.

Online algorithms on graphs have been studied for many problems such as matching [35] and independent set [30], but closest to our work is the extensive literature on online graph coloring [1, 10, 29, 31, 33, 38, 47]. There is also prior work that has considered various ways to strengthen the notion of online algorithms; the performance of online algorithms can be improved by letting the algorithm know the input graph [20, 32], by giving it an advice string [12, 14, 22] with knowledge about the request sequence, or allowing the algorithm to delay decisions [23]. The online-LOCAL model can be interpreted as online graph algorithms with spatial advice, and it can also be interpreted as a model where the online algorithm can delay its decision for node v until it has seen the whole neighborhood around v (this interpretation is equivalent to the definition we give next).

Online-LOCAL model. We define the online-LOCAL model as follows. The nodes are processed sequentially with respect to an adversarial input sequence $\sigma = v_1, v_2, \ldots, v_n$. Let $\sigma_i = v_1, v_2, \ldots, v_i$ denote the first i nodes of the sequence, and let $G_i = G\big[\bigcup_{j=1}^{i} B(v_j, T)\big]$ be the subgraph induced by the radius-T neighborhoods of these nodes. When the adversary presents a node v_i, the algorithm has to label v_i based on σ_i and G_i.

Observe that any online graph algorithm is an online-LOCAL algorithm with locality 0. Further note that in the online-LOCAL model, unique identifiers would not give any additional information. This is because the nodes can always be numbered with respect to the point in time when the algorithm first sees them in some G_i.

Yet another way to interpret the online-LOCAL model is that it is an extension of the SLOCAL model, where the algorithm is equipped with unbounded *global memory* where it can store arbitrary information on what has been revealed so far. When they introduced

the SLOCAL model, Ghaffari, Kuhn, and Maus [26] mentioned the possibility of such an extension but pointed out that it would make the model "too powerful", as just one bit of global memory would already make it possible to solve e.g. leader election (and this observation already shows that the online-LOCAL model is indeed strictly stronger than the SLOCAL model). In our work, we show that even though online-LOCAL can trivially solve e.g. leader election thanks to the global memory, it is not that easy to exploit this extra power in the context of LCL problems. Indeed, online-LOCAL turns out to be as weak as SLOCAL when we look at LCL problems in paths, cycles, and rooted trees.

Local computation algorithms. We do not discuss local computation algorithms (LCAs) [2, 24, 39, 40, 46, 46] in this work in more detail, but we briefly point out a direct connection between the online-LOCAL model and LCAs. It is known that for a broad family of graph problems (that includes LCLs), we can w.l.o.g. assume that whenever the adversary queries a node v, the LCA makes probes to learn a *connected* subgraph around node v [27]. For such problems, an online-LOCAL algorithm with locality T is at least as strong as an LCA that makes T probes per query: an LCA can learn some *subgraph* of the radius-T neighborhood of v and, depending on the size of the state space, remember some part of that, while in the online-LOCAL model the algorithm can learn the entire radius-T neighborhood of v and remember all of that. We leave a more detailed exploration of the distinction between distance (how far to see) and volume (how much to see), in the spirit of e.g. [41, 45], for future work.

3 Landscape of models

As an introduction to the models, we first check that all relations in Figure 1 indeed hold. In each case, we are interested in *asymptotic* equivalence: for example, when we claim that $A \subsetneq B$, the interpretation is that locality T in model A implies locality $O(T)$ in model B, but the converse is not true. Note that the relation between the online-LOCAL problems and the online graph algorithms has already been discussed in Sections 1 and 2.

Inclusions. Let us first argue that the subset relations in Figure 1 hold. These cases are trivial:

- Any LOCAL algorithm can be simulated in the SLOCAL model, and any SLOCAL algorithm can be simulated in the online-LOCAL model (this is easiest to see if one interprets online-LOCAL as an extension of SLOCAL with the global memory).
- Any dynamic-LOCAL$^{\pm}$ algorithm can be directly used in the dynamic-LOCAL model (an algorithm that supports both additions and deletions can handle additions).

These are a bit more interesting cases:

- To simulate a LOCAL algorithm A in the dynamic-LOCAL$^{\pm}$ model, we can simply recompute the entire output with A after each change. If the locality of A is T, then the output of A only changes within distance T from a point of change.
- To simulate a dynamic-LOCAL algorithm A in the online-LOCAL model, we proceed as follows: When the adversary reveals a node v, we feed v along with the new nodes in its radius-$O(T)$ neighborhood to A edge by edge. Now there will not be any further changes within distance T from v, and hence A will not change the label $L(v)$ of v anymore. Hence the online-LOCAL algorithm can also label v with $L(v)$.

Table 3 Problems that we use to separate the models, and the bounds that we show for their locality.

Problem	LOCAL	SLOCAL	dynamic-LOCAL$^{\pm}$	dynamic-LOCAL	online-LOCAL
3-coloring paths	$\Omega(\log^* n)$	$O(1)$	$O(1)$	$O(1)$	$O(1)$
weak reconstruction	$\Omega(n)$	$\Omega(n)$	$O(1)$	$O(1)$	$O(1)$
cycle detection	$\Omega(n)$	$\Omega(n)$	$\Omega(n)$	$O(1)$	$O(1)$
component-wise leader election	$\Omega(n)$	$\Omega(n)$	$\Omega(n)$	$\Omega(n)$	$O(1)$
nested orientation	$\omega(1)$	$O(1)$	$\omega(1)$	$\omega(1)$	$O(1)$

Separations. To prove the separations of Figure 1, we make use of the classic distributed graph problem of 3-*coloring paths*, as well as the following problems that are constructed to highlight the differences between the models:

- *Weak reconstruction:* in each connected component C there has to be at least one node v such that its label $L(v)$ is an encoding of a graph isomorphic to C.
- *Cycle detection:* for each cycle there has to be at least one node that outputs "yes", and each node that outputs "yes" has to be part of at least one cycle.
- *Component-wise leader election:* in each connected component exactly one node has to be marked as the leader.
- *Nested orientation:* find an acyclic orientation of the edges and label each node recursively with its own identifier, the identifiers of its neighbors, and the labels of its in-neighbors (see the full version for the precise definition).

We can prove the bounds shown in Table 3 for the locality of these problems in the five models; see the full version for the details. Now each separation in Figure 1 follows from one of the rows of Table 3.

4 3-coloring bipartite graphs

In this section, we present our Contribution 3: we design an algorithm for 3-coloring bipartite graphs in the online-LOCAL model and show that this gives us an exponential separation between the SLOCAL and online-LOCAL models. This section also serves as an introduction into the algorithmic techniques that work in online-LOCAL. Equipped with this understanding, in Section 5, we start to develop more technical tools that we need for our Contribution 2.

By prior work [13], it is known that the locality of 3-coloring in $\sqrt{n} \times \sqrt{n}$ grids is at least $\Omega(\sqrt{n})$ in the LOCAL model. The aforementioned paper considers the case of *toroidal* grid graphs, but the same argument can be applied for non-toroidal grids (in essence, if you could color locally anywhere in the middle of a non-toroidal grid, you could also apply the same algorithm to color a toroidal grid). We can easily extend this result to show a polynomial lower bound for 3-coloring grids in the SLOCAL model:

▶ **Theorem 2.** *There is no SLOCAL algorithm that finds a 3-coloring in 2-dimensional grids with locality $o(n^{1/10})$.*

To prove the result, we show that we can simulate SLOCAL algorithms sufficiently efficiently in the LOCAL model. We use the standard technique of first precomputing a distance-$o(n^{1/10})$ coloring, and then using the colors as a schedule for applying the SLOCAL algorithm. Such a simulation can be done efficiently and would lead to a LOCAL algorithm running in $o(\sqrt{n})$ time, which is a contradiction. The full proof of the lower bound is presented

in the full version of the paper. As grids are bipartite graphs, the problem of 3-coloring in grids already gives an exponential separation between the SLOCAL and online-LOCAL models. For the special case of grids, we discuss the known locality bounds for the coloring problem in the full version. A summary of these results can be found in Table 2.

In Section 4.1, we introduce the 3-coloring algorithm in the online-LOCAL, and we use the special case of grids in order to visualize it. Besides providing a natural separation between the SLOCAL and online-LOCAL models, the 3-coloring problem also shows the advantage of allowing online algorithms to look around: while the best online coloring algorithm on bipartite graphs is $\Theta(\log n)$-competitive, our algorithm in the online-LOCAL model achieves a competitive ratio of 1.5.

Note that an optimal solution would be to color a bipartite graph with 2 colors. In all models that we consider here, we know it is not possible to solve 2-coloring with locality $o(n)$, the worst case being a path with n nodes. We show that allowing an online-LOCAL algorithm to use only one extra color makes it possible to find a valid coloring with locality $O(\log n)$:

▶ **Theorem 1.** *There is an online-LOCAL algorithm that finds a 3-coloring in bipartite graphs with locality $O(\log n)$.*

4.1 Algorithm for 3-coloring bipartite graphs in online-LOCAL

Algorithm overview. The high-level idea of our online-LOCAL algorithm is to color the presented nodes of the graph with 2 colors until the algorithm sees two areas where the 2-colorings are not compatible. In essence, when the adversary presents a node far from any other node the algorithm has seen, the algorithm blindly start constructing a 2-coloring. When the adversary presents nodes in the neighborhood of already colored nodes, the algorithm simply expands the 2-colored component – we call such a component a *group*. The algorithm keeps expanding such properly 2-colored groups until, eventually, two groups with incompatible 2-colorings meet (i.e., groups that have different *parities*). Then, the algorithm uses the third color in order to create a *barrier* around one of the groups, effectively flipping its parity. Our algorithm thereby makes use of the knowledge of previously queried neighborhoods that are given by the online-LOCAL model: the algorithm is *committing* to colors for nodes in the revealed subgraphs before they are queried.

Algorithm in detail. At the beginning, no nodes are revealed to the algorithm, and we therefore say that all nodes are *unseen*. We refer to connected components of the subgraph G_i of G as *groups*. With each of these groups, we associate a *border count*, which is a natural number that is initially 0. The algorithm uses colors 0 and 1 for the 2-coloring, reserving color 2 as the barrier color. Each time the adversary points at a node v_i, the algorithm gets to see the radius-T neighborhood $B(v_i, T)$ of this node. Now consider different types of nodes in $B(v_i, T+1)$. There are three different cases that the algorithm needs to address (we visualize them in Figures 2–4 using grids as an example):

1. *All nodes in $B(v_i, T+1)$ are unseen.* In this case, the nodes in $B(v_i, T)$ form a new connected component, i.e. a new *group*. This group has a *border count* of 0. The algorithm colors v_i with 0, thus fixing the parity for this group (see Figure 2).
2. *The algorithm has already seen some nodes in $B(v_i, T+1)$, but all of them belong to the same group.* In this case, the adversary has shown an area next to an existing group. If v_i was already committed to a color, the algorithm uses that color. Otherwise, the algorithm colors v_i according to the 2-coloring of the group. All nodes in $B(v_i, T)$ are now considered to be in this group (see Figure 3).

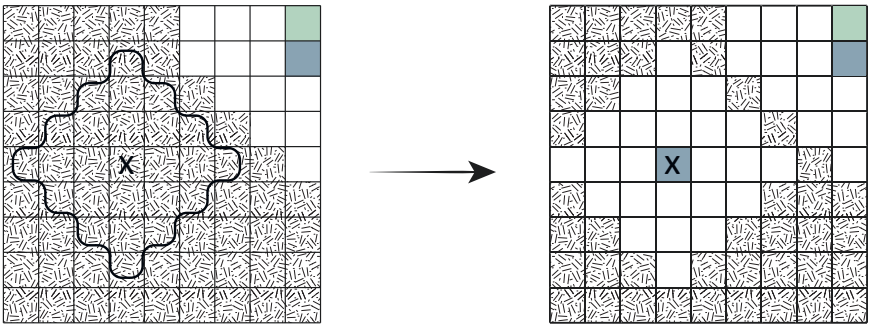

Figure 2 3-coloring algorithm, case 1/3. The adversary queries node x. Here node x is in the middle of an unseen region (shaded). The algorithm creates a new group (white) and fixes the color of node x arbitrarily.

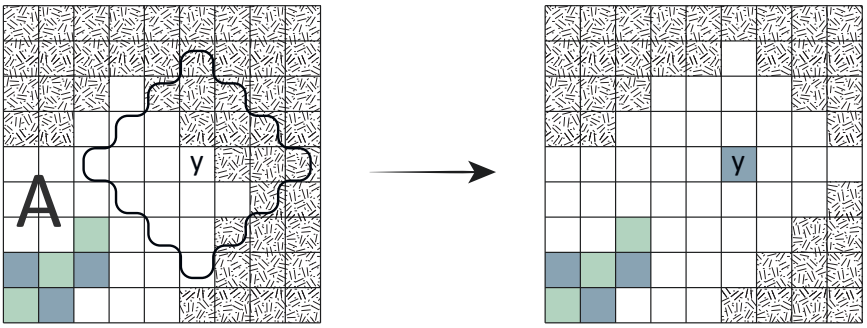

Figure 3 3-coloring algorithm, case 2/3. The adversary queries node y. Some nodes in the local neighborhood of y are already part of a group (white), and hence y joins this group. The algorithm fixes the color of node y so that it is consistent with the coloring of the group.

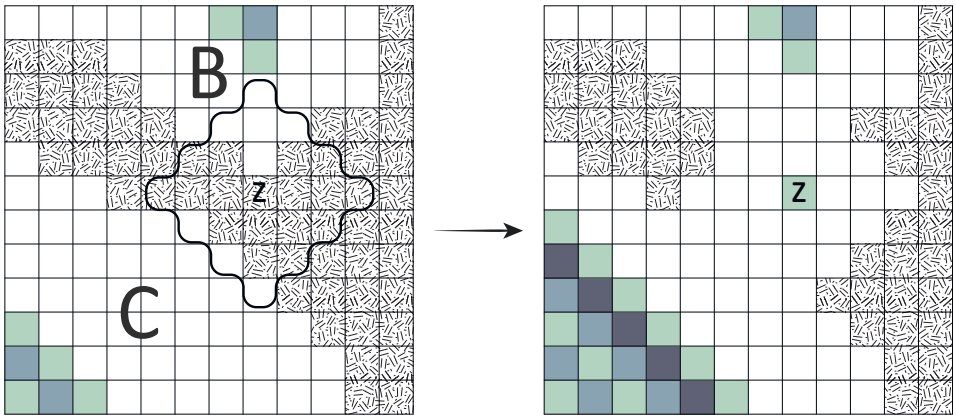

Figure 4 3-coloring algorithm, case 3/3. The adversary queries node z. Some nodes in the local neighborhood of z belong to two different groups, B and C. The algorithm merges the groups. As they have incompatible parities, the algorithm adds a new border around one of the groups, in this case C, as both groups have the same number of borders around them and the algorithm can choose arbitrarily. Nodes in the local neighborhood of z join the group, and z is colored in a way compatible with the coloring of the newly created group.

Algorithm 1 join_groups(A, B).

Input: Groups A, B
Output: Group X
if *A and B have different parities* **then**
  Let S be the group with the smaller border count. If they are equal, $S = A$;
  For all nodes of color 0 in S, commit all uncolored neighbors to color 1;
  For all nodes of color 1 in S, commit all uncolored neighbors to color 2;
  For all nodes of color 2 in S, commit all uncolored neighbors to color 0;
  Increase border count of S by 1.
end
Set all nodes in groups A, B to be in group X;
Set the border count for X to be the maximum of border counts for A, B and S;
return X

3. *There are nodes in $B(v_i, T+1)$ that belong to different groups.* In this case, the algorithm has to join groups. Here, we only define the join of two groups A and B; if there are more groups, this join can be applied iteratively.
   If A and B have different parities (i.e., the 2-colorings at their boundaries are not compatible), the algorithm takes the group with the smaller border count and uses a layer of nodes of color 2 to create a barrier that changes its parity, and then it increases the group's border count; see Algorithm 1 for the details. Then, the algorithm joins the groups, that are now compatible, and sets the border count of the newly created group to the maximum of the border counts of A and B.
   By merging all groups in the local neighborhood of v_i, the algorithm eventually ends up in a situation where v_i only sees nodes in a single group, and we are in a scenario similar to case 2 above: nodes in the local neighborhood of v_i also join the newly created group, and if v_i has not already committed to a color, the algorithm colors it according to the 2-coloring of this group (see Figure 4).

4.2 Analysis of the 3-coloring Algorithm in online-LOCAL

In order to show the correctness of the coloring algorithm, we first prove that this process creates a valid 3-coloring provided that all our commitments remain within the visible area, that is, inside subgraph G_i. Next, we show that by choosing $T(n) = O(\log n)$, all our commitments indeed remain inside the visible area. Together, these parts prove Theorem 1.

Validity of the 3-coloring. We first prove that our algorithm always continues a valid 3-coloring, as long as it does not need to make commitments to unseen nodes. We consider all three cases of the algorithm individually.

1. *All nodes in $B(v_i, T+1)$ are unseen.* In this case, the algorithm colors v_i with 0. As all neighboring nodes were unseen, they have not been committed to any color, and thus this case causes no errors.
2. *The algorithm has already seen some nodes in $B(v_i, T+1)$, but all of them belong to the same group.* In this case, the algorithm would either use the committed color or the parity of the group. As previously committed colors do not cause errors, and the group has consistent parity, this case cannot cause any errors.

3. *There are nodes in $B(v_i, T+1)$ that belong to different groups.* In this case, we want to join groups without breaking the coloring. If the two groups have the same parity, clearly, no errors can be caused by continuing the 2-coloring. The interesting case is when the two groups have different parities. Then, we need to show that the new commitments made by Algorithm 1 do not create any errors.

   Let S be the group with the smaller border count. By examining Algorithm 1, we can see that all colored nodes that have uncolored neighbors are either of color 0 or color 1: only in line 4, nodes can be colored with color 2, and all of those nodes' neighbors are then colored in line 5. Thus, in order for an error to occur, there either needs to be two nodes of colors 0 and 1 that have uncolored neighbors and different parities in S, or the algorithm commits to a color of a node that it has not yet seen. This could cause an error, as two groups could commit a single node to two different colors.

   As for the first case, we assume that all nodes in S that have uncolored neighbors also have consistent parity. This trivially holds for a group that has border count 0, as all colored nodes in it have the same parity. From the assumption, it follows that all nodes colored with 1 in line 3 have the same parity, so they cannot create an error. After this, all colored nodes with uncolored neighbors in the group have the same parity, and are colored with 1. Thus all nodes colored with 2 in line 4 also have the same parity, as do the nodes colored with 0 in line 5. As these are the only lines where nodes are colored, this procedure cannot create any errors. It also ensures that, after the procedure, the only colored nodes in the group that have uncolored neighbors are the nodes colored in line 5, which have the same parity. Therefore, our assumption holds for all groups. Those nodes also have a parity different from the nodes in S that had uncolored neighbors before this procedure, so in essence, we have flipped the parity of group S to match the parity of the other group.

   As for the second case, this can be avoided by choosing a large enough T, so that all commitments remain within the visible area of G_i. Next, we discuss how to choose such a T.

Locality of the 3-coloring algorithm. In this part, we prove that by choosing locality $T(n) = 3\lceil \log_2 n \rceil = O(\log n)$, no nodes outside the visible area of G_i need to be committed.

We first make the observation that a group with border count b contains at least 2^b nodes; this is a simple induction:

$b = 0$: A newly created group contains at least 1 node.

$b > 0$: Consider the cases in which Algorithm 1 returns a group X with border count b. One possibility is that A or B already had border count b, and hence by assumption it already contained at least 2^b nodes. The only other possibility is that both A and B had border count exactly $b-1$, they had different parities, one of the border counts was increased, and hence X has now got a border count of b. But, in this case, both A and B contained at least 2^{b-1} nodes each.

Hence the border count is bounded by $b \leq \log_2 n$ in a graph with n nodes.

We next consider the maximum distance between a node that the adversary has queried and a node with a committed color. Note that the only place where the algorithm commits a color to a node that the adversary has not queried yet is when building a border around a group. There are three steps (lines 3–5) where the algorithm commits to the color of a neighbor of a committed node, and thus effectively extends the distance by at most one in each step. Therefore, if the border count is b, in the worst case, the algorithm commits a color for a node that is within distance $3b$ from a node that was queried by the adversary.

As we have $b \leq \log_2 n$, a locality of $3\lceil \log_2 n \rceil \geq 3b$ suffices to ensure that all the commitments of the algorithm are safely within the visible region. This concludes the proof of Theorem 1.

5 LCL problems in paths, cycles, rooted regular trees

We just showed that the online-LOCAL model is much more powerful than LOCAL and SLOCAL for an LCL on bipartite graphs and grids. In this section, we discuss what happens when we restrict our attention to LCL problems in paths, cycles, and trees. We start by defining LCL problems more formally.

We say that Π is a *locally verifiable problem* with verification radius r if the following holds: there is a collection of labeled local neighborhoods $\mathcal{T}$ such that L is a feasible solution for input (G, I) if and only if for all nodes v, the radius-r neighborhood of v in (G, I, L) is in $\mathcal{T}$. Informally, a solution is feasible if it looks good in all radius-r neighborhoods.

▶ **Definition 3** (Locally checkable labeling [42]). *A locally verifiable problem Π is a* locally checkable labeling (LCL) *problem if the set of the input labels Σ is finite, the set of the output labels Γ is finite, and there is a natural number Δ such that maximum degree of any graph $G \in \mathcal{G}$ is at most Δ.*

Note that in LCL problems, $\mathcal{T}$ is also finite since there are only finitely many possible non-isomorphic labeled local neighborhoods.

It turns out that in the case of paths, cycles, and rooted regular trees, the LOCAL, SLOCAL, dynamic-LOCAL, and online-LOCAL models are all approximately equally expressive for LCL problems. In particular, all classification and decidability results related to LCLs in paths, cycles, and rooted regular trees in the LOCAL model [4, 7, 18] directly apply also in the online-LOCAL model, the SLOCAL model, and both versions of the dynamic-LOCAL model.

We show first that the LOCAL and online-LOCAL models are equivalent in the case of paths and cycles, even when the LCL problems can have inputs. We then continue to prove that the models are equivalent also in the more general case of LCL problems rooted regular trees, but in this case we do not consider the possibility of having input labels.

Formally, we prove the following theorem for cycles and paths:

▶ **Theorem 4.** *Let Π be an LCL problem in paths or cycles (possibly with inputs). If the locality of Π is T in the online-LOCAL model, then its locality is $O(T + \log^* n)$ in the LOCAL model.*

For the case of rooted trees, we prove the following two theorems:

▶ **Theorem 5.** *Let Π be an LCL problem in rooted regular trees (without inputs). Problem Π has locality $n^{\Omega(1)}$ in the LOCAL model if and only if it has locality $n^{\Omega(1)}$ in the online-LOCAL model.*

▶ **Theorem 6.** *Let Π be an LCL problem in rooted regular trees (without inputs). Problem Π has locality $\Omega(\log n)$ in the LOCAL model if and only if it has locality $\Omega(\log n)$ in the online-LOCAL model.*

These two theorems show that all LCL problems in rooted regular trees belong to one of the known complexity classes $O(\log^* n)$, $\Theta(\log n)$ and $n^{\Omega(1)}$ in all of the models we study. In what follows, we introduce the high-level ideas of the proofs of these theorems. For full proofs, we refer the reader to the full version.

5.1 Cycles and paths

We prove Theorem 4 by first showing that any LCL problem in cycles and paths has either locality $O(1)$ or $\Omega(n)$ in the online-LOCAL model. Next, we show that if a problem is solvable with locality $O(1)$ in the online-LOCAL model, then it is also solvable in locality $O(\log^* n)$ in the LOCAL model. These steps are described by the following two lemmas:

▶ **Lemma 7.** *Let Π be an LCL problem in paths or cycles (possibly with inputs), and let $\mathcal{A}$ be an online-LOCAL algorithm solving Π with locality $o(n)$. Then, there exists an online-LOCAL algorithm $\mathcal{A}'$ solving Π with locality $O(1)$.*

The high-level idea of the proof of Lemma 7 is to construct a large virtual graph P' such that when the original algorithm runs on the virtual graph P', the labeling produced by the algorithm is locally compatible with the labeling in the original graph P. We ensure this by applying a pumping-lemma-style argument on the LCL problem. The proof uses similar ideas as the ones presented by Chang and Pettie [17].

▶ **Lemma 8.** *Let Π be an LCL problem in paths or cycles (possibly with inputs), and let $\mathcal{A}$ be an online-LOCAL algorithm solving Π with locality $O(1)$. Then, there exists a LOCAL algorithm $\mathcal{A}'$ solving Π with locality $O(\log^* n)$.*

The high-level idea of the proof of Lemma 8 is to use the constant locality online-LOCAL algorithm to construct a canonical output labeling for each possible neighborhood of input labels. The fast LOCAL algorithm can then use these canonical labelings in disjoint neighborhoods of the real graph, and the construction of the canonical labelings ensures that the labeling also extends to the path segments between these neighborhoods.

The full proofs of these lemmas can be found in the full version of this paper. In order to prove Theorem 4, it is sufficient to combine these lemmas with the fact that the possible localities on paths and cycles in the LOCAL model are $O(1)$, $\Theta(\log^* n)$ and $\Theta(n)$ [18].

5.2 Rooted regular trees

We prove the equivalence of the LOCAL and the online-LOCAL models for LCL problems in rooted regular trees in two parts. We start out with Theorem 5 and show that if an LCL problem requires locality $n^{\Omega(1)}$ in the LOCAL model, then for every locality-$n^{o(1)}$ online-LOCAL algorithm we can construct an input instance which the algorithm must fail to solve. To prove Theorem 6, we show that a locality-$o(\log n)$ online-LOCAL algorithm for solving an LCL problem implies that there exists a locality-$O(\log^* n)$ LOCAL algorithm for solving that same problem. In the following, we outline the proofs of both theorems; the full proofs can be found in the full version of the paper. Before considering the full proof, we advise the reader to look at the example in the full version of this paper, where we show that the 2.5-coloring problem requires locality $\Omega(\sqrt{n})$ in the online-LOCAL model.

Proof outline of Theorem 5. Our proof is based on the fact that any LCL problem requiring locality $n^{\Omega(1)}$ in the LOCAL model has a specific structure. In particular, the problem can be decomposed into a sequence of *path-inflexible* labels and the corresponding sequence of more and more restricted problems [7]. Informally, a label is path-inflexible if two nodes having that label can exist only at specific distances apart from each other. For example, when 2-coloring a graph, two nodes having label 1 can exist only at even distances from each other. The problems in the path-inflexible decomposition are formed by removing the path-inflexible labels from the previous problem in the sequence until an empty problem is reached.

This decomposition of the problem into restricted problems with path-inflexible labels allows us to construct an input graph for any locality-$n^{o(1)}$ online-LOCAL algorithm. In particular, we force the algorithm to commit labels in disjoint fragments of the graph. Any label that the algorithm uses must be a path-inflexible label in some problem of the sequence of restricted problems. By combining two fragments containing labels that are path-inflexible in the same problem, we can ensure that the algorithm cannot solve that problem in the resulting graph. Hence the algorithm must use a label from a problem earlier in the sequence. At some point, the algorithm must use labels that are path-inflexible in the original problem. At that point, we can combine two fragments having path-inflexible labels in the original problem in such a way that no valid labeling for the original problem exists, and hence the algorithm must fail to solve the problem on the resulting graph.

Proof outline of Theorem 6. Here, we show that a locality-$o(\log n)$ online-LOCAL algorithm solving an LCL problem implies that there exists a *certificate for* $O(\log^* n)$ *solvability* for that problem. It is known that the existence of such a certificate for a problem implies that there exists a locality-$O(\log^* n)$ LOCAL algorithm for solving the problem [7].

Informally, the certificate for $O(\log^* n)$ solvability for LCL problem Π with label set Γ and arity δ consists of a subset $\Gamma_{\mathcal{T}} = \{\gamma_1, \ldots, \gamma_t\}$ of labels Γ, and two sequences of correctly labeled complete δ-ary trees $\mathcal{T}^1$ and $\mathcal{T}^2$. The leaves of each tree in the sequence $\mathcal{T}^1$ (resp. $\mathcal{T}^2$) are labeled in the same way using only labels from set $\Gamma_{\mathcal{T}}$. For every label of set $\Gamma_{\mathcal{T}}$, there exists a tree in both of the sequences having a root labeled with that label.

We can use the online-LOCAL algorithm to construct such a certificate. We do this by constructing exponentially many deep complete δ-ary trees and using the algorithm to label nodes in the middle of those trees. We then glue these trees together in various ways. When the trees are glued together, we use the online-LOCAL algorithm to label the rest of the nodes to form one tree of the sequence. We repeat this procedure until all trees of both sequences have been constructed.

An Efficient Algorithm for All-Pairs Bounded Edge Connectivity

Shyan Akmal
MIT EECS and CSAIL, Cambridge, MA, USA

Ce Jin
MIT EECS and CSAIL, Cambridge, MA, USA

Abstract

Our work concerns algorithms for a variant of Maximum Flow in unweighted graphs. In the All-Pairs Connectivity (APC) problem, we are given a graph G on n vertices and m edges, and are tasked with computing the maximum number of edge-disjoint paths from s to t (equivalently, the size of a minimum (s,t)-cut) in G, for all pairs of vertices (s,t). Over undirected graphs, it is known that APC can be solved in essentially optimal $n^{2+o(1)}$ time. In contrast, the true time complexity of APC over directed graphs remains open: this problem can be solved in $\tilde{O}(m^\omega)$ time, where $\omega \in [2, 2.373)$ is the exponent of matrix multiplication, but no matching conditional lower bound is known.

Following [Abboud et al., ICALP 2019], we study a bounded version of APC called the k-Bounded All Pairs Connectivity (k-APC) problem. In this variant of APC, we are given an integer k in addition to the graph G, and are now tasked with reporting the size of a minimum (s,t)-cut only for pairs (s,t) of vertices with min-cut value less than k (if the minimum (s,t)-cut has size at least k, we can just report it is "large" instead of computing the exact value).

Our main result is an $\tilde{O}((kn)^\omega)$ time algorithm solving k-APC in directed graphs. This is the first algorithm which solves k-APC faster than simply solving the more general APC problem exactly, for all $k \geq 3$. This runtime is $\tilde{O}(n^\omega)$ for all $k \leq \text{poly}(\log n)$, which essentially matches the optimal runtime for the $k = 1$ case of k-APC, under popular conjectures from fine-grained complexity. Previously, this runtime was only achieved for general directed graphs when $k \leq 2$ [Georgiadis et al., ICALP 2017]. Our result employs the same algebraic framework used in previous work, introduced by [Cheung, Lau, and Leung, FOCS 2011]. A direct implementation of this framework involves inverting a large random matrix. Our new algorithm is based off the insight that for solving k-APC, it suffices to invert a low-rank random matrix instead of a generic random matrix.

We also obtain a new algorithm for a variant of k-APC, the k-Bounded All-Pairs Vertex Connectivity (k-APVC) problem, where for every pair of vertices (s,t), we are now tasked with reporting the maximum number of internally vertex-disjoint (rather than edge-disjoint) paths from s to t if this number is less than k, and otherwise reporting that this number is at least k.

Our second result is an $\tilde{O}(k^2 n^\omega)$ time algorithm solving k-APVC in directed graphs. Previous work showed how to solve an easier version of the k-APVC problem (where answers only need to be returned for pairs of vertices (s,t) which are not edges in the graph) in $\tilde{O}((kn)^\omega)$ time [Abboud et al, ICALP 2019]. In comparison, our algorithm solves the full k-APVC problem, and is faster if $\omega > 2$.

1 Introduction

Computing maximum flows is a classic problem which has been extensively studied in graph theory and computer science. In unweighted graphs, this task specializes to computing connectivities, an interesting computational problem in its own right. Given a graph G on n vertices and m edges, for any vertices s and t in G, the *connectivity* $\lambda(s,t)$ from s to t is defined to be the maximum number of edge-disjoint paths[1] from s to t. Since maximum flow can be computed in almost-linear time, we can compute $\lambda(s,t)$ for any given vertices s and t in $m^{1+o(1)}$ time [5].

What if instead of merely returning the value of a single connectivity, our goal is to compute all connectivities in the graph? This brings us to the All-Pairs Connectivity (APC) problem: in this problem, we are given a graph G as above, and are tasked with computing $\lambda(s,t)$ for all pairs of vertices (s,t) in G. In undirected graphs, APC can be solved in $n^{2+o(1)}$ time [2], so that this "all-pairs" problem is essentially no harder than outputting a single connectivity in dense graphs.

In directed graphs, APC appears to be much harder, with various conditional lower bounds (discussed in Section 1.2) suggesting it is unlikely this problem can be solved in quadratic time. Naively computing the connectivity separately for each pair yields an $n^2m^{1+o(1)}$ time algorithm for this problem. Using the flow vector framework (discussed in Section 3), it is possible to solve APC in directed graphs in $\tilde{O}(m^\omega)$ time[2] [7], where ω is the exponent of matrix multiplication. Known algorithms imply that $\omega < 2.37286$ [4], so the $\tilde{O}(m^\omega)$ time algorithm is faster than the naive algorithm whenever the input graph is not too dense.

Our work focuses on a bounded version of the APC problem, which we formally state as the k-Bounded All-Pairs Connectivity (k-APC) problem: in this problem, we are given a *directed* graph G as above, and are tasked with computing $\min(k, \lambda(s,t))$ for all pairs of vertices (s,t) in G. Intuitively, this is a relaxation of the APC problem, where our goal is to compute the exact values of $\lambda(s,t)$ only for pairs (s,t) with small connectivity. For all other pairs, it suffices to report that the connectivity is large, where k is our threshold for distinguishing between small and large connectivity values.

When $k = 1$, the k-APC problem is equivalent to computing the transitive closure of the input graph (in this problem, for each pair of vertices (s,t), we are tasked with determining if G contains a path from s to t), which can be done in $\tilde{O}(n^\omega)$ time [8]. Similarly, for the special case of $k = 2$, it is known that k-APC can be solved in $\tilde{O}(n^\omega)$ time, by a divide-and-conquer algorithm employing a cleverly tailored matrix product [10]. As we discuss in Section 1.2, there is evidence that these runtimes for k-APC when $k \leq 2$ are essentially optimal.

Already for $k = 3$ however, it is open whether k-APC can be solved faster than computing the *exact values* of $\lambda(s,t)$ for all pairs (s,t) of vertices! Roughly speaking, this is because the known $\tilde{O}(m^\omega)$ time algorithm for APC involves encoding the connectivity information in the inverse of an $m \times m$ matrix, and inverting an $m \times m$ matrix takes $O(m^\omega)$ time in general. This encoding step appears to be necessary for k-APC as well. For $k = 2$, clever combinatorial observations about the structure of strongly connected graphs allow one to skip this computation, but for $k \geq 3$ it is not clear at all from previous work how to avoid this bottleneck. Moreover, it is consistent with existing hardness results that k-APC could be solved in $O(n^\omega)$ time for any constant k.

---

[1] By Menger's theorem, $\lambda(s,t)$ is also equal to the minimum number of edges that must be deleted from the graph G to produce a graph with no s to t path.

[2] Given a function f, we write $\tilde{O}(f)$ to denote $f \cdot \text{poly}(\log f)$.

▶ **Open Problem 1.** Can k-APC be solved in faster than $\tilde{O}(m^\omega)$ time for $k = 3$?

Due to this lack of knowledge about the complexity of k-APC, researchers have also studied easier versions of this problem. Given vertices s and t in the graph G, we define the *vertex connectivity* $\nu(s,t)$ from s to t to be the maximum number of internally vertex-disjoint paths from s to t. We can consider vertex connectivity analogues of the APC and k-APC problems. In the All-Pairs Vertex Connectivity (APVC) problem, we are given a graph G on n vertices and m edges, and are tasked with computing the value of $\nu(s,t)$ for all pairs of vertices (s,t) in G. In the k-Bounded All-Pairs Vertex Connectivity (k-APVC) problem, we are given the same input G as above, but are now tasked with only computing $\min(k, \nu(s,t))$ for all pairs of vertices (s,t) in G.

The k-APVC problem does not face the $O(m^\omega)$ barrier which existing algorithmic techniques for k-APC seem to encounter, intuitively because it is possible to encode all the vertex-connectivity information of a graph in the inverse of an $n \times n$ matrix instead of an $m \times m$ matrix. As a consequence, [1] was able to present an $\tilde{O}((kn)^\omega)$ time algorithm which computes $\min(k, \nu(s,t))$ for all pairs of vertices (s,t) such that (s,t) is not an edge. Given this result, it is natural to ask whether the more general k-APVC and k-APC problems can also be solved in this same running time.

▶ **Open Problem 2.** Can k-APVC be solved in $\tilde{O}((kn)^\omega)$ time?

▶ **Open Problem 3.** Can k-APC be solved in $\tilde{O}((kn)^\omega)$ time?

1.1 Our Contribution

We resolve all three open problems raised in the previous section.

First, we present a faster algorithm for k-APC, whose time complexity matches the runtime given by previous work for solving an easier version of k-APVC.

▶ **Theorem 4.** *For any positive integer k, k-APC can be solved in $\tilde{O}((kn)^\omega)$ time.*

This is the first algorithm which solves k-APC faster than simply solving APC exactly using the $\tilde{O}(m^\omega)$ time algorithm of [7], for all constant $k \geq 3$.

Second, we present an algorithm for k-APVC, which is faster than the $\tilde{O}((kn)^\omega)$ time algorithm from [1] (which only solves a restricted version of k-APVC) if $\omega > 2$.

▶ **Theorem 5.** *For any positive integer k, k-APVC can be solved in $\tilde{O}(k^2 n^\omega)$ time.*

1.2 Comparison to Previous Results

Conditional Lower Bounds

The field of fine-grained complexity contains many popular conjectures (which hypothesize lower bounds on the complexity of certain computational tasks) which are used as the basis of conditional hardness results for problems in computer science. In this section, we review known hardness results for APC and its variants. The definitions of the problems and conjectures used in this section can be found in...

Assuming that Boolean Matrix Multiplication (BMM) requires $n^{\omega - o(1)}$ time, it is known that k-APC and k-APVC require $n^{\omega - o(1)}$ time to solve, even for $k = 1$ [8]. In particular, this hypothesis implies our algorithms for k-APC and k-APVC are optimal for constant k.

Assuming the Strong Exponential Time Hypothesis (SETH), previous work shows that APC requires $(mn)^{1-o(1)}$ time [12, Theorem 1.8], APVC requires $m^{3/2-o(1)}$ time [14, Theorem 1.7], and k-APC requires $\left(kn^2\right)^{1-o(1)}$ time [12, Theorem 4.3].

Let $\omega(1,2,1)$ be the smallest real number[3] such that we can compute the product of an $n \times n^2$ matrix and $n^2 \times n$ matrix in $n^{\omega(1,2,1)+o(1)}$ time. Assuming the 4-Clique Conjecture, the k-APVC problem over directed graphs (and thus the k-APC problem as well) requires $\left(k^2 n^{\omega(1,2,1)-2}\right)^{1-o(1)}$ time [1]. This conjecture also implies that solving APVC even in undirected graphs requires $n^{\omega(1,2,1)-o(1)}$ time [11].

Algorithms for Related Problems

As mentioned previously, no nontrivial algorithms for k-APC over general directed graphs were known for $k \geq 3$, prior to our work. However, faster algorithms were already known for k-APC over directed acyclic graphs (DAGs). In particular, [1] presented two algorithms to solve k-APC in DAGs, running in $2^{O(k^2)}mn$ time and $(k \log n)^{4^k+o(k)} n^\omega$ time respectively.

In comparison, our algorithm from Theorem 4 solves k-APC in *general* directed graphs, is faster than the former algorithm whenever $m \geq n^{\omega-1}$ or $k \geq \omega(\sqrt{\log n})$ (for example), is always faster than the latter algorithm, and is significantly simpler from a technical perspective than these earlier arguments. However, these algorithms for k-APC on DAGs also return cuts witnessing the connectivity values, while our algorithm does not.

In the special case of undirected graphs, APVC can be solved in $m^{2+o(1)}$ time [14, Theorem 1.8], which is faster than the aforementioned $\tilde{O}(m^\omega)$ time algorithm if $\omega > 2$. Over undirected graphs, k-APVC can be solved in $k^3 m^{1+o(1)} + n^2 \operatorname{poly}(\log n)$ time. In comparison, our algorithm from Theorem 5 can handle k-APVC in both undirected *and* directed graphs, and is faster for large enough values of k in dense graphs.

In directed planar graphs with maximum degree d, [7, Theorem 1.5] proves that APC can be solved in $O\left(d^{\omega-2} n^{\omega/2+1}\right)$ time.

In [15], the authors consider a symmetric variant of k-APC. Here, the input is a directed graph G on n vertices and m edges, and the goal is to compute for all pairs of vertices (s,t), the value of $\min(k, \lambda(s,t), \lambda(t,s))$. This easier problem can be solved in $O(kmn)$ time [15].

1.3 Organization

The rest of this paper is devoted to proving Theorems 4 and 5. In Section 2 we introduce notation, some useful definitions, and results on matrix computation which will be useful in proving correctness of our algorithms. In Section 3 we provide an intuitive overview of our algorithms for k-APC and k-APVC. In Section 4 we describe a framework of "flow vectors" for capturing connectivity values, and in Section 5 use this framework to prove Theorem 4. In Section 6 we present helpful results about vertex-connectivity, and in Section 7 use these results to prove Theorem 5.

2 Preliminaries

Graph Assumptions

Throughout, we let G denote a directed graph on n vertices and m edges. Without loss of generality, we assume that the underlying undirected graph of G is connected, i.e., G is weakly connected (since, if not, we could simply run our algorithms separately on each weakly connected component of G), so we have $m \geq n-1$. We assume G has no self-loops, since these do not affect the connectivity or vertex-connectivity values between distinct vertices.

[3] Known fast matrix multiplication algorithms imply that $\omega(1,2,1) < 3.25669$ [9, Table 2].

In Sections 4 and 5 we focus on the k-APC problem, and so allow G to have parallel edges between vertices (i.e., G can be a multigraph). We assume however, without loss of generality, that for any distinct vertices s and t, there are at most k edges from s to t (since if there were more than k parallel edges from s to t, we could delete some and bring the count of parallel edges down to k without changing the value of $\min(k, \lambda(s,t))$). In Sections 6 and 7 we focus on the k-APVC problem, and so assume that G is a simple graph with no parallel edges, since parallel edges from u to v cannot affect the value of a vertex connectivity $\nu(s,t)$, unless $u = s$ and $v = t$, in which case the value of $\nu(s,t)$ is simply increased by the number of additional parallel edges from s to t.

Graph Terminology and Notation

Given an edge e from u to v in G, we write $e = (u, v)$. We call u the tail of e and v the head of e. Vertices which are tails of edges entering a vertex v are called *in-neighbors* of v. Similarly, vertices which are heads of edges exiting v are called *out-neighbors* of v. Given a vertex u in G, we let $E_{\text{in}}(u)$ denote the set of edges entering u, and $E_{\text{out}}(u)$ denote the set of edges exiting u. Similarly, $V_{\text{in}}(u)$ denotes the set of in-neighbors of u, and $V_{\text{out}}(u)$ denotes the set of out-neighbors of u. Furthermore, we define $V_{\text{in}}[u] = V_{\text{in}}(u) \cup \{u\}$ and $V_{\text{out}}[u] = V_{\text{out}}(u) \cup \{u\}$. Finally, let $\deg_{\text{in}}(u) = |E_{\text{in}}(u)|$ and $\deg_{\text{out}}(u) = |E_{\text{out}}(u)|$ denote the indegree and outdegree of u respectively.

Given vertices s and t, an (s,t)-cut is a set C of edges, such that deleting the edges in C produces a graph with no s to t path. By Menger's theorem, the size of a minimum (s,t)-cut is equal to the connectivity $\lambda(s,t)$ from s to t. Similarly, an (s,t)-vertex cut is a set of C' of vertices with $s, t \notin C'$, such that deleting C' produces a graph with no s to t path. Clearly, a vertex cut exists if and only if (s,t) is not an edge. When (s,t) is not an edge, Menger's theorem implies that the size of a minimum (s,t)-vertex cut is equal to the vertex connectivity $\nu(s,t)$ from s to t.

Matrix Notation

Let A be a matrix. For indices i and j, we let $A[i,j]$ denote the (i,j) entry of A. More generally, if S is a set of row indices and T a set of column indices, we let $A[S,T]$ denote the submatrix of A restricted to rows from S and columns from T. Similarly, $A[S,*]$ denotes A restricted to rows from S, and $A[*,T]$ denotes A restricted to columns from T. We let $A^\top$ denote the transpose of A. If A is a square matrix, then we let $\text{adj}(A)$ denote the adjugate of A. If A is invertible, we let A^{-1} denote its inverse. If a theorem, lemma, or proposition statement refers to A^{-1}, it is generally asserting that A^{-1} exists (or if A is a random matrix, asserting that A^{-1} exists with some probability) as part of the statement. We let I denote the identity matrix (the dimensions of this matrix will always be clear from context). Given a vector $\vec{v}$, for any index i we let $\vec{v}[i]$ denote the i^{th} entry in $\vec{v}$. We let $\vec{0}$ denote the zero vector (the dimensions of this vector will always be clear from context). Given a positive integer k, we let $[k] = \{1, \ldots, k\}$ denote the set of the first k positive integers.

Matrix and Polynomial Computation

Given a prime p, we let $\mathbb{F}_p$ denote the finite field on p elements. Arithmetic operations over elements of $\mathbb{F}_p$ can be performed in $\tilde{O}(\log p)$ time.

We now recall some well-known results about computation with matrices and polynomials, which will be useful for our algorithms.

▶ **Proposition 6.** *Let A be an $a \times b$ matrix, and B be a $b \times a$ matrix. If $(I - BA)$ is invertible, then the matrix $(I - AB)$ is also invertible, with inverse*

$$(I - AB)^{-1} = I + A(I - BA)^{-1}B.$$

Proof. It suffices to verify that the product of $(I - AB)$ with the right hand side of the above equation yields the identity matrix. Indeed, we have

$$\begin{aligned}
&(I - AB)\left(I + A(I - BA)^{-1}B\right) \\
&= I + A(I - BA)^{-1}B - AB - ABA(I - BA)^{-1}B \\
&= I + A(I - BA)^{-1}B - AB - A\big(I - (I - BA)\big)(I - BA)^{-1}B \\
&= I + A(I - BA)^{-1}B - AB - A(I - BA)^{-1}B + AB,
\end{aligned}$$

which simplifies to I, as desired. ◀

▶ **Proposition 7.** *Let A be an $a \times a$ matrix over $\mathbb{F}_p$. We can compute the inverse A^{-1} (if it exists) in $O(a^\omega)$ field operations.*

▶ **Proposition 8** ([6, Theorem 1.1])**.** *Let A be an $a \times b$ matrix over $\mathbb{F}_p$. Then for any positive integer k, we can compute $\min(k, \operatorname{rank} A)$ in $O(ab + k^\omega)$ field operations.*

▶ **Proposition 9** (Schwartz-Zippel Lemma [13, Theorem 7.2])**.** *Let $f \in \mathbb{F}_p[x_1, \ldots, x_r]$ be a degree d, nonzero polynomial. Let $\vec{a}$ be a uniform random point in $\mathbb{F}_p^r$. Then $f(\vec{a})$ is nonzero with probability at least $1 - d/p$.*

3 Proof Overview

3.1 Flow Vector Encodings

Previous algorithms for APC [7] and its variants work in two steps:

Step 1: Encode
In this step, we prepare a matrix M which implicitly encodes the connectivity information of the input graph.

Step 2: Decode
In this step, we iterate over all pairs (s, t) of vertices in the graph, and for each pair run a small computation on a submatrix of M to compute the desired connectivity value.

The construction in the **encode** step is based off the framework of *flow vectors*, introduced in [7] as a generalization of classical techniques from network-coding. We give a high-level overview of how this method has been previously applied in the APC problem.[4]

Given the input graph G, we fix a source vertex s. Let $d = \deg_{\text{out}}(s)$, and let $\mathbb{F}$ be some ground field.[5] Our end goal is to assign to each edge e in the graph a special vector $\vec{e} \in \mathbb{F}^d$ which we call a *flow vector*.

First, for each edge $e \in E_{\text{out}}(s)$, we introduce a d-dimensional vector $\vec{v_e}$. These vectors intuitively correspond to some starting flow that is pumping out of s. It is important that these vectors are linearly independent (and previous applications have always picked these vectors to be distinct d-dimensional unit vectors). We then push this flow through the rest of the graph, by having each edge get assigned a vector which is a random linear combination

[4] For the APVC problem we employ a different, but analogous, framework described in Section 3.3.
[5] In our applications, we will pick $\mathbb{F}$ to be a finite field of size $\text{poly}(m)$.

of the flow vectors assigned to the edges entering its tail. That is, given an edge $e = (u, v)$ with $u \neq s$, the final flow vector $\vec{e}$ will be a random linear combination of the flow vectors for the edges entering u. If instead the edge $e = (s, v)$ is in $E_{\text{out}}(s)$, the final flow vector $\vec{e}$ will be a random linear combination of the flow vectors for the edges entering s, added to the initial flow $\vec{v}_e$.

The point of this random linear combination is to (with high probability) preserve linear independence. In this setup, for any vertex v and integer ℓ, if some subset of ℓ flow vectors assigned to edges in $E_{\text{in}}(v)$ is independent, then we expect that every subset of at most ℓ flow vectors assigned to edges in $E_{\text{out}}(v)$ is also independent. This sort of behavior turns out to generalize to preserving linear independence of flow vectors across cuts, which implies that (with high probability) for any vertex t, the rank of the flow vectors assigned to edges in $E_{\text{in}}(t)$ equals $\lambda(s, t)$.

Intuitively, this is because the flow vectors assigned to edges in $E_{\text{in}}(t)$ will be a linear combination of the $\lambda(s, t)$ flow vectors assigned to edges in a minimum (s, t)-cut, and the flow vectors assigned to edges in this cut should be independent.

Collecting all the flow vectors as column vectors in a matrix allows us to produce a single matrix M_s, such that computing the rank of $M_s[*, E_{\text{in}}(t)]$ yields the desired connectivity value $\lambda(s, t)$ (computing these ranks constitutes the **decode** step mentioned previously). Previous work [7, 1] set the initial pumped $\vec{v}_e$ to be distinct unit vectors. It turns out that for this choice of starting vectors, it is possible to construct a single matrix M (independent of a fixed choice of s), such that rank queries to submatrices of M correspond to the answers we wish to output in the APC problem and its variants.

In Section 3.2 we describe how we employ the flow vector framework to prove Theorem 4. Then in Section 3.3, we describe how we modify these methods to prove Theorem 5.

3.2 All-Pairs Connectivity

Our starting point is the $\tilde{O}(m^\omega)$ time algorithm for APC presented in [7], which uses the flow vector encoding scheme outlined in Section 3.1.

Let K be an $m \times m$ matrix, whose rows and columns are indexed by edges in the input graph. For each pair (e, f) of edges, if the head of e coincides with the tail of f, we set $K[e, f]$ to be a uniform random field element in $\mathbb{F}$. Otherwise, $K[e, f] = 0$. These field elements correspond precisely to the coefficients used in the random linear combinations of the flow vector framework. Define the matrix

$$M = (I - K)^{-1}. \tag{1}$$

Then [7] proves that with high probability, for any pair (s, t) of vertices, we have

$$\operatorname{rank} M[E_{\text{out}}(s), E_{\text{in}}(t)] = \lambda(s, t). \tag{2}$$

With this setup, the algorithm for APC is simple: first compute M (the **encode** step), and then for each pair of vertices (s, t), return the value of $\operatorname{rank} M[E_{\text{out}}(s), E_{\text{in}}(t)]$ as the connectivity from s to t (the **decode** step).

By Equation (1), we can complete the **encode** step in $\tilde{O}(m^\omega)$ time, simply by inverting an $m \times m$ matrix with entries from $\mathbb{F}$. It turns out we can also complete the **decode** step in the same time bound. So this gives an $\tilde{O}(m^\omega)$ time algorithm for APC.

Suppose now we want to solve the k-APC problem. A simple trick (observed in the proof of [1, Theorem 5.2] for example) in this setting can allow us to speed up the runtime of the **decode** step. However, it is not at all obvious how to speed up the **encode** step. To

implement the flow vector scheme of Section 3.1 as written, it seems almost inherent that one needs to invert an $m \times m$ matrix. Indeed, an inability to overcome this bottleneck is stated explicitly as part of the motivation in [1] for focusing on the k-APVC problem instead.

Our Improvement

The main idea behind our new algorithm for k-APC is to work with a low-rank version of the matrix K used in Equation (1) for the **encode** step.

Specifically, we construct certain random sparse matrices L and R with dimensions $m \times kn$ and $kn \times m$ respectively. We then set $K = LR$, and argue that with high probability, the matrix M defined in Equation (1) for this choice of K satisfies

$$\operatorname{rank} M[E_{\text{out}}(s), E_{\text{in}}(t)] = \min(k, \lambda(s,t)). \tag{3}$$

This equation is just a k-bounded version of Equation (2). By Proposition 6, we have

$$M = (I - K)^{-1} = (I - LR)^{-1} = I + L(I - RL)^{-1}R.$$

Note that $(I - RL)$ is a $kn \times kn$ matrix. So, to compute M (and thus complete the **encode** step) we no longer need to invert an $m \times m$ matrix! Instead we just need to invert a matrix of size $kn \times kn$. This is essentially where the $\tilde{O}\left((kn)^\omega\right)$ runtime in Theorem 4 comes from.

Conceptually, this argument corresponds to assigning flow vectors through the graph by replacing random linear combinations with random "low-rank combinations." That is, for an edge $e \in E_{\text{out}}(u)$ exiting a vertex u, we define the flow vector at e to be

$$\vec{e} = \sum_{i=1}^{k} \left(\sum_{f \in E_{\text{in}}(u)} L_i[f,u]\vec{f} \right) \cdot R_i[u,e],$$

where the inner summation is over all edges f entering u, $\vec{f}$ denotes the flow vector assigned to edge f, and the $L_i[f,u]$ and $R_i[u,e]$ terms correspond to random field elements uniquely determined by the index i and some (edge, vertex) pair.

Here, unlike in the method described in Section 3.1, the coefficient in front of $\vec{f}$ in its contribution to $\vec{e}$ is not uniquely determined by the pair of edges f and e. Rather, if edge f enters node u, then it has the same set of "weights" $L_i[f,u]$ it contributes to every flow vector exiting u. However, since we use k distinct weights, this restricted rule for propagating flow vectors still suffices to compute $\min(k, \lambda(s,t))$.

A good way to think about the effect of this alternate approach is that now for any vertex v and any integer $\ell \leq k$, if some subset of ℓ flow vectors assigned to edges in $E_{\text{in}}(v)$ is independent, then we expect that every subset of at most ℓ flow vectors assigned to edges in $E_{\text{out}}(v)$ is also independent. In the previous framework, this result held even for $\ell > k$. By relaxing the method used to determine flow vectors, we achieve a weaker condition, but this is still enough to solve k-APC.

This modification makes the **encode** step more complicated (it now consists of two parts: one where we invert a matrix, and one where we multiply that inverse with other matrices), but speeds it up overall. To speed up the **decode** step, we use a variant of an observation from the proof of [1, Theorem 5.2] to argue that we can assume every vertex in our graph has indegree and outdegree k. By Proposition 8 and Equation (3), this means we can compute $\min(k, \lambda(s,t))$ for all pairs (s,t) of vertices in $\tilde{O}(k^\omega n^2)$ time. So the bottleneck in our algorithm comes from the **encode** step, which yields the $\tilde{O}\left((kn)^\omega\right)$ runtime.

3.3 All-Pairs Vertex Connectivity

Our starting point is the $\tilde{O}((kn)^\omega)$ time algorithm in [1], which computes $\min(k, \nu(s,t))$ for all pairs of vertices (s,t) which are not edges. That algorithm is based off a variant of the flow vector encoding scheme outlined Section 3.1. Rather than assign vectors to edges, we instead assign flow vectors to vertices (intuitively this is fine because we are working with vertex connectivities in the k-APVC problem). The rest of the construction is similar: we imagine pumping some initial vectors to s and its out-neighbors, and then we propagate the flow through the graph so that at the end, for any vertex v, the flow vector assigned to v is a random linear combination of flow vectors assigned to in-neighbors of v.[6]

Let K be an $n \times n$ matrix, whose rows and columns are indexed by vertices in the input graph. For each pair (u,v) of vertices, if there is an edge from u to v, we set $K[u,v]$ to be a uniform random element in $\mathbb{F}$. Otherwise, $K[u,v] = 0$. These entries correspond precisely to coefficients used in the random linear combinations of the flow vector framework.

Now define the matrix

$$M = (I - K)^{-1}. \tag{4}$$

Then we argue that for any pair (s,t) of vertices, we have

$$\operatorname{rank} M[V_{\text{out}}[s], V_{\text{in}}[t]] = \begin{cases} \nu(s,t) + 1 & \text{if } (s,t) \text{ is an edge} \\ \nu(s,t) & \text{otherwise.} \end{cases} \tag{5}$$

Previously, [1, Proof of Lemma 5.1] sketched a different argument, which shows that $\operatorname{rank} M[V_{\text{out}}(s), V_{\text{in}}(t)] = \nu(s,t)$ when (s,t) is not an edge.

We use Equation (5) to solve k-APVC. For the **encode** step, we compute M. By Equation (4), we can do this by inverting an $n \times n$ matrix, which takes $\tilde{O}(n^\omega)$ time. For the **decode** step, by Equation (5) and Proposition 8, we can compute $\min(k, \nu(s,t))$ for all pairs (s,t) of vertices in asymptotically

$$\sum_{s,t} (\deg_{\text{out}}(s) \deg_{\text{in}}(t) + k^\omega) = m^2 + k^\omega n^2$$

time, where the sum is over all vertices s and t in the graph. The runtime bound we get here for the **decode** step is far too high – naively computing the ranks of submatrices is too slow if the graph has many high-degree vertices.

To avoid this slowdown, [1] employs a simple trick to reduce degrees in the graph: we can add layers of k new nodes to block off the ingoing and outgoing edges from each vertex in the original graph. That is, for each vertex s in G, we add a set S of k new nodes, replace the edges in $E_{\text{out}}(s)$ with edges from s to all the nodes in S, and add edges from every node in S to every vertex originally in $V_{\text{out}}(s)$. Similarly, for each vertex t in G, we add a set T of k new nodes, replace the edges in $E_{\text{in}}(t)$ with edges from all the nodes in T to t, and add edges from every vertex originally in $V_{\text{in}}(t)$ to every node in T.

It is easy to check that this transformation preserves the value of $\min(k, \nu(s,t))$ for all pairs (s,t) of vertices in the original graph where (s,t) is not an edge. Moreover, all vertices in the original graph have indegree and outdegree exactly k in the new graph. Consequently, the **decode** step can now be implemented to run in $\tilde{O}(k^\omega n^2)$ time. Unfortunately, this

[6] Actually, this behavior only holds for vertices $v \notin V_{\text{out}}[s]$. The rule for flow vectors assigned to vertices in $V_{\text{out}}[s]$ is a little more complicated, and depends on the values of the initial pumped vectors.

construction increases the number of vertices in the graph from n to $(2k+1)n$. As a consequence, in the **encode** step, the matrix K we work with is no longer $n \times n$, but instead is of size $(2k+1)n \times (2k+1)n$. Now inverting $I - K$ to compute M requires $\tilde{O}((kn)^\omega)$ time, which is why [1] obtains this runtime for their algorithm.

Our Improvement

Intuitively, the modification used by [1] to reduce degrees in the graph feels very inefficient. This transformation makes the graph larger in order to "lose information" about connectivity values greater than k. Rather than modify the graph in this way, can we modify the flow vector scheme itself to speed up the **decode** step? Our algorithm does this, essentially modifying the matrix of flow vectors to simulate the effect of the previously described transformation, without ever explicitly adding new nodes to the graph.

Instead of working directly with the matrix M from Equation (4), for each pair (s,t) of vertices we define a $(k+1) \times (k+1)$ matrix

$$M_{s,t} = B_s \left(M[V_{\text{out}}[s], V_{\text{in}}[t]]\right) C_t$$

which is obtained from multiplying a submatrix of M on the left and right by small random matrices B_s and C_t, with $k+1$ rows and columns respectively. Since B_s has $k+1$ rows and C_t has $k+1$ columns, we can argue that with high probability, Equation (5) implies that

$$\operatorname{rank} M_{s,t} = \begin{cases} \min(k+1, \nu(s,t)+1) & \text{if } (s,t) \text{ is an edge} \\ \min(k+1, \nu(s,t)) & \text{otherwise.} \end{cases}$$

So we can compute $\min(k, \nu(s,t))$ from the value of $\operatorname{rank} M_{s,t}$. This idea is similar to the preconditioning method used in algorithms for computing matrix rank efficiently (see [6] and the references therein). Conceptually, we can view this approach as a modification of the flow vector framework. Let $d = \deg_{\text{out}}(s)$. As noted in Section 3.1, previous work

1. starts by pumping out distinct d-dimensional unit vectors to nodes in $V_{\text{out}}(s)$, and then
2. computes the rank of all flow vectors of vertices in $V_{\text{in}}(t)$.

In our work, we instead

1. start by pumping out $(d+1)$ random $(k+1)$-dimensional vectors to nodes in $V_{\text{out}}[s]$, and then
2. compute the rank of $(k+1)$ random linear combinations of flow vectors for vertices in $V_{\text{in}}[t]$.

This alternate approach suffices for solving the k-APVC problem, while avoiding the slow $\tilde{O}((kn)^\omega)$ **encode** step of previous work.

So, in the **decode** step of our algorithm, we compute $\min(k, \nu(s,t))$ for each pair (s,t) of vertices by computing the rank of the $(k+1) \times (k+1)$ matrix $M_{s,t}$, in $\tilde{O}(k^\omega n^2)$ time overall.

Our **encode** step is more complicated than previous work, because not only do we need to compute the inverse $(I-K)^{-1}$, we also have to construct the $M_{s,t}$ matrices. Naively computing each $M_{s,t}$ matrix separately is too slow, so we end up using an indirect approach to compute all entries of the $M_{s,t}$ matrices *simultaneously*, with just $O(k^2)$ multiplications of $n \times n$ matrices. This takes $\tilde{O}(k^2 n^\omega)$ time, which is the bottleneck for our algorithm.

4 Flow Vector Encoding

The arguments in this section are similar to the arguments from [7, Section 2], but involve more complicated proofs because we work with low-rank random matrices as opposed to generic random matrices.

Fix a source vertex s in the input graph G. Let $d = \deg_{\text{out}}(s)$ denote the number of edges leaving s. Let $e_1, \ldots, e_d \in E_{\text{out}}(s)$ be the outgoing edges from s.

Take a prime $p = \Theta(m^5)$. Let $\vec{u}_1, \ldots, \vec{u}_d$ be distinct unit vectors in $\mathbb{F}_p^d$.

Eventually, we will assign each edge e in G a vector $\vec{e} \in \mathbb{F}_p^d$, which we call a *flow vector*. These flow vectors will be determined by a certain system of vector equations. To describe these equations, we first introduce some symbolic matrices.

For each index $i \in [k]$, we define an $m \times n$ matrix X_i, whose rows are indexed by edges of G and columns are indexed by vertices of G, such that for each edge $e = (u, v)$, entry $X_i[e, v] = x_{i,ev}$ is an indeterminate. All entries in X_i not of this type are zero. Similarly, we define $n \times m$ matrices Y_i, with rows indexed by vertices of G and columns indexed by edges of G, such that for every edge $f = (u, v)$, the entry $Y_i[u, f] = y_{i,uf}$ is an indeterminate. All entries in Y_i not of this type are zero. Let X be the $m \times kn$ matrix formed by horizontally concatenating the X_i matrices. Similarly, let Y be the $kn \times m$ matrix formed by vertically concatenating the Y_i matrices. Then we define the matrix

$$Z = XY = X_1Y_1 + \cdots + X_kY_k. \tag{6}$$

By construction, Z is an $m \times m$ matrix, with rows and columns indexed by edges of G, such that for any edges $e = (u, v)$ and $f = (v, w)$, we have

$$Z[e, f] = \sum_{i=1}^{k} x_{i,ev} y_{i,vf} \tag{7}$$

and all other entries of Z are set to zero.

Consider the following procedure. We assign independent, uniform random values from $\mathbb{F}_p$ to each variable $x_{i,ev}$ and $y_{i,uf}$. Let L_i, L, R_i, R, and K be the matrices over $\mathbb{F}_p$ resulting from this assignment to X_i, X, Y_i, Y, and Z respectively. In particular, we have

$$K = LR. \tag{8}$$

Now, to each edge e, we assign a flow vector $\vec{e} \in \mathbb{F}_p^d$, satisfying the following equalities:

1. Recall that $e_1, \ldots, e_d$ are all the edges exiting s, and $\vec{u}_1, \ldots, \vec{u}_d$ are distinct unit vectors in $\mathbb{F}_p^d$. For each edge $e_i \in E_{\text{out}}(s)$, we require its flow vector satisfy
$$\vec{e}_i = \left(\sum_{f \in E_{\text{in}}(s)} \vec{f} \cdot K[f, e_i] \right) + \vec{u}_i. \tag{9}$$
2. For each edge $e = (u, v)$ with $u \neq s$, we require its flow vector satisfy
$$\vec{e} = \sum_{f \in E_{\text{in}}(u)} \vec{f} \cdot K[f, e]. \tag{10}$$

A priori it is not obvious that flow vectors satisfying the above two conditions exist, but we show below that they do (with high probability). Let H_s be the $d \times m$ matrix whose columns are indexed by edges in G, such that the column associated with e_i is $\vec{u}_i$ for each index i, and the rest of the columns are zero vectors. Let F be the $d \times m$ matrix, with columns indexed by edges in G, whose columns $F[*, e] = \vec{e}$ are flow vectors for the corresponding edges. Then Equations (9) and (10) are encapsulated by the simple matrix equation

$$F = FK + H_s. \tag{11}$$

The following lemma shows we can solve for F in the above equation, with high probability.

▶ **Lemma 10.** *We have* $\det(I - K) \neq 0$*, with probability at least* $1 - 1/m^3$*.*

Proof. Since the input graph has no self-loops, by Equation (7) and the discussion immediately following it, we know that the diagonal entries of the $m \times m$ matrix Z are zero. By Equation (7), each entry of Z is a polynomial of degree at most two, with constant term set to zero. Hence, $\det(I - Z)$ is a polynomial over $\mathbb{F}_p$ with degree at most $2m$, and constant term equal to 1. In particular, this polynomial is nonzero. Then by the Schwartz-Zippel Lemma (Proposition 9), $\det(I - K)$ is nonzero with probability at least

$$1 - 2m/p \geq 1 - 1/m^3$$

by setting $p \geq 2m^4$. ◀

Suppose from now on that $\det(I-K) \neq 0$ (by Lemma 10, this occurs with high probability). Then with this assumption, we can solve for F in Equation (11) to get

$$F = H_s(I - K)^{-1} = \frac{H_s\left(\operatorname{adj}(I - K)\right)}{\det(I - K)}. \tag{12}$$

This equation will allow us to relate ranks of collections of flow vectors to connectivity values in the input graph.

▶ **Lemma 11.** *For any vertex* t *in* G*, with probability at least* $1 - 2/m^3$*, we have*

$$\operatorname{rank} F[*, E_{\text{in}}(t)] \leq \lambda(s, t).$$

Proof. Abbreviate $\lambda = \lambda(s, t)$. Conceptually, this proof works by arguing that the flow vectors assigned to all edges entering t are linear combinations of the flow vectors assigned to edges in a minimum (s, t)-cut of G.

Let C be a minimum (s, t)-cut. By Menger's theorem, $|C| = \lambda$.

Let S be the set of nodes reachable from s without using an edge in C, and let T be the set of nodes which can reach t without using an edge in C. By definition of an (s, t)-cut, S and T partition the vertices in G.

Now, let E' be the set of edges $e = (u, v)$ with $v \in T$. Set $K' = K[E', E']$ and $F' = F[*, E']$. Finally, let H' be a matrix whose columns are indexed by edges in E', such that the column associated with an edge $e \in C$ is $\vec{e}$, and all other columns are equal to $\vec{0}$.

Then by Equations (9) and (10), we have

$$F' = F'K' + H'.$$

Indeed, for any edge $e = (u, v) \in E'$, if $u \in S$ then $e \in C$ so $H'[*, e] = \vec{e}$, and there can be no edge $f \in E'$ entering u, so $(F'K')[*, e] = \vec{0}$. If instead $u \in T$, then $H'[*, e] = \vec{0}$, but every edge f entering u is in E', so by Equation (10), we have $(F'K')[*, e] = F'[*, e]$ as desired.

Using similar reasoning to the proof of Lemma 10, we have $\det(I-K') \neq 0$ with probability at least $1 - 1/m^3$. If this event occurs, we can solve for F' in the previous equation to get

$$F' = H'(I - K')^{-1}.$$

Since H' has at most λ nonzero columns, $\operatorname{rank} H \leq \lambda$. So by the above equation, $\operatorname{rank} F' \leq \lambda$. By definition, $E_{\text{in}}(t) \subseteq E'$. Thus $F[*, E_{\text{in}}(t)]$ is a submatrix of F'. Combining this with the previous results, we see that $\operatorname{rank} F[*, E_{\text{in}}(t)] \leq \lambda$, as desired. The claimed probability bound follows by a union bound over the events that $I - K$ and $I - K'$ are both invertible. ◀

▶ **Lemma 12.** *For any vertex t in G, with probability at least $1 - 2/m^3$, we have*

$$\operatorname{rank} F[*, E_{\text{in}}(t)] \geq \min(k, \lambda(s,t)).$$

Proof. Abbreviate $\lambda = \min(k, \lambda(s,t))$. Intuitively, our proof will argue that the presence of edge-disjoint paths from s to t will lead to certain edges in $E_{\text{in}}(t)$ being assigned linearly independent flow vectors (with high probability), which will then imply the desired rank lower bound.

By Menger's theorem, G contains λ edge-disjoint paths $P_1, \ldots, P_\lambda$ from s to t.

Consider the following assignment to the variables of the symbolic matrices X_i and Y_i. For each index $i \leq \lambda$ and edge $e = (u, v)$, we set variable $x_{i,ev} = 1$ if e is an edge in P_i. Similarly, for each index $i \leq \lambda$ and edge $f = (u, v)$, we set variable $y_{i,uf} = 1$ if f is an edge in P_i. All other variables are set to zero. In particular, if $i > \lambda$, then X_i and Y_i have all their entries set to zero. With respect to this assignment, the matrix X_iY_i (whose rows and columns are indexed by edges in the graph) has the property that $(X_iY_i)[e, f] = 1$ if f is the edge following e on path P_i, and all other entries are set to zero.

Then by Equation (6), we see that under this assignment, $Z[e, f] = 1$ if e and f are consecutive edges in some path P_i, and all other entries of Z are set to zero. For this particular assignment, because the P_i are edge-disjoint paths, Equations (9) and (10) imply that the last edge of each path P_i is assigned a distinct d-dimensional unit vector. These vectors are independent, so, $\operatorname{rank} F[*, E_{\text{in}}(t)] = \lambda$ in this case.

With respect to this assignment, this means that $F[*, E_{\text{in}}(t)]$ contains a $\lambda \times \lambda$ full-rank submatrix. Let F' be a submatrix of $F[*, E_{\text{in}}(t)]$ with this property. Since F' has full rank, we have $\det F' \neq 0$ for the assignment described above.

Now, before assigning values to variables, each entry of $\operatorname{adj}(I - Z)$ is a polynomial of degree at most $2m$. So by Equation (12), $\det F'$ is equal to some polynomial P of degree at most $2\lambda m$, divided by $(\det(I - Z))^\lambda$. We know P is a nonzero polynomial, because we saw above that $\det F'$ is nonzero for some assignment of values to the variables (and if P were the zero polynomial, then $\det F'$ would evaluate to zero under every assignment).

By Lemma 10, with probability at least $1 - 1/m^3$, a random evaluation to the variables will have $\det(I - Z)$ evaluate to a nonzero value. Assuming this event occurs, by Schwartz-Zippel Lemma (Proposition 9), a random evaluation to the variables in Z will have $\det F' \neq 0$ with probability at least $1 - (2\lambda m)/p \geq 1 - 1/m^3$ by setting $p \geq 2m^5$.

So by union bound, a particular $\lambda \times \lambda$ submatrix of $F[*, E_{\text{in}}(t)]$ will be full rank with probability at least $1 - 2/m^3$. This proves the desired result. ◀

▶ **Lemma 13.** *Fix vertices s and t. Define $\lambda = \operatorname{rank} (I - K)^{-1}[E_{\text{out}}(s), E_{\text{in}}(t)]$. With probability at least $1 - 4/m^3$, we have $\min(k, \lambda) = \min(k, \lambda(s,t))$.*

Proof. The definition of H_s together with Equation (12) implies that

$$F[*, E_{\text{in}}(t)] = (I - K)^{-1}[E_{\text{out}}(s), E_{\text{in}}(t)]. \tag{13}$$

By union bound over Lemmas 11 and 12, with probability at least $1 - 4/m^3$ the inequalities

$$\lambda = \operatorname{rank} (I - K)^{-1}[E_{\text{out}}(s), E_{\text{in}}(t)] = \operatorname{rank} F[*, E_{\text{in}}(t)] \leq \lambda(s,t)$$

and

$$\lambda = \operatorname{rank} (I - K)^{-1}[E_{\text{out}}(s), E_{\text{in}}(t)] = \operatorname{rank} F[*, E_{\text{in}}(t)] \geq \min(k, \lambda(s,t))$$

simultaneously hold. The desired result follows. ◀

5 Connectivity Algorithm

In this section, we present our algorithm for k-APC.

We begin by modifying the input graph G as follows. For every vertex v in G, we introduce two new nodes v_{out} and v_{in}. We replace each edge (u, v) originally in G is by the edge $(u_{\text{out}}, v_{\text{in}})$. We add k parallel edges from v to v_{out}, and k parallel edges from v_{in} to v, for all u and v. We call vertices present in the graph before modification the *original vertices*.

Suppose G originally had n nodes and m edges. Then the modified graph has $n_{\text{new}} = 3n$ nodes and $m_{\text{new}} = m + 2kn$ edges. For any original vertices s and t, edge-disjoint paths from s to t in the new graph correspond to edge disjoint paths from s to t in the original graph. Moreover, for any integer $\ell \leq k$, if the original graph contained ℓ edge-disjoint paths from s to t, then the new graph contains ℓ edge-disjoint paths from s to t as well.

Thus, for any original vertices s and t, the value of $\min(k, \lambda(s, t))$ remains the same in the old graph and the new graph. So, it suffices to solve k-APC on the new graph. In this new graph, the indegrees and outdegrees of every original vertex are equal to k. Moreover, sets $E_{\text{out}}(s)$ and $E_{\text{in}}(t)$ are pairwise disjoint, over all original vertices s and t.

We make use of the matrices defined in Section 4, except now these matrices are defined with respect to the modified graph. In particular, K, L, and R are now matrices with dimensions $m_{\text{new}} \times m_{\text{new}}$, $m_{\text{new}} \times n_{\text{new}}$, and $n_{\text{new}} \times m_{\text{new}}$ respectively.

Define $\tilde{L}$ to be the $kn \times n_{\text{new}}$ matrix obtained by vertically concatenating $L[E_{\text{out}}(s), *]$ over all original vertices s. Similarly, define $\tilde{R}$ to be the $n_{\text{new}} \times kn$ matrix obtained by horizontally concatenating $R[*, E_{\text{in}}(t)]$ over all original vertices t.

The Algorithm

Using the above definitions, we present our approach for solving k-APC in Algorithm 1.

Algorithm 1 Our algorithm for solving k-APC.

1: Compute the $n_{\text{new}} \times n_{\text{new}}$ matrix $(I - RL)^{-1}$.
2: Compute the $kn_{\text{new}} \times kn_{\text{new}}$ matrix $M = \tilde{L}(I - RL)^{-1}\tilde{R}$.
3: For each pair (s, t) of original vertices, compute

$$\operatorname{rank} M[E_{\text{out}}(s), E_{\text{in}}(t)]$$

and output this as the value for $\min(k, \lambda(s, t))$.

▶ **Theorem 14.** *With probability at least $1 - 5/(m_{\text{new}})$, Algorithm 1 correctly solves k-APC.*

Proof. By Lemma 10, with probability at least $1 - 1/(m_{\text{new}})^4$ the matrix $I - K$ is invertible. Going forward, we assume that $I - K$ is invertible.

By Lemma 13, with probability at least $1 - 4/(m_{\text{new}})^3$, we have

$$\operatorname{rank}(I - K)^{-1}[E_{\text{out}}(s), E_{\text{in}}(t)] = \min(k, \lambda(s, t)) \tag{14}$$

for any given original vertices s and t. By union bound over all $n^2 \leq (m_{\text{new}})^2$ pairs of original vertices (s, t), we see that Equation (14) holds for all original vertices s and t with probability at least $1 - 4/(m_{\text{new}})$.

Since $I - K$ is invertible, by Equation (8) and Proposition 6 we have

$$(I - K)^{-1} = (I - LR)^{-1} = I + L(I - RL)^{-1}R.$$

Using the above equation in Equation (14) shows that for original vertices s and t, the quantity $\min(k, \lambda(s,t))$ is equal to the rank of

$$(I + L(I - RL)^{-1}R)[E_{\text{out}}(s), E_{\text{in}}(t)] = L[E_{\text{out}}(s), *](I - RL)^{-1}R[*, E_{\text{in}}(t)]$$

where we use the fact that $I[E_{\text{out}}(s), E_{\text{in}}(t)]$ is the all zeroes matrix, since in the modified graph, $E_{\text{out}}(s)$ and $E_{\text{in}}(t)$ are disjoint sets for all pairs of original vertices (s,t).

Then by definition of $\tilde{L}$ and $\tilde{R}$, the above equation and discussion imply that

$$\min(k, \lambda(s,t)) = \text{rank } (\tilde{L}(I - RL)^{-1}\tilde{R})[E_{\text{out}}(s), E_{\text{in}}(t)] = \text{rank } M[E_{\text{out}}(s), E_{\text{in}}(t)]$$

which proves that Algorithm 1 outputs the correct answers.

A union bound over the events that $I - K$ is invertible and that Equation (14) holds for all (s,t), shows that Algorithm 1 is correct with probability at least $1 - 5/(m_{\text{new}})$. ◀

We are now ready to prove our main result.

▶ **Theorem 4.** *For any positive integer k, k-APC can be solved in $\tilde{O}((kn)^\omega)$ time.*

Proof. By Theorem 14, Algorithm 1 correctly solves the k-APC problem. We now argue that Algorithm 1 can be implemented to run in $\tilde{O}((kn)^\omega)$ time.

In step 1 of Algorithm 1, we need to compute $(I - RL)^{-1}$.

From the definitions of R and L, we see that to compute RL, it suffices to compute the products R_iL_j for each pair of indices $(i,j) \in [k]^2$. The matrix R_iL_j is $n_{\text{new}} \times n_{\text{new}}$, and its rows and columns are indexed by vertices in the graph. Given vertices u and v, let $E(u,v)$ denote the set of parallel edges from u to v. From the definitions of the R_i and L_j matrices, we see that for any vertices u and v, we have

$$(R_iL_j)[u,v] = \sum_{e \in E(u,v)} R_i[u,e]L_j[e,v]. \tag{15}$$

As noted in Section 2, for all vertices u and v we may assume that $|E(u,v)| \leq k$.

For each vertex u, define the $k \times \deg_{\text{out}}(u)$ matrix R'_u, with rows indexed by $[k]$ and columns indexed by edges exiting u, by setting

$$R'_u[i,e] = R_i[u,e]$$

for all $i \in [k]$ and $e \in E_{\text{out}}(u)$.

Similarly, for each vertex v, define the $\deg_{\text{in}}(v) \times k$ matrix L'_v by setting

$$L'_v[e,j] = L_j[e,v]$$

for all $e \in E_{\text{in}}(v)$ and $j \in [k]$.

Finally, for each pair (u,v) of vertices, define $R'_{uv} = R'_u[*, E(u,v)]$ and $L'_{uv} = L'_v[E(u,v), *]$. Then by Equation (15), we have

$$(R_iL_j)[u,v] = R'_{uv}L'_{uv}[i,j].$$

Thus, to compute the R_iL_j products, it suffices to build the R'_u and L'_v matrices in $O(km_{\text{new}})$ time, and then compute the $R'_{uv}L'_{uv}$ products. We can do this by computing $(n_{\text{new}})^2$ products of pairs of $k \times k$ matrices. Since for every pair of vertices (u,v), there are at most k parallel edges from u to v, $km_{\text{new}} \leq k^2n^2$, we can compute all the R_iL_j products, and hence the entire matrix RL, in $\tilde{O}(n^2k^\omega)$ time.

We can then compute $I - RL$ by modifying $O(kn)$ entries of RL. Finally, by Proposition 7 we can compute $(I - RL)^{-1}$ in $\tilde{O}((kn)^\omega)$ time.

So overall, step 1 of Algorithm 1 takes $\tilde{O}((kn)^\omega)$ time.

In step 2 of Algorithm 1, we need to compute $M = \tilde{L}(I - RL)^{-1}\tilde{R}$.

Recall that $\tilde{L}$ is a $kn \times n_{\text{new}}$ matrix. By definition, each row of $\tilde{L}$ has a single nonzero entry. Similarly, $\tilde{R}$ is an $n_{\text{new}} \times kn$ matrix, with a single nonzero entry in each column.

Thus we can compute M, and complete step 2 of Algorithm 1 in $\tilde{O}((kn)^2)$ time.

Finally, in step 3 of Algorithm 1, we need to compute

$$\operatorname{rank} M[E_{\text{out}}(s), E_{\text{in}}(t)] \tag{16}$$

for each pair of original vertices (s, t) in the graph. In the modified graph, each original vertex has indegree and outdegree k, so each $M[E_{\text{out}}(s), E_{\text{in}}(t)]$ is a $k \times k$ matrix. For any fixed (s, t), by Proposition 8 we can compute the rank of $M[E_{\text{out}}(s), E_{\text{in}}(t)]$ in $\tilde{O}(k^\omega)$ time.

So we can compute the ranks from Equation (16) for all n^2 pairs of original vertices (s, t) and complete step 3 of Algorithm 1 in $\tilde{O}(k^\omega n^2)$ time.

Thus we can solve k-APC in $\tilde{O}((kn)^\omega)$ time overall, as claimed. ◀

6 Encoding Vertex Connectivities

Take a prime $p = \tilde{\Theta}(n^5)$. Let K be an $n \times n$ matrix, whose rows and columns are indexed by vertices of G. For each pair (u, v) of vertices, if (u, v) is an edge in G, we set $K[u, v]$ to be a uniform random element of $\mathbb{F}_p$. Otherwise, $K[u, v] = 0$.

Recall from Section 2 that given a vertex v in G, we let $V_{\text{in}}[v] = V_{\text{in}}(v) \cup \{v\}$ be the set consisting of v and all in-neighbors of v, and $V_{\text{out}}[v] = V_{\text{out}}(v) \cup \{v\}$ be the set consisting of v and all out-neighbors of v. The following proposition[7] is based off ideas from [7, Section 2]. A proof of this result can be found in the full version of this paper [3, Appendix B.2].

▶ **Proposition 15.** *For any vertices s and t in G, with probability at least $1 - 3/n^3$, the matrix $(I - K)$ is invertible and we have*

$$\operatorname{rank}\ (I - K)^{-1}[V_{\text{out}}[s], V_{\text{in}}[t]] = \begin{cases} \nu(s,t) + 1 & \text{if } (s,t) \text{ is an edge} \\ \nu(s,t) & \text{otherwise.} \end{cases}$$

Proposition 15 shows that we can compute vertex connectivities in G simply by computing ranks of certain submatrices of $(I - K)^{-1}$. However, these submatrices could potentially be quite large, which is bad if we want to compute the vertex connectivities quickly. To overcome this issue, we show how to decrease the size of $(I - K)^{-1}$ while still preserving relevant information about the value of $\nu(s, t)$.

▶ **Lemma 16.** *Let M be an $a \times b$ matrix over $\mathbb{F}_p$. Let Γ be a $(k+1) \times a$ matrix with uniform random entries from $\mathbb{F}_p$. Then with probability at least $1 - (k+1)/p$, we have*

$$\operatorname{rank} \Gamma M = \min(k + 1, \operatorname{rank} M).$$

[7] The result stated here differs from a similar claim used in [1, Section 5]. See the full version of this paper [3, Appendix B.1] for a comparison of these arguments.

Proof. Since ΓM has $k+1$ rows, $\operatorname{rank}(\Gamma M) \leq k+1$.

Similarly, since ΓM has M as a factor, $\operatorname{rank}(\Gamma M) \leq \operatorname{rank} M$. Thus

$$\operatorname{rank} \Gamma M \leq \min(k+1, \operatorname{rank} M). \tag{17}$$

So, it suffices to show that ΓM has rank at least $\min(k+1, \operatorname{rank} M)$.

Set $r = \min(k+1, \operatorname{rank} M)$. Then there exist subsets S and T of row and column indices respectively, such that $|S| = |T| = r$ and $M[S,T]$ has rank r. Now, let U be an arbitrary set of r rows in Γ. Consider the matrix $M' = (\Gamma M)[U,T]$.

We can view each entry of M' as a polynomial of degree at most 1 in the entries of Γ. This means that $\det M'$ is a polynomial of degree at most r in the entries of Γ. Moreover, if the submatrix $\Gamma[U,T] = I$ happens to be the identity matrix, then $M' = M[S,T]$. This implies that $\det M'$ is a nonzero polynomial in the entries of Γ, because for some assignment of values to the entries of Γ, this polynomial has nonzero evaluation $\det M[S,T] \neq 0$ (where we are using the fact that $M[S,T]$ has full rank).

So by the Schwartz-Zippel Lemma (Proposition 9), the matrix ΓM has rank at least r, with probability at least $1 - r/p$.

Together with Equation (17), this implies the desired result. ◀

Now, to each vertex u in the graph, we assign a $(k+1)$-dimensional column vector $\vec{b}_u$ and a $(k+1)$-dimensional row vector $\vec{c}_u$.

Let B be the $(k+1) \times n$ matrix formed by concatenating all of the $\vec{b}_u$ vectors horizontally, and let C be the $n \times (k+1)$ matrix formed by concatenating all of the $\vec{c}_u$ vectors vertically. For each pair of distinct vertices (s,t), define the $(k+1) \times (k+1)$ matrix

$$M_{s,t} = B[*, V_{\text{out}}[s]] \left((I-K)^{-1}[V_{\text{out}}[s], V_{\text{in}}[t]] \right) C[V_{\text{in}}[t], *]. \tag{18}$$

The following result is the basis of our algorithm for k-APVC.

▶ **Lemma 17.** *For any vertices s and t in G, with probability at least $1 - 5/n^3$, we have*

$$\operatorname{rank} M_{s,t} = \begin{cases} \min(k+1, \nu(s,t)+1) & \text{if } (s,t) \text{ is an edge} \\ \min(k+1, \nu(s,t)) & \text{otherwise.} \end{cases}$$

Proof. Fix vertices s and t. Then, by Proposition 15, we have

$$\operatorname{rank}\ (I-K)^{-1}[V_{\text{out}}[s], V_{\text{in}}[t]] = \begin{cases} \nu(s,t)+1 & \text{if } (s,t) \text{ is an edge} \\ \nu(s,t) & \text{otherwise} \end{cases}$$

with probability at least $1 - 3/n^3$. Assume the above equation holds.

Then, by setting $\Gamma = B[*, V_{\text{out}}[s]]$ and $M = (I-K)^{-1}[V_{\text{out}}[s], V_{\text{in}}[t]]$ in Lemma 16, we see that with probability at least $1 - 1/n^3$ we have

$$\operatorname{rank} B[*, V_{\text{out}}[s]](I-K)^{-1}[V_{\text{out}}[s], V_{\text{in}}(t)] = \begin{cases} \min(k+1, \nu(s,t)+1) & \text{if } (s,t) \text{ is an edge} \\ \min(k+1, \nu(s,t)) & \text{otherwise.} \end{cases}.$$

Assume the above equation holds.

Finally, by setting $\Gamma = C^\top[*, V_{\text{in}}(t)]$ and $M = (B[*, V_{\text{out}}[s]](I-K)^{-1}[V_{\text{out}}[s], V_{\text{in}}(t)])^\top$ in Lemma 16 and transposition, we see that with probability at least $1 - 1/n^3$ we have

$$\operatorname{rank} B[*, V_{\text{out}}[s]] \left((I-K)^{-1}[V_{\text{out}}[s], V_{\text{in}}(t)] \right) C[V_{\text{in}}(t), *] = \min(k+1, \nu(s,t)+1)$$

if there is an edge from s to t, and

$$\operatorname{rank} B[*, V_{\text{out}}[s]] \left((I-K)^{-1}[V_{\text{out}}[s], V_{\text{in}}(t)] \right) C[V_{\text{in}}(t), *] = \min(k+1, \nu(s,t))$$

otherwise. So by union bound, the desired result holds with probability at least $1 - 5/n^3$. ◀

7 Vertex Connectivity Algorithm

Let A be the adjacency matrix of the graph G with self-loops. That is, A is the $n \times n$ matrix whose rows and columns are indexed by vertices of G, and for every pair (u, v) of vertices, $A[u, v] = 1$ if $v \in V_{\text{out}}[u]$ (equivalently, $u \in V_{\text{in}}[v]$), and $A[u, v] = 0$ otherwise.

Recall the definitions of the $\vec{b}_u$ and $\vec{c}_u$ vectors, and the K, B, C and $M_{s,t}$ matrices from Section 6. For each $i \in [k+1]$, let P_i be the $n \times n$ diagonal matrix, with rows and columns indexed by vertices of G, such that $P_i[u, u] = \vec{b}_u[i]$. Similarly, let Q_i be the $n \times n$ diagonal matrix, with rows and columns indexed by vertices of G, such that $Q_i[u, u] = \vec{c}_u[i]$.

With these definitions, we present our approach for solving k-APVC in Algorithm 2.

Algorithm 2 Our algorithm for solving k-APVC.

1: Compute the $n \times n$ matrix $(I - K)^{-1}$.
2: For each pair $(i, j) \in [k+1]^2$ of indices, compute the $n \times n$ matrix

$$D_{ij} = AP_i(I - K)^{-1}Q_jA^\top.$$

3: For each pair (s, t) of vertices, let $F_{s,t}$ be the $(k+1) \times (k+1)$ matrix whose (i, j) entry is equal to $D_{ij}[s, t]$. If (s, t) is an edge, output $(\operatorname{rank} F_{s,t}) - 1$ as the value for $\min(k, \nu(s, t))$. Otherwise, output $\min(k, \operatorname{rank} F_{s,t})$ as the value for $\min(k, \nu(s, t))$.

The main idea of Algorithm 2 is to use Lemma 17 to reduce computing $\min(k, \nu(s, t))$ for a given pair of vertices (s, t) to computing the rank of a corresponding $(k+1) \times (k+1)$ matrix, $M_{s,t}$. To make this approach efficient, we compute the entries of all $M_{s,t}$ matrices simultaneously, using a somewhat indirect argument.

▶ **Theorem 18.** *With probability at least $1 - 5/n$, Algorithm 2 correctly solves k-APVC.*

Proof. We prove correctness of Algorithm 2 using the following claim.

▷ Claim 19. For all pairs of indices $(i, j) \in [k+1]^2$ and all pairs of vertices (s, t), we have

$$M_{s,t}[i, j] = D_{ij}[s, t],$$

where D_{ij} is the matrix computed in step 2 of Algorithm 2.

Proof. By expanding out the expression for D_{ij} from step 2 of Algorithm 2, we have

$$D_{ij}[s, t] = \sum_{u,v} A[s, u]P_i[u, u]\left((I - K)^{-1}[u, v]\right)Q_j[v, v]A[v, t],$$

where the sum is over all vertices u, v in the graph (here, we use the fact that P_i and Q_j are diagonal matrices). By the definitions of A, the P_i, and the Q_j matrices, we have

$$D_{ij}[s, t] = \sum_{\substack{u \in V_{\text{out}}[s] \\ v \in V_{\text{in}}[t]}} \vec{b}_u[i]\left((I - K)^{-1}[u, v]\right)\vec{c}_v[j]. \tag{19}$$

On the other hand, the definition of $M_{s,t}$ from Equation (18) implies that

$$M_{s,t}[i, j] = \sum_{\substack{u \in V_{\text{out}}[s] \\ v \in V_{\text{in}}[t]}} B[i, u]\left((I - K)^{-1}[u, v]\right)C[v, j].$$

Since $B[i,u] = \vec{b}_u[i]$ and $C[v,j] = \vec{c}_v[j]$, the above equation and Equation (19) imply that

$$M_{s,t}[i,j] = D_{ij}[s,t]$$

for all (i,j) and (s,t), as desired. ◁

By Claim 19, the matrix $F_{s,t}$ computed in step 3 of Algorithm 2 is equal to $M_{s,t}$. So by Lemma 17, for any fixed pair (s,t) of vertices we have

$$\operatorname{rank} F_{s,t} = \begin{cases} \min(k+1, \nu(s,t)+1) & \text{if } (s,t) \text{ is an edge} \\ \min(k+1, \nu(s,t)) & \text{otherwise.} \end{cases} \tag{20}$$

with probability at least $1 - 5/n^3$. Then by a union bound over all pairs of vertices (s,t), we see that Equation (20) holds for all pairs (s,t), with probability at least $1 - 5/n$.

Assume this event occurs. Then if (s,t) is an edge, by Equation (20) we correctly return

$$(\operatorname{rank} F_{s,t}) - 1 = \min(k+1, \nu(s,t)+1) - 1 = \min(k, \nu(s,t))$$

as our answer for this pair.

Similarly, if (s,t) is not an edge, by Equation (20) we correctly return

$$\min(k, \operatorname{rank} F_{s,t}) = \min(k, k+1, \nu(s,t)) = \min(k, \nu(s,t))$$

as our answer for this pair. This proves the desired result. ◀

With Theorem 18 established, we can prove our result for vertex connectivities.

▶ **Theorem 5.** *For any positive integer k, k-APVC can be solved in $\tilde{O}(k^2 n^\omega)$ time.*

Proof. By Theorem 18, Algorithm 2 correctly solves the k-APVC problem. We now argue that Algorithm 2 can be implemented to run in $\tilde{O}(k^2 n^\omega)$ time.

In step 1 of Algorithm 2, we need to compute $(I-K)^{-1}$. Since K is an $n \times n$ matrix, by Proposition 7 we can complete this step in $\tilde{O}(n^\omega)$ time.

In step 2 of Algorithm 2, we need to compute D_{ij} for each pair $(i,j) \in [k+1]^2$. For each fixed pair (i,j), the D_{ij} matrix is defined as a product of five $n \times n$ matrices whose entries we know, so this step takes $\tilde{O}(k^2 n^\omega)$ time overall.

In step 3 of Algorithm 2, we need to construct each F_{st} matrix, and compute its rank. Since each F_{st} matrix has dimensions $(k+1) \times (k+1)$ and its entries can be filled in simply by reading entries of the D_{ij} matrices we have already computed, by Proposition 8 this step can be completed in $\tilde{O}(k^\omega n^2)$ time.

By adding up the runtimes for each of the steps and noting that $k \leq n$, we see that Algorithm 2 solves k-APVC in $\tilde{O}(k^2 n^\omega)$ time, as claimed. ◀

Abstract

A recent breakthrough work of Limaye, Srinivasan and Tavenas [29] proved superpolynomial lower bounds for low-depth arithmetic circuits via a "hardness escalation" approach: they proved lower bounds for low-depth *set-multilinear* circuits and then lifted the bounds to low-depth general circuits. In this work, we prove superpolynomial lower bounds for low-depth circuits by bypassing the hardness escalation, i.e., the set-multilinearization, step. As set-multilinearization comes with an exponential blow-up in circuit size, our direct proof opens up the possibility of proving an exponential lower bound for low-depth homogeneous circuits by evading a crucial bottleneck. Our bounds hold for the iterated matrix multiplication and the Nisan-Wigderson design polynomials. We also define a subclass of unrestricted depth homogeneous formulas which we call *unique parse tree* (UPT) formulas, and prove superpolynomial lower bounds for these. This significantly generalizes the superpolynomial lower bounds for *regular* formulas [6, 19].

1 Introduction

Arithmetic circuits are a natural model for computing polynomials using the basic operations of addition and multiplication. One of the most fundamental questions about arithmetic circuits is about finding a family of explicit polynomials (if they exist) that cannot be computed by polynomial-sized arithmetic circuits. The existence of such explicit polynomials was conjectured by Valiant in 1979 [40] and is the famed VP vs VNP conjecture. Arithmetic

circuit lower bounds are expected to be easier than Boolean circuit lower bounds. Among many reasons, one is due to the phenomenon of depth reduction. Arithmetic circuits can be converted into low-depth circuits preserving the output polynomial and not blowing up the size too much [1, 10, 22, 39, 41]. Due to this, strong enough lower bounds even for restrictive models of computation like depth-3 circuits or homogeneous depth-4 circuits can lead to superpolynomial arithmetic circuit lower bounds.

Arithmetic formulas are an important subclass of arithmetic circuits where the out-degree of every gate is at most 1. For constant-depth, formulas and circuits are polynomially related. Also, all our results deal with formulas. So we will only refer to formulas from here on. We consider (families of) polynomials having degree at most polynomial in n, the number of variables. One of the first results studying low-depth arithmetic formulas was that of [32], who proved lower bounds for homogeneous depth-3 formulas. Progress on homogeneous formula lower bound was stalled for a while, and then various lower bounds for homogeneous depth-4 formulas were proven in a series of works [6, 9, 13, 14, 19, 25, 26]. There was limited progress for higher-depth formulas, and lower bounds remained open even for depth-5 formulas. In a recent breakthrough work, [29] proved superpolynomial lower bounds for constant-depth arithmetic formulas. Their lower bounds are of the form $n^{\Omega(\log(n)^{c_\Delta})}$ for a constant $0 < c_\Delta < 1$ depending on the depth Δ of the formula. The following two open problems naturally emerge out of their work.

▶ **Open Problem 1.** *Prove superpolynomial lower bounds for* general *formulas or even homogeneous formulas. (A formula is homogeneous if every gate computes a homogeneous polynomial.)*

▶ **Open Problem 2.** *Prove* exponential *lower bounds for constant-depth arithmetic formulas. This is interesting even for homogeneous depth-*5 *formulas.*

Towards answering Open Problems 1.1 and 1.2, let us examine the lower bound proof in [29] at a high level. Their proof has two main steps: First, they reduce the problem of proving lower bounds for low-depth formulas to the problem of proving lower bounds for low-depth *set-multilinear* formulas; set-multilinear formulas are special homogeneous formulas with an underlying partition of the variables into subsets. [29] calls such reductions "hardness escalation". Second, they use an interesting adaptation of the rank of the partial derivatives matrix measure [31] to prove a lower bound for low-depth set-multilinear formulas. They call this measure *relative rank* (relrk). The effectiveness of the relrk measure crucially depends on a certain "imbalance" between the sizes of the sets used to define set-multilinear polynomials. The proof in [29] raises two natural questions:

Question 1: Can we bypass the hardness escalation, i.e., the set-multilinearization, step?

Question 2: Can we design a measure that exploits some weakness of homogeneous (but not necessarily set-multilinear) formulas directly?

Motivations for studying Question 1. Set-multilinear circuits form a natural circuit class as most interesting polynomial families, such as the determinant, permanent, iterated matrix multiplication, etc., are set-multilinear. However, set-multilinearization comes with an exponential blow up in size – a homogeneous, depth-Δ formula computing a set-multilinear polynomial of degree d can be converted to a set-multilinear formula of depth Δ and size $d^{O(d)} \cdot s$ (see [29]). So, an exponential lower bound for low-depth set-multilinear formulas does not imply an exponential lower bound for low-depth homogeneous formulas since we are restricted to work with $d \leq \frac{\log n}{\log \log n}$. Indeed, it is possible to strengthen and refine the argument in [29] to get an *exponential* lower bound for low-depth set-multilinear formulas (see [2]). An approach that evades the hardness escalation step, which is a critical bottleneck,

and directly works with homogeneous formulas has the potential to avoid the $d^{O(d)}$ loss and give an exponential lower bound for low-depth homogeneous formulas. For instance, the direct arguments in [14,26] yield exponential lower bounds for homogeneous depth-4 formulas. If we go via the hardness escalation approach, we get a quasi-polynomial lower bound for the same model. Besides, a direct argument can also be used to prove lower bounds for polynomials that do not have a non-trivial set-multilinear component, see the full version of this article [2] for more details. The hardness escalation approach of [29] can not yield such a lower bound. Furthermore, it is conceivable that a direct argument can also be used to obtain functional lower bounds for low-depth formulas which might be useful in proof complexity.

Motivations for studying Question 2. Typical measures used for proving lower bounds for arithmetic circuits include the partial derivatives measure (PD) [32,38], the rank of the partial derivatives matrix measure (a.k.a. evaluation dimension) [31, 34, 36], the shifted partials measure (SP) and its variants [9,14,19], the affine projections of partials measure (APP) [7,15], etc. All these measures are defined for *any* polynomial, which is not necessarily set-multilinear. Whereas the relrk measure used in [29], although very effective, is defined for set-multilinear polynomials. Measures such as PD, SP, and APP have the geometrically appealing property that they are invariant under the application of invertible linear transformations on the variables. Since low-depth formulas, as well as low-depth homogeneous formulas, are closed under linear transformations, it is natural to look for measures that do not blow up much on applying linear transformations. Another important motivation for studying Question 2 is to learn low-depth homogeneous formulas. While the "hardness escalation" paradigm of reducing to the set-multilinear case works for proving lower bounds, it is not clear how to exploit it to design learning algorithms for low-depth formulas. Lower bounds for arithmetic circuits are intimately connected to learning [5, 7, 18, 42]. Hence if we have a lower bound measure that directly exploits the weakness of low-depth homogeneous formulas, it opens up the possibility of new learning algorithms for such models.

1.1 Our results

We answer Questions 1 and 2 by giving a direct lower bound for low-depth homogeneous formulas via the SP measure which was used in the series of works on homogeneous depth-4 exponential lower bounds. While our proof also yields lower bounds only in the low-degree setting, the hope is that it could potentially lead to a stronger lower bound in the future.

Consider the *shifted partials* measure: $\mathsf{SP}_{k,\ell}(f) := \dim\langle \mathbf{x}^{\ell} \cdot \boldsymbol{\partial}^{k}(f)\rangle$, where f is a polynomial. That is, $\mathsf{SP}_{k,\ell}(f)$ is the dimension of the space spanned by the polynomials obtained by multiplying degree ℓ monomials to partial derivatives of f of order k. Also, for convenience, let us denote by $M(n,k) := \binom{n+k-1}{k}$ the number of monomials of degree k in n variables. Then note that for a homogeneous polynomial f of degree d, $\mathsf{SP}_{k,\ell}(f) \leq \min\{M(n,k)M(n,\ell), M(n,d-k+\ell)\}$.

We show that for polynomials computed by low-depth homogeneous formulas, the shifted partials measure with an appropriate setting of k and ℓ is substantially smaller than the above upper bound. At the same time, we exhibit explicit "hard" polynomials for which the shifted partials measure is close to the above bound, hence yielding a lower bound.

▶ **Theorem 3** (Lower bound for low-depth homogeneous formulas via shifted partials)**.** *Let C be a homogeneous formula of size s and product-depth Δ that computes a polynomial of degree d in n variables. Then for appropriate values of k and ℓ,*

$$\mathsf{SP}_{k,\ell}(C) \leq \frac{s\, 2^{O(d)}}{n^{\Omega(d^{2^{1-\Delta}})}} \min\{M(n,k)M(n,\ell), M(n,d-k+\ell)\}.$$

At the same time, there are homogeneous polynomials f of degree d in n variables (e.g., an appropriate projection of iterated matrix multiplication polynomial, Nisan-Wigderson design polynomial, etc.) such that

$$\mathsf{SP}_{k,\ell}(f) \geq 2^{-O(d)} \min\{M(n,k)M(n,\ell), M(n,d-k+\ell)\}.$$

This gives a lower bound of $\frac{n^{\Omega(d^{2^{1-\Delta}})}}{2^{O(d)}}$ on the size of homogeneous product-depth Δ formulas for f.

▶ Remark 4.

1. At the end of this section, we briefly remark why it is surprising that we are able to obtain the above lower bound using shifted partials. We also show that the lower bound can be derived using the *affine projections of partials* (APP) measure (Lemma 19).
2. The above lower bound is slightly better than the bound of [29]. Instead of the $d^{O(d)}$ loss incurred due to converting homogeneous to set-multilinear formulas, our analysis incurs a $2^{O(d)}$ loss; in fact, this loss can be brought down to $2^{O(k)}$, but we ignore this distinction as we set $k = \Theta(d)$ in the analysis. So, for example, for homogeneous product-depth 2 formulas, our superpolynomial lower bound continues to hold for a higher degree ($\log^2(n)$ vs $(\log(n)/\log\log(n))^2$ in [29]). While the improvement may be insignificant, this hints at something interesting going on with the direct approach (see Section 1.2).

Lower bounds for general-depth arithmetic formulas are expected to be easier than arithmetic circuit lower bounds. However, despite several approaches and attempts (e.g. via tensor rank lower bounds [35]), we still do not have superpolynomial arithmetic formula lower bounds. There has been some success though in proving lower bounds for some natural restricted models (apart from the depth restrictions considered above). For example, [19] considered the model of *regular* arithmetic formulas. These are formulas which consist of alternating layers of addition ($+$) and multiplication ($\times$) gates such that the fanin of all gates in any fixed layer is the same. This is a natural model and the best-known formulas for many interesting polynomial families like determinant, permanent, iterated matrix multiplication, etc. are all regular. [19] proved a superpolynomial lower bound on the size of regular formulas for an explicit polynomial and later [6] proved a tight lower bound for the iterated matrix multiplication polynomial.

We prove superpolynomial lower bounds for a more general model.[1] Consider a model of homogeneous arithmetic formulas consisting of alternating layers of addition ($+$) and multiplication ($\times$) gates such that the fanin of all addition gates can be arbitrary but fanin of product gates in any fixed layer is the same. We call these *product-regular*. We prove super-polynomial lower bounds for homogeneous product-regular formulas. Previously we did not know of lower bounds for even a much simpler model where the fanins of all the product gates are fixed to 2.

In fact, we prove lower bounds for an even more general model which we call *Unique Parse Tree* (UPT) formulas. A parse tree of a formula is a tree where for every $+$ gate, one picks exactly one child and for every product gate, we pick all the children. Then we "short circuit" all the addition gates. Parse trees capture the way monomials are generated in a formula. We say that a formula is UPT if all its parse trees are isomorphic. A product-regular formula is clearly UPT. In the theorem below, $IMM_{n,\log n}$ is the iterated multiplication polynomial of degree $\log n$.

[1] The model in [6, 19] allowed slight non-homogeneity with the formal degree upper bounded by a small constant times the actual degree. However, we only work with homogeneous formulas.

▶ **Theorem 5.** *Any UPT formula computing $IMM_{n,\log(n)}$ has size at least $n^{\Omega(\log\log(n))}$. A similar lower bound holds for the Nisan-Wigderson design polynomial.*

▶ Remark 6.

1. While homogeneous product-regular formulas are restricted to compute polynomials with only certain degrees (e.g., higher product-depth cannot compute prime degrees), homogeneous UPT formulas do not suffer from this restriction.
2. While this result (which is obtained using the SP and the APP measures) could possibly also be obtained by defining a similar model in the set-multilinear world, proving a lower bound there and then transporting it back to the homogeneous world, our framework has fewer number of moving parts and hence makes it easier to derive such results.

Challenges to using the SP measure. Let us remark briefly why it is surprising that we are able to prove low-depth lower bounds via shifted partials. [8, 37] showed that the PD measure of the polynomial $(x_1^2 + \cdots + x_n^2)^{\frac{d}{2}}$ is the maximum possible when the order of derivatives, k, is at most $\frac{d}{2}$. Notice that $(x_1^2 + \cdots + x_n^2)^{\frac{d}{2}}$ can be computed by a homogeneous depth-4 formula of size $O(nd)$. So, it is not possible to prove super-polynomial lower bounds for low-depth homogeneous formulas using the PD measure as it is. One may ask if the SP measure also has a similar limitation. Some of the finer separation results in [23, 24] indicate that the SP measure (and some of its variants) can be fairly large for homogeneous depth-4 and depth-5 formulas for the choices of k used in prior work. Also, the exponential lower bounds for homogeneous depth-4 circuits in [14, 26] use random restrictions along with a variant of the SP measure. It is not clear how to leverage random restrictions for even homogeneous depth-5 circuits – this is also pointed out in [29]. Fortunately, [23, 24] do not rule out the possibility of using SP for all choices of parameters, like, say, $k \approx \frac{d}{2}$, to prove lower bounds for low-depth homogeneous formulas. But, the original intuition from algebraic geometry that led to the development of the SP measure (see [9] Section 2.1) breaks down completely when k is so large (see [2]). Despite these apparent hurdles, and to our surprise, we overcome these challenges and are able to use SP with $k \approx \frac{d}{2}$ to prove super-polynomial lower bounds for low-depth homogeneous formulas. To the best of our knowledge, no previous work uses SP with this high a value of k.

1.2 Techniques and proof overview

In this section, we explain the proof idea and compare it with that in [29]. A lot of lower bounds in arithmetic complexity follow the following outline.

Step 1: Depth reduction. One first shows that if $f(\mathbf{x})$ is computed by a *small* circuit from some restricted subclass of circuits, then there is a corresponding subclass of depth-4 circuits such that $f(\mathbf{x})$ is also computed by a *relatively small* circuit from this subclass[2]. The resulting subclass is of the form: $f(\mathbf{x}) = \sum_{i=1}^{s} \prod_{j=1}^{t_i} Q_{i,j}$. Usually there are simple restrictions on the degrees of $Q_{i,j}$'s. For example, they could be upper bounded by some number.

[2] Some major results in the area such as [29, 33] did not originally proceed via a depth reduction but instead analysed formulas directly. These results can however be restated as first doing a depth reduction and then applying the appropriate measure.

Step 2: Employing a suitable set of linear maps. Let $\mathbb{F}[\mathbf{x}]^{=d}$ be the space of homogeneous polynomials of degree d, W be a suitable vector space, and $\mathrm{Lin}(\mathbb{F}[\mathbf{x}]^{=d}, W)$ be the space of linear maps from $\mathbb{F}[\mathbf{x}]^{=d}$ to W. We choose a suitable set of linear maps $\mathcal{L} \subseteq \mathrm{Lin}(\mathbb{F}[\mathbf{x}]^{=d}, W)$ that define a complexity measure $\mu_{\mathcal{L}}(f) := \dim(\mathcal{L}(f))$, where $\mathcal{L}(f) := \langle \{L(f) \ : \ L \in \mathcal{L}\} \rangle$.

We would like to choose $\mathcal{L}$ so that it identifies some weakness of the terms $\prod_{j=1}^{t} Q_j$ in the depth-4 circuit. That is, $\mu_{\mathcal{L}}\left(\prod_{j=1}^{t} Q_j\right)$ should be much smaller than $\mu_{\mathcal{L}}(f)$ for a generic f. For e.g., if Q_j's are all linear polynomials, we can choose $\mathcal{L}$ to be the partial derivatives of order k, $\boldsymbol{\partial}^k$. Then, $\mu_{\mathcal{L}}\left(\prod_{j=1}^{t} Q_j\right) \leq \binom{t}{k} \ll \binom{n+k-1}{k}$ which is the value for a generic f (for $k \leq t/2$). This is the basis of the homogeneous depth-3 formula lower bound in [32].

For proving lower bounds for bounded bottom fan-in depth-4 circuits (i.e., when degree of Q_j's is upper bounded by some number), [9, 13] introduced the SP measure and used the linear maps $\mathcal{L} = \mathbf{x}^{\ell} \cdot \boldsymbol{\partial}^k$. The main insight in their proof was that if we apply a partial derivative of order k on $\prod_{j=1}^{t} Q_j$ and use the product rule, then at least $t-k$ of the Q_j's remain untouched. This structure can then be exploited by the shifts to get a lower bound. This intuition however completely breaks down for $k \geq t$ (see [2]). Due to this, progress remain stalled for higher depth arithmetic circuit lower bounds via SP.

In a major breakthrough, [29] gets around the above obstacle by working with set-multilinear circuits which entails working with polynomials over d sets of variables $(\mathbf{x}_1, \ldots, \mathbf{x}_d)$, $|\mathbf{x}_i| = n$. Let us use the shorthand $\mathbf{x}_S = (\mathbf{x}_i)_{i \in S}$. The products they deal with are of the form $\prod_{j=1}^{t} Q_j(\mathbf{x}_{S_j})$, where $S_1, S_2, \ldots, S_t$ form a partition of $[d]$. The set of linear maps they use are $\mathcal{L} = \Pi \circ \partial_{\mathbf{x}_A}$ for a subset $A \subseteq [d]$. Here, Π is a map that sets $n - n_0$ variables in each of the variable sets in $\mathbf{x}_{[d]\setminus A}$ to 0. They observe (for the appropriate choice of n_0) that $\mu_{\mathcal{L}}\left(\prod_{j=1}^{t} Q_j(\mathbf{x}_{S_j})\right) \leq \frac{n^{|A|}}{2^{\frac{1}{2}\sum_{j=1}^{t} \mathrm{imbalance}_j}}$.

Here, $\mathrm{imbalance}_j = ||A \cap S_j| \log(n) - |S_j \setminus A| \log(n_0)|$. For the appropriate choice of n_0, a generic set-multilinear f satisfies $\mu_{\mathcal{L}}(f) = n^{|A|}$, so that lower bound (on the number of summands) obtained is exponential in the total imbalance $\sum_{j=1}^{t} \mathrm{imbalance}_j$. [29] observe that this quantity is *somewhat large* for the depth-4 circuits that they consider.

The core of the above derivatives-based argument allows us to unravel some structure in partial derivatives of order k applied on $\prod_{j=1}^{t} Q_j$ for values of $k \gg t$. We use this to derive a structure for the partial derivative space of a product $\prod_{j=1}^{t} Q_j(\mathbf{x})$. Consider a partial derivative operator of order k indexed by a multiset α of size k. Using the chain rule,

$$\partial_{\alpha} \prod_{j=1}^{t} Q_j = \sum_{\alpha_1, \ldots, \alpha_t : \sum_{i=1}^{t} \alpha_i = \alpha} c^{\alpha}_{\alpha_1, \ldots, \alpha_t} \prod_{j=1}^{t} \partial_{\alpha_j} Q_j$$

for appropriate constants $c^{\alpha}_{\alpha_1, \ldots, \alpha_t}$'s. In the product $\prod_{j=1}^{t} \partial_{\alpha_j} Q_j$, we can try to club terms into two groups depending on if the size of $|\alpha_j|$ is small or large. It turns out that the right threshold for $|\alpha_j|$ is $k \deg(Q_j)/d$ (i.e., if we divide the order of the derivatives proportional to the degrees of the terms). Let $S := \{j : |\alpha_j| \leq k \deg(Q_j)/d\}$. Define $k_0 := \sum_{j \in S} |\alpha_j|$ and $\ell_0 := \sum_{j \in \overline{S}} (\deg(Q_j) - |\alpha_j|)$. Notice that we can write the product $\prod_{j=1}^{t} \partial_{\alpha_j} Q_j$ as $P \prod_{j \in S} \partial_{\alpha_j} Q_j$, for a degree ℓ_0 polynomial P. Hence, $\partial_{\alpha} \prod_{j=1}^{t} Q_j$ is a sum of terms of this form. While it is not immediate (due to the condition on α_j's in S), with a bit more work, one can combine the product of partials into a single partial.

What can we say about k_0 and ℓ_0? It turns out that the quantity that comes up in the calculations is $k_0 + \frac{k}{d-k}\ell_0$ and it satisfies $k_0 + \frac{k}{d-k}\ell_0 \leq k$. Note that k_0 is between 0 and k, and ℓ_0 between 0 and $d-k$. So the normalization brings ℓ_0 to the right "scale".

It turns out we can give a better bound in terms of a quantity we call *residue* defined as

$$\mathsf{residue}_k(d_1,\ldots,d_t) := \frac{1}{2}\cdot \min_{k_1,\ldots,k_t\in\mathbb{Z}} \sum_{j=1}^{t}\left|k_j - \frac{k}{d}\cdot d_j\right|.$$

and having the property that:

▶ **Proposition 7.** *Let k_0 and ℓ_0 be defined as above. Then, $k_0 + \frac{k}{d-k}\ell_0 \le k - \mathsf{residue}_k(d_1,\ldots,d_t)$, where $d_j = deg(Q_j)$.*

We want to spread the derivatives equally among all terms but cannot due to *integrality issues*. The residue captures this quantitatively and as described below, is what gives us our lower bounds. While the proof in [29] also relies on an integrality issue, there it originates from an imbalance between the sizes of the variable sets involved in a set-multilinear partition (as the map Π sets some variables in certain sets to 0). In contrast, we show that the integrality issue arising directly from the derivatives can be leveraged without involving set-multilinearity. In this sense, our approach is *conceptually* direct and simpler. Combined with the above discussion, we get the following structural lemma about the derivative space of $\prod_{j=1}^{t} Q_j$.

▶ **Lemma 8.**

$$\left\langle \boldsymbol{\partial}^k\left(Q_1\cdots Q_t\right)\right\rangle \subseteq \sum_{\substack{S\subseteq[t],\ k_0\in[0..k],\ \ell_0\in[0..(d-k)],\\ k_0+\frac{k}{d-k}\cdot\ell_0\ \le\ k-\mathsf{residue}_k(d_1,\ldots,d_t)}} \left\langle \mathbf{x}^{\ell_0}\cdot\boldsymbol{\partial}^{k_0}\left(\prod_{j\in S} Q_j\right)\right\rangle.$$

Now we have the choice to utilize the above structure using an additional set of linear maps. Both shifts and projections give similar lower bounds, so let us explain shifts here. Note that there is an intriguing possibility of getting even better lower bounds (in terms of dependence on d) using other sets of linear maps! From the above structural result, we have

$$\left\langle \mathbf{x}^{\ell}\cdot\boldsymbol{\partial}^k\left(Q_1\cdots Q_t\right)\right\rangle \subseteq \sum_{\substack{S\subseteq[t],\ k_0\in[0..k],\ \ell_0\in[0..(d-k)],\\ k_0+\frac{k}{d-k}\cdot\ell_0\ \le\ k-\mathsf{residue}_k(d_1,\ldots,d_t)}} \left\langle \mathbf{x}^{\ell+\ell_0}\cdot\boldsymbol{\partial}^{k_0}\left(\prod_{j\in S} Q_j\right)\right\rangle.$$

Thus we can upper bound,

$$\begin{aligned}\mathsf{SP}_{k,\ell}((Q_1\cdots Q_t)) &\le 2^t\cdot d^2\cdot \max_{\substack{k_0,\ell_0\ge 0\\ k_0+\frac{k}{d-k}\cdot\ell_0\ \le\ k-\mathsf{residue}_k(d_1,\ldots,d_t)}} M(n,k_0)\cdot M(n,\ell_0+\ell)\\ &\le 2^t\cdot d^2\frac{2^{O(d)}}{n^{\mathsf{residue}_k(d_1,\ldots,d_t)}}\ \min\{M(n,k)M(n,\ell), M(n,d-k+\ell)\},\end{aligned}$$

where the second inequality follows from elementary calculations.

Now to upper bound the shifted partial dimension of polynomials computed by low-depth formulas, we give a decomposition for such formulas into sums of products of polynomials (Lemma 16) where the degree sequences are carefully chosen so that that the residues can be simultaneously lower bounded for all the terms (Lemma 17). While in a different context, these calculations do bear similarity with related calculations in [29].

Step 3: Lower bounding $\dim(\mathcal{L}(f))$ for an explicit f. As a last step, one shows that for some explicit candidate hard polynomial $\dim(\mathcal{L}(f))$ is large and thereby obtains a lower bound. This is another step where bypassing set-multilinearity helps as one is not constrained

to pick a set-multilinear hard polynomial. Indeed, using a straightforward analysis we show that the APP measure is high for an explicit non-set-multilinear polynomial (see Remark 23). We also show that the measures are high for more standard polynomial families such as the iterated matrix multiplication polynomials and the Nisan-Wigderson design polynomials.

Application to UPT formulas. We observe here that for the subclass of homogeneous formulas that we call UPT formulas, one can do a depth-reduction to obtain a depth-4 formula in which all the summands have the same factorization pattern (i.e. the sequence of degrees of the factors in all the summands is that same) - see Lemma 30. We further observe (Lemma 31) that for any fixed sequence of degrees, there exists a suitable value of the parameter k such that the residue is *sufficiently large*. This gives us the superpolynomial lower bound for UPT formulas as stated in Theorem 5.

Despite the conceptual directness and simplicity of our approach, in bypassing set-multilinearity, some of the calculations in the analysis become evidently more involved than that in [29]. This is primarily due to the delicate choice of parameters in ratios involving binomial coefficients; this is also the case in several prior exponential lower bound proofs using SP and its variants [14, 16, 26]. Nevertheless, we think that by circumventing a critical bottleneck, the analysis opens up the possibility of an exponential lower bound for low-depth arithmetic circuits. Some of the ideas may indeed yield stronger bounds in the future.

Organization. After describing preliminaries in Section 2, we present a structural theorem about the derivative space of a product of homogeneous polynomials in Section 3. This result is then directly used to upper bound both the SP and APP measures of a product of polynomials. Using this result and a decomposition result for low-depth formulas, we obtain lower bounds for low-depth formulas in Section 4. Finally, we prove lower bounds for UPT formulas in Section 5.

2 Preliminaries

In this section, we give the essential notations and definitions necessary to follow the article.

Let a, b, c be real numbers. Then we define the sets $[a..b] := \{x \in \mathbb{Z} : x \in [a, b]\}$ and $[a] := [1..a]$. For a constant $c \geq 1$ and $b \geq 0$, we say $a \approx_c b$ if $a \in [b/c, b]$. We write $a \approx b$ if $a \approx_c b$ for some (unspecified) constant c. All logarithms have base 2 unless specified otherwise. We denote the fractional part of a by $\{a\} := a - \lfloor a \rfloor$ and the nearest integer of a by $\lfloor a \rceil$. The following quantity will be crucially used in the proofs of our lower bounds. Here we think of $d_1, \ldots, d_t$ as degrees of certain homogeneous polynomials, d as the degree of the product of those polynomials, and k is the order of partial derivatives used for the complexity measures.

▶ **Definition 9** (residue). *For non-negative integers $d_1, \ldots, d_t$ such that $d := \sum_{i=1}^{t} d_i \geq 1$ and $k \in [0..(d-1)]$, we define* $\mathsf{residue}_k(d_1, \ldots, d_t) := \frac{1}{2} \cdot \min_{k_1, \ldots, k_t \in \mathbb{Z}} \sum_{i=1}^{t} \left| k_i - \frac{k}{d} \cdot d_i \right|$.

The factor of half has been included in the definition just to make the statements of some of the lemmas in our analysis simple. It is easy to show that $\mathsf{residue}_k(d_1, \ldots, d_t) \leq \frac{k}{2}$. The minimum is attained when for all $i \in [t]$, $k_i = \left\lfloor \frac{k}{d} \cdot d_i \right\rceil$. When we use residue in the analysis of complexity measures, we would also have the following additional constraints that $k_i \geq 0$ and $k_i \leq d_i$, $k_1 + \cdots + k_n = k$, where k shall be the order of derivatives. As the value of residue can not decrease when we impose these constraints, we omit them.

Let n and n_0 be positive integers. Define variable sets $\mathbf{x} := \{x_1, \ldots, x_n\}$ and $\mathbf{z} := \{z_1, \ldots, z_{n_0}\}$. For a monic monomial m and a $P \in \mathbb{F}[\mathbf{x}]$, we define $\partial_m P \in \mathbb{F}[\mathbf{x}]$ to be the polynomial obtained by successively taking partial derivatives with respect to all the variables of m (counted with their multiplicities). For an integer $\ell \geq 0$, $\mathbf{x}^{\ell} := \{{x_1}^{e_1} \cdots {x_n}^{e_n} : e_1, \ldots, e_n \in \mathbb{Z}_{\geq 0} \text{ and } \sum_{i \in [n]} e_i = \ell\}$. For an integer $k \geq 0$ and $P \in \mathbb{F}[\mathbf{x}]$, $\boldsymbol{\partial}^k P := \left\{\partial_m P : m \in \mathbf{x}^k\right\}$. For a $P \in \mathbb{F}[\mathbf{x}]$, a map $L : \mathbf{x} \to \langle \mathbf{z} \rangle$, and $\mathcal{S} \subseteq \mathbb{F}[\mathbf{x}]$, $\pi_L(P) \in \mathbb{F}[\mathbf{z}]$ and $\pi_L(\mathcal{S}) \subseteq \mathbb{F}[\mathbf{z}]$ are defined as $\pi_L(P) := P(L(x_1), \ldots, L(x_n))$ and $\pi_L(\mathcal{S}) := \{\pi_L(P) : P \in \mathcal{S}\}$, respectively.

For $\mathcal{S}, \mathcal{T} \subseteq \mathbb{F}[\mathbf{x}]$, $\mathcal{S} \cdot \mathcal{T} := \{P \cdot Q : P \in \mathcal{S} \text{ and } Q \in \mathcal{T}\}$ and $\mathcal{S} + \mathcal{T} := \{P + Q : P \in \mathcal{S} \text{ and } Q \in \mathcal{T}\}$. For a $\mathcal{S} \subseteq \mathbb{F}[\mathbf{x}]$, we define its *span* as $\langle \mathcal{S} \rangle \subseteq \mathbb{F}[\mathbf{x}]$ to be the set of all polynomials which can be expressed as $\mathbb{F}$-linear combinations of elements in $\mathcal{S}$. For a $\mathcal{S} \subseteq \mathbb{F}[\mathbf{x}]$, its *dimension*, denoted by $\dim \mathcal{S}$, refers to the maximum number of *linearly independent* polynomials in $\mathcal{S}$. We can now define the complexity measures for polynomials that we use to prove our lower bounds: the *shifted partials* (SP) measure and the *affine projections of partials* (APP) measure.

▶ **Definition 10** (SP and APP measures). *For a polynomial $P \in \mathbb{F}[\mathbf{x}]$, non-negative integers k, ℓ, and $n_0 \in [n]$, we define $\mathsf{SP}_{k,\ell}(P) := \dim \left\langle \mathbf{x}^{\ell} \cdot \boldsymbol{\partial}^k P \right\rangle$ and $\mathsf{APP}_{k,n_0}(P) := \max_{L:\mathbf{x} \to \langle \mathbf{z} \rangle} \dim \left\langle \pi_L\left(\boldsymbol{\partial}^k P\right) \right\rangle$.*

SP and APP are *sub-additive*. APP is related to the *skewed partials* and relrk measures used in [15] and [29], respectively. For a comparison, see [2].

Next, we define a subclass of homogeneous formulas which we call *UPT formulas*[3].

▶ **Definition 11.** *A homogeneous formula C is said to be a* unique-parse-tree formula *if all of its parse trees are isomorphic to each other as directed graphs.*

For a UPT formula C, we define its *canonical parse tree* to be some fixed tree among all the parse trees (this is a binary tree without loss of generality). For a detailed definition of (canonical) parse tree, we refer the reader to the full version of this article [2].

Iterated Matrix Multiplication. The iterated matrix multiplication, $IMM_{n,d}$ is a polynomial in $N = d \cdot n^2$ variables defined as the $(1,1)$-th entry of the matrix product of d many $n \times n$ matrices whose entries are distinct variables. To prove a lower bound for IMM, we analyze the SP and APP for a projection of IMM, $P_{\mathbf{w}}$ that was introduced in [29].

▶ **Definition 12** (Word polynomial $P_{\mathbf{w}}$ [29]). *Given a word $\mathbf{w} = (w_1, \ldots, w_d) \in \mathbb{Z}^d$, let $\mathbf{x}(\mathbf{w})$ be a tuple of d pairwise disjoint sets of variables $(\mathbf{x}_1(\mathbf{w}), \ldots, \mathbf{x}_d(\mathbf{w}))$ with $|\mathbf{x}_i(\mathbf{w})| = 2^{|w_i|}$ for all $i \in [d]$. $\mathbf{x}_i(\mathbf{w})$ will be called negative if $w_i < 0$ and positive otherwise. As the set sizes are powers of 2, we can map the variables in a set $\mathbf{x}_i(\mathbf{w})$ to Boolean strings of length $|w_i|$. Let $\sigma : \mathbf{x} \to \{0,1\}^*$ be such a mapping.*[4] *We extend the definition of σ from variables to set-multilinear monomials as follows: Let $X = x_1 \cdots x_r$ be a set-multilinear monomial where $x_i \in \mathbf{x}_{\phi(i)}(\mathbf{w})$ and $\phi : [r] \to [d]$ be an increasing function. Then, we define a Boolean string $\sigma(X) := \sigma(x_1) \circ \cdots \circ \sigma(x_r)$, where $\circ$ denotes the concatenation of bits. Let $\mathcal{M}_+(\mathbf{w})$ and $\mathcal{M}_-(\mathbf{w})$ denote the set of all (monic) set-multilinear monomials over all the positive sets*

[3] Our definition for UPT formulas is more general than the model considered in a recent paper by Limaye, Srinivasan and Tavenas [30] as we do not impose set-multilinearity.

[4] Note that σ may map a variable from $\mathbf{x}_i(\mathbf{w})$ and a variable from $\mathbf{x}_j(\mathbf{w})$ to the same string if $i \neq j$.

and all the negative sets, respectively. For two Boolean strings a, b, we say $a \sim b$ if a is a prefix of b or vice versa. For a word $\mathbf{w}$, the corresponding word polynomial $P_{\mathbf{w}}$ is defined as $P_{\mathbf{w}} := \sum_{\substack{m_+ \in \mathcal{M}_+(\mathbf{w}),\ m_- \in \mathcal{M}_-(\mathbf{w}) \\ \sigma(m_+) \sim \sigma(m_-)}} m_+ \cdot m_-$.

We will make use of the following lemma from [29] which shows that computing IMM is at least as hard as computing $P_{\mathbf{w}}$. For this, we recall the notion of *unbiased*-ness of $\mathbf{w} = (w_1, \ldots, w_d)$ from [29] – we say that $\mathbf{w}$ is *h-unbiased* if $\max_{i \in [d]} |w_1 + \cdots + w_i| \leq h$.

▶ **Lemma 13** (Lemma 7 in [29]). *Let $\mathbf{w} \in [-h..h]^d$ be h-unbiased. If for some $n \geq 2^h$, $IMM_{n,d}$ has a formula C of product-depth[5] Δ and size s, then $P_{\mathbf{w}}$ has a formula C' of product-depth at most Δ and size at most s. Moreover, if C is homogeneous, then so is C' and if C is UPT, then so is C' with the same canonical parse tree.*[6]

Nisan-Wigderson design polynomial. For a prime power q and $d \in \mathbb{N}$, let $\mathbf{x} = \{x_{1,1}, \ldots, x_{1,q}, \ldots, x_{d,1}, \ldots, x_{d,q}\}$. For any $k \in [d]$, the Nisan-Wigderson design polynomial on qd variables, denoted by $NW_{q,d,k}$ or simply NW, is defined as follows:

$$NW_{q,d,k} = \sum_{\substack{h(z) \in \mathbb{F}_q[z]: \\ \deg(h) < k}} \prod_{i \in [d]} x_{i,h(i)}.$$

The IMM and the NW polynomials, and their variants, have been extensively used to prove various circuit lower bounds [3, 4, 11, 14, 16, 19–21, 23, 26, 27, 29, 32].

3 Structure of the space of partials of a product

In this section, we bound the partial derivative space of a product of homogeneous polynomials. In the following lemma, we show that the space of k-th order partial derivatives of a product of polynomials is contained in a sum of shifted partial spaces with shift ℓ_0 and order of derivatives k_0 such that $k_0 + \frac{k}{d-k} \cdot \ell_0$ is "small". Using this lemma, we upper bound the SP and APP measures of a product of homogeneous polynomials. These bounds are then used in Sections 4 and 5 for proving lower bounds for low-depth homogeneous formulas and UPT formulas respectively. Missing proofs from this section can be found in the full version of this article [2],

▶ **Lemma 14** (Upper bounding the partials of a product). *Let n and t be positive integers and $Q_1, \ldots, Q_t$ be non-constant, homogeneous polynomials in $\mathbb{F}[\mathbf{x}]$ with degrees $d_1, \ldots, d_t$ respectively. Let $d := \deg(Q_1 \cdots Q_t) = \sum_{i=1}^{t} d_i$ and $k < d$ be a non-negative integer. Then,*

$$\left\langle \boldsymbol{\partial}^k (Q_1 \cdots Q_t) \right\rangle \subseteq \sum_{\substack{S \subseteq [t],\ k_0 \in [0..k],\ \ell_0 \in [0..(d-k)], \\ k_0 + \frac{k}{d-k} \cdot \ell_0 \ \leq\ k - \mathsf{residue}_k(d_1, \ldots, d_t)}} \left\langle \mathbf{x}^{\ell_0} \cdot \boldsymbol{\partial}^{k_0} \left(\prod_{i \in S} Q_i \right) \right\rangle.$$

We now use the above lemma to upper bound the shifted partials and affine projections of partials measures of a product of polynomials.

[5] The product-depth of a formula is the maximum number of product gates on any path from the root to a leaf in the formula.

[6] Although the lemma in [29] is stated for set-multilinear circuits, it also applies to homogeneous formulas and UPT formulas (albeit with a mild blow-up in size) by the same argument.

▶ **Lemma 15** (Upper bounding SP and APP of a product). *Let $Q = Q_1 \cdots Q_t$ be a homogeneous polynomial in $\mathbb{F}[x_1, \ldots, x_n]$ of degree $d = d_1 + \cdots + d_t \geq 1$, where Q_i is homogeneous and $d_i := \deg(Q_i)$ for $i \in [t]$. Then, for any non-negative integers $k < d$, $\ell \geq 0$, and $n_0 \leq n$,*

1.
$$\mathsf{SP}_{k,\ell}(Q) \leq 2^t \cdot d^2 \cdot \max_{\substack{k_0,\ell_0 \geq 0 \\ k_0 + \frac{k}{d-k}\cdot\ell_0 \;\leq\; k-\mathsf{residue}_k(d_1,\ldots,d_t)}} M(n,k_0) \cdot M(n,\ell_0+\ell),$$

2.
$$\mathsf{APP}_{k,n_0}(Q) \leq 2^t \cdot d^2 \cdot \max_{\substack{k_0,\ell_0 \geq 0 \\ k_0 + \frac{k}{d-k}\cdot\ell_0 \;\leq\; k-\mathsf{residue}_k(d_1,\ldots,d_t)}} M(n,k_0) \cdot M(n_0,\ell_0).$$

4 Lower bound for low-depth homogeneous formulas

In this section, we present a superpolynomial lower bound for "low-depth" homogeneous formulas computing the IMM and NW polynomials. We begin by proving a structural result for homogeneous formulas. Missing proofs from this section can be found in the full version of this article [2].

4.1 Decomposition of low-depth formulas

We show that any homogeneous formula can be decomposed as a sum of products of homogeneous polynomials of lower degrees, where the number of summands is bounded by the number of gates in the original formula. The decomposition lemma given below bears some resemblance to a decomposition of homogeneous formulas in [12]. In the decomposition in [12], the degrees of the factors of every summand roughly form a geometric sequence, and hence each summand is a product of a "large" number of factors. Here we show that each summand has "many" low-degree factors. While the lower bound argument in [29] does not explicitly make use of such a decomposition, their inductive argument can be formulated as a depth-reduction or decomposition lemma (with slightly different thresholds for the degrees).

▶ **Lemma 16** (Decomposition of low-depth formulas). *Suppose C is a homogeneous formula of product-depth $\Delta \geq 1$ computing a homogeneous polynomial in $\mathbb{F}[x_1, \ldots, x_n]$ of degree* at least *$d > 0$. Then, there exist homogeneous polynomials $\{Q_{i,j}\}_{i,j}$ in $\mathbb{F}[x_1, \ldots, x_n]$ such that*

1. *$C = \sum_{i=1}^{s} Q_{i,1} \cdots Q_{i,t_i}$, for some $s \leq \mathrm{size}(C)$, and*
2. *for all $i \in [s]$, either*

$$|\{j \in [t_i] : \deg(Q_{i,j}) = 1\}| \geq d^{2^{1-\Delta}} \text{ , or}$$

$$\left|\left\{j \in [t_i] : \deg(Q_{i,j}) \approx_2 d^{2^{1-\delta}}\right\}\right| \geq d^{2^{1-\delta}} - 1 \text{ , for some } \delta \in [2..\Delta].$$

4.2 Low-depth formulas have high residue

The following lemma gives us a value for the order of derivatives k with respect to which low-depth formulas yield high residue. Its proof uses Lemma 16.

▶ **Lemma 17** (Low-depth formulas have high residue). *Suppose C is a homogeneous formula of product-depth $\Delta \geq 1$ computing a polynomial in $\mathbb{F}[x_1, \ldots, x_n]$ of degree d, where $d^{2^{1-\Delta}} = \omega(1)$. Then, there exist homogeneous polynomials $\{Q_{i,j}\}_{i,j}$ in $\mathbb{F}[x_1, \ldots, x_n]$ such that $C = \sum_{i=1}^{s} Q_{i,1} \cdots Q_{i,t_i}$, for some $s \leq \text{size}(C)$. Fixing an arbitrary $i \in [s]$, let $t := t_i$ and define $d_j := \deg(Q_{i,j})$ for $j \in [t]$. Then, $\mathsf{residue}_k(d_1, \ldots, d_t) \geq \Omega\left(d^{2^{1-\Delta}}\right)$, where $k := \left\lfloor \frac{\alpha \cdot d}{1+\alpha} \right\rfloor$, $\alpha := \sum_{\nu=0}^{\Delta-1} \frac{(-1)^\nu}{\tau^{2^\nu - 1}}$, and $\tau := \left\lfloor d^{2^{1-\Delta}} \right\rfloor$.*

4.3 High residue implies lower bounds

For a "random" homogeneous degree-d polynomial in $\mathbb{F}[x_1, \ldots, x_n]$, if the shift ℓ is not too large, we expect the SP measure to be close to the maximum number of operators used to construct the shifted partials space, i.e., $M(n,k) \cdot M(n,\ell)$. Explicit examples of such polynomials are given in Section 4.4. In the lemma below, we derive a lower bound corresponding to the decompositions established above. The main step is to show that the SP measure of a high-residue-decomposition is small.

▶ **Lemma 18** (High residue implies lower bounds). *Let $P = \sum_{i=1}^{s} Q_{i,1} \cdots Q_{i,t_i}$ be a homogeneous n-variate polynomial of degree d where $\{Q_{i,j}\}_{i,j}$ are homogeneous and $\mathsf{SP}_{k,\ell}(P) \geq 2^{-O(d)} \cdot M(n,k) \cdot M(n,\ell)$ for some $1 \leq k < \frac{d}{2}, n_0 \leq n$ and $\ell = \left\lfloor \frac{n \cdot d}{n_0} \right\rfloor$ such that $d \leq n_0 \approx 2(d-k) \cdot \left(\frac{n}{k}\right)^{\frac{k}{d-k}}$. If there is a $\gamma > 0$ such that for all $i \in [s]$, $\mathsf{residue}_k(\deg(Q_{i,1}), \ldots, \deg(Q_{i,t_i})) \geq \gamma$, then $s \geq 2^{-O(d)} \left(\frac{n}{d}\right)^{\Omega(\gamma)}$.*

We state an analogous lemma with APP instead of SP.

▶ **Lemma 19** (High residue implies lower bounds, using APP). *Let $P = \sum_{i=1}^{s} Q_{i,1} \cdots Q_{i,t_i}$ be a homogeneous n-variate polynomial of degree d where $\{Q_{i,j}\}_{i,j}$ are homogeneous and $\mathsf{APP}_{k,n_0}(P) \geq 2^{-O(d)} \cdot M(n,k)$ for some $1 \leq k < \frac{d}{2}, n_0 \leq n$ such that $d \leq n_0 \approx 2(d-k).\left(\frac{n}{k}\right)^{\frac{k}{d-k}}$. If there is a $\gamma > 0$ such that for all $i \in [s]$, $\mathsf{residue}_k(\deg(Q_{i,1}), \ldots, \deg(Q_{i,t_i})) \geq \gamma$, then $s \geq 2^{-O(d)} \cdot \left(\frac{n}{d}\right)^{\Omega(\gamma)}$.*

▶ Remark 20. In the above lemmas, although our lower bound appears as $2^{-O(d)} \cdot n^{\Omega(\gamma)}$, similar calculations actually give a lower bound of $2^{-O(k)} \cdot n^{\Omega(\gamma)}$ for any choice of k and an appropriate choice of ℓ (or n_0 in the case of APP). We do not differentiate between the two, as for our applications (i.e., low-depth circuits and UPT formulas), the value of k we choose is $\Theta(d)$. Moreover, we observe that the factor of $2^{-O(k)}$ in our lower bounds is likely unavoidable for any choice of k and ℓ (or n_0 in the case of APP) *using our current estimates for the complexity measures*. We refer the reader to the full version of this article [2] for more details.

4.4 The hard polynomials

We shall prove our lower bound for the word polynomial $P_{\mathbf{w}}$ introduced in [29] as well as for the Nisan-Wigderson design polynomial. In order to do this, we show that the SP and APP measures of $P_{\mathbf{w}}$ and the SP measure of NW are large for suitable choices of k, ℓ and n_0.

▶ **Lemma 21** ($P_{\mathbf{w}}$ as a hard polynomial). *For integers h, d such that $h > 100$ and any $k \in \left[\frac{d}{30}, \frac{d}{2}\right]$, there exists an h-*unbiased *word $\mathbf{w} \in [-h..h]^d$, integers $n_0 \leq n$, $\ell = \left\lfloor \frac{n \cdot d}{n_0} \right\rfloor$ such that $n_0 \approx 2(d-k) \cdot \left(\frac{n}{k}\right)^{\frac{k}{d-k}}$ and the following bounds hold: $\mathsf{SP}_{k,\ell}(P_{\mathbf{w}}) \geq 2^{-O(d)} \cdot M(n,k) \cdot M(n,\ell)$ and $\mathsf{APP}_{k,n_0}(P_{\mathbf{w}}) \geq 2^{-O(d)} \cdot M(n,k)$. Here n refers to the number of variables in $P_{\mathbf{w}}$, i.e., $n = \sum_{i \in [d]} 2^{|w_i|}$.*

The following lemma shows that the SP measure of the Nisan-Wigderson design polynomial is "large" for k as high as $\Theta(d)$, if ℓ is chosen suitably.

▶ **Lemma 22** (NW as a hard polynomial). *For $n, d \in \mathbb{N}$ such that $120 \leq d \leq \frac{1}{150}\left(\frac{\log n}{\log\log n}\right)^2$, let q be the largest prime number between $\left\lfloor \frac{n}{2d} \right\rfloor$ and $\left\lfloor \frac{n}{d} \right\rfloor$. For parameters $k \in \left[\frac{d}{30}, \frac{d}{2} - \frac{\sqrt{d}}{8}\right]$ and $\ell = \left\lfloor \frac{qd^2}{n_0} \right\rfloor$, where $n_0 = 2(d-k) \cdot \left(\frac{qd}{k}\right)^{\frac{k}{d-k}}$, $\mathsf{SP}_{k,\ell}(NW_{q,d,k}) \geq 2^{-O(d)} \cdot M(qd,k) \cdot M(qd,\ell)$.*

▶ Remark 23. An advantage of directly analysing the complexity measures for homogeneous formulas instead of for set-multilinear formulas is that our hard polynomial need not be set multilinear. In the full version of this article [2], we describe an explicit non set-multilinear polynomial P (in VNP) with a large APP measure; the construction is similar to a polynomial in [7]. The proof that APP of P is large is considerably simpler than the proofs of the above lemmas.

4.5 Putting everything together: the low-depth lower bound

▶ **Theorem 24** (Low-depth homogeneous formula lower bound for IMM). *For any d, n, Δ such that $n = \omega(d)$, any homogeneous formula of product-depth at most Δ computing $IMM_{n,d}$ over any field $\mathbb{F}$ has size at least $2^{-O(d)} \cdot n^{\Omega\left(d^{2^{1-\Delta}}\right)}$. In particular, when $d = O(\log n)$, we get a lower bound of $n^{\Omega\left(d^{2^{1-\Delta}}\right)}$.*

▶ **Theorem 25** (Low-depth homogeneous formula lower bound for NW). *Let n, d, Δ be positive integers. If $\Delta = 1$, let $d = n^{1-\epsilon}$ for any constant $\epsilon > 0$ and $k = \left\lfloor \frac{d-1}{2} \right\rfloor$. Otherwise, let $d \leq \frac{1}{150}\left(\frac{\log n}{\log\log n}\right)^2$, let $\tau = \left\lfloor d^{2^{1-\Delta}} \right\rfloor$, $\alpha = \sum_{\nu=0}^{\Delta-1} \frac{(-1)^\nu}{\tau^{2^\nu - 1}}$, and $k = \left\lfloor \frac{\alpha \cdot d}{1+\alpha} \right\rfloor$. In both cases, let q be the largest prime between $\left\lfloor \frac{n}{2d} \right\rfloor$ and $\left\lfloor \frac{n}{d} \right\rfloor$. Then, any homogeneous formula of product-depth at most Δ computing $NW_{q,d,k}$ over any field $\mathbb{F}$ has size at least $2^{-O(d)} \cdot n^{\Omega\left(d^{2^{1-\Delta}}\right)}$. In particular, when $d = O(\log n)$, we get a lower bound of $n^{\Omega\left(d^{2^{1-\Delta}}\right)}$.*

▶ Remark 26. Notice that in the above theorem, as k depends on the product-depth Δ, the polynomial $NW_{q,d,k}$ may be different for different values of Δ. However, much like in [19], there is a way to "stitch" all the different NW polynomials for different values of Δ into a single polynomial P such that any homogeneous formula of product-depth Δ computing P has size at least $2^{-O(d)} n^{\Omega\left(d^{2^{1-\Delta}}\right)}$. See Theorem 34 for more details.

In [29], the authors showed how to convert a circuit of product-depth Δ computing a homogeneous polynomial to a homogeneous formula of product-depth 2Δ without much increase in the size. Combining Lemma 11 from [29] with Theorems 24 and 25, we get:

▶ **Corollary 27** (Low-depth circuit lower bound for IMM). *For any positive integers d, n, Δ such that $n = \omega(d)$, any circuit of product-depth at most Δ computing $IMM_{n,d}$ over any field $\mathbb{F}$ with characteristic 0 or more than d has size at least $2^{-O(d)} \cdot n^{\Omega\left(\frac{d^{2^{1-2\Delta}}}{\Delta}\right)}$.*

In particular, when $d = O(\log n)$, we get a lower bound of $n^{\Omega\left(\frac{d^{2^{1-2\Delta}}}{\Delta}\right)}$.

▶ **Corollary 28** (Low-depth circuit lower bound for NW). *Let n, d, Δ be positive integers. If $\Delta = 1$, let $d = n^{1-\epsilon}$ for any constant $\epsilon > 0$ and $k = \left\lfloor \frac{d-1}{2} \right\rfloor$. Otherwise, let $d \leq \frac{1}{150}\left(\frac{\log n}{\log\log n}\right)^2$, let $\tau = \left\lfloor d^{2^{1-\Delta}} \right\rfloor$, $\alpha = \sum_{\nu=0}^{\Delta-1} \frac{(-1)^\nu}{\tau^{2^\nu - 1}}$, and $k = \left\lfloor \frac{\alpha \cdot d}{1+\alpha} \right\rfloor$. In both cases, let q be the largest prime number between $\left\lfloor \frac{n}{2d} \right\rfloor$ and $\left\lfloor \frac{n}{d} \right\rfloor$. Then, any circuit of product-depth at most Δ computing $NW_{q,d,k}$ over any field $\mathbb{F}$ of characteristic 0 or more than d has size at least $2^{-O(d)} \cdot n^{\Omega\left(\frac{d^{2^{1-2\Delta}}}{\Delta}\right)}$.*

In particular, when $d = O(\log n)$, we get a lower bound of $n^{\Omega\left(\frac{d^{2^{1-2\Delta}}}{\Delta}\right)}$.

We note that our lower bounds quantitatively improve on the original homogeneous formula lower bound of [29] in terms of the dependence on the degree. While [29] gives a lower bound of $d^{O(-d)} \cdot n^{\Omega\left(d^{1/2^\Delta - 1}\right)}$ (as the conversion from homogeneous to set-multilinear formulas increases the size by a factor of $d^{O(d)}$), our lower bound is $2^{-O(d)} \cdot n^{\Omega\left(d^{2^{1-\Delta}}\right)}$. Thus, we get slight improvement both in the multiplicative factor (from $d^{O(d)}$ to $2^{O(d)}$) and in the exponent of n (from $d^{\frac{1}{2^\Delta - 1}}$ to $d^{\frac{1}{2^{(\Delta-1)}}}$). We point out what these improvements mean for smaller depths: For $\Delta = 2$, our lower bound for homogeneous formulas computing IMM is superpolynomial as long as $d \leq \epsilon \cdot \log^2 n$ for a small enough positive constant ϵ, whereas the lower bound in [29] does not work beyond $d = O\left(\left(\frac{\log n}{\log\log n}\right)^2\right)$. In particular, we obtain a lower bound of $n^{\Omega(\log n)}$ for the size of homogeneous depth-5 formulas computing $IMM_{n,d}$ when $d = \Theta(\log^2 n)$. Finally, for $\Delta = 3$ and $d \leq \epsilon \cdot \log^{4/3} n$, we get a lower bound of $n^{\Omega\left(d^{1/4}\right)}$, as compared to $n^{\Omega\left(d^{1/7}\right)}$ from [29].

5 Lower bound for unique-parse-tree formulas

In this section, we show that UPT formulas computing IMM must have a "large" size. We begin by giving a decomposition for such formulas. Missing proofs from this section can be found in the full version of this article [2].

5.1 Decomposition of UPT formulas

In order to upper bound the SP (or APP) measure of a UPT formula, we need certain results about binary trees and UPT formulas. For a given canonical parse tree $\mathcal{T}$ with d leaves, we define its *degree sequence* $(d_1, \ldots, d_t)$ using the function Deg-seq described in Algorithm 1.

We prove the following lemma in the full version of this article [2]. The idea here is to "break" the tree at various nodes so that the successive sizes of the smaller trees are far from each other.

Algorithm 1 Degree sequence of a right-heavy binary tree.

```
function DEG-SEQ(𝒯)
    v_0 ← root node of 𝒯.
    if v_0 is a leaf then
        return (1).
    end if
    d ← leaves(v_0), i ← 0.
    while v_i is not a leaf do
        v_{i+1} ← right child of v_i, i ← i + 1.
    end while
    v ← v_j corresponding to the largest index j such that leaves(v_j) > d/3.
    d_1 ← d − leaves(v).
    return (d_1, DEG-SEQ(𝒯_v)).
end function
```

▶ **Lemma 29.** *For a given canonical parse tree $\mathcal{T}$ with $d \geq 1$ leaves, let $(d_1, \ldots, d_t) :=$ DEG-SEQ$(\mathcal{T})$, where the function* DEG-SEQ *is given in Algorithm 1. Also let $e_i := d - \sum_{j=1}^{i} d_j$ for $i \in [t]$ and $e_0 := d$. Then, for all $i \in [t-1]$, $e_i \in \left(\frac{e_{i-1}}{3}, \frac{2 \cdot e_{i-1}}{3}\right]$. Additionally, $d_t = 1$, $e_t = 0$, and $\log_3 d + 1 \leq t \leq \log_{3/2} d + 1$.*

As mentioned in Section 4.1, it was shown in [12] that a homogeneous formula can be expressed as a "small" sum of products of homogeneous polynomials such that in each summand, the degrees of the factors roughly form a geometric sequence. We observe that this result can be strengthened for UPT formulas; in particular, we show that for UPT formulas, the "degree sequences" of all the summands are identical.

▶ **Lemma 30** (Log-product decomposition of UPT formulas)**.** *Let $f \in \mathbb{F}[\mathbf{x}]$ be a homogeneous polynomial of degree $d \geq 1$ computed by a UPT formula C with canonical parse tree $\mathcal{T}(C)$. Let $(d_1, \ldots, d_t) :=$ DEG-SEQ$(\mathcal{T}(C))$. Then there exist an integer $s \leq \text{size}(C)$ and homogeneous polynomials $\{Q_{i,j}\}_{i,j}$ where $\deg(Q_{i,j}) = d_j$ for $i \in [s]$, $j \in [t]$, such that*

$$f = \sum_{i=1}^{s} Q_{i,1} \cdots Q_{i,t}.$$

5.2 UPT formulas have high residue

Now we show that there exists a value of k that has high residue with respect to the degrees of the factors given by the above log-product lemma.

▶ **Lemma 31** (High residue for a degree sequence)**.** *For any given canonical parse tree $\mathcal{T}$ with $d \geq 1$ leaves, let $(d_1, \ldots, d_t) :=$ DEG-SEQ$(\mathcal{T})$ and $k :=$ UPT-K$(d_1, \ldots, d_t)$ where the function* UPT-K *is described in Algorithm 2. Then*

$$\text{residue}_k(d_1, \ldots, d_t) \geq \frac{\log_3 d - 10}{216}.$$

Algorithm 2 The value of k for a given sequence of degrees.

function UPT-K$(d_1, \ldots, d_t)$
  /* Returns k which shall be the order of derivatives for the SP and APP measures. */
  $d = d_1 + \cdots + d_t$.
  for $i \in [0..t]$ **do**
    $e_i \leftarrow d - \sum_{j=1}^{i} d_j$.
  end for
  $m \leftarrow \left\lfloor \frac{\log_3 d - 1}{3} \right\rfloor$.
  /* Defining a function $\mathcal{J} : [3m] \to [t-2]$. */
  for $i \in [3m]$ **do**
    $\mathcal{J}(i) \leftarrow \min\left\{ j \in [0..t] : e_j \leq 3^i \right\}$.
  end for
  $(a_1, \ldots, a_m) \leftarrow$ *undefined*.
  for $i \in [m]$ **do**
    $j \leftarrow \mathcal{J}(3i)$.
    $b_0 \leftarrow \left(\sum_{p=1}^{i-1} \frac{a_p}{3^{3p}} \right) \cdot d_{j+1}$.
  /* b_1 defined below is not used in the algorithm but will be useful in the analysis. */
    $b_1 \leftarrow \left(\sum_{p=1}^{i-1} \frac{a_p}{3^{3p}} + \frac{1}{3^{3i}} \right) \cdot d_{j+1}$.
    if $\{b_0\} \in \left[\frac{1}{18}, \frac{17}{18}\right]$ **then**
      $a_i \leftarrow 0$.
    else
      $a_i \leftarrow 1$.
    end if
  end for
  $\alpha \leftarrow \sum_{p=1}^{m} \frac{a_p}{3^{3p}}$
  $k \leftarrow \lfloor \alpha \cdot d \rfloor$
  return k.
end function

5.3 Putting everything together: the UPT formula lower bound

In this section, we state our lower bounds for UPT formulas.

▶ **Theorem 32** (UPT formula lower bound for IMM)**.** *For $n \in \mathbb{N}$ and $d \leq \epsilon \cdot \log n \cdot \log\log n$, where $\epsilon > 0$ is a small enough constant, any UPT formula computing $IMM_{n,d}$ over any field $\mathbb{F}$ has size $n^{\Omega(\log d)}$.*

▶ Remark 33. The above theorem can also be derived by using the complexity measure studied in [29] along with the observation that the *unbounded-depth* set-multilinearization due to [35] (which increases the size by a factor of $2^{O(d)}$) preserves parse trees.

We also get an analogous theorem for a polynomial related to the NW polynomial.

▶ **Theorem 34.** *Let $n \in \mathbb{N}$, $d \leq \epsilon \cdot \log n \cdot \log\log n$, where $\epsilon > 0$ is a small enough constant, and q be the largest prime number between $\left\lfloor \frac{n}{2d} \right\rfloor$ and $\left\lfloor \frac{n}{d} \right\rfloor$. Then, any UPT formula computing $P = \sum_{i=\lfloor d/30 \rfloor}^{\lceil d/2 \rceil} y_i \cdot NW_{q,d,i}$ (where the y variables are distinct from the $\mathbf{x}$ variables), over any field $\mathbb{F}$ has size $n^{\Omega(\log d)}$.*

6 Conclusion

Recently, [29] made remarkable progress on arithmetic circuit lower bounds by giving the first super-polynomial lower bound for low-depth formulas. They achieve this by a hardness escalation approach via set-multilinearization. But, set-multilinearization is an inherently expensive process that seems to restrict us from obtaining an exponential lower bound for even homogeneous low-depth formulas. In this work, we take the vital first step of sidestepping set-multilinearization and showing a super-polynomial lower bound for low-depth formulas via a direct approach. A direct approach does not seem to incur an *inherent* exponential loss. So, it might be possible to prove stronger lower bounds for low-depth homogeneous formulas or other related models using this approach or an adaptation of it.

Problem 1. Prove exponential lower bounds for low-depth homogeneous arithmetic formulas. Prove exponential lower bounds for low-depth, *multi-r-ic* formulas.

A formula is said to be multi-r-ic, if the formal degree of every gate with respect to every variable is at most r [17, 21]. The UPT formula lower bound proved in this work is for formulas computing polynomials of degree at most $O(\log n \cdot \log\log n)$. It would be interesting to increase the range of degrees for which our bound works. In the non-commutative setting, exponential lower bounds are known for formulas with exponentially many parse trees [28].

Problem 2. Prove an $n^{\Omega(\log d)}$ lower bound for UPT formulas for $d = n^{O(1)}$. Prove a superpolynomial lower bound for formulas with "many" parse trees.

Our work also raises the prospect of learning low-depth homogeneous formulas given black-box access using the "learning from lower bounds" paradigm proposed in [7, 18].

Problem 3. Obtain learning algorithms for random low-depth homogeneous formulas.

To upper bound SP or APP of a homogeneous formula C, we first show in Section 3 that the space of partial derivatives of C has some structure and then exploit this structure using shifts or affine projections. There might be a better way to exploit this structure, say by going modulo an appropriately chosen ideal or using random restrictions along with shifts as done in [14, 26]. Exploring this possibility is also an interesting direction for future work.

Multi Layer Peeling for Linear Arrangement and Hierarchical Clustering

Yossi Azar

Abstract

We present a new multi-layer peeling technique to cluster points in a metric space. A well-known non-parametric objective is to embed the metric space into a simpler structured metric space such as a line (i.e., Linear Arrangement) or a binary tree (i.e., Hierarchical Clustering). Points which are close in the metric space should be mapped to close points/leaves in the line/tree; similarly, points which are far in the metric space should be far in the line or on the tree. In particular we consider the Maximum Linear Arrangement problem [20] and the Maximum Hierarchical Clustering problem [12] applied to metrics.

We design approximation schemes ($1 - \epsilon$ approximation for any constant $\epsilon > 0$) for these objectives. In particular this shows that by considering metrics one may significantly improve former approximations (0.5 for Max Linear Arrangement and 0.74 for Max Hierarchical Clustering). Our main technique, which is called multi-layer peeling, consists of recursively peeling off points which are far from the "core" of the metric space. The recursion ends once the core becomes a sufficiently densely weighted metric space (i.e. the average distance is at least a constant times the diameter) or once it becomes negligible with respect to its inner contribution to the objective. Interestingly, the algorithm in the Linear Arrangement case is much more involved than that in the Hierarchical Clustering case, and uses a significantly more delicate peeling.

1 Introduction

Unsupervised learning plays a major role in the field of machine learning. Arguably the most prominent type of unsupervised learning is done through clustering. Abstractly, in this setting we are given a set of data points with some notion of pairwise relations which is captured via a metric space (such that closer points are more similar). In order to better understand the data, the goal is to embed this space into a simpler structured space while preserving the original pairwise relationships. A prevalent solution in this domain is to build a flat clustering (or partition) of the data (e.g., by using the k-means algorithm). However, these types of solutions ultimately fail to capture all pairwise relations (e.g., intra-cluster relations). To overcome this difficulty, often the metric space is mapped to structures that may capture all pairwise relations - in our case into a Linear Arrangement (LA) or a Hierarchical Clustering (HC).

The idea of embedding spaces by using a Linear Arrangement or Hierarchical Clustering structure is not new. These types of solutions have been extensively used in practice (e.g., see [11, 30, 5, 6, 26]) and have also been extensively researched from a theoretical point of view (e.g., see [13, 12, 24, 10, 17, 20]). Notably, the Linear Arrangement type objectives were first considered by Hansen [19] who considered the embedding of graphs into 2-dimensional and higher planes. On the other hand, the study of Hierarchical Clustering type objectives was initiated by Dasgupta [13] - spurring a fruitful line of work resulting in many novel algorithms. In practice, more often than not, the data considered adheres to the triangle inequality (in particular guaranteeing that if point a is similar, equivalently close, to points b and c then so are b and c) and thus may be captured by a metric (e.g., see [9, 25, 26]).
The first objective we consider is the Max Linear Arrangement objective.

▶ **Definition 1.** *Let $G = (V, w)$ denote a metric (specifically, w satisfies the triangle inequality) with $|V| = n$. In the **Max Linear Arrangement problem** our goal is to return a 1-1 mapping $y : V \to [n]$ so as to maximize $\sum_{i,j} w_{i,j} y_{i,j}$, where $y_{i,j} = |y_i - y_j|$.*

The second objective we consider is the Max Hierarchical Clustering objective.

▶ **Definition 2.** *Let $G = (V, w)$ denote a metric (specifically, w satisfies the triangle inequality). In the **Max Hierarchical Clustering problem** our goal is to return a binary HC tree T such that its leaves are in a 1-1 correspondence with V. Furthermore, we would like to return T so as to maximize $\sum_{i,j} w_{i,j} |T_{i,j}|$, where T_{ij} is the subtree rooted at the lowest-common-ancestor of the leaves i and j in the Hierarchical Clustering tree T and $|T_{i,j}|$ is the number of leaves in $T_{i,j}$.*

These objectives were first considered by Hassin and Rubinstein [20] and Cohen-Addad et al. [12] (respectively) with respect to the non-metric case. For these (non-metric) objectives the best known approximation ratios are 0.5 for the Linear Arrangement objective [20] and 0.74 for the Hierarchical Clustering objective [25]). The former was achieved by was achieved by bisecting the data points randomly and thereafter greedily arranging each set and the latter was achieved by approximating the Balanced Max-2-SAT problem.

As stated earlier, more often than not, the data considered in practical applications adheres to the triangle inequality. Therefore, our results' merits are two fold. First, we offer a generalized framework to tackle these types of embedding objectives. Second, our results show that by applying this natural assumption we may significantly improve former best known approximations (from 0.5 (LA) and 0.74 (HC) to $1 - \epsilon$ for any constant $\epsilon > 0$).

Our Results

We provide the following results.

- We design a general framework in order to tackle the embedding of metric spaces into simpler structured spaces (see Algorithm 1). We then concretely apply our framework to both the Linear Arrangement and Hierarchical Clustering settings. For an extended discussion see Our Techniques.
- We apply our framework to the Linear Arrangement case. In this case we prove that our applied algorithm (2) is an EPRAS (see Definition 8) - i.e., for any constant $\epsilon > 0$ it yields a $1 - \epsilon$ approximation.
- We apply our framework to the Hierarchical Clustering case. In this case we prove that our applied algorithm (4) is an EPRAS (see Definition 8) - i.e., for any constant $\epsilon > 0$ it yields a $1 - \epsilon$ approximation.

Our Techniques

Our generic multi-layer peeling approach appears in Algorithm 1. We begin by checking whether the metric space is sufficiently densely weighted (i.e., whether the average distance is at least a constant times the diameter, or equivalently the metric's weighted density (see Definition 3) is constant). If this is the case then we apply a specific algorithm that handles such instances. In the LA case we devise our own algorithm (see Algorithm 3). Algorithm 3 leverages the General Graph Partitioning algorithm of Goldreich et al. [18] in order to "guess" an optimal graph partition that induces an almost optimal linear arrangement. In the HC case we leverage the work of Vainstein et al. [31].

If, however, the metric is not sufficiently densely weighted, then we observe that it must contain a **core** - a subset of nodes containing almost all data points with a diameter significantly smaller than the original metric's. Our general algorithm then peels off data points *far* from the core (in the LA setting) or *not in* the core (in the HC setting). We then embed these peeled off points; by placing them on one of the extreme sides of the line (in the LA setting) or by arranging them in a ladder structure (in the HC case; see Definition 11). Thus, we are left with handling the core (in the HC setting) or the extended core (in the LA setting).

Once again we consider two cases - either the total weight within the (extended) core is small enough, in which case we embed the core arbitrarily. Otherwise, we recurse on the instance induced by these data points. We claim that in every recursion step the density of the (extended) core increases significantly until eventually the recursion ends either when the (extended) core is sufficiently densely weighted or the total weight within the (extended) core is small enough.

Our proof is based on several claims. First, we consider the metric's (extended) core compared to the peeled off layer. Since our algorithm embeds the two sets separately, we need to bound the resulting loss in objective value. We show that the weights within the peeled off layer contribute negligibly towards the objective while the weights between the peeled off layer and the (extended) core, contribute significantly. Hence, it makes sense then to peel off this layer in order to maximize the gain in objective value.

While the aforementioned is enough to bound the loss in a single recursion step, it is not enough. The number of recursion steps may not be constant which, in principle, may cause a blow up of the error. Nevertheless, we show that the error in each level is bounded by a geometric sequence and hence is dominated by the error of the deepest recursion step. Consequently, we manage to upper bound the total accumulated error by a constant that we may take to be as small as we wish.

While at large this describes our proof techniques, the algorithm and analysis of LA objective is a bit more nuanced as we will be considering 3 sets: the metric's core, the peeled off layer, and any remaining points which together with the core are labeled as the extended core. In this case, to be able to justify peeling off a layer, we must choose the layer more aggressively. Specifically, we define this layer as points that are sufficiently far from the core (rather than any point outside the core, as in the HC case). Fortunately, this defined layer (see Algorithm 2) fits our criteria (of our general algorithm, Algorithm 1).

Related Work

While the concept of hierarchical clustering has been around for a long time, the HC objective is relatively recent. In their seminal work, Dasgupta [13] considered the problem of HC from an optimization view point. Thereafter, Cohen-Addad et al. [12] were the

first to consider the objective we use in our manuscript. In their work they showed that the well known Average-Linkage algorithm yields an approximation of $\frac{2}{3}$. Subsequently, Charikar et al. [8] improved upon this result through the use of semidefinite programming - resulting in a 0.6671 approximation. Finally, Naumov et al. [25] improved this to 0.74 by approximating the Balanced Max-2-SAT problem. With respect to the Max LA objective, Hassin and Rubinstein [20] were first to consider the problem. Through an approach of bisection and then greedily arranging the points, Hassin and Rubinstein managed to achieve a 0.5 approximation. We note that the previous mentioned results all hold for arbitrary weights, while our main contribution is showing that by assuming the triangle inequality (i.e., metric-based dissimilarity weights) we may achieve PTAS's for both objectives. We further note that with respect to metric-based dissimilarity weights, specifically an L1 metric, Rajagopalan et al. [26] proved a 0.9 approximation through the use of random cut trees.

Both objectives have been originally studied with respect to their minimization variants. The minimum LA setting was first considered by Hansen [19]. Hansen leveraged the work of Leighton and Rao [23] on balanced separators in order to approximate the minimum linear arrangement objective to facor of $O(\log^2 n)$. Following several works improving upon this result, both Charikar et al. [10] and Feige and Lee [17] leveraged the novel work of Arora et al. [4] on rounding of semidefinite programs, and combined this with the rounding algorithm of Rao and Reicha [27] in order to show a $O(\sqrt{\log n}\log\log n)$ approximation. For further reading on these are related types of objectives see [16, 27, 29, 28]. On the other hand, as mentioned earlier the minimum HC setting was introduced by Dasgupta [13] and extensively studied as well (e.g., see [13, 12, 7, 8, 1, 2, 31]).

Most related to our work is that of de la Vega and Kenyon [15]. In their work they provide a PTAS for the Max Cut problem given a metric. The algorithm works by first creating a graph of clones (wherein each original vertex is cloned a number of times that is based on its outgoing weight in the original metric) with the property of being dense. It thereafter solves the problem in this new graph by applying the algorithm of de la Vega and Karpinski [14]. For our objectives (HC and LA) such an approach seems to fail - specifically due to the fact that our objectives take into consideration the number of nodes in every induced cut and the cloned graph inflates the number of nodes which in turn inflates our objective values. Thus, for our considered types of objectives we need the more intricate process of iterative peeling (and subsequently terminating the process with more suited algorithms that leverage the General Graph Partitioning algorithm of Goldreich et al. [18]). It is worth while mentioning that there has also been an extensive study of closely related objectives with respect to dense instances (e.g. see [22, 3, 21]). However these types of approaches seem to fall short since our considered metrics need not be dense.

2 Multi-Layer Peeling Framework

Before defining our algorithms we need the following definitions.

▶ **Definition 3.** *Let $G = (V, w)$ denote a metric and $U \subset V$ denote a subset of its nodes. We introduce the following notations: (1) let $\mathbf{D_U} = \max_{i,j\in U} w_{i,j}$ denote U's **diameter**, (2) let $\mathbf{W_U} = \sum_{i,j\in U} w_{i,j}$ denote U's **sum of weights**, (3) let $\mathbf{n_U} = |U|$ denote U's **size** and (4) let $\rho_{\mathbf{U}} = \frac{W_U}{n_U^2 D_U}$ denote U's **weighted density**[1].*

[1] Typically the density is defined with respect to $\binom{n}{2}$. For ease of presentation, we chose to define it with respect to n^2 - the proofs remain the same using the former definition.

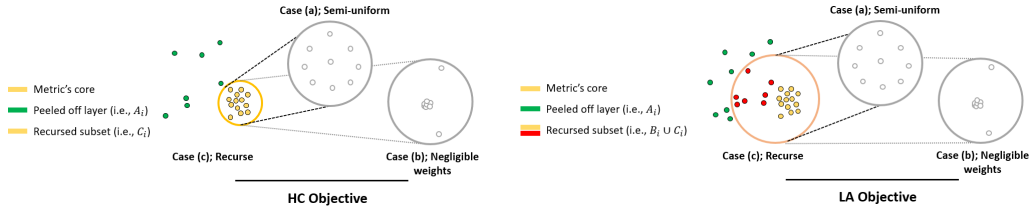

Figure 1 A recursion step (case (c)) and the two possible halting steps (cases (a) and (b)). The yellow points define the metric's core. In the HC case we peel off both red and green points in a single step, while in the LA we must be more delicate and only peel off the green points.

All our algorithms will make use of the following simple yet useful structural lemma that states that for small-density instances there exists a large cluster of nodes with a small diameter. The proof appears in the full version.

▶ **Lemma 4.** *For any metric $G = (V, w)$ there exists a set $U \subset V$ such that $D_U \leq 4D_V\sqrt{\rho_V}$ and $n_U \geq n_V(1 - \sqrt{\rho_V})$.*

▶ **Definition 5.** *Given a metric $G = (V, w)$ we denote $U \subset V$ as guaranteed by Lemma 4 as a metric's* ***core****.*

Note that the core can be found algorithmicaly simply through brute force (while the core need not be unique, our algorithms will choose one arbitrarily).

Throughout our paper we consider different metric-based objectives. In order to solve them, we apply the same recipe - if the instance is sufficiently densely weighted, apply an algorithm for these types of instances. Otherwise, the algorithm detects the metric's core (which is a small-diameter subset containing almost all nodes) and peel off (and subsequently embed) a layer of data points that are far from the core. The algorithm then considers the core; if it is sufficiently small (in terms of inner weights) then we embed the core arbitrarily and halt. Otherwise, we recurse on the core. Our algorithms for both objectives (LA and HC) will follow the same structure as defined in Algorithm 1.

Algorithm 1 General Algorithm.

if *the instance is sufficiently densely weighted* **then** `// case (a)`
  Solve it using ALG_{d-w}.
else
  Let C denote the metric's core (as defined by Definition 5).
  Define the layer to peel off $A \subset V \setminus C$ appropriately.
  Embed A.
  if $W_{V \setminus A}$ *is negligible* **then** Embed $V \setminus A$ arbitrarily and return. ; `// case (b)`
  else Continue recursively on $V \setminus A$; `// case (c)`

We denote by cases (a) and (b) the different cases for which the algorithm may terminate and by case (c) the recursive step. We further denote by ALG_{d-w} an auxiliary algorithm that will handle sufficiently densely weighted instances. (These algorithms will differ according to the different objectives).

Henceforth, given an algorithm ALG and metric G we denote by $ALG(G)$ the algorithm's returned embedding. We note that when clear from context we overload the notation and denote $ALG(G)$ as the embedding's value under the respective objectives. Equivalently, we will use the term $OPT(G)$ for the optimal embedding.

Our different algorithms will be similarly defined and thus so will their analyses. Thus, we introduce a general scheme for analyzing such algorithms. Let k denote the number of recursive calls our algorithm performs. Furthermore, let G_i denote the instance the algorithm is called upon in step i for $i = 0, 1, \ldots, k$. (I.e., $G = G_0$ and $ALG(G_k)$ does not perform a recursive step, meaning that it terminates with case (a) or (b)). We first observe that by applying a simple averaging argument we get the following useful observation.

▶ **Observation 6.** *If there exist $\alpha_i, \beta_i, \gamma_i > 0$ such that $ALG(G_i) \geq \alpha_i + ALG(G_{i+1})$ and $OPT(G_i) \leq \beta_i + \gamma_i OPT(G_{i+1})$ for all $i = 0, \ldots, k-1$ then*

$$\begin{aligned}\frac{ALG(G)}{OPT(G)} &\geq \frac{\sum_{i=0}^{k-1} \alpha_i + ALG(G_k)}{\sum_{i=0}^{k-1} \left(\beta_i \Pi_{j=0}^{i-1} \gamma_j\right) + (\Pi_{i=0}^{k-1} \gamma_i) OPT(G_k)} \\ &\geq \min\{\min_i\{\frac{\alpha_i}{\beta_i \Pi_{j=0}^{i-1} \gamma_j}\}, \frac{ALG(G_k)}{(\Pi_{i=0}^{k-1} \gamma_i) OPT(G_k)}\}.\end{aligned}$$

Thus, in order to analyze a given algorithm, it will be enough to set the values of α_i, β_i and γ_i, and further analyze the approximation ratio of $\frac{ALG(G_k)}{OPT(G_k)}$ for the different terminating cases (cases (a) and (b)).

3 Notations and Preliminaries

We introduce the following notation to ease our presentation later on.

▶ **Definition 7.** *Given a metric $G = (V, w)$, a solution $\mathbf{SOL(G)}$ for the LA objective and disjoints sets $A, B \subset V$ we define: $\mathbf{SOL(G)}|_{\mathbf{A}} = \sum_{i,j \in A} w_{i,j} y_{i,j}$ and $\mathbf{SOL(G)}|_{\mathbf{A,B}} = \sum_{i \in A, j \in B} w_{i,j} y_{i,j}$. For the HC objective the notations are defined symmetrically by replacing $y_{i,j}$ with $|T_{i,j}|$.*

We will make use of algorithms belonging to the following class of algorithms.

▶ **Definition 8.** *An algorithm is considered an Efficient Polytime Randomized Approximation Scheme (EPRAS) if for any $\epsilon > 0$ the algorithm has expected running time of $f(\frac{1}{\epsilon}) n^{O(1)}$ and approximates the optimal solution's value up to a factor of $1 - \epsilon$.*

We will frequently use the following (simple) observations and thus we state them here.

▶ **Observation 9.** *Given values $\alpha_i \geq 0$, $\alpha \in (0, \frac{1}{k(k+1)})$ and $k \in \mathbb{N}$ we have: **(1)** $\Pi_i(1-\alpha_i) \geq 1 - \sum_i \alpha_i$, **(2)** $1 + k\alpha < \frac{1}{1-k\alpha} < 1 + (k+1)\alpha$ and **(3)** $1 + k\alpha < e^{k\alpha} < 1 + (k+1)\alpha$.*

The following facts will prove useful in our subsequent proofs and are therefore stated here.

▶ **Fact 10.** *Given a metric G, if the optimal linear arrangement under the LA objective is $OPT_{LA}(G)$ and the optimal hierarchical clustering under the HC objective is $OPT_{HC}(G)$ then we have $OPT_{LA}(G) \geq \frac{1}{3} n \sum_{i,j} w_{i,j} y_{i,j}$ and $OPT_{HC}(G) \geq \frac{2}{3} n \sum_{i,j} w_{i,j} |T_{i,j}|$.*

We note that the HC portion of Fact 10 has been used widely in the literature (e.g., see proof in [12]). The LA portion of Fact 10 is mentioned in Hassin and Rubinstein [20]. Finally, in the HC section we make use of "ladder" HC trees. We define them here.

▶ **Definition 11.** *We define a "ladder" as an HC tree that cuts a single data point from the rest at every cut (or internal node).*

4 The Linear Arrangement Objective

We will outline the section as follows. We begin by presenting our algorithms (first the algorithm that handles case (a) and thereafter the general algorithm). We will then bound the algorithm's approximation guarantee (by following the bounding scheme of Observation 6). Finally, we will analyze the algorithm's running time.

4.1 Defining the Algorithms

Here we begin by applying our general algorithm to the linear arrangement problem (which we will denote simply as ALG). The algorithm uses, as a subroutine, an algorithm to handle case (a). We denote this subroutine as ALG_{d-w} and define it following the definition of ALG.

4.1.1 Defining ALG

Here we apply our general algorithm (Algorithm 1) to the linear arrangement setting. In order to do so, roughly speaking, we define the layer to peel off A as the set of all points which are "far" from the metric's core. We also introduce a subroutine to handle densely weighted instances, ALG_{d-w}.

Algorithm 2 Linear Arrangement Algorithm (ALG).

if $\rho \geq \epsilon^6$ **then** solve it using ALG_{d-w}. ; `// case (a)`
else
  Let C denote the metric's core (as defined by Lemma 4).
  Let A denote all data points that are of distance $\geq \epsilon^2 D_V$ from C.
  Place A to the left of $V \setminus A$. Arrange A arbitrarily.
  if $W_{V \setminus A} < \epsilon W_V$ **then** Arrange $V \setminus A$ arbitrarily and return. ; `// case (b)`
  else Continue recursively on $V \setminus A$. ; `// case (c)`

The set $V \setminus \{A \cup C\}$ will be used frequently in the upcoming proofs and thus we give it its own notation.

▶ **Definition 12.** *Denote $B = V \setminus \{A \cup C\}$ where A and C are defined as in Algorithm 2.*

4.1.2 Defining ALG_{d-w}

Here we will introduce an algorithm to handle case (a) type instances. Before formally defining the algorithm, we will first provide some intuition. Towards that end we first introduce the following definition.

▶ **Definition 13.** *Consider $OPT(G_k)$'s embedding into the line, $[n]$. Partition $[n]$ into $\frac{1}{\epsilon}$ consecutive sets each of size ϵn and let P_i^* denote the points embedded by $OPT(G_k)$ into the i'th consecutive set. Furthermore, denote by $P^* = \{P_i^*\}$ the induced partition of the metric.*

Later on, we will show that $OPT(G_k)$'s objective value is closely approximated by the value generated solely from inter-partition-set edges (i.e., any (u, v) where u, v lie in different partition sets of P^*). While $OPT(G_k)$ cannot be found algorithmically, assuming the above holds, it is enough for ALG_{d-w} to guess the partition P^*. Indeed, that is exactly what we will do, by using the general graph partitioning algorithm of Goldreich et al. [18].

We denote the General Graph Partitioning algorithm of Goldreich et al. [18] as $PT(G, \Phi, \epsilon_{err})$. See Definition 21 for a definition of Φ and ϵ_{err} (these will be defined by ALG_{d-w} as well) and see Theorem 22 for the tester's guarantees. We are now ready to define our algorithm that handles sufficiently densely weighted instances (Algorithm 3).

Algorithm 3 LA Algorithm for Sufficiently Densely Weighted Instances (ALG_{d-w}).

Let $k = \frac{1}{\epsilon}$ denote the size of the partition.
for $\{\mu_{j,j'}\}_{j \leq k, j' \leq k, j \neq j'} \subset \{i\epsilon^9 n^2 D_V : i \in \mathbb{N} \wedge i \leq \frac{1}{\epsilon^7}\}$ **do**
  Let $\Phi = \{\epsilon n, \epsilon n\}_{j=1}^{k} \cup \{\mu_{j,j'}, \mu_{j,j'}\}_{j,j'=1}^{k}$.
  Run $PT(G, \Phi, \epsilon_{err} = \epsilon^9)$. Let P denote the output partition (if succeeded).
  Let $\widehat{y}$ denote the linear arrangement obtained from embedding P consecutively on the line (and arbitrarily within the partition sets).
  Compute the value $\sum_e w_e \widehat{y_e}$ for P.
Return the partition with maximum $\sum_e w_e \widehat{y_e}$ value.

4.2 Analyzing the Approximation Ratio of ALG

Now that we have defined ALG we are ready to analyze its approximation ratio. Recall that by Observation 6 it is enough to analyze the approximation ratio of cases (a), (b) and the total loss incurred by the recursion steps (i.e., by setting α_i, β_i and γ_i).

4.2.1 Structural Lemmas

Recall that we defined k to be the number of recursion steps used by ALG and that G_i is the instance that ALG is applied to at recursion step i. Further recall that given G_i, $ALG(G_i)$ partitioned the instance into A_i, B_i and C_i and that, informally, by Lemma 4 n_{C_i} contains the majority of the data points and D_{C_i} is relatively small compared to D_{V_i}.

By the definition of C_i, A_i could be considered as a set of outliers. Therefore, intuitively it makes sense to split A_i from C_i. In order to prove our algorithm's approximation ratio we will show that in fact one does not lose too much compared to optimal solution, by splitting A_i from C_i. In order to do so we will show that in fact, both the values of ALG and OPT will be roughly equal to $\frac{1}{2} n W_{A_i,C_i}$ (which makes sense intuitively since C_i is of low diameter and contains many points and A_i are the points that are far from this cluster).

The following lemmas consider 2 types of algorithms - algorithms that split A_i and C_i and algorithms that do not. Furthermore, they show that in fact, by the structural properties of A_i and C_i, if we consider the values generated by these 2 types of algorithms restricted to the objective value generated by the inter-weights W_{A_i,C_i}, are approximately equal. We begin by lower bounding the value generated by algorithms that split A_i and C_i. Due to lack of space, we defer the following proofs to the full version.

▶ **Lemma 14.** *Given the two disjoint sets C_i and A_i and a linear arrangement y that places all nodes in A_i to the left of all nodes in C_i we are guaranteed that*

$$\sum_{c \in C_i, a \in A_i} w_{a,c} y_{a,c} \geq \frac{n_{C_i}}{2} (W_{C_i,A_i} - n_{C_i} n_{A_i} D_{C_i}).$$

Due to the fact that C_i is a small cluster containing most of the data points the above lemma reduces to the following corollary.

▶ **Corollary 15.** *Given any linear arrangement y that places all nodes in A_i to the left of all nodes in C_i we are guaranteed that*

$$\sum_{a\in A_i, c\in C_i} w_{a,c}y_{a,c} \geq \frac{1}{2}nW_{A_i,C_i}(1-\frac{5\sqrt{\rho}}{\epsilon^2})$$

Now that we have lower bounded algorithms that split A_i and C_i we will upper bound algorithms that do not have this restriction. (Note that we begin by handling the case where one of the disjoint sets is a single data point and thereafter generalize it to two disjoint sets).

▶ **Lemma 16.** *Given a set C_i and a point $p \notin C_i$, we are guaranteed that*

$$\sum_{c\in C_i} w_{p,c}y_{p,c} \leq (W_{p,C_i} + n_{C_i}D_{C_i})(n-\frac{n_{C_i}}{2}).$$

We are now ready to upper bound the inter-objective-value of two sets of disjoint points.

▶ **Lemma 17.** *Given the two disjoint sets C_i and A_i and any linear arrangement y we are guaranteed that*

$$\sum_{c\in C_i, a\in A_i} w_{a,c}y_{a,c} \leq (n-\frac{n_{C_i}}{2})(W_{C_i,A_i} + n_{C_i}n_{A_i}D_{C_i}).$$

Due to the fact that C_i is a small cluster containing most of the data points the lemma reduces to the following corollary.

▶ **Corollary 18.** *Given any linear arrangement y we are guaranteed that*

$$\sum_{a\in A_i, c\in C_i} w_{a,c}y_{a,c} \leq \frac{1}{2}nW_{A_i,C_i}(1+\frac{9\sqrt{\rho}}{\epsilon^2}).$$

We will want to show that the objective values of both ALG and OPT (and some other intermediate values that will be defined later on) are approximately determined by their value on the inter-weights of W_{A_i,C_i}. In order to do so, we first introduce the following structural lemma that will help us explain this behaviour.

▶ **Lemma 19.** *Given an instance G and sets A, B and C as defined by $ALG(G)$ we have $W_A + W_{A,B} \leq 2\frac{\sqrt{\rho}}{\epsilon^2}W_{A,C}$.*

4.2.2 Analyzing the Approximation Ratio of Case (a) of ALG

We first give an overview the approximation ratio analysis. Recall the definition of P^* (Definition 13). The first step towards our proof, is to show that instead of trying to approximate $OPT(G_k)$, it will be enough to consider its value restricted to intra-partition-set weights with respect to P^*. Even more, for such weights $w_{u,v}$, incident to P^*_i and P^*_{i+j}, it will be enough to assume that their generated value towards the objective (i.e., the value $y_{u,v}$) is only $(j-1)\epsilon n$ (while it may be as large as $(j+1)\epsilon n$). Formally, this will be done in Lemma 20 (whose proof is deferred to the full version).

Next, recall that ALG_{d-w} tries to guess the partition P^* (up to some additive error) and let P denote the partition guessed by ALG_{d-w}. Observe that if guessed correctly, the value generated towards ALG's objective for any intra-partition-set weight crossing between P_i and P_{i+j} is at least $|P_{i+1}| + \cdots |P_{i+j-1}|$ and if we managed to guess the set sizes as well then this value is exactly $(j-1)\epsilon n$ (equivalent to that of OPT's). This will be done in Proposition 23.

▶ **Lemma 20.** *Given the balanced line partition of set sizes ϵn, denoted as P^*, we have*

$$OPT(G_k) \leq (1+13\epsilon) \sum_{\substack{1\leq i\leq k-1\\ 1\leq j\leq k-i}} W_{P_i^*,P_{i+j}^*}(|P_{i+1}^*|+\cdots+|P_{i+j-1}^*|).$$

Before proving Proposition 23 we state the properties of the general graph partitioning algorithm of Goldreich et al. [18].

▶ **Definition 21** ([18])**.** *Let $\Phi = \{\lambda_j^{LB},\lambda_j^{UB}\}_{j=1}^k \cup \{\mu_{j,j'}^{LB},\mu_{j,j'}^{UB}\}_{j,j'=1}^k$ denote a set of non-negative values such that $\lambda_j^{LB} \leq \lambda_j^{UB}$ and $\mu_{j,j'}^{LB} \leq \mu_{j,j'}^{UB}$. We define $\mathcal{GP}_\Phi$ the set of graphs G on n vertices that have a k partition $(V_1,\ldots,V_k)$ upholding the following constraints*

$$\forall j:\ \lambda_j^{LB} \leq \frac{|V_j|}{n} \leq \lambda_j^{UB};\quad \forall j,j':\ \mu_{j,j'}^{LB} \leq \frac{W_{V_j,V_{j'}}}{n^2} \leq \mu_{j,j'}^{UB}.$$

▶ **Theorem 22** ([18])**.** *Given inputs $G=(V,w)$ with $|V|=n$ and $w: V\times V\to[0,1]$ describing the graph and Φ describing bounds on the wanted partition, ϵ_{err}, the algorithm $PT(G,\Phi,\epsilon_{err})$ has expected running time*[2] *of*

$$\exp\left(\log(\frac{1}{\epsilon_{err}})\cdot(\frac{O(1)}{\epsilon_{err}})^{k+1}\right) + O(\frac{\log\frac{k}{\epsilon_{err}}}{\epsilon_{err}^2})\cdot n.$$

Furthermore, if $G\in\mathcal{GP}_\Phi$ as in Definition 21 then the algorithm outputs a partition satisfying

- $\forall j:\ \lambda_j^{LB}-\epsilon_{err} \leq \frac{|V_j|}{n} \leq \lambda_j^{UB}+\epsilon_{err}$,
- $\forall j,j':\ \mu_{j,j'}^{LB}-\epsilon_{err} \leq \frac{W_{V_j,V_{j'}}}{n^2} \leq \mu_{j,j'}^{UB}+\epsilon_{err}$.

We are now ready to prove Proposition 23.

▶ **Proposition 23.** *If ALG terminates in case (a) then $\frac{ALG_{d-w}(G_k)}{OPT(G_k)} = \frac{ALG(G_k)}{OPT(G_k)} \geq 1-20\epsilon$.*

Proof. Let $P=\{P_i\}$ denote the partition returned by $PT(G_k,\Phi,\epsilon_{err})$ and recall that its number of sets is $k=\frac{1}{\epsilon}$ and that $\epsilon_{err}=\epsilon^9$. We first observe that by Theorem 22 we are guaranteed that the error in $|P_i|$ compared to $|P_i^*|=\epsilon n$ is at most $|P_i|\geq \epsilon n-\epsilon_{err}n$ (due to the fact that in Φ we requested sets of size exactly ϵn). Therefore

$$ALG_{d-w} \geq \sum_{\substack{1\leq i\leq k-1\\ 1\leq j\leq k-i}} W_{P_i,P_{i+j}}(|P_{i+1}|+\cdots+|P_{i+j-1}|) \geq \sum_{\substack{1\leq i\leq k-1\\ 1\leq j\leq k-i}} (j-1)(\epsilon n-\epsilon_{err}n)W_{P_i,P_{i+j}}, \quad (1)$$

where $W_{P_i,P_{i+j}}$ denotes the weight crossing between P_i and P_{i+j}. For ease of presentation we will remove the subscript in the summation henceforth.

Consider the difference between the cut size of $W_{P_i,P_{i+j}}$ and $W_{P_i^*,P_{i+j}^*}$. Their difference originates from two errors: (1) the error that incurred by the PT algorithm (see Theorem 22) and (2) the error ALG_{d-w} incurred in order to guess the partition of $OPT(G_k)$ (see Algorithm 3). Therefore,

$$W_{P_i,P_{i+j}} \geq W_{P_i^*,P_{i+j}^*} - \epsilon_{err}n^2D_V - \epsilon^9n^2D_V = W_{P_i^*,P_{i+j}^*} - 2\epsilon^9n^2D_V$$

where the last equality is since $\epsilon_{err}=\epsilon^9$. Combining this with inequality 1 yields

$$\begin{aligned} ALG_{d-w} \geq (\epsilon n-\epsilon_{err}n)\cdot\sum(j-1)W_{P_i^*,P_{i+j}^*} - (\epsilon n-\epsilon_{err}n)\cdot 2(\epsilon^9n^2)D_V\sum(j-1) \geq \\ (\epsilon n-\epsilon_{err}n)\cdot\sum(j-1)W_{P_i^*,P_{i+j}^*} - 2n^3\epsilon^7D_V, \end{aligned} \quad (2)$$

[2] We remark that the original algorithm contains a probability of error δ, that appears in the running time. We disregard this error and bound the expected running time of the algorithm.

where the last inequality follows since $\epsilon_{err} > 0$ and $\sum(j-1) = \sum_{i=1}^{k}\sum_{j=i+1}^{k}(j-1) \leq k^3 = \epsilon^{-3}$.

Due to the fact that we are in case (a) we have that $\frac{W}{n^2 D_V} = \rho \geq \epsilon^6$. By Fact 10 we have that $OPT \geq \frac{1}{3}nW$ and therefore $2n^3\epsilon^7 D_V$ can be bounded by $2n^3\epsilon^7 D_V \leq 2\epsilon nW \leq 6\epsilon OPT$. Thus we get $2n^3\epsilon^7 D_V \leq 6\epsilon OPT(G_k)$. Combining this with inequality 2 yields

$$ALG_{d-w} \geq (\epsilon n - \epsilon_{err} n) \cdot \sum(j-1) W_{P_i^*, P_{i+j}^*} - 6\epsilon OPT(G_k). \tag{3}$$

On the other hand, recall that P^* denotes the balanced partition where all sets are of size ϵn. Therefore, by Lemma 20 we therefore get

$$\begin{aligned} &OPT(G_k) \leq (1+13\epsilon)\sum W_{P_i^*, P_{i+j}^*}(|P_{i+1}^*| + \cdots + |P_{i+j-1}^*|) = \\ &(1+13\epsilon)\sum(j-1)(\epsilon n) W_{P_i^*, P_{i+j}^*} = \epsilon n(1+13\epsilon) \cdot \sum(j-1) W_{P_i^*, P_{i+j}^*}. \end{aligned} \tag{4}$$

Combining inequalities 3 and 4 yields

$$\begin{aligned} &ALG_{d-w} \geq \frac{\epsilon n - \epsilon_{err} n}{\epsilon n(1+13\epsilon)} OPT(G_k) - 6\epsilon OPT(G_k) = \\ &\frac{1-\epsilon^8}{1+13\epsilon} OPT(G_k) - 6\epsilon OPT(G_k) \geq (1-20\epsilon) OPT(G_k), \end{aligned}$$

thereby concluding the proof. ◀

4.2.3 Analyzing the Approximation Ratio of Case (b) of *ALG*

Using our structural lemmas we will analyze the approximation ratio of ALG applied to G_k under the assumption that the algorithm terminated in case (b) (i.e., that $\rho < \epsilon^6$ and $W_{B \cup C} \leq \epsilon W_{G_k}$). The full proof is deferred to the full version.

▶ **Proposition 24.** *If ALG terminates in case (b) then* $\frac{ALG(G_k)}{OPT(G_k)} \geq 1 - 33\epsilon$.

Sketch. The proof follows the following path. Due to the fact that most of the instance's density is centered at the metric's core C, the majority of $OPT(G_k)$'s objective is derived from weights incident to C. Since we are case (b), the weight of $W_{B \cup C}$ is negligible and therefore we will show that in fact $OPT(G_k)$'s objective is defined by $OPT(G_k)|_{A,C}$. Thereafter, we show that in fact the best strategy to optimize for weights in $W_{A,C}$ is to place A at one extreme of the line and C at the other - which, fortunately, is what $ALG(G_k)$ (approximately) does - thereby approximating $OPT(G_k)$. ◀

4.2.4 Setting the Values α_i, β_i and γ_i

Due to lack of space, the following proofs are deferred to the full version.

▶ **Proposition 25.** *For A_i and C_i as defined by our algorithm applied to G_i and for $\alpha_i = \frac{1}{2}nW_{A,C}(1 - \frac{5\sqrt{\rho}}{\epsilon^2})$, we have $ALG(G_i) \geq \alpha_i + ALG(G_{i+1})$.*

▶ **Proposition 26.** *Let $G_i = (V_i, w_i)$ and $G_{i+1} = (V_{i+1}, w_{i+1})$ denote the instances defined by the i and $i+1$ recursion steps. Furthermore let $\beta_i = \frac{1}{2}n_{V_i}W_{A_i,C_i}(1 + \frac{13\sqrt{\rho}}{\epsilon^2})$ and $\gamma_i = 1 + 4\sqrt{\rho_i}$. Therefore, $OPT(G_i) \leq \beta_i + \gamma_i OPT(G_{i+1})$.*

Thus, we have managed to set the values of α_i, β_i and γ_i as follows.

▶ **Definition 27.** *We define the values α_i, β_i and γ_i as follows*

$$\alpha_i = \frac{1}{2}nW_{A_i,C_i}(1 - \frac{5\sqrt{\rho_i}}{\epsilon^2}); \quad \beta_i = \frac{1}{2}n_{V_i}W_{A_i,C_i}(1 + \frac{13\sqrt{\rho_i}}{\epsilon^2}); \quad \gamma_i = 1 + 4\sqrt{\rho_i}. \tag{5}$$

4.2.5 Putting it all Together

Now that we have analyzed the terminal cases of the algorithm (cases (a) and (b)) and that we have set the values of α_i, β_i and γ_i we will to combine these results to prove ALG's approximation ratio (as in Observation 9). In order to so we must therefore bound the values $\min_i\{\frac{\alpha_i}{\beta_i\Pi_{j=0}^{i-1}\gamma_j}\}$ and $\frac{ALG(G_k)}{(\Pi_{i=0}^{k-1}\gamma_i)OPT(G_k)}$. However, before doing so we will first show that $\Pi_{j=0}^{i-1}\gamma_j$ converges. Recall that $\gamma_i = 1+4\sqrt{\rho_i}$. The following lemma shows that the instances' densities (ρ_i) increase at a fast enough rate (exponentially) in order for $\Pi_{j=0}^{i-1}\gamma_j$ to converge.

▶ **Lemma 28.** *For all $i = 1,\ldots,k-1$ we are guaranteed that $\rho_{i+1} \geq 4\rho_i$.*

Proof. Let V denote the set of nodes of G_i. Recall the notations A, B and C defined by our algorithm applied to V (in particular, the set of nodes of G_{i+1} is exactly $B \cup C$). Therefore, if we denote by D_{B-C} the largest distance between any point in B and its closest point in C, then $D_{B\cup C} \leq 2D_{B-C} + D_C \leq 2\epsilon^2 D_V + 4D_V\sqrt{\rho_i}$, where the first inequality follow from the triangle inequality and the second follows due to the fact that B is defined as the set of all points of distance at most ϵ^2 from C. Therefore,

$$\rho_{i+1} = \frac{W_{B\cup C}}{n_{B\cup C}^2 \cdot D_{B\cup C}} \geq \frac{W_V}{n_V^2 \cdot D_V}\left(\frac{\epsilon}{2\epsilon^2+4\sqrt{\rho_i}}\right) = \rho_i\left(\frac{\epsilon}{2\epsilon^2+4\sqrt{\rho_i}}\right), \tag{6}$$

where the equalities follows by the definition of ρ_i and the inequality follows due to the fact that $W_{B\cup C} \geq \epsilon W_V$ (which follows due to the fact that we are in case (c)), $n_{B\cup C} \leq n_V$ and $D_{B\cup C} \leq (2\epsilon^2+4\sqrt{\rho_i})D_V$ (as stated above). Since we are in case (c), we are guaranteed that $\rho_i \leq \epsilon^6$ and therefore

$$\frac{\epsilon}{2\epsilon^2+4\sqrt{\rho_i}} \geq \frac{\epsilon}{2\epsilon^2+4\epsilon^3} \geq \frac{1}{3\epsilon}, \tag{7}$$

since $\epsilon \leq 10^{-2}$. Combining inequalities 6 and 7, and since $\epsilon < 10^{-2}$ yields $\rho_{i+1} \geq \rho_i(\frac{\epsilon}{2\epsilon^2+4\sqrt{\rho_i}}) \geq \frac{\rho_i}{3\epsilon} \geq 4\rho_i$, thereby concluding the proof. ◀

We are now ready to show that $\Pi_{j=0}^{i-1}\gamma_j$ converges.

▶ **Lemma 29.** *For $\gamma_i = 1+4\sqrt{\rho_i}$ we have $\Pi_{j=0}^{i-1}\gamma_j \leq 1+5\sqrt{\rho_i}$.*

Proof. Observe that $\Pi_{j=0}^{i-1}(1+4\sqrt{\rho_j}) \leq e^{4\cdot\sum_j\sqrt{\rho_j}} \leq e^{4\sqrt{\rho_i}} \leq 1+5\sqrt{\rho_i}$, where the first inequality follows from Observation 9, the second follows since $\sqrt{\rho_j}$ are exponentially increasing (see full version) and the third inequality follows again by Observation 9 combined with the fact that $\rho < \epsilon^2$ and $\epsilon < 10^{-2}$. ◀

Next we leverage the former lemma to bound $\min_i\{\frac{\alpha_i}{\beta_i\Pi_{j=0}^{i-1}\gamma_j}\}$ and $\frac{ALG(G_k)}{(\Pi_{i=0}^{k-1}\gamma_i)OPT(G_k)}$.

▶ **Proposition 30.** *For α_i, β_i and γ_i as in Definition 27, we have $\min_i\{\frac{\alpha_i}{\beta_i\Pi_{j=0}^{i-1}\gamma_j}\} \geq 1-23\epsilon$.*

Proof. We first bound $\frac{\alpha_i}{\beta_i}$. By the definitions of α_i and β_i we have

$$\frac{\alpha_i}{\beta_i} = \frac{1-\frac{5\sqrt{\rho_i}}{\epsilon^2}}{1+\frac{13\sqrt{\rho_i}}{\epsilon^2}} \geq \left(1-\frac{5\sqrt{\rho_i}}{\epsilon^2}\right)\left(1-\frac{13\sqrt{\rho_i}}{\epsilon^2}\right) \geq 1-\frac{18\sqrt{\rho_i}}{\epsilon^2}, \tag{8}$$

where the first inequality follows from the definitions of α_i and β_i and the rest of the inequalities follow since $\epsilon < 10^2$ and $\rho < \epsilon^6$.

By Lemma 29 we are guaranteed that $\Pi_{j=0}^{i-1}\gamma_j \leq 1+5\sqrt{\rho_i}$. Combining this with inequality 8 yields

$$\frac{\alpha_i}{\beta_i\Pi_{j=0}^{i-1}\gamma_j} \geq \frac{1-\frac{18\sqrt{\rho_i}}{\epsilon^2}}{1+5\sqrt{\rho_i}} \geq (1-\frac{18}{\epsilon^2}\sqrt{\rho_i})(1-5\sqrt{\rho_i}) \geq 1-\frac{23}{\epsilon^2}\sqrt{\rho_i},$$

and since ρ_i only increases and $\rho_{k-1} \leq \epsilon^6$ we have $\min_i\{\frac{\alpha_i}{\beta_i\Pi_{j=0}^{i-1}\gamma_j}\} \geq 1-\frac{23}{\epsilon^2}\sqrt{\rho_{k-1}} \geq 1-23\epsilon$, thereby concluding the proof. ◀

▶ **Proposition 31.** *For $\gamma_i = 1+4\sqrt{\rho_i}$ we have $\frac{ALG(G_k)}{(\Pi_{i=0}^{k-1}\gamma_i)OPT(G_k)} \geq 1-34\epsilon$.*

Proof. By Propositions 23 and 24 we are guaranteed that $\frac{ALG(G_k)}{OPT(G_k)} \geq 1-33\epsilon$. On the other hand by by Lemma 29 we are guaranteed that $\Pi_{i=0}^{k-2}\gamma_i \leq 1+5\sqrt{\rho_{k-1}}$. Therefore, if $k=1$ then $\frac{ALG(G_k)}{(\Pi_{i=0}^{k-1}\gamma_i)OPT(G_k)} = \frac{ALG(G_k)}{OPT(G_k)} \geq 1-33\epsilon$. Otherwise, we have

$$\frac{ALG(G_k)}{(\Pi_{i=0}^{k-1}\gamma_i)OPT(G_k)} \geq \frac{1-33\epsilon}{(1+4\sqrt{\rho_{k-1}})(1+5\sqrt{\rho_{k-1}})} \geq \frac{1-33\epsilon}{(1+4\epsilon^3)(1+5\epsilon^3)} \geq 1-34\epsilon,$$

where the second inequality follows since $\rho_{k-1} < \epsilon^6$ (since we recursed to step k) and the subsequent inequalities follow since $\epsilon < 10^{-3}$ - thereby concluding the proof. ◀

Finally, we combine Propositions 30 and 31 to bound ALG's approximation ratio.

▶ **Theorem 32.** *For any metric G, $\frac{ALG(G)}{OPT(G)} \geq 1-34\epsilon$.*

4.3 Analyzing the Running Time of *ALG*

Consider the definition of ALG. We observe that in each recursion step, the algorithm finds the layer to peel off, A, and then recurses. Therefore the running time is defined by the sum of these recursion steps, plus the terminating cases (i.e., either case (a) or case (b)). Recall that case (a) applies ALG_{d-w} on the instance, while case (b) arranges the instance arbitrarily. Therefore, a bound on cases (a) and (b) is simply a bound on the running time of ALG_{d-w} which is given by Lemma 33 (whose proof appears in the full version).

▶ **Lemma 33.** *Given an instance G, the running time of $ALG_{d-w}(G)$ is at most $(\frac{1}{\epsilon^7})^{\frac{1}{\epsilon^2}} \cdot O(n^2)$.*

▶ Remark 34. A bi-product of Lemma 28 is that the number of recursion steps is bounded by $O(\log n)$. The proof follows similarly to the proof of Lemma 48 substituting the inequality $\rho_{i+1} \geq 4\epsilon\sqrt{\rho_i}$ with $\rho_{i+1} \geq 4\sqrt{\rho_i}$ (which holds due to Lemma 28).

We are now ready to analyze the running time of ALG. (The proof is deferred to the full version.)

▶ **Theorem 35.** *The algorithm ALG is an EPRAS (with running time $O(n^2 \log n)$ plus the running time of ALG_{d-w}).*

▶ Remark 36. We remark that one may improve the running time by replacing ALG_{d-w} with any faster algorithm while slightly degrading the quality of the approximation.

5 The Hierarchical Clustering Objective

The section is outlined as follows. We begin by presenting our algorithms (first the algorithm to handle case (a) and subsequently the general algorithm). Thereafter we will bound the algorithm's approximation guarantee (by following the bounding scheme of Observation 6). Finally, we will analyze the algorithm's running time.

5.1 Defining the Algorithms

As in the linear arragement setting, we will begin by applying our general algorithm to the linear arrangement problem (which we will denote simply as ALG). The algorithm uses, as a subroutine, an algorithm to handle case (a). We denote this subroutine as ALG_{d-w} and define it following the definition of ALG.

5.1.1 Defining ALG

Here we apply our general algorithm (Algorithm 1) to the hierarchical clustering setting. In order to do so, roughly speaking, we define the layer to peel off A as all points outside of the metric's core.

Algorithm 4 Hierarchical Clustering Algorithm (ALG).

if $\rho \geq \epsilon^2$ **then** Solve the instance using ALG_{d-w}. ; `// case (a)`
else
  Let C denote the metric's core (as defined by Lemma 4).
  Let $A = V \setminus C$ denote the rest of the points.
  Arrange A as a (arbitrary) ladder and denote the tree by T_A.
  if $W_C < 16\epsilon \cdot W_V$ **then** `// case (b)`
    Arrange C arbitrarily and denote the resulting tree by T_C.
    Attach T_C's root as a child of the bottom most internal node of T_A and return.
  else `// case (c)`
    Continue recursively on C and denote the resulting tree by T_C.
    Attach T_C's root as a child of the bottom most internal node of T_A and return.

▶ Remark 37. Note that Algorithm 4 conforms to the general Algorithm 1 since $C = V \setminus A$.

5.1.2 Defining ALG_{d-w}

We will use the algorithm of Vainstein et al. [31] as ALG_{d-w}. As part of their algorithm they make use of the general graph partitioning algorithm of Goldreich et al. [18] which is denoted by $PT(\cdot)$. Since we will use $PT(\cdot)$ to devise our own algorithm for the LA objective we refer the reader to Definition 21 and Theorem 22 for a more in-depth explanation of the $PT(\cdot)$ algorithm. We restate ALG_{d-w} in Algorithm 5 as defined in Vainstein et al. [31].

Algorithm 5 HC Algorithm for Sufficiently Densely Weighted Instances (ALG_{d-w}).

Enumerate over all trees T with $k = \frac{1}{\epsilon}$ internal nodes.
for *each such* T **do**
  for $\{\lambda_i\}_{i \leq k} \subset \{i\epsilon^2 n : i \in \mathbb{N} \wedge i \leq \frac{3}{\epsilon}\}$ **do**
    for $\{\mu_{j,j'}\}_{j \leq k, j' \leq k, j \neq j'} \subset \{i\epsilon^3 n^2 D_V : i \in \mathbb{N} \wedge i \leq \frac{9}{\epsilon}\}$ **do**
      Let $\Phi = \{\lambda_i, \lambda_i\}_{i=1}^{k} \cup \{\mu_{j,j'}, \mu_{j,j'}\}_{j,j'=1}^{k}$.
      Run $PT(G, \Phi, \epsilon_{err} = \epsilon^3)$. Let P denote the output partition (if succeeded).
      Compute the HC objective value based on T and P.
Return the partition P and tree T with maximal HC objective value.

5.2 Analyzing the Approximation Ratio of ALG

Now that we have defined ALG we are ready to analyze its approximation ratio. Recall that by Observation 6 it is enough to analyze the approximation ratio of cases (a), (b) and the total approximation loss generated by the recursion steps (i.e., by finding α_i, β_i and γ_i).

5.2.1 Analyzing the Approximation Ratio of Case (a) of ALG

In order to analyse the approximation ratio of ALG_{d-w} in our setting we must first recall the definition of instances with not-all-small-weights (as defined by Vainstein et al. [31]).

▶ **Definition 38.** *A metric G is said to have not all small weights if there exist constants (with respect to n_V) $c_0, c_1 < 1$ such that the fraction of weights smaller than $c_0 \cdot D_V$ is at most $1 - c_1$.*

The following theorem was presented in Vainstein et al. [31].

▶ **Theorem 39.** *For any constant $\xi > 0$ and any metric $G = (V, w)$ with not all small weights (with constants c_0 and c_1) we are guaranteed that $\frac{ALG_{d-w}(G)}{OPT(G)} \geq 1 - O(\frac{\xi}{c_0 \cdot c_1})$ and that ALG_{d-w}'s expected running time is at most $f(\frac{1}{\xi}) \cdot n^2$.*

Applying the above theorem with $\xi = \epsilon^5$ to our metric instance G_k yields Proposition 40 (whose proof is deferred to the full version).

▶ **Proposition 40.** *If ALG terminates in case (a) then $\frac{ALG_{d-w}(G_k)}{OPT(G_k)} = \frac{ALG(G_k)}{OPT(G_k)} \geq 1 - \epsilon$.*

5.2.2 Analyzing the Approximation Ratio of Case (b) of ALG

▶ **Proposition 41.** *If ALG terminates in case (b) then $\frac{ALG(G_k)}{OPT(G_k)} \geq 1 - 17\epsilon$.*

Proof. The proof appears in the full version. ◀

5.2.3 Setting the Values α_i, β_i and γ_i

Due to lack of space, we defer the following proofs to the full version.

▶ **Lemma 42.** *For A_i and C_i as defined by our algorithm applied to G_i and for $\alpha_i = n_{V_i}(W_{A_i} + W_{A_i,C_i})(1 - \sqrt{\rho_i})$ we have $ALG(G_i) \geq \alpha_i + ALG(G_{i+1})$.*

▶ **Lemma 43.** *Let $G_i = (V_i, w_i)$ and $G_{i+1} = (V_{i+1}, w_{i+1})$ denote the instances defined by the i and $i+1$ recursion steps. Furthermore, let $\beta_i = n_{V_i}(W_{A_i} + W_{A_i,C_i})$ and $\gamma_i = 1 + 2\sqrt{\rho_i}$. Therefore, $OPT(G_i) \leq \beta_i + \gamma_i OPT(G_{i+1})$.*

Thus, we combine these values in Definition 44.

▶ **Definition 44.** *We define the values α_i, β_i and γ_i as follows*

$$\alpha_i = n_{V_i}(W_{A_i} + W_{A_i,C_i})(1 - \sqrt{\rho_i}); \quad \beta_i = n_{V_i}(W_{A_i} + W_{A_i,C_i}); \quad \gamma_i = 1 + 2\sqrt{\rho_i}.$$

5.2.4 Putting it all Together

Now that we have analyzed the terminal cases of the algorithm (cases (a) and (b)) and that we have set the values of α_i, β_i and γ_i we will combine these results to prove ALG's approximation ratio (as in Observation 6). Due to lack of space we defer the proofs of this section to the full version.

▶ **Proposition 45.** *For α_i, β_i and γ_i as in Definition 44, we have* $\min_i\{\frac{\alpha_i}{\beta_i \Pi_{j=0}^{i-1}\gamma_j}\} \geq 1 - 4\epsilon$.

▶ **Proposition 46.** *For $\gamma_i = 1 + 2\sqrt{\rho_i}$ we have* $\frac{ALG(G_k)}{(\Pi_{i=0}^{k-1}\gamma_i)OPT(G_k)} \geq 1 - 23\epsilon$.

▶ **Theorem 47.** *For any metric G,* $\frac{ALG(G)}{OPT(G)} \geq 1 - 23\epsilon$.

5.3 Analyzing the Running Time of ALG

Consider the definition of ALG. In each recursion step, the algorithm finds the layer to peel off and then recurses. Therefore the running time is defined by the sum of these recursion steps, plus the terminating cases (i.e., either case (a) or case (b)). Recall that case (a) applies ALG_{d-w} on the instance, while case (b) arranges the instance arbitrarily. Therefore, a bound on cases (a) and (b) is simply a bound on the running time of ALG_{d-w} which is given by Theorem 39 [31]. In Lemma 48 we bound the number of recursion steps and subsequently prove Theorem 49 (the proofs of which appears in the full version).

▶ **Lemma 48.** *The number of recursion steps performed by Algorithm 4 is bounded by* $O(\log\log n)$.

▶ **Theorem 49.** *The algorithm ALG is an EPRAS (with running time $O(n^2 \log\log n)$ plus the running time of ALG_{d-w}).*

▶ Remark 50. We remark that one may improve the running time by replacing ALG_{d-w} with any faster algorithm while slightly degrading the quality of the approximation.

Robust Communication Complexity of Matching: EDCS Achieves 5/6 Approximation

Amir Azarmehr
Northeastern University, Boston, MA, USA

Soheil Behnezhad
Northeastern University, Boston, MA, USA

Abstract

We study the *robust communication complexity* of maximum matching. Edges of an *arbitrary* n-vertex graph G are *randomly* partitioned between Alice and Bob independently and uniformly. Alice has to send a single message to Bob such that Bob can find an (approximate) maximum matching of the whole graph G. We specifically study the best approximation ratio achievable via protocols where Alice communicates only $\widetilde{O}(n)$ bits to Bob.

There has been a growing interest on the robust communication model due to its connections to the random-order streaming model. An algorithm of Assadi and Behnezhad [ICALP'21] implies a $(2/3 + \varepsilon_0 \sim .667)$-approximation for a small constant $0 < \varepsilon_0 < 10^{-18}$, which remains the best-known approximation for general graphs. For bipartite graphs, Assadi and Behnezhad [Random'21] improved the approximation to .716 albeit with a computationally inefficient (i.e., exponential time) protocol.

In this paper, we study a natural and efficient protocol implied by a random-order streaming algorithm of Bernstein [ICALP'20] which is based on *edge-degree constrained subgraphs* (EDCS) [Bernstein and Stein; ICALP'15]. The result of Bernstein immediately implies that this protocol achieves an (almost) $(2/3 \sim .666)$-approximation in the robust communication model. We present a new analysis, proving that it achieves a much better (almost) $(5/6 \sim .833)$-approximation. This significantly improves previous approximations both for general and bipartite graphs. We also prove that our analysis of Bernstein's protocol is tight.

1 Introduction

Given an n-vertex graph $G = (V, E)$, a *matching* is a collection of vertex disjoint edges in G and a *maximum matching* is the matching with the maximum size. In this paper, we study matchings in Yao's (one-way) communication model [14]. The edge-set E is partitioned between two players Alice and Bob. Alice has to send a single message to Bob such that Bob can find an (approximate) maximum matching of the whole graph G. We are particularly interested in the trade-off between the size of the message sent by Alice and the approximation ratio of the output solution. Besides being a natural problem, this communication model is closely related to streaming algorithms and has thus been studied extensively over the years [11, 13, 9, 1, 2].

In order to obtain an *exact* maximum matching, it is known that $\Omega(n^2)$ bits of communication are needed [10]. That is, the trivial protocol where Alice sends her whole input to Bob is optimal. The situation is more interesting for approximate solutions. It is clear that $\Omega(n)$ words of communication are needed for any approximation as the whole matching can be given to Alice. A natural question, therefore, studied in numerous prior works [11, 12, 13, 1, 2], is the best approximation achievable via protocols that have a near-optimal communication complexity of $\widetilde{O}(n) = O(n \operatorname{poly} \log)$.

It is not hard to see that if Alice sends a maximum matching of her input to Bob, then Bob can find a 1/2-approximate matching. There is, however, a more sophisticated approach based on the powerful *edge-degree constrained subgraph (EDCS)* of Bernstein and Stein [7] that achieves an (almost) 2/3-approximation (see the paper of Assadi and Bernstein [3]). This turns out to be the right approximation under an adversarial partitioning of edges. In their seminal paper, Goel, Kapralov, and Khanna [11] proved that obtaining a better than 2/3-approximation requires $n^{1+1/(\log \log n)} \gg n \operatorname{poly} \log n$ communication.

The communication model discussed above is *doubly worst-case* in that both the input graph and the edge partitioning are chosen by an adversary. In this paper, we study the so called *robust communication* model – à la Chakrabarti, Cormode, and McGregor [9] – where the graph G is still chosen by an adversary but its edges are now *randomly* partitioned between Alice and Bob (i.e., each edge is uniformly given either to Alice or Bob independently). This model goes beyond the doubly worst-case scenario discussed above and sheds light on whether the hardness of a problem is inherent to the input graph or rather a pathological partitioning of its edges. Another motivation behind the study of the robust communication model is its connections to *random-order* streams. In particular, almost all known lower bounds for random-order streams are proved in this robust communication model.

While existing protocols for adversarial partitionings already imply an (almost) 2/3-approximation in the robust communication model, a random-order streaming algorithm of Assadi and Behnezhad [1] implies a better bound. Their algorithm starts with an EDCS-based algorithm of Bernstein [6], and then augments it with a number of short *augmenting paths*, achieving a $(2/3 + \varepsilon_0)$-approximation for some fixed constant $0 < \varepsilon_0 < 10^{-18}$. This remains the best-known approximation in general graphs. For bipartite graphs, an entirely different approach of Assadi and Behnezhad [2] achieves a larger .716-approximtaion although their protocol runs in doubly exponential time.

In this paper, we give a new analysis for the EDCS-based protocol of Bernstein [6] showing that, without any augmentation, it already achieves a much better than 2/3-approximation.

▶ **Theorem 1.1.** *Bernstein's protocol [6] with high probability achieves a* $(1-\varepsilon)5/6 \sim .833$ *approximation in the robust communication model using* $O(n \cdot \log n \cdot \operatorname{poly}(1/\varepsilon))$ *words of communication.*

Theorem 1.1 improves, rather significantly, the state-of-the-art approximation for both general and bipartite graphs from .667 [1] and .716 [2] respectively to .833. We note that Bernstein's protocol runs in linear time in the input size; hence Theorem 1.1, in addition to improving approximation, also improves the running time of the algorithm of [2] from doubly exponential to linear. Besides these quantitative improvements, we believe that a more important qualitative implication of Theorem 1.1 is that EDCS, which has been used in the literature to only obtain 2/3 or slightly-larger-than-2/3 approximations in various models, can be used to obtain a significantly better approximation in the robust communication model.

Our analysis can be applied to the more general *multi-party* one-way robust communication model where instead of two players Alice and Bob, the input is randomly partitioned between k players (see Section 3 for the formal definition of the model). This communication model is particularly of interest since any lower bound in it, for any choice of k, also implies a lower bound for random-order streams. We show the following, which generalizes Theorem 1.1:

▶ **Theorem 1.2.** *For any $k \geq 2$ and any $\varepsilon > 0$, Bernstein's protocol [6] in the k-party one-way robust communication model achieves a $(1-\varepsilon)(\frac{2}{3}+\frac{1}{3k})$-approximation of maximum matching using messages of length $O(n \cdot \log n \cdot \text{poly}(1/\varepsilon))$.*

We note that the current best approximation known in the random-order streaming setting for maximum matching is $(2/3 + 10^{-18})$ by Assadi and Behnezhad [1]. Theorem 1.2 implies that either there is a better random-order streaming algorithm for maximum matching (which likely is the case), or else to prove a tight lower bound via the multi-party communication model, one has to consider at least $k \geq 10^{18}/3$ parties!

Finally, we show that our guarantees of Theorems 1.1 and 1.2 are tight for Bernstein's protocol. That is, we show that:

▶ **Theorem 1.3.** *For any $k \geq 2$, there exist an infinite family of graphs G such that the expected approximation ratio of Bernstein's protocol in the k-party one-way robust communication model is at most $(\frac{2}{3} + \frac{1}{3k})$.*

2 Technical Overview

Bernstein's protocol constructs two subgraphs H and U of size $O(n \log n)$ both of which will be communicated to Bob. Subgraph H is constructed solely by Alice who does so by revealing only ε fraction of her input graph. The construction guarantees that for some sufficiently large constant $\beta \geq 1$, every edge $(u, v) \in H$ satisfies $\deg_H(u) + \deg_H(v) \leq \beta$. That is, H has edge-degree upper bounded by β. This already implies that H has at most $O(n\beta) = O(n)$ edges. The subgraph U is simply the set of all the remaining edges (u, v) in the graph G (given either to Alice or Bob) for which $\deg_H(u) + \deg_H(v) \leq \beta - 1$. In other words, all the remaining "underfull" edges whose edge-degree is less than β are added to U. While it is not at all clear that H can be constructed in such a way that guarantees $|U| = O(n \log n)$, Bernstein [6] showed this is indeed possible. At the end, Bob returns a maximum matching of all the edges that he receives.

The subgraph $H \cup U$ can be shown to include an *edge-degree constrained subgraph* (EDCS) of G, which is known to include a $(2/3 - O(\varepsilon))$-approximate maximum matching of the base graph G for $\beta \geq 1/\varepsilon$ [7, 5]. This already implies an (almost) 2/3-approximation in our model. This guarantee is in fact tight for the maximum matching contained in $H \cup U$ as illustrated in Figure 1. In the example of Figure 1, the missed (red dashed) edges have edge-degree β in H, and so they do not belong to U. While the graph in the example of Figure 1 has a perfect matching, any matching in $H \cup U$ can only match 2/3-fraction of vertices.

The crucial insight is that although $H \cup U$ may only include a 2/3-approximate matching of the graph, Bob in addition will also have access to the set E_B of the edges originally given to him in the random partitioning. So instead of $H \cup U$, we need to focus on the size of the maximum matching contained in $H \cup U \cup E_B$. Let us now revisit the example of Figure 1. As we discussed, the set H is only constructed using a small ε fraction of the edges. Moreover, conditioned on H, the subgraph U will also be fully determined regardless

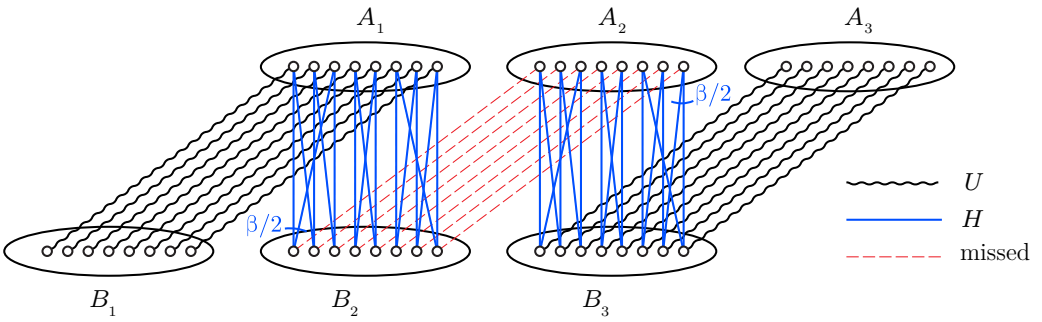

Figure 1 An example where subgraph $H \cup U$ in Bernstein's protocol does not include a better than 2/3-approximation.

of how the edges are partitioned between Alice and Bob. This implies that, *even conditioned on the outcome of H and U*, each dashed edge is given to Bob with probability (almost) 1/2. This results in an (almost) 5/6-approximation in the example of Figure 1: We can combine the 2/3-approximate black matching in U with half of the dashed edges, obtaining an (almost) $\frac{2}{3} + \frac{1}{2} \cdot \frac{1}{3} = \frac{5}{6}$ approximation. We remark that this example already shows that our 5/6-approximation guarantee of Theorem 1.1 is tight for Bernstein's protocol (see Theorem 1.3 for the formal proof).

The nice property of the example of Figure 1 is that subgraph $H \cup U$ includes a 2/3-approximate matching M (the black matching in U) where removing its vertices from the graph still leaves a 1/3-approximate matching in G (the dashed red edges). If we prove that this holds for every graph, then we immediately get an (almost) 5/6-approximation analysis for Bernstein's protocol. Unfortunately, however, this property does not hold for all graphs. In Section 6, we provide examples of H, U such that for *every* matching M in $H \cup U$, it holds that

$$|M| + \frac{1}{2}\mu(G - V(M)) \leq 0.75\mu(G),$$

where $\mu(G - V(M))$ here is the size of maximum matching remained in graph G after removing vertices of M. This implies that this idea is not sufficient to guarantee an (almost) 5/6-approximation for Bernstein's protocol.

In our analysis, instead of first committing to a 2/3-approximate matching in $H \cup U$ and then augmenting it using the edges in E_B, we first commit to a smaller 1/2-approximate matching by fixing an arbitrary maximum matching M^* and taking half of its edges that are given to Bob. The advantage of this smaller 1/2-approximate matching is that it can be augmented much better. Specifically, we show that this 1/2-approximate matching, in expectation, can be augmented by a matching of size (almost) $\mu(G)/3$ using the edges in $H \cup U$, achieving overall a matching of size (almost) $\frac{1}{2}\mu(G) + \frac{1}{3}\mu(G) = \frac{5}{6}\mu(G)$. The proof of why a matching of size $\mu(G)/3$ can be found within the available vertices is the crux of our analysis and is formalized via fractional matchings.

3 Preliminaries

We start by formally defining the robust communication model for maximum matching.

▶ **Definition 3.1.** *In the k-party one-way robust communication model, each edge is assigned independently and uniformly to one of the parties. The i-th party, supplied with the assigned edges and a message m_i from the $(i-1)$-th party, decides what message to send to the $(i+1)$-th*

party. The k-th and last party is responsible for reporting a matching. The communication complexity of a protocol in this model, is defined as the maximum number of words in the messages communicated between the parties, i.e. $\max_i |m_i|$, where $|m_i|$ denotes the number of words in m_i.

In case $k = 2$, we refer to the first party as Alice and to the second party as Bob.

We use $\mu(G)$ to denote the size of the maximum matching in graph G. For an edge e, we define its edge-degree as the sum of the degrees of its endpoints.

3.1 Background on Matching Theory

▶ **Proposition 3.2** (folklore). *Let G be any graph, and let x be a fractional matching on G, such that for every vertex set $S \subseteq V$ that $|S|$ is smaller than $\frac{1}{\varepsilon}$, we have*

$$\sum_{e \in G[S]} x_e \leq \left\lfloor \frac{|S|}{2} \right\rfloor.$$

Then, it holds that $\mu(G) \geq (1-\varepsilon) \sum_e x_e$.

Proof sketch. Let z be another fractional matching where $z_e = (1-\varepsilon)x_e$. If the x satisfies the blossom inequality, i.e. $\sum_{e \in G[S]} x_e \leq \left\lfloor \frac{|S|}{2} \right\rfloor$, for all S of size at most $\frac{1}{\varepsilon}$, Then z satisfies it for all S. To see this, let S be an odd-sized vertex set size at least $\frac{1}{\varepsilon}$ such that $\sum_{e \in G[S]} x_e \geq \left\lfloor \frac{|S|}{2} \right\rfloor$. Then it holds:

$$\sum_{e \in G[S]} z_e = (1-\varepsilon) \sum_{e \in G[S]} x_e \leq \sum_{e \in G[S]} x_e - \frac{1}{2} \leq \frac{|S|}{2} - \frac{1}{2} \leq \left\lfloor \frac{|S|}{2} \right\rfloor.$$

Hence there exists an integral matching of size at least $\sum_e z_e = (1-\varepsilon) \sum_e x_e$. ◀

The following definitions were introduced by Bernstein [6]. The proposition, from the same paper, plays a key role in our analysis.

▶ **Definition 3.3.** *A graph H has bounded edge-degree β, if for all edges $(u,v) \in E_H$ it holds that $d_H(u) + d_H(v) \leq \beta$.*

▶ **Definition 3.4.** *Given a graph G, and a subgraph $H \subseteq G$ an edge $(u,v) \in E_G \setminus E_H$ is (H, β, λ)-underfull if $d_H(u) + d_H(v) < (1-\lambda)\beta$.*

▶ **Proposition 3.5** (Lemma 3.1 from [6]). *Fix any $\varepsilon \in \left[0, \frac{1}{2}\right]$, let λ, β be parameters such that $\lambda \leq \frac{\varepsilon}{384}$, $\beta \geq 50\lambda^{-2} \log\left(\frac{1}{\lambda}\right)$. Consider any graph G, and any subgraph H with bounded edge-degree β. Let U contain all the $(H, \beta, 3\lambda)$-underfull edges in $G \setminus H$. Then $\mu(H \cup U) \geq \left(\frac{2}{3} - \varepsilon\right) \mu(G)$.*

3.2 Concentration Inequalities

We use the following concentration inequalities in our proofs.

▶ **Proposition 3.6** (Chernoff bound). *Let $X_1, \ldots, X_n$ be independent random variables taking values in $[0,1]$. Let $X = \sum X_i$ and let $\mu = \mathbb{E}[X]$. Then, for any $0 < \delta \leq 1$ and $0 < a \leq \mu$, we have*

$$\Pr(X \geq (1+\delta)\mu) \leq \exp\left(-\frac{\delta^2 \mu}{3}\right) \qquad \text{and} \qquad \Pr(X \geq \mu + a) \leq \exp\left(-\frac{a^2}{3\mu}\right).$$

▶ **Definition 3.7** ([8]). *A function $f : \{0,1\}^n \to \mathbb{N}$ is self-bounding if there exist functions $f_1, \ldots, f_n : \{0,1\}^{n-1} \to \mathbb{N}$ such that for all $x \in \{0,1\}^n$ satisfy*

$$0 \leq f(x) - f_i(x^{(i)}) \leq 1 \qquad \forall i \in [n],$$

and

$$\sum_{i=1}^{n} \left(f(x) - f_i(x^{(i)}) \right) \leq f(x).$$

Where $x^{(i)}$ is obtained by dropping the i-th component of x.

▶ **Proposition 3.8** ([8]). *Take a self-bounding function $f : \{0,1\}^n \to \mathbb{N}$, and independent $0-1$ variables $X_1, \ldots, X_n$. Define $Z = f(X_1, \ldots, X_n)$. Then, it holds that*

$$\Pr\left(Z \leq \mathbb{E}\, Z - t\right) \leq \exp\left(\frac{-t^2}{2\,\mathbb{E}\, Z}\right).$$

4 A New Analysis of Bernstein's Protocol

This section is devoted to the proof of Theorems 1.1 and 1.2. We will provide an analysis of Bernstein's protocol (Protocol 1) in the two-party model. To make this analysis applicable to the multi-party model, we assume that each edge is assigned to Bob independently with probability $p \leq \frac{1}{2}$.

We give a description of the protocol for the two-party model here. The multi-party protocol is rather similar and we describe it in the Proof of Theorem 2. Let E_A be the set of edges assigned to Alice, and E_B be the set of edges assigned to Bob. Also, fix a constant $\varepsilon \in \left[0, \frac{1}{2}\right]$ and let $\lambda = \frac{\varepsilon}{384}$, and $\beta = 50\lambda^{-4}$. The protocol is formalized as Protocol 1.

Protocol 1: Bernstein's protocol via EDCS in the two-party one-way robust communication model.

Alice:

1. Take a subsample E_s that includes each edge of E_A independently with probability $\frac{\varepsilon}{1-p}$.
2. Take a subgraph H of bounded edge-degree β from E_s, such that the number of (H, β, λ)-underfull edges in $E_r = E(G) \setminus E_s$ is $O(n \cdot \log n \cdot \text{poly}(1/\varepsilon))$ with high probability. (See Claim 4.1 for the existence of H.)
3. Find the (H, β, λ)-underfull edges of $E_A \setminus E_s$, call them U_A.
4. Communicate $H \cup U_A$ to Bob.

Bob:

1. Return the maximum matching in $E_B \cup H \cup U_A$.

Claim 4.1 shows that Alice can execute step 2, and that Protocol 1 has communication complexity $O(n \cdot \log n \cdot \text{poly}(1/\varepsilon))$. Note that taking into account the randomization in dividing the edges between Alice and Bob, E_s can be considered a uniform sample from the whole edge set that contains each edge with probability ε.

▷ Claim 4.1 (Lemma 4.1 in [6]). Alice, by looking only at the edges of E_s, can take a subgraph $H \subseteq E_s$ that has bounded degree β, and with high probability $E_r = E(G) \setminus E_s$ has at most $O(n \cdot \log n \cdot \text{poly}(1/\varepsilon))$ many (H, β, λ)-underfull edges.

For the analysis, we first construct a fractional matching x of expected size $\left(\frac{2}{3} - O(\varepsilon)\right)\mu(G)$, the support of which is contained in $H \cup U$. Then we show that a fractional matching y can be obtained from x, such that its support is contained in $E_B \cup H \cup U_A$ and has expected size at least $\left(\frac{2}{3} + \frac{p}{3} - O(\varepsilon)\right)\mu(G)$. Finally, we use the structure of y to show that its existence implies $E_B \cup H \cup U_A$ has an integral matching almost as large as the size of y. In Section 5, we show that the approximation ratio is also achieved with high probability.

First, we describe how to obtain the fractional matching x given $H \cup U$, where recall that U is the set of (H, β, λ)-underfull edges in E_r. Fix a maximum matching M^* in E_r. Let M_{in} be the edges of M^* that appear in $H \cup U$, i.e. $M_{\text{in}} = M^* \cap (H \cup U)$, and let $M_{\text{out}} = M^* \setminus M_{\text{in}}$.

1. Start with $H_1 = H$, and $U_1 = U$.
2. For $i = 1, \ldots, \lambda\beta$:
3. Let M_i be a maximum matching in $H_i \cup U_i$.
4. Let $H_{i+1} = H_i \setminus (M_i \setminus M_{\text{in}})$, $U_{i+1} = U_i \setminus (M_i \setminus M_{\text{in}})$.
5. For every edge e, let $x_e = \dfrac{|\{i : e \in M_i\}|}{\lambda\beta}$.

One can think of this process as, starting with $H \cup U$, taking a maximum matching M_i each time, and removing $M_i \setminus M_{\text{in}}$ from the graph, then, letting x_e equal to the fraction of matchings we have taken that include e. Note that the matchings $M_1, \ldots M_{\lambda\beta}$ can intersect only in M_{in}. We will use Proposition 3.5 to show that x has expected size at least $\left(\frac{2}{3} - O(\varepsilon)\right)\mu(G)$.

▶ **Lemma 4.2.** *It holds that* $\mathbb{E}\left[\sum_e x_e\right] \geq \left(\frac{2}{3} - \frac{5}{3}\varepsilon\right)\mu(G)$.

Proof. We apply Proposition 3.5 to $G_i = (H \cup E_r) \setminus \left(\bigcup_{j<i} M_j \setminus M_{\text{in}}\right)$, H_i, and U_i. After removing a matching from H, for any edge, its degree in H will decrease by at most 2. Also, U contains all the (H, β, λ)-underfull edges of E_r. Hence, U_i contains all the edges of $G_i \setminus H_i$ that have H_i-degree smaller than $(1-\lambda)\beta - 2(i-1) \geq (1-3\lambda)\beta$. Therefore, Proposition 3.5 implies

$$|M_i| \geq \left(\frac{2}{3} - \varepsilon\right)\mu(G_i).$$

Also, notice that G_i always includes M^*, consequently it holds $\mu(G_i) = \mu(E_r)$, and we have:

$$\sum_e x_e \geq \frac{1}{\lambda\beta}\sum_i |M_i| \geq \left(\frac{2}{3} - \varepsilon\right)\mu(E_r)$$

Taking into account the fact that $\mathbb{E}\left[\mu(E_R)\right] \geq (1-\varepsilon)\mu(G)$, we get:

$$\mathbb{E}\left[\sum_e x_e\right] \geq \left(\frac{2}{3} - \varepsilon\right)(1-\varepsilon)\mu(G) \geq \left(\frac{2}{3} - \frac{5}{3}\varepsilon\right)\mu(G). \qquad \blacktriangleleft$$

To describe how y is obtained, we condition on E_s, thereby fixing H, U, and x. The support of y is included in $E_B \cup H \cup U_A$, i.e. the edges that Bob will have access to in the end. We show that y has expected size at least about $p \cdot \mu(E_r) + (1-p)\sum_e x_e$, where the randomness is over how the remaining edges E_r are divided between Alice and Bob. Lifting the condition on E_s, the expectation of this value, by Lemma 4.2, is larger than $\left(\frac{2}{3} + \frac{p}{3} - O(\varepsilon)\right)\mu(G)$.

After drawing E_B, take a matching M', which includes each edge of M_{in} independently with probability p, and includes each edge of $M_{\text{out}} \cap E_B$ independently with probability $1-\varepsilon$. Note, that conditioned on E_s, each edge of M_{out} is assigned to Bob with probability $\frac{p}{1-\varepsilon}$. Hence, each edge of M_{out} ends up in M' with probability $\frac{p}{1-\varepsilon}(1-\varepsilon) = p$, i.e. M' includes each edge of M^* independently with probability p.

For any edge $e \notin M^*$, define p_e as the probability of e not being adjacent to any edge in M'. Notice, p_e is simply equal to $(1-p)$ to the power of the number of edges in M' that are adjacent to e. We define matching $\hat{y}$ as follows:

$$\hat{y}_e = \begin{cases} 1 & \text{if } e \in M', \\ x_e & \text{if } e \in M^* \setminus M', \\ 0 & \text{if } e \notin M^* \text{ and } e \text{ is adjacent to an edge of } M', \\ (1-p) \cdot \dfrac{x_e}{p_e} & \text{otherwise.} \end{cases}$$

We then scale down $\hat{y}$ by a factor of $1+\varepsilon$, and zero out some edges to obtain a fractional matching. Formally, we let:

$$y_{(u,v)} = \begin{cases} 0 & \text{if } \hat{y}_u/(1+\varepsilon) > 1 \text{ or } \hat{y}_v/(1+\varepsilon) > 1, \\ \dfrac{\hat{y}_{(u,v)}}{1+\varepsilon} & \text{otherwise.} \end{cases}$$

▶ **Lemma 4.3.** *Conditioned on E_s, it holds that*

$$\mathbb{E}\left[\sum_e y_e\right] \geq (1-3\varepsilon)p \cdot \mu(E_r) + (1-3\varepsilon)(1-p)\sum_e x_e - 2\varepsilon\mu(G).$$

Proof. All the arguments made in this proof are conditioned on E_s.

▷ Claim 4.4. For every vertex u, it holds that $\mathbb{E}[\hat{y}_u] = p \cdot \chi_{M^*}(u) + (1-p)x_u$, where $\chi_{M^*}(u)$ is equal to 1 if u is covered by M^* and zero otherwise.

Proof. First, consider a vertex u that is covered by M^*, say by edge $e^* \in M^*$. When e^* appears in M', we have $\hat{y}_{e^*} = 1$, and for all the other edges e adjacent to u, the value of $\hat{y}_e$ is equal to zero. Thus, we will have $\hat{y}_u = 1$, i.e. $\mathbb{E}[\hat{y}_u \mid e^* \in M^*] = 1$.

Now, we condition on $e^* \notin M'$. In this case, we will have $\hat{y}_{e^*} = x_{e^*}$. Also, for any other edge e adjacent to u, the probability that e is not adjacent to any edge in M' is equal to $\frac{p_e}{1-p}$. Thus with probability $\frac{p_e}{1-p}$ it holds that $\hat{y}_e = (1-p)\cdot\frac{x_e}{p_e}$, and we will have $\hat{y}_e = 0$ otherwise. Hence, we can write:

$$\mathbb{E}[\hat{y}_u \mid e^* \notin M'] = x_{e^*} + \sum_{\substack{e \ni u \\ e \neq e^*}} \frac{p_e}{1-p} \cdot \left((1-p)\cdot\frac{x_e}{p_e}\right) = \sum_{e \ni u} x_e = x_u.$$

Therefore, for a vertex u that is covered by M^*, it holds that

$$\mathbb{E}[\hat{y}_u] = p \cdot \mathbb{E}[\hat{y}_u \mid e^* \in M'] + (1-p)\cdot\mathbb{E}[\hat{y}_u \mid e^* \notin M'] = p + (1-p)x_u.$$

The case where the vertex u is not covered by M^* follows similarly. For each edge e adjacent to u we have $\hat{y}_e = (1-p)\cdot\frac{x_e}{p_e}$ with probability p_e, and we have $\hat{y}_e = 0$ otherwise. Thus

$$\mathbb{E}[\hat{y}_u] = \sum_{e \ni u} p_e \cdot \left((1-p)\cdot\frac{x_e}{p_e}\right) = (1-p)x_u. \qquad \triangleleft$$

The following claim helps us show that we do not lose much of $\hat{y}$ when we scale it down and zero out some of the edges.

▷ Claim 4.5. For every vertex u, we have $\hat{y}_u \leq 1$ if u is not covered by M^* or $x_u \leq \frac{1}{2}$, otherwise it holds that $\Pr(\hat{y}_u > 1+\varepsilon) \leq \varepsilon$.

Proof. Consider a vertex u not covered by M^*. For each edge e adjacent to u it holds that $p_e \geq 1-p$ because e has at most one neighbouring edge in M^*. Hence we have:

$$\hat{y}_u \leq \sum_{e \ni u} (1-p) \cdot \frac{x_e}{p_e} \leq \sum_{e \ni u} x_e \leq 1.$$

Now take a vertex u that is covered by M^*, say by edge $e^* \in M^*$. If $e^* \in M'$, then we have $\hat{y}_u = 1$. Therefore we assume $e^* \notin M'$, and accordingly $\hat{y}_e = x_e$. For any other edge e it holds that $p_e \geq (1-p)^2$. Hence we have:

$$\hat{y}_u \leq x_{e^*} + \sum_{\substack{e \ni u \\ e \neq e^*}} (1-p) \cdot \frac{x_e}{p_e} \leq x_{e^*} + \sum_{\substack{e \ni u \\ e \neq e^*}} \frac{x_e}{1-p} \leq 2 \sum_{e \ni u} x_e = 2x_u.$$

Thus, if it holds that $x_u \leq \frac{1}{2}$, then it follows $\hat{y}_u \leq 1$.

For the other cases, we use the Chernoff bound to show that with high probability $\hat{y}_u$ is not much larger than 1. As mentioned before, if e^* appears in M', it holds that $\hat{y}_u = 1$. Therefore, we condition on $e^* \notin M'$. We express $X = y_u - y_{e^*}$ as a sum of independent random variables that take values in $[0, 4/\lambda\beta]$. Note that since the edges outside M_{in} appear in at most one M_i, for $e \notin M^*$ we have $x_e \leq \frac{1}{\lambda\beta}$.

Take an edge $e = (u,v) \neq e^*$. If v is not matched in M^* to another neighbour of u, then the value of y_e is independent of the value of the other edges adjacent to u. It is equal to $(1-p) \cdot \frac{x_e}{p_e} \leq \frac{2}{\lambda\beta}$ with probability $\frac{p_e}{1-p}$, and zero otherwise.

If v is matched in M^* to another neighbour v' of u. Let $e' = (u,v')$. Then the value of $y_e + y'_e$ is independent of the value of the other edges adjacent to u. It is equal to $(1-p) \cdot \frac{x_e + x'_e}{(1-p)^2} \leq \frac{4}{\lambda\beta}$, with probability $(1-p)$, and zero otherwise.

Thus, by pairing the edges that are matched together, we can express X as a sum of independent random variables in $[0, 4/\lambda\beta]$. The expectation of X, as calculated in Claim 4.4, is equal to $x_u - x_{e^*} \leq 1$. From the Chernoff bound we get:

$$\begin{aligned}
\Pr(\hat{y}_u > 1+\varepsilon) &\leq \Pr(X > \mathbb{E}\,X + \varepsilon) \\
&\leq \Pr\left(X \cdot \frac{\lambda\beta}{4} > \mu\frac{\lambda\beta}{4} + \varepsilon\frac{\lambda\beta}{4}\right) \\
&\leq \exp\left(-\frac{\varepsilon^2\lambda^2\beta^2/16}{3\mu\lambda\beta/4}\right) \\
&\text{(By Chernoff bound, noting that } X\lambda\beta/4 \text{ is a sum of independent random variables in } [0,1].) \\
&= \exp\left(-\frac{\varepsilon^2\lambda\beta}{12}\right) \\
&< \varepsilon, \qquad \text{(Since } \lambda = \tfrac{\varepsilon}{384} \text{ and } \beta = 50\lambda^{-4})
\end{aligned}$$

concluding the proof. ◁

We analyze $\mathbb{E}[y_u]$. Consider generating y_u, in two steps. First, for every edge (u,v), we let $y_{(u,v)}$ be equal to $\frac{1}{1+\varepsilon}\hat{y}_{(u,v)}$ if $\hat{y}_v \leq 1+\varepsilon$, and zero otherwise. Then, we zero out y for all the edges adjacent to u if $\hat{y}_u > 1+\varepsilon$.

In the first step, we lose a factor $(1+\varepsilon)$ when we scale $\hat{y}_u$ down. Also, by Claim 4.5, when we zero out edge (u,v) because $y_v > 1+\varepsilon$, we lose an ε-fraction from each edge, and consequently from $\mathbb{E}[\hat{y}_u]$. In the second step, again by Claim 4.5, if $x_u \le \frac{1}{2}$ or u is not covered by M^* we lose nothing. Otherwise, we zero out all the edges with probability at most ε. We have $\hat{y}_u \le 2x_u \le 2$, hence we lose an additive factor of 2ε. Overall for any vertex u we get:

$$\mathbb{E}[y_u] \ge (1-\varepsilon)\frac{\mathbb{E}[\hat{y}_u]}{1+\varepsilon} - 2\varepsilon \ge (1-3\varepsilon)\left(p \cdot \chi_{M^*}(u) + (1-p)x_u\right) - 2\varepsilon,$$

and for any vertex u with $x_u \le \frac{1}{2}$, we get:

$$\mathbb{E}[y_u] \ge (1-3\varepsilon)\left(p \cdot \chi_{M^*}(u) + (1-p)x_u\right).$$

Notice that since the sum of the components of x is at most $\mu(G)$, there are at most $2\mu(G)$ vertices with $x_u \ge \frac{1}{2}$. Thus, by summing the last two equations over u we get:

$$\begin{aligned}
\sum_u \mathbb{E}[y_u] &= \sum_{u\in V(M^*)} \mathbb{E}[y_u] + \sum_{u\notin V(M^*)} \mathbb{E}[y_u] \\
&\ge \left((1-3\varepsilon)\sum_{u\in V(M^*)} p + (1-p)x_u\right) + \left((1-3\varepsilon)\sum_{u\notin V(M^*)} (1-p)x_u\right) - 2\varepsilon\cdot 2\mu(G) \\
&= (1-3\varepsilon)2p\cdot|M^*| + (1-3\varepsilon)(1-p)\sum_u x_u - 4\varepsilon\mu(G).
\end{aligned}$$

Recall that $|M^*| = \mu(E_r)$. Finally, by dividing both sides by 2, we get:

$$\sum_e \mathbb{E}[y_e] \ge (1-3\varepsilon)p\cdot\mu(E_r) + (1-3\varepsilon)(1-p)\sum_e x_e - 2\varepsilon\mu(G). \qquad \blacktriangleleft$$

Now we lift the condition on E_s.

▶ **Lemma 4.6.** *It holds that* $\mathbb{E}\left[\sum_e y_e\right] \ge \left(\frac{2}{3} + \frac{p}{3} - 6\varepsilon\right)\mu(G)$.

Proof. We have:

$$\begin{aligned}
\mathbb{E}\left[\sum_e y_e\right] &= \mathbb{E}\left[\mathbb{E}\left[\sum_e y_e \;\middle|\; E_s\right]\right] \\
&\ge \mathbb{E}\left[(1-3\varepsilon)p\cdot\mu(E_r) + (1-3\varepsilon)(1-p)\sum_e x_e - 2\varepsilon\mu(G)\right] \\
&\ge (1-3\varepsilon)p\cdot(1-\varepsilon)\mu(G) + (1-3\varepsilon)(1-p)\left(\frac{2}{3} - \frac{5}{3}\varepsilon\right)\mu(G) - 2\varepsilon\mu(G) \\
&\qquad\qquad \text{(by } \mathbb{E}[\mu(E_r)] = (1-\varepsilon)\mu(G) \text{ and Lemma 4.2)} \\
&\ge \left(\frac{2}{3} + \frac{p}{3} - \left(\frac{7}{6}p + \frac{29}{6}\right)\varepsilon\right)\mu(G) \\
&\ge \left(\frac{2}{3} + \frac{p}{3} - 6\varepsilon\right)\mu(G).
\end{aligned}$$

We show that $E_B \cup H \cup U_A$ has an integral matching almost as large as the size of y.

▶ **Lemma 4.7.** *There exists a matching of size* $(1-3\varepsilon)\sum_e y_e$ *in* $E_B \cup H \cup U_A$.

Proof. Notice that for every edge e, except the edges of M^* which is a matching, it holds that $y_e \leq \frac{4}{\lambda\beta} \leq \varepsilon^3$. Therefore, for any vertex set $S \subseteq V$ that $|S|$ is smaller than $\frac{1}{\varepsilon}$, we have:

$$\sum_{e \in G[S]} x_e = \sum_{e \in G[S] \cap M^*} x_e + \sum_{e \in G[S] \setminus M^*} x_e \leq |G[S] \cap M^*| + \frac{1}{\varepsilon^2}\varepsilon^3 \leq \left\lfloor \frac{|S|}{2} \right\rfloor + \varepsilon.$$

Hence, we can apply Proposition 3.2 to $(1-2\varepsilon)y$, to get $\mu(E_B \cup H \cup U_A) \geq (1-3\varepsilon)\sum_e y_e$. ◀

Proof of Theorem 1.1. By Claim 4.1, Bernstein's protocol (Protocol 1) is implementable using only $O(n \cdot \log n \cdot \text{poly}(1/\varepsilon))$ words of communication.

By Lemma 4.6 there exists a fractional matching y of expected size $\left(\frac{2}{3} + \frac{p}{3} - 6\varepsilon\right)\mu(G)$. Putting this together with Lemma 4.7, we can conclude Protocol 1 achieves a $\left(\frac{2}{3} + \frac{p}{3} - 9\varepsilon\right)$ approximation ratio. To see this approximation ratio is also achieved with high probability, refer to Section 5. Finally, letting $p = \frac{1}{2}$ and rescaling ε proves the theorem. ◀

Proof of Theorem 1.2. We need to adjust Protocol 1 for the k-party model. The first party will sample each of its edges independently with probability $\varepsilon/(1-1/k)$ to obtain E_s. It will then construct the subgraph $H \subseteq E_s$ with bounded edge-degree, and send it to the next party along with the (H, β, λ)-underfull edges. Each of the next parties, except the last, communicates the (H, β, λ)-underfull edges it has been assigned along with the edges in the message it has received, to the next party. Finally, the last party will report the maximum matching in the graph consisting of all the edges to which it has access.

This way, setting $p = \frac{1}{k}$, the first $k-1$ parties will act as Alice in our analysis, and the last party acts as Bob. Hence, by a similar argument as in the Proof of Theorem 1, Protocol 1 achieves a $(\frac{2}{3} + \frac{1}{3k} - 9\varepsilon)$ approximation ratio, and a rescaling of ε proves the theorem. ◀

5 From Expectation to High Probability

In this section, we show that with a slight modification, Bernstein's protocol (Protocol 1) achieves the $\frac{5}{6}$-approximation with high probability. To do so, Alice should send all the edges to Bob when the number of edges is too small.

▷ Claim 5.1. Without loss of generality, we can assume $\mu(G) = \Omega(\log n)$.

Proof. A charging argument can be used to show that the number of edges in G is less than $2n\mu(G)$. Fix a maximum matching M in G. For any edge e, charge a unit to an edge of M that is adjacent to e. Such an edge must exist since M is a maximum matching. This way, we charge once for every edge in G, and every edge of M is charged at most n times through each of its endpoints.

To see why the claim is true, note that in case $\mu(G)$ is too small, i.e. $\mu(G) = O(\log n)$, the number of edges in the graph will be $O(n \log n)$ and Alice can send all of its edges to Bob. ◁

▶ **Lemma 5.2.** *Assuming that $\mu(G) = \Omega(\log n)$, whatever approximation ratio Protocol 1 achieves in expectation, it will achieve with high probability.*

Proof. We condition on the sample edge set E_s, thereby fixing H and U. Bob will have access to the edges of $H \cup U$ because they are either assigned to Bob, or they are communicated to Bob by Alice. Let $e_1, \ldots, e_k$ be the other edges, i.e. the edges of $E_r \setminus U$. Each of these edges is assigned to Bob independently with probability $\frac{1/2}{1-\varepsilon}$.

We define a self-bounding function $f : \{0,1\}^k \to \mathbb{Z}$. For $x \in \{0,1\}^k$, the value of $f(x)$ is equal to the maximum matching of $H \cup U \cup E_x$, where $E_x = \{e_i \mid x_i = 1\}$. Equivalently, $f(x)$ is the size of the output matching when the edges $\{e_i \mid x_i = 1\}$ are assigned to Bob, i.e. $E_B \cup H \cup U_A$ is equal to $E_x \cup H \cup U$. Also, let $f_i(x^{(i)}) = f(x_1, \dots x_{i-1}, 0, x_{i+1}, \dots x_k)$.

Take any $x \in \{0,1\}^k$. Notice that $f_i(x^{(i)})$ is equal to $\mu(E_x \setminus e_i)$, and removing an edge from a graph, will decrease its maximum matching by at most 1. Therefore, it holds:

$$0 \le f(x) - f_i(x^{(i)}) \le 1, \qquad \forall i : 1 \le i \le k.$$

Take the maximum matching M in $H \cup U \cup E_x$, and let I be the indices of the edges in $E_x \cap M$, i.e. $I = \{i \mid x_i = 1 \text{ and } e_i \in M\}$. For any $i \notin I$, the edge set $E_x \setminus e_i$ includes M. Therefore, $f_i(x^{(i)})$ is equal to $f(x)$, and we have:

$$\sum_{i=1}^{k} \Big(f(x) - f_i(x^{(i)}) \Big) \le |I| = f(x).$$

Thus, f is a self-bounding function.

We can now apply Proposition 3.8. Let X_i be the indicator variable that e_i is assigned to Bob, i.e. X_i is equal to 1 when $e_i \in E_B$. Let $Z = f(X_1, \dots, X_k)$, and $\mu = \mathbb{E}[Z] = r\mu(G)$. That is, Z is the size of the output matching, and r is the approximation ratio that Protocol 1 achieves in expectation. By Proposition 3.8, we have:

$$\Pr\left(Z \le r\mu(G) - \sqrt{2\mu(G)\log n}\right) \le \exp\left(-\frac{2\mu(G)\log n}{2\mu(G)}\right) = \frac{1}{n}.$$

Thus, with high probability Protocol 1 outputs a matching of size $(1 - o(1))r\mu(G)$. Note that the deviation is $o(1)$ by the assumption that $\mu(G) = \Omega(\log n)$. ◀

6 Some Instances for Bernstein's Protocol

In this section, we first prove Theorem 1.3 that our analysis of Bernstein's protocol in Theorems 1.1 and 1.2 are tight. Then, we formalize a remark we made in Section 2.

Proof of Theorem 1.3. Consider a bipartite graph $G(L, R)$, such that $|L| = |R|$. Where L consists of three equally-sized groups of vertices A_1, A_2, and A_3, and similarly R consists of B_1, B_2, and B_3. The induced subgraphs $M_1 = G[A_1, B_1]$, $M_2 = G[A_2, B_2]$, and $M_3 = G[A_3, B_3]$ are perfect matchings. The induced subgraphs $K_1 = G[A_1, B_2]$ and $K_2 = G[A_2, B_3]$ are complete bipartite graphs, and there are no other edges in the graph (see Figure 1). Note that G has a perfect matching, i.e. the size of the maximum matching is equal to $|L| = |R|$. Let $\beta \le \frac{|V(G)|}{12k}$ which is $O(|V(G)|)$.

Let E_L be the set of edges assigned to the last party. To upper bound the approximation ratio of the multi-party protocol, we construct a vertex cover for $E_L \cup H \cup U$. It is a well-known fact that the size of the minimum vertex cover is larger than the size of the maximum matching. With high probability, the first party can take H to be completely inside $K_1 \cup K_2$, so that U will be equal the $M_1 \cup M_3$, and no edges of M_2 will appear in $H \cup U$.

Let $X = V(M_2 \cap E_L) \cap A_2$, i.e. X includes one endpoint from every edge of M_2 that is assigned to the last party. We claim $A_1 \cup B_3 \cup X$ is a vertex cover for $E_L \cup H \cup U$. This is true because A_1 covers the edges of M_1 and K_1, B_3 covers the edges of M_3 and K_2, and X covers all the remaining edges, which is $E_L \cap M_2$.

Conditioned on the H as described above, each edge of M_2 will be assigned to Bob with probability $\frac{1/k}{1-\varepsilon}$. Thus the expected size of the vertex cover is equal to

$$|A_1| + |B_3| + \frac{1/k}{1-\varepsilon}|A_2| = \left(\frac{1}{3} + \frac{1}{3} + \frac{1/k}{1-\varepsilon} \cdot \frac{1}{3}\right)\mu(G) \leq (1+2\varepsilon)\left(\frac{2}{3} + \frac{1}{3k}\right)\mu(G).$$

Letting ε be arbitrarily small proves the theorem. ◀

As mentioned in Section 2, the graph discussed in Theorem 1.3 (see Figure 1) has a nice property, i.e. there exists a large matching M such that $G - V(M)$ also has a large matching. As the output of Bernstein's protocol has expected size of at least $|M| + \frac{1}{2}\mu(G - V(M))$, which in this case is equal to $\frac{5}{6}\mu(G)$, this property might seem useful to analyze the protocol. However, the following claim shows that such an M does not generally exist.

▷ Claim 6.1. There exists a graph G, with arbitrarily large number of vertices, such that for $\beta \leq |V(G)|/4$, there is a choice of H and U, such that every matching M in $H \cup U$ satisfies $|M| + \frac{1}{2}\mu(G - V(M)) \leq 0.75\mu(G)$. Where here H is subgraph with bounded edge-degree β, and U is the set of the underfull edges in $G \setminus H$, i.e. the edges of $G \setminus H$ with H-degree smaller than $\beta - 1$.

Proof. Let $G(L, R)$ be a bipratite graph, such that $|L| = |R|$. Where L consists of four equally-sized groups of vertices A_1, A_2, A_3, and A_4, and similarly R consists of B_1, B_2, B_3, and B_4. The induced subgraphs $M_1 = G[A_1, B_1]$, $M_2 = G[A_2, B_2]$, $M_3 = G[A_3, B_3]$, and $M_4 = G[A_4, B_4]$ are perfect matchings. The induced subgraphs $K_1 = G[A_1, B_2]$, $K_2 = G[A_2, B_3]$, and $K_3 = G[A_3, B_4]$ are complete bipartite graphs, and there are no other edges in the graph. Note that G has a perfect matching (see Figure 2).

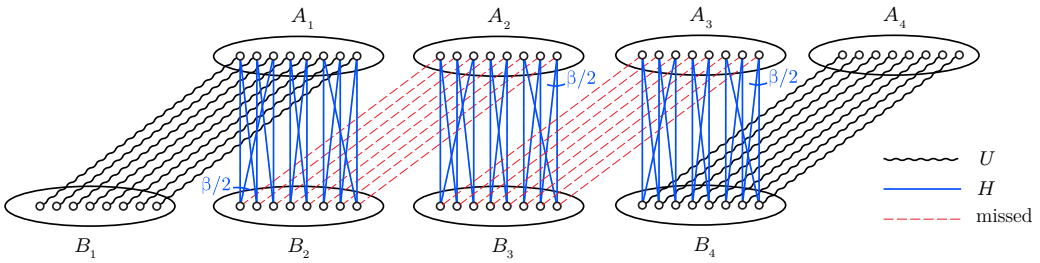

Figure 2 An example where every matching M satisfies $|M| + \frac{1}{2}\mu(G - V(M)) \leq 0.75\mu(G)$.

Let H be a $(\beta/2)$-regular subgraph of $K_1 \cup K_2 \cup K_3$. The corresponding U is equal to $M_1 \cup M_4$, and none of the edges in $M_2 \cup M_3$ appear in $H \cup U$. We prove that $\max_M |M| + \frac{1}{2}\mu(G - V(M)) \leq 0.75\mu(G)$, where M ranges over all the matchings in $H \cup U$. We say that a matching is optimal if it achieves the maximum possible value for $|M| + \frac{1}{2}\mu(G - V(M))$.

First, we prove there exists an optimal matching that includes all of $M_1 \cup M_4$. To see this, take an optimal matching M. Take any vertex u in A_1, and let its adjacent edge in M_1 be e. If u is covered by some edge $e' \in M$, then removing e' from M and adding e does not decrease $|M| + \frac{1}{2}\mu(G - V(M))$. Because this would not change $|M|$ and can only increase $\mu(G - V(M))$. Also, when u is not covered by M, adding the e to M will cause $|M|$ to grow by one, and $\mu(G - V(M))$ to decrease by at most one. A similar argument holds for the vertices in B_4. Hence, by repeatedly adding such edges, we can obtain an optimal matching containing $M_1 \cup M_4$.

Now we can restrict our attention to $A_2 \cup A_3 \cup B_2 \cup B_3$. We claim no matter what the rest of M (a.k.a. $M \setminus (M_1 \cup M_2) = M \cap K_2$) is, the value of $|M| + \frac{1}{2}\mu(G - V(M))$ would be the same. Because if $|M \cap K_2|$ is equal to k, it holds that $\mu(G - V(M)) = \frac{1}{2}\mu(G) - 2k$.

Hence the optimal value of $|M| + \frac{1}{2}\mu(G - V(M))$ is equal to

$$|M_1| + |M_2| + k + \frac{1}{2}\left(\frac{1}{2}\mu(G) - 2k\right) = \frac{3}{4}\mu(G).$$

To see why $\mu(G - V(M)) = \frac{1}{2}\mu(G) - 2k$, note that since $M_1 \cup M_4 \subseteq M$, any vertex of $B_2 \cup A_3$ is a singleton in $G - V(M)$. Hence, a maximum matching in $G - V(M)$ is the set of edges in $M_2 \cup M_3$ that are not adjacent to an edge of M, which has size $\frac{1}{2}\mu(G) - 2k$. ◁

Abstract

We address long-standing open questions raised by Williamson, Goemans, Vazirani and Mihail pertaining to the design of approximation algorithms for problems in network design via the primal-dual method (Combinatorica 15(3):435-454, 1995). Williamson et al. prove an approximation ratio of two for connectivity augmentation problems where the connectivity requirements can be specified by uncrossable functions. They state: "Extending our algorithm to handle non-uncrossable functions remains a challenging open problem. The key feature of uncrossable functions is that there exists an optimal dual solution which is laminar ... A larger open issue is to explore further the power of the primal-dual approach for obtaining approximation algorithms for other combinatorial optimization problems."

Our main result proves a 16-approximation ratio via the primal-dual method for a class of functions that generalizes the notion of an uncrossable function. There exist instances that can be handled by our methods where none of the optimal dual solutions have a laminar support.

We present applications of our main result to three network-design problems.

1. A 16-approximation algorithm for augmenting the family of small cuts of a graph G. The previous best approximation ratio was $O(\log |V(G)|)$.
2. A $16 \cdot \lceil k/u_{min} \rceil$-approximation algorithm for the Cap-k-ECSS problem which is as follows: Given an undirected graph $G = (V, E)$ with edge costs $c \in \mathbb{Q}^E_{\geq 0}$ and edge capacities $u \in \mathbb{Z}^E_{\geq 0}$, find a minimum cost subset of the edges $F \subseteq E$ such that the capacity across any cut in (V, F) is at least k; u_{min} (respectively, u_{max}) denote the minimum (respectively, maximum) capacity of an edge in E, and w.l.o.g. $u_{max} \leq k$. The previous best approximation ratio was $\min(O(\log |V|), k, 2u_{max})$.
3. A 20-approximation algorithm for the model of $(p, 2)$-Flexible Graph Connectivity. The previous best approximation ratio was $O(\log |V(G)|)$, where G denotes the input graph.

1 Introduction

The primal-dual method is a well-known algorithmic discovery of the past century. Kuhn (1955) [25] presented a primal-dual algorithm for weighted bipartite matching, and Dantzig et al. (1957) [9] presented a generalization for solving linear programs. Primal-dual methods for problems in combinatorial optimization are based on linear programming (LP) relaxations; the associated linear programs (LPs) are crucial for the design and analysis of these algorithms. A key feature of the primal-dual method is that it does not require solving the underlying LPs, which makes it attractive for both theoretical studies and real-world applications. Several computational studies of some of the well-known primal-dual approximation algorithms have been conducted, and the consensus is that these algorithms work well in practice, see [19, Section 4.9], [16], [21], [27], [32].

Several decades after the pioneering work of Kuhn, Dantzig et al., the design of approximation algorithms for NP-hard problems emerged as an important area of research. Agrawal, Klein and Ravi [2] designed and analyzed a primal-dual approximation algorithm for the Steiner forest problem. Goemans and Williamson [18] generalized these algorithms to constrained forest problems. Subsequently, Williamson, Goemans, Vazirani and Mihail [33] (abbreviated WGMV) extended the methods of [18] to obtain a primal-dual 2-approximation algorithm for the problem of augmenting the connectivity of a graph to satisfy requirements specified by *uncrossable* functions. These functions are versatile tools for modeling several network-design problems.

Network design encompasses a wide class of problems that find applications in sectors like transportation, facility location, information security, and resource connectivity, to name a few. Due to its wide scope and usefulness, the area has been studied for decades and it has led to major algorithmic innovations. Most network-design problems are NP-Hard, and oftentimes even APX-hard, so researchers in the area have focused on designing good approximation algorithms, preferably with a small constant-factor approximation ratio. In the context of network design, many of the $O(1)$ approximation algorithms rely on a particular property called *uncrossability*, see the books by Lau, Ravi & Singh [26], Vazirani [31], and Williamson & Shmoys [34]. This property has been leveraged in various ways to obtain $O(1)$ approximation ratios for problems such as survivable network design [20], min-cost/min-size k-edge connected spanning subgraph [15, 14], min-cost 2-node connected spanning subgraph [11], $(p, 1)$-flexible graph connectivity [5], etc. The primal-dual method is one of the most successful algorithmic paradigms that leverages these uncrossability properties.

On the other hand, when the uncrossability property does not hold, most known techniques for designing $O(1)$ approximation algorithms fail to work. Indeed, only logarithmic approximation ratios are known for some of the problems where the uncrossability property does not hold. These logarithmic approximation ratios are usually obtained via a reduction to the set cover problem, for which a greedy strategy yields a logarithmic approximation. WGMV [33] conclude their paper with the following remark:

> Extending our algorithm to handle non-uncrossable functions remains a challenging open problem. The key feature of uncrossable functions is that there exists an optimal dual solution which is laminar ... A larger open issue is to explore further the power of the primal-dual approach for obtaining approximation algorithms for other combinatorial optimization problems. Handling all non-uncrossable functions is ruled out by the fact that there exist instances corresponding to non-uncrossable $\{0,1\}$ functions whose relative duality gap is larger than any constant.

Our main contribution in this work is a novel analysis of the WGMV primal-dual approximation algorithm applied to a class of functions that strictly contain the class of uncrossable functions; we show that the algorithm still yields an $O(1)$ approximation guarantee for this larger class. This new class of functions captures some well-studied network design problems. An application of our main result provides improved approximation ratios for the capacitated k-edge connected subgraph problem, some instances of the flexible graph connectivity problem, and the problem of augmenting all *small* cuts of a graph. A detailed discussion of our results can be found in Section 1.1. For the benefit of the reader, in Section 2.1 we give an overview of WGMV's primal-dual algorithm and its analysis.

The primal-dual algorithm for solving network design problems follows the common strategy of starting with a graph that has no edges and then iteratively buying (i.e., including) a subset of edges into the infeasible solution until feasibility is attained. Within each iteration, the algorithm's goal is to buy a cheap edge-set that fixes some or all of the infeasibility of the current solution. Let F denote the edge-set that has been bought until some step in the algorithm. A set of nodes S is said to be *violated* if the number of F-edges in the cut of S is less than the prespecified connectivity requirement of S. The algorithm deems an edge to be useful if it is in the cut of a violated set S. Clearly, the family of violated sets is important for the design and analysis of these algorithms, especially the inclusion-wise minimal violated sets. A family $\mathcal{F}$ of sets is called *uncrossable* if the following holds:

$$A, B \in \mathcal{F} \implies \text{either } A \cap B, A \cup B \in \mathcal{F} \text{ or } A \setminus B, B \setminus A \in \mathcal{F}.$$

Informally speaking, the uncrossability property ensures that the the minimal sets within the family can be considered independently. Formally, a minimal violated set A in an uncrossable family $\mathcal{F}$ cannot cross another set $S \in \mathcal{F}$; otherwise, we get a contradiction since $A, S \in \mathcal{F}$ implies that either $A \cap S$ or $A \setminus S$ is in $\mathcal{F}$. This key property is one of the levers used in the design of $O(1)$-approximation algorithms for some network-design problems. Unfortunately, there are important problems in network design where the family of violated sets does not form an uncrossable family. For instance, see the instance described in Appendix B. This leads us to define a new class of set families that contains all uncrossable families.

Call a family $\mathcal{F}$ *pliable* if the following holds:

$$A, B \in \mathcal{F} \implies \text{at least two of } A \cap B, A \cup B, A \setminus B, B \setminus A \text{ are in } \mathcal{F}.$$

In the full version of our paper, we show that the WGMV primal-dual algorithm has a super-constant approximation ratio for pliable families. Nevertheless, by enforcing an additional property on the given pliable family, we can establish that the WGMV algorithm yields an $O(1)$ approximation. We call this additional assumption property (γ); see Section 1.1.1 for the formal definition. From a structural standpoint, this property still allows a minimal violated set to cross another violated set, but, crucially, it does not allow them to cross an arbitrary number of violated sets in arbitrary ways. As we show later, the fact that disparate network design problems can be captured by pliable families with property (γ) hints that this property is "just right".

The above connectivity augmentation problems can be understood in a general framework called f-connectivity. In this problem, we are given an undirected graph $G = (V, E)$ on n vertices with nonnegative costs $c \in \mathbb{Q}^E_{\geq 0}$ on the edges and a requirement function $f : 2^V \to \{0, 1\}$ on subsets of vertices. We are interested in finding an edge-set $F \subseteq E$ with minimum cost $c(F) := \sum_{e \in F} c_e$ such that for all cuts $\delta(S),\ S \subseteq V$, we have $|\delta(S) \cap F| \geq f(S)$. This problem can be formulated as the following integer program where binary variables x_e model inclusion of edge e in F:

$$\begin{aligned} \min \quad & \sum_{e \in E} c_e x_e & & \qquad (f\text{-IP}) \\ \text{subject to:} \quad & x(\delta(S)) \geq f(S) & \forall\ S \subseteq V \\ & x_e \in \{0, 1\} & \forall\ e \in E. \end{aligned}$$

We remark that in its most-general form, f-connectivity is hard to approximate within a logarithmic factor. This can be shown via a reduction from the hitting set problem.[1] Thus, research on f-connectivity has focused on instances where f has some nice structural properties.

▶ **Definition 1** ([33]). *A function $f : 2^V \to \{0, 1\}$ satisfying $f(V) = 0$ is called* uncrossable *if for any $A, B \subseteq V$ with $f(A) = f(B) = 1$, we have $f(A \cap B) = f(A \cup B) = 1$ or $f(A \setminus B) = f(B \setminus A) = 1$.*

▶ **Definition 2.** *A function $f : 2^V \to \{0, 1\}$ satisfying $f(V) = 0$ is called* pliable *if for any $A, B \subseteq V$ with $f(A) = f(B) = 1$, we have $f(A \cap B) + f(A \cup B) + f(A \setminus B) + f(B \setminus A) \geq 2$.*

Note that the problem of augmenting an uncrossable (pliable) family can be seen as an f-connectivity problem whose requirement function is an uncrossable (pliable) function.

1.1 Our Contributions

In this work, we introduce the class of pliable functions and study the approximation ratio of WGMV's algorithm on f-connectivity instances arising from pliable functions. To the best of our knowledge, we are the first to investigate the f-connectivity problem beyond uncrossable functions. As mentioned before, the algorithm of WGMV can perform poorly on an arbitrary instance with a pliable function f. In the full version [3, Section 6], we present an instance where the solution returned by the WGMV algorithm costs $\Omega(\sqrt{n})$ times the optimal cost.

1.1.1 Pliable Functions and Property (γ)

As alluded to in the introduction, the analysis of WGMV relies on the property that for any inclusion-wise minimal violated set C and any violated set S, either C is a subset of S or C is disjoint from S ([33, Lemma 5.1(3)]). This property does not hold when we apply the primal-dual method to augment a pliable function; see the instance described in Appendix B. Nevertheless, we carve out a subclass of pliable functions – still containing all uncrossable functions – for which the WGMV algorithm yields an $O(1)$-approximate solution. This subclass is characterized by the following structural property that allows for minimal violated sets to cross other violated sets, but in a limited way.

[1] Given a ground-set X and a family $\mathcal{S}$ of subsets of X to hit, we define $L := \{\ell_x : x \in X\}$, $R := \{r_x : x \in X\}$, and $E := \{e_x = \ell_x r_x : x \in X\}$. We then take $G = (L \sqcup R, E)$ to be a bipartite graph with a perfect matching E and f to be the indicator function of the family $\{\{\ell_x : x \in A\} : A \in \mathcal{S}\}$.

Property (γ) : For any edge-set $F \subseteq E$ and for any violated sets (w.r.t. f and F) C, S_1, S_2, with $S_1 \subsetneq S_2$, the following conditional proposition holds:
(C is inclusion-wise minimal) and (C crosses both S_1 and S_2)
$\implies S_2 \setminus (S_1 \cup C)$ is either empty or violated.

▶ **Theorem 3.** *Let $G = (V, E)$ be an undirected graph with nonnegative costs $c : E \to \mathbb{Q}_{\geq 0}$ on its edges, and let $f : 2^V \to \{0, 1\}$ be a pliable function satisfying property (γ). Suppose that there is a subroutine that, for any given $F \subseteq E$, computes all minimal violated sets w.r.t. f and F. Then, in polynomial time and using a polynomial number of calls to the subroutine, we can compute a 16-approximate solution to the given instance of the f-connectivity problem.*

In the next three sections, we introduce the network-design applications where Theorem 3 gives new/improved approximation algorithms. In each of these applications, we setup an f-connectivity problem where the function f is a pliable function with property (γ).

1.1.2 Application 1: Augmenting a Family of Small Cuts

Our first application is on finding a minimum-cost augmentation of a family of small cuts in a graph. Formally, in an instance of the AugSmallCuts problem we are given an undirected capacitated graph $G = (V, E)$ with edge-capacities $u \in \mathbb{Q}^E_{\geq 0}$, a set of links $L \subseteq \binom{V}{2}$ with costs $c \in \mathbb{Q}^L_{\geq 0}$, and a threshold $\widetilde{\lambda} \in \mathbb{Q}_{\geq 0}$. A subset $F \subseteq L$ of links is said to *augment* a node-set S if there exists a link $e \in F$ with exactly one end-node in S. The objective is to find a minimum-cost $F \subseteq L$ that augments all non-empty $S \subsetneq V$ with $u(\delta(S) \cap E) < \widetilde{\lambda}$.

We remark that some special cases of the AugSmallCuts problem have been studied previously, and, to the best of our knowledge, there is no previous publication on the general version of this problem. Let $\lambda(G)$ denote the minimum capacity of a cut of G, thus, $\lambda(G) := \min\{u(\delta(S) \cap E) \ : \ \emptyset \subsetneq S \subsetneq V\}$. Assuming u is integral and $\widetilde{\lambda} = \lambda(G) + 1$, we get the well-known connectivity augmentation problem for which constant-factor approximation algorithms are known [13, 23]. On the other hand, when $\widetilde{\lambda} = \infty$, a minimum-cost spanning tree of (V, L), if one exists, gives an optimal solution to the problem.

Our main result here is an $O(1)$-approximation algorithm for the AugSmallCuts problem that works for any choice of $\widetilde{\lambda}$. The proof of the following theorem is given in Section 4.

▶ **Theorem 4.** *There is a 16-approximation algorithm for the* AugSmallCuts *problem.*

As an aside, we refer the reader to Benczur & Goemans [4] and the references therein for results on the representations of the near-minimum cuts of graphs; they do not study the problem of augmenting the near-minimum cuts.

In Appendix B, we give a small instance of the AugSmallCuts problem that illustrates some of the technical challenges which arise while working with the f-connectivity problem for a pliable function with property (γ). The instance described has bizarre properties that do not arise when working with uncrossable functions. First, it has a minimal violated set which crosses another violated set. Second, none of the optimal solutions to the dual LP of the f-connectivity problem are supported on a laminar family. The latter was believed to be a major hindrance to developing constant-factor approximation algorithms for general network-design problems.

1.1.3 Application 2: Capacitated k-Edge-Connected Subgraph Problem

In the capacitated k-edge-connected subgraph problem (Cap-k-ECSS), we are given an undirected graph $G = (V, E)$ with edge costs $c \in \mathbb{Q}^E_{\geq 0}$ and edge capacities $u \in \mathbb{Z}^E_{\geq 0}$. The goal is to find a minimum-cost subset of the edges $F \subseteq E$ such that the capacity across any cut in (V, F) is at least k, i.e., $u(\delta_F(S)) \geq k$ for all non-empty sets $S \subsetneq V$. Let u_{max} and u_{min}, respectively, denote the maximum capacity of an edge in E and the minimum capacity of an edge in E. We may assume (w.l.o.g.) that $u_{max} \leq k$.

We mention that there are well-known 2-approximation algorithms for the special case of the Cap-k-ECSS problem with $u_{max} = u_{min} = 1$, which is the problem of finding a minimum-cost k-edge connected spanning subgraph. Khuller & Vishkin [24] presented a combinatorial 2-approximation algorithm and Jain [20] matched this approximation guarantee via the iterative rounding method.

Goemans et al. [17] gave a $2k$-approximation algorithm for the general Cap-k-ECSS problem. Chakrabarty et al. [6] gave a randomized $O(\log |V(G)|)$-approximation algorithm; note that this approximation guarantee is independent of k but does depend on the size of the underlying graph. Recently, Boyd et al. [5] improved on these results by providing a $\min(k, 2u_{max})$-approximation algorithm. In this work, we give a $(16 \cdot \lceil k/u_{\min} \rceil)$-approximation algorithm, which leads to improved approximation guarantees when both $u_{\min}$ and $u_{\max}$ are sufficiently large. In particular, in the regime when $k \geq u_{\max} \geq u_{\min} \geq 32$ and $u_{\min} \cdot u_{\max} \geq 16k$.

▶ **Theorem 5.** *There is a $16 \cdot \lceil k/u_{min} \rceil$-approximation algorithm for the Cap-k-ECSS problem.*

The proof of Theorem 5 can be found in Section 5.

1.1.4 Application 3: $(p, 2)$-Flexible Graph Connectivity

Adjiashvili, Hommelsheim and Mühlenthaler [1] introduced the model of Flexible Graph Connectivity that we denote by FGC. Boyd, Cheriyan, Haddadan and Ibrahimpur [5] introduced a generalization of FGC. Let $p \geq 1$ and $q \geq 0$ be integers. In an instance of the (p, q)-Flexible Graph Connectivity problem, denoted (p, q)-FGC, we are given an undirected graph $G = (V, E)$, a partition of E into a set of safe edges $\mathcal{S}$ and a set of unsafe edges $\mathcal{U}$, and nonnegative edge-costs $c \in \mathbb{Q}^E_{\geq 0}$. A subset $F \subseteq E$ of edges is feasible for the (p, q)-FGC problem if for any set F' consisting of at most q unsafe edges, the subgraph $(V, F \setminus F')$ is p-edge connected. The objective is to find a feasible solution F that minimizes $c(F) = \sum_{e \in F} c_e$.

Boyd et al. [5] presented a 4-approximation algorithm for $(p, 1)$-FGC based on the WGMV primal-dual method, and they gave an $O(q \log n)$-approximation algorithm for general (p, q)-FGC and a $(q + 1)$-approximation for $(1, q)$-FGC. Concurrently with our work, Chekuri and Jain [8] obtained $O(p)$-approximation algorithms for $(p, 2)$-FGC, $(p, 3)$-FGC and $(2p, 4)$-FGC; in particular, they present a $(2p + 4)$-approximation ratio for $(p, 2)$-FGC. Chekuri and Jain have several other results for network design in non-uniform fault models; [7] have results on the flexible graph connectivity problem that arises from the classical survivable network design problem, which they call (p, q)-Flex-SNDP.

Our main result here is an $O(1)$-approximation algorithm for the $(p, 2)$-FGC problem.

▶ **Theorem 6.** *There is a 20-approximation algorithm for the $(p, 2)$-FGC problem. Moreover, for even p, the approximation ratio is 6.*

Note that in comparison to [8], Theorem 6 yields a better approximation ratio when $p > 8$ or $p \in \{2, 4, 6, 8\}$. For $p = 1$, the approximation ratio of 3 from [5] is better than the guarantees given by [8] and Theorem 6. The proof of Theorem 6 can be found in Section 6.

1.2 Related work

Goemans & Williamson [18] introduced the notion of proper functions with the motivation of designing approximation algorithms for problems in network design. They formulated several of these problems as the f-connectivity problem where f is a proper function. A symmetric function $f : 2^V \to \mathbb{Z}_{>0}$ with $f(V) = 0$ is said to be *proper* if $f(A \cup B) \leq \max(f(A), f(B))$ for any pair of disjoint sets $A, B \subseteq V$.

Jain [20] designed the iterative rounding framework for the setting when f is weakly supermodular and presented a 2-approximation algorithm. A function f is said to be *weakly supermodular* if $f(A) + f(B) \leq \max(f(A \cap B) + f(A \cup B),\ f(A \setminus B) + f(B \setminus A))$ for any $A, B \subseteq V$. One can show that proper functions are weakly supermodular. We mention that there are examples of uncrossable functions that are not weakly supermodular, see [5].

2 Preliminaries

This section has definitions and preliminary results. Our notation and terms are consistent with [10, 30], and readers are referred to those texts for further information.

For a positive integer k, we use $[k]$ to denote the set $\{1, \ldots, k\}$. For a ground-set V and a subset S of V, the complement of S (w.r.t. V) is denoted $V \setminus S$. Sets $A, B \subseteq V$ are said to *cross*, denoted $A \bowtie B$, if each of the four sets $A \cap B$, $V \setminus (A \cup B)$, $A \setminus B$, $B \setminus A$ is non-empty; on the other hand, if A, B do not cross, then either $A \cup B = V$, or A, B are disjoint, or one of A, B is a subset of the other one. A family of sets $\mathcal{L} \subseteq 2^V$ is said to be *laminar* if for any two sets $A, B \in \mathcal{L}$ either A and B are disjoint or one of them is a subset of the other one.

We may use abbreviations for some standard terms, e.g., we may use "(p, q)-FGC" as an abbreviation for "the (p, q)-FGC problem". In some of our discussions, we may use the informal phrasing "we apply the primal-dual method to augment a pliable function" instead of the phrasing "we apply the primal-dual method to an f-connectivity problem where the function f is a pliable function".

Graphs, Subgraphs, and Related Notions

Let $G = (V, E)$ be an undirected multi-graph (possibly containing parallel edges but no loops) with non-negative costs $c \in \mathbb{R}^E_{\geq 0}$ on the edges. We take G to be the input graph, and we use n to denote $|V(G)|$. For a set of edges $F \subseteq E(G)$, $c(F) := \sum_{e \in F} c(e)$, and for a subgraph G' of G, $c(G') := c(E(G'))$. For any instance G, we use $\textsc{opt}(G)$ to denote the minimum cost of a feasible subgraph (i.e., a subgraph that satisfies the requirements of the problem). When there is no danger of ambiguity, we use $\textsc{opt}$ rather than $\textsc{opt}(G)$.

Let $G = (V, E)$ be any multi-graph, let $A, B \subseteq V$ be two disjoint node-sets, and let $F \subseteq V$ be an edge-set. We denote the multi-set of edges of G with exactly one end-node in each of A and B by $E(A, B)$, thus, $E(A, B) := \{e = uv : u \in A, v \in B\}$. Moreover, we use $\delta_E(A)$ or $\delta(A)$ to denote $E(A, V \setminus A)$. By a p-cut we mean a cut of size p. We use $G[A]$ to denote the subgraph of G induced by A, $G - A$ to denote the subgraph of G induced by $V \setminus A$, and $G - F$ to denote the graph $(V,\ E \setminus F)$. We may use relaxed notation for singleton sets, e.g., we may use $G - v$ instead of $G - \{v\}$, etc. A multi-graph G is called k-edge connected if $|V(G)| \geq 2$ and for every $F \subseteq E(G)$ of size $< k$, $G - F$ is connected.

We use the following observations.

▶ **Fact 7.** *Let $A, B \subseteq V$ be a pair of crossing sets. For any edge-set $F \subseteq \binom{V}{2}$ and any $S \in \{A \cap B, A \cup B, A \setminus B, B \setminus A\}$, we have $\delta_F(S) \subseteq \delta_F(A) \cup \delta_F(B)$.*

Proof. By examining cases, we can show that $e \in \delta_F(S) \implies e \in \delta_F(A)$ or $e \in \delta_F(B)$. ◀

For any function $f : 2^V \to \{0,1\}$ and any edge-set $F \subseteq E$, we say that $S \subseteq V$ is *violated w.r.t. f, F* if $|\delta_F(S)| < f(S)$, i.e., if $f(S) = 1$ and there are no F-edges in the cut $\delta(S)$. We drop f and F when they are clear from the context. The next observation states that the violated sets w.r.t. any pliable function f and any "augmenting" edge-set F form a pliable family.

▶ **Fact 8.** *Let $f : 2^V \to \{0,1\}$ be a pliable function and $F \subseteq E$ be an edge-set. Define the function $f' : 2^V \to \{0,1\}$ such that $f'(S) = 1$ if and only if both $f(S) = 1$ and $\delta_F(S) = \emptyset$ hold. Then, f' is also pliable.*

Proof. Consider $A, B \subsetneq V$ such that $f'(A) = 1 = f'(B)$. Clearly, $f(A) = 1 = f(B)$. Moreover, for any $S \in \{A \cap B, A \cup B, A \setminus B, B \setminus A\}$, we have $\delta_F(S) = \emptyset$, by Fact 7. Since f is pliable, there are at least two distinct sets $S_1, S_2 \in \{A \cap B, A \cup B, A \setminus B, B \setminus A\}$ with f-value one. Then, we have $f'(S_1) = 1 = f'(S_2)$ (since $\delta_F(S_1) = \emptyset = \delta_F(S_2)$). Hence, f' is pliable. ◀

2.1 The WGMV Primal-Dual Algorithm for Uncrossable Functions

In this section, we give a brief description of the primal-dual algorithm of Williamson et al. [33] that achieves approximation ratio 2 for an f-connectivity problem where the function f is an uncrossable function.

▶ **Theorem 9** (Lemma 2.1 in [33])**.** *Let $f : 2^V \to \{0,1\}$ be an uncrossable function. Suppose we have a subroutine that for any given $F \subseteq E$, computes all minimal violated sets w.r.t. f, F. Then, in polynomial time and using a polynomial number of calls to the subroutine, we can compute a 2-approximate solution to the given instance of the f-connectivity problem.*

The algorithm and its analysis are based on the following LP relaxation of (f-IP) (stated on the left) and its dual. Define $\mathcal{S} := \{S \subseteq V : f(S) = 1\}$.

Primal LP

$$\min \sum_{e \in E} c_e x_e$$

$$\text{subject to: } \sum_{e \in \delta(S)} x_e \geq 1 \quad \forall S \in \mathcal{S}$$

$$0 \leq x_e \leq 1 \quad \forall e \in E$$

Dual LP

$$\max \sum_{S \in \mathcal{S}} y_S$$

$$\text{subject to: } \sum_{S \in \mathcal{S} : e \in \delta(S)} y_S \leq c_e \quad \forall e \in E$$

$$y_S \geq 0 \quad \forall S \in \mathcal{S}$$

The algorithm starts with an infeasible primal solution $F = \emptyset$, which corresponds to $x = \chi^F = \mathbf{0} \in \{0,1\}^E$, and a feasible dual solution $y = \mathbf{0}$. At any time, we say that $S \in \mathcal{S}$ is *violated* if $\delta_F(S) = \emptyset$, i.e., the primal-covering constraint for S is not satisfied. We call inclusion-wise minimal violated sets as *active sets*. An edge $e \in E$ is said to be *tight* if $\sum_{S \in \mathcal{S} : e \in \delta(S)} y_S = c_e$, i.e., the dual-packing constraint for e is tight. Throughout the algorithm, the following conditions are maintained: (i) integrality of the primal solution; (ii) feasibility of the dual solution; (iii) y_S is never decreased for any S; and (iv) y_S may only be increased for $S \in \mathcal{S}$ that are active.

The algorithm has two stages. In the first stage, the algorithm iteratively improves primal feasibility by including tight edges in F that are incident to active sets. If no such edge exists, then the algorithm uniformly increases y_S for all active sets S until a new edge becomes tight. The first stage ends when $x = \chi^F$ becomes feasible. In the second stage, called *reverse delete*, the algorithm removes redundant edges from F. Initially $F' = F$. The algorithm examines edges picked in the first stage in reverse order, and discards edges from F' as long as feasibility is maintained. Note that F' is feasible if the subroutine in the hypothesis of Theorem 9 does not find any (minimal) violated sets.

The analysis of the 2-approximation ratio is based on showing that a relaxed form of the complementary slackness conditions hold on "average". Let F' and y be the primal and dual solutions returned by the algorithm. By the design of the algorithm, $\sum_{S \in \mathcal{S}: e \in \delta(S)} y_S = c_e$ holds for any edge $e \in F'$. Thus, the cost of F' can be written as $\sum_{e \in F'} \sum_{S \in \mathcal{S}: e \in \delta(S)} y_S = \sum_{S \in \mathcal{S}} y_S \cdot |\delta_{F'}(S)|$. Observe that the approximation ratio follows from showing that the algorithm always maintains the following inequality:

$$\sum_{S \in \mathcal{S}} y_S \cdot |\delta_{F'}(S)| \leq 2 \sum_{S \in \mathcal{S}} y_S. \tag{1}$$

Consider any iteration and recall that the dual variables corresponding to active sets were uniformly increased by an $\varepsilon > 0$ amount, until some edge became tight. Let $\mathcal{C}$ denote the collection of active sets during this iteration. During this iteration, the left-hand side of (1) increases by $\varepsilon \cdot \sum_{S \in \mathcal{C}} |\delta_{F'}(S)|$ and the right-hand side increases by $2 \cdot \varepsilon \cdot |\mathcal{C}|$. Thus, (1) is maintained if one can show that the average F'-degree of active sets in any iteration is ≤ 2, and this forms the crux of the WGMV analysis.

We refer the reader to [19] for a detailed discussion of the primal-dual method for network design problems.

3 Extending the WGMV Primal-Dual Method to Pliable functions

In this section, we prove our main result, Theorem 3: we show that the primal-dual algorithm outlined in Section 2.1 is a 16-approximation algorithm for the f-connectivity problem where f is a pliable function with property (γ). Our analysis follows the same high-level plan as that of Williamson et al. [33] which was outlined in Section 2.1. We will show that, in any iteration of the first stage of the primal-dual algorithm, $\sum_{C \in \mathcal{C}} |\delta_{F'}(C)| \leq 16|\mathcal{C}|$, where $\mathcal{C}$ is the collection of active sets in that iteration, and F' is the set of edges output by the algorithm at termination, after the reverse delete stage.

For the remainder of this proof we assume that the iteration, and thus $\mathcal{C}$, is fixed. We define $H := \cup_{C \in \mathcal{C}} \delta_{F'}(C)$. (Informally speaking, H is the subset of F' that is relevant for the analysis of our fixed iteration.) Additionally, to ease notation when discussing a laminar family of sets, we say that two sets A, B *overlap* if $A \setminus B, A \cap B$ and $B \setminus A$ are all non-empty. (Clearly, if A, B cross, then A, B overlap; if $A \cup B = V$, then A, B do not cross but A, B could overlap.)

We begin with a lemma which can be proved by the same arguments as in the proof of [33, Lemma 5.1].

▶ **Lemma 10.** *For any edge $e \in H := \cup_{C \in \mathcal{C}} \delta_{F'}(C)$, there exists a witness set $S_e \subseteq V$ with:*
(i) *$f(S_e) = 1$ and S_e is violated in the current iteration, and*
(ii) *$\delta_{F'}(S_e) = \{e\}$.*

Our proof of the following key lemma is presented in Appendix A.

▶ **Lemma 11.** *There exists a laminar family of witness sets.*

▶ **Lemma 12.** *The active sets in $\mathcal{C}$ are pair-wise disjoint.*

Proof. Suppose that two sets $C_1, C_2 \in \mathcal{C}$ intersect. Then due to property (i) of pliable functions, one of the sets $C_1 \cap C_2$, $C_1 \setminus C_2$, or $C_2 \setminus C_1$ is violated; thus, a proper subset of either C_1 or C_2 is violated. This is a contradiction because C_1 and C_2 are minimal violated sets and no proper subset of C_1 (respectively, C_2) is violated. ◀

Let $\mathcal{L}$ be the laminar family of witness sets together with the node-set V. Let $\mathcal{T}$ be a rooted tree that represents $\mathcal{L}$; for each set $S \in \mathcal{L}$, there is a node v_S in $\mathcal{T}$, and the node v_V is taken to be the root of $\mathcal{T}$. The edges of $\mathcal{T}$ are oriented away from the root; thus, $\mathcal{T}$ has an oriented edge (v_Q, v_S) iff Q is the smallest set of $\mathcal{L}$ that properly contains the set S of $\mathcal{L}$. Let ψ be a mapping from $\mathcal{C}$ to $\mathcal{L}$ that maps each active set C to the smallest set $S \in \mathcal{L}$ that contains it. If a node v_S of $\mathcal{T}$ has some active set mapped to its associated set S, then we call v_S *active* and we assign the color red to v_S. Moreover, we assign the color green to each of the non-active nodes of $\mathcal{T}$ that are incident to three or more edges of $\mathcal{T}$; thus, node v_S of $\mathcal{T}$ is green iff $\deg_{\mathcal{T}}(v_S) \geq 3$ and v_S is not active. Finally, we assign the color black to each of the remaining nodes of $\mathcal{T}$; thus, node v_S of $\mathcal{T}$ is black iff $\deg_{\mathcal{T}}(v_S) \leq 2$ and v_S is not active.

Let the number of red, green and black nodes of $\mathcal{T}$ be denoted by n_R, n_G and n_B, respectively. Clearly, $n_R + n_G + n_B = |\mathcal{T}| = |F'| + 1$. Let n_L denote the number of leaf nodes of $\mathcal{T}$.

▶ **Lemma 13.** *The following are true:*

(i) *Each leaf node of $\mathcal{T}$ is red.*

(ii) *We have $n_G \leq n_L \leq n_R$.*

Proof. The first claim follows by repeating the argument in [33, Lemma 5.3]. Next, by (i), we have $n_L \leq n_R$. Moreover, we have $n_G \leq n_L$ because the number of leaves in any tree is at least the number of nodes that are incident to three or more edges of the tree. ◀

Observe that each black node of $\mathcal{T}$ is incident to two edges of $\mathcal{T}$; thus, every black non-root node of $\mathcal{T}$ has a unique child.

Let us sketch our plan for proving Theorem 3. Clearly, the theorem would follow from the inequality $\sum_{C \in \mathcal{C}} |\delta_{F'}(C)| \leq O(1) \cdot |\mathcal{C}|$; thus, we need to prove an upper bound of $O(|\mathcal{C}|)$ on the number of "incidences" between the edges of F' and the cuts $\delta(C)$ of the active sets $C \in \mathcal{C}$. We start by assigning a token to $\mathcal{T}$ corresponding to each "incidence". In more detail, for each edge $e \in F'$ and cut $\delta(C)$ such that $C \in \mathcal{C}$ and $e \in \delta(C)$ we assign one token to the node v_{S_e} of $\mathcal{T}$ that represents the witness set S_e of the edge e. Thus, the total number of tokens assigned to $\mathcal{T}$ is $\sum_{C \in \mathcal{C}} |\delta_{F'}(C)|$; moreover, after the initial assignment, it can be seen that each node of $\mathcal{T}$ has ≤ 2 tokens (see Lemma 14 below). Then we redistribute the tokens according to a simple rule such that (after redistributing) each of the red/green nodes has ≤ 8 tokens and each of the black nodes has no tokens. Lemma 15 (below) proves this key claim by applying property (γ). The key claim implies that the total number of tokens assigned to $\mathcal{T}$ is $\leq 8n_R + 8n_G \leq 16n_R \leq 16|\mathcal{C}|$ (by Lemma 13). This concludes our sketch.

We apply the following two-phase scheme to assign tokens to the nodes of $\mathcal{T}$.

- In the first phase, for $C \in \mathcal{C}$ and $e \in \delta_{F'}(C)$, we assign a new token to the node v_{S_e} corresponding to the witness set S_e for the edge e. At the end of the first phase, observe that the root v_V of $\mathcal{T}$ has no tokens (since the set V cannot be a witness set).

- In the second phase, we apply a root-to-leaves scan of $\mathcal{T}$ (starting from the root v_V). Whenever we scan a black node, then we move all the tokens at that node to its unique child node. (There are no changes to the token distribution when we scan a red node or a green node.)

▶ **Lemma 14.** *At the end of the first phase, each node of $\mathcal{T}$ has ≤ 2 tokens.*

Proof. Consider a non-root node v_{S_e} of $\mathcal{T}$. This node corresponds to a witness set $S_e \in \mathcal{L}$ and e is the unique edge of F' in $\delta(S_e)$. The edge e is in ≤ 2 of the cuts $\delta(C), C \in \mathcal{C}$, because the active sets are pairwise disjoint (in other words, the number of "incidences" for e is ≤ 2). No other edge of F' can assign tokens to v_{S_e} during the first phase. ◀

▶ **Lemma 15.** *We have that:*

(i) *Any oriented path of $\mathcal{T} \setminus \{v_V\}$ with four nodes has at least one non-black node.*

(ii) *Hence, after token redistribution, each red or green node of $\mathcal{T}$ has ≤ 8 tokens and each black node of $\mathcal{T}$ has zero tokens.*

Proof. For the sake of contradiction, assume that there exists an oriented path of $\mathcal{T}$ that has four black nodes and that is not incident to the root v_V; let $v_{S_4} \to v_{S_3} \to v_{S_2} \to v_{S_1}$ be such an oriented path. Thus, $S_1 \subsetneq S_2 \subsetneq S_3 \subsetneq S_4$ are witness sets of $\mathcal{L}$. For $i \in \{1,2,3,4\}$, let S_i be the witness set of edge $e_i = \{a_i, b_i\} \in F'$; note that e_i has exactly one end-node in S_i, call it a_i. Clearly, for $i \in \{1,2,3\}$, both nodes a_i, b_i are in S_{i+1} (since e_{i+1} is the unique edge of F' in $\delta(S_{i+1})$).

Let $C \in \mathcal{C}$ be an active set such that $e_1 \in \delta(C)$.

▷ Claim 16. C is not a subset of S_1.

For the sake of contradiction, suppose that C is a subset of S_1. Since e_1 has (exactly) one end-node in C and $b_1 \notin S_1$, we have $a_1 \in C$. Let W be the smallest set in $\mathcal{L}$ that contains C. Then $W \subseteq S_1$, and, possibly, $W = S_1$. Thus, we have $a_1 \in W$ and $b_1 \notin W$, hence, $e_1 \in \delta(W)$. Then we must have $W = S_1$ (since e_1 is in exactly one of the cuts $\delta(S), S \in \mathcal{L}$). Then the mapping ψ from $\mathcal{C}$ to $\mathcal{L}$ maps C to $W = S_1$, hence, v_{S_1} is colored red. This is a contradiction.

▷ Claim 17. C crosses each of the sets S_2, S_3, S_4.

First, observe that e_1 has (exactly) one end-node in C and has both end-nodes in S_2. Hence, both $S_2 \cap C$ and $S_2 \setminus C$ are non-empty. Next, using Claim 16, we can prove that C is not a subset of S_2. (Otherwise, S_2 would be the smallest set in $\mathcal{L}$ that contains C, hence, v_{S_2} would be colored red.) Repeating the same argument, we can prove that C is not a subset of S_3, and, moreover, C is not a subset of S_4. Finally, note that $V \setminus (C \cup S_4)$ is non-empty. (Otherwise, at least one of $C \setminus S_4$ or $C \cap S_4$ would be violated, since f is a pliable function, and that would contradict the fact that C is a minimal violated set.) Observe that S_2 crosses C because all four sets $S_2 \cap C$, $S_2 \setminus C$, $C \setminus S_2$, $V \setminus (S_2 \cup C)$ are non-empty (in more detail, we have $|\{a_1, b_1\} \cap (S_2 \cap C)| = 1$, $|\{a_1, b_1\} \cap (S_2 \setminus C)| = 1$, $C \not\subseteq S_2 \implies C \setminus S_2 \neq \emptyset$, $V \setminus (C \cup S_2) \supseteq V \setminus (C \cup S_4) \neq \emptyset$). Similarly, it can be seen that S_3 crosses C, and S_4 crosses C.

▷ Claim 18. Either $S_3 \setminus (C \cup S_2)$ is non-empty or $S_4 \setminus (C \cup S_3)$ is non-empty.

For the sake of contradiction, suppose that both sets $S_3 \setminus (C \cup S_2)$, $S_4 \setminus (C \cup S_3)$ are empty. Then $C \supseteq S_4 \setminus S_3$ and $C \supseteq S_3 \setminus S_2$. Consequently, both end-nodes of e_3 are in C (since $a_3 \in S_3 \setminus S_2$ and $b_3 \in S_4 \setminus S_3$). This leads to a contradiction, since $e_3 \in F'$ is incident to an active set in $\mathcal{C}$, call it C_3 (i.e., $e_3 \in \delta(C_3)$), hence, one of the end-nodes of e_3 is in both C and C_3, whereas the active sets are pairwise disjoint.

To conclude the proof of the lemma, suppose that $S_4 \setminus (C \cup S_3)$ is non-empty (by Claim 18); the other case, namely, $S_3 \setminus (C \cup S_2) \neq \emptyset$, can be handled by the same arguments. Then, by property (γ), $S_4 \setminus (C \cup S_3)$ is a violated set, therefore, it contains a minimal violated set, call it $\widetilde{C}$. Clearly, the mapping ψ from $\mathcal{C}$ to $\mathcal{L}$ maps the active set $\widetilde{C}$ to a set $S_{\widetilde{C}}$. Either $S_{\widetilde{C}} = S_4$ or else $S_{\widetilde{C}}$ is a subset of of $S_4 \setminus S_3$. Both cases give contradictions; in the first case, S_4 is colored red, and in the second case, v_{S_4} has ≥ 2 children in $\mathcal{T}$ so that S_4 is colored either green or red. Thus, we have proved the first part of the lemma.

The second part of the lemma follows by Lemma 13 and the sketch given below Lemma 13. In more detail, at the start of the second phase, each node of $\mathcal{T}$ has ≤ 2 tokens, by Lemma 14. In the second phase, we redistribute the tokens such that each (non-root) black node ends up with no tokens, and each red/green node v_S receives ≤ 6 redistributed tokens because there are ≤ 3 black ancestor nodes of v_S that could send their tokens to v_S (by the first part of the lemma). Hence, each non-root non-black node has ≤ 8 tokens, after token redistribution. ◀

4 $O(1)$-Approximation Algorithm for Augmenting Small Cuts

In this section, we give a 16-approximation algorithm for the AugSmallCuts problem, thereby proving Theorem 4. Our algorithm for AugSmallCuts is based on a reduction to an instance of the f-connectivity problem on the graph $H = (V, L)$ for a pliable function f with property (γ).

Recall the AugSmallCuts problem: we are given an undirected graph $G = (V, E)$ with edge-capacities $u \in \mathbb{Q}^E_{\geq 0}$, a set of links $L \subseteq \binom{V}{2}$ with costs $c \in \mathbb{Q}^L_{\geq 0}$, and a threshold $\widetilde{\lambda} \in \mathbb{Q}_{\geq 0}$. A subset $F \subseteq L$ of links is said to *augment* a node-set S if there exists a link $e \in F$ with exactly one end-node in S. The objective is to find a minimum-cost $F \subseteq L$ that augments all non-empty $S \subsetneq V$ with $u(\delta_E(S)) < \widetilde{\lambda}$.

Proof of Theorem 4. Define $f : 2^V \to \{0, 1\}$ such that $f(S) = 1$ if and only if $S \notin \{\emptyset, V\}$ and $u(\delta_E(S)) < \widetilde{\lambda}$. We apply Theorem 3 for the f-connectivity problem on the graph $H = (V, L)$ with edge-costs $c \in \mathbb{Q}^L_{\geq 0}$ to obtain a 16-approximate solution $F \subseteq L$. By our choice of f, there is a one-to-one cost-preserving correspondence between feasible augmentations for AugSmallCuts and feasible solutions to the f-connectivity problem. Thus, it remains to argue that the assumptions of Theorem 3 hold.

First, we show that f is pliable. Note that f is symmetric and $f(V) = 0$. Consider sets $A, B \subseteq V$ with $f(A) = f(B) = 1$. By submodularity and symmetry of cuts in undirected graphs, we have: $\max\{u(\delta(A \cup B)) + u(\delta(A \cap B)),\ u(\delta(A \setminus B)) + u(\delta(B \setminus A))\} \leq u(\delta(A)) + u(\delta(B))$. Since the right hand side is strictly less than $2\widetilde{\lambda}$, we have $f(A \cap B) + f(A \cup B) \geq 1$ and $f(A \setminus B) + f(B \setminus A) \geq 1$, hence, f is pliable.

Second, we argue that f satisfies property (γ). Fix some edge-set $F \subseteq L$, and define $f' : 2^V \to \{0, 1\}$ such that $f'(S) = 1$ if and only if $f(S) = 1$ and $\delta_F(S) = \emptyset$. By Fact 8, f' is also pliable. Consider sets $C, S_1, S_2 \subseteq V$, $S_1 \subsetneq S_2$, that are violated w.r.t. f, F, i.e., $f'(C) = f'(S_1) = f'(S_2) = 1$. Further, suppose that C is minimally violated, and C crosses both S_1 and S_2. Suppose that $S_2 \setminus (S_1 \cup C)$ is non-empty (the other case is trivial). To show that $S_2 \setminus (S_1 \cup C)$ is violated w.r.t. f, F, we have to show that (i) $\delta_F(S_2 \setminus (S_1 \cup C))$ is empty and (ii) $u(\delta_E(S_2 \setminus (S_1 \cup C))) < \widetilde{\lambda}$. Observe that S_2 crosses $(S_1 \cup C)$. To show (i), we apply Fact 7 twice; first, we show that $\delta_F(S_1 \cup C)$ is empty (since $\delta_F(C)$, $\delta_F(S_1)$ are empty), and then we show that $\delta_F(S_2 \setminus (S_1 \cup C))$ is empty (since $\delta_F(S_2)$ is empty). To show (ii), observe that the multiset

$$\delta_E(S_2 \setminus (S_1 \cup C)) \cup \delta_E(C \setminus S_2) \text{ is a (multi-)subset of } \delta_E(S_2) \cup \delta_E(C \cup S_1).$$

(Note that for disjoint sets $A_1, A_2, A_3 \subsetneq V$, $\delta(A_1) \cup \delta(A_2)$ is a (multi-)subset of $\delta(A_1 \cup A_3) \cup \delta(A_2 \cup A_3)$.) Moreover, we claim that $u(\delta_E(C \cup S_1)) < \widetilde{\lambda}$ and $u(\delta_E(C \setminus S_2)) \geq \widetilde{\lambda}$. The two claims immediately imply (ii) (since $u(\delta_E(S_2)) < \widetilde{\lambda}$).

Next, we prove the two claims. Note that the sets $C \cap S_1, C \setminus S_1, S_1 \setminus C, V \setminus (C \cup S_1)$ are non-empty, and note that $f'(C \cap S_1) = 0 = f'(C \setminus S_1)$ since C is a minimal violated set. Since f' is pliable and $f'(C) = 1 = f'(S_1)$, we have $f'(C \cup S_1) = 1$. By Fact 7, $\delta_F(C \cup S_1) = \emptyset$, hence, $f(C \cup S_1) = 1$; equivalently, $u(\delta_E(C \cup S_1)) < \widetilde{\lambda}$. Since C is a minimal violated set, $f'(C \setminus S_2) = 0$. Moreover, $\delta_F(C \setminus S_2) = \emptyset$, by Fact 7. Hence, $f(C \setminus S_2) = 0$; equivalently, $u(\delta_E(C \setminus S_2)) \geq \widetilde{\lambda}$.

Last, we describe a polynomial-time subroutine that for any $F \subseteq L$ gives the collection of all minimal violated sets w.r.t. f, F. Assign a capacity of $\widetilde{\lambda}$ to all edges in F, and consider the graph $G' = (V, E')$ where $E' := E \cup F$. Then, the family of minimal violated sets is given by $\{\emptyset \subsetneq S \subsetneq V : u(\delta_{E'}(S)) < \widetilde{\lambda}, u(\delta_{E'}(A)) \geq \widetilde{\lambda} \; \forall \, \emptyset \subsetneq A \subsetneq S\}$. We use the notion of solid sets to find all such minimally violated sets; see Naor, Gusfield, and Martel [29] and see Frank's book [12]. A solid set of an undirected graph $H = (V, E'')$ with capacities $w \in \mathbb{R}^{E''}_{\geq 0}$ on its edges is a non-empty node-set $Z \subsetneq V$ such that $w(\delta_{E''}(X)) > w(\delta_{E''}(Z))$ for all non-empty $X \subsetneq Z$. Note that the family of minimal violated sets of interest to us is a sub-family of the family of solid sets of G'. The family of all solid sets of a graph can be listed in polynomial time, see [29] and [12, Chapter 7.3]. Hence, we can find all minimal violated sets w.r.t. f, F in polynomial time, by examining the list of solid sets to check (1) whether there is a solid set S that is violated, and (2) whether every proper subset of S that is a solid set is *not* violated. This completes the proof of the theorem. ◀

5 $O(k/u_{min})$-Approximation Algorithm for the Capacitated k-Edge-Connected Subgraph Problem

In this section, we give a $16 \cdot \lceil k/u_{\min} \rceil$-approximation algorithm for the Cap-k-ECSS problem, thereby proving Theorem 5. Our algorithm is based on repeated applications of Theorem 4.

Recall the capacitated k-edge-connected subgraph problem (Cap-k-ECSS): we are given an undirected graph $G = (V, E)$ with edge costs $c \in \mathbb{Q}^E_{\geq 0}$ and edge capacities $u \in \mathbb{Z}^E_{\geq 0}$. The goal is to find a minimum-cost subset of the edges $F \subseteq E$ such that the capacity across any cut in (V, F) is at least k, i.e., $u(\delta_F(S)) \geq k$ for all non-empty sets $S \subsetneq V$.

Proof of Theorem 5. The algorithm is as follows: Initialize $F := \emptyset$. While the minimum capacity of a cut $\delta(S)$, $\emptyset \neq S \subsetneq V$, in (V, F) is less than k, run the approximation algorithm from Theorem 4 with input $G = (V, F)$ and $L = E \setminus F$, to augment all cuts $\delta(S)$, $\emptyset \neq S \subsetneq V$, with $u(\delta(S)) < k$ and obtain a valid augmentation $F' \subseteq L$. Update F by adding F', that is, $F := F \cup F'$. On exiting the while loop, output the set of edges F.

At any step of the algorithm, let λ denote the minimum capacity of a cut in (V, F), i.e., $\lambda := \min\{u(\delta_F(S)) \; : \; \emptyset \subsetneq S \subsetneq V\}$.

The above algorithm outputs a feasible solution since, upon exiting the while loop, λ is at least k. Let $F^* \subseteq E$ be an optimal solution to the Cap-k-ECSS instance. Notice that $F^* \setminus F$ is a feasible choice for F' during any iteration of the while loop. Hence, by Theorem 4, $c(F') \leq 16 \cdot c(F^*)$. We claim that the above algorithm requires at most $\lceil \frac{k}{u_{min}} \rceil$ iterations of the while loop. This holds because each iteration of the while loop (except possibly the last iteration) raises λ by at least u_{min}. (At the start of the last iteration, $k - \lambda$ could be less than u_{min}, and, at the end of the last iteration, λ could be equal to k). Hence, at the end of the algorithm, $c(F) \leq 16 \cdot \lceil \frac{k}{u_{min}} \rceil c(F^*)$. This completes the proof. ◀

We remark that our new result (Theorem 4) is critical for the bound of $\lceil \frac{k}{u_{min}} \rceil$ on the number of iterations of this algorithm. Earlier methods only allowed augmentations of minimum cuts, so such methods may require as many as $\Omega(k)$ iterations. (In more detail, the earlier methods would augment the cuts of (V, F) of capacity λ but would not augment the cuts of capacity $\geq \lambda + 1$; thus, cuts of capacity $\lambda + 1$ could survive the augmentation step.)

6 $O(1)$-Approximation Algorithm for $(p, 2)$-FGC

In this section, we present a 20-approximation algorithm for $(p, 2)$-FGC, by applying our results from Section 3.

Recall (from Section 1) that the algorithmic goal in $(p, 2)$-FGC is to find a minimum-cost edge-set F such that for any pair of unsafe edges $e, f \in F \cap \mathcal{U}$, the subgraph $(V, F \setminus \{e, f\})$ is p-edge connected.

Our algorithm works in two stages. First, we compute a feasible edge-set F_1 for $(p, 1)$-FGC on the same input graph, by applying the 4-approximation algorithm of [5]. We then augment the subgraph (V, F_1) using additional edges. Since F_1 is a feasible edge-set for $(p, 1)$-FGC, any cut $\delta(S)$, $\emptyset \subsetneq S \subsetneq V$, in the subgraph (V, F_1) either (i) has at least p safe edges or (ii) has at least $p + 1$ edges (see below for a detailed argument). Thus the cuts that need to be augmented have exactly $p + 1$ edges and contain at least two unsafe edges. Let us call such cuts *deficient*. Augmenting all deficient cuts by at least one (safe or unsafe) edge will ensure that we have a feasible solution to $(p, 2)$-FGC.

The following example shows that when p is odd, then the function f in the f-connectivity problem associated with $(p, 2)$-FGC may *not* be an uncrossable function. In other words, the indicator function $f : 2^V \to \{0, 1\}$ of the sets S such that $\delta(S)$ is a deficient cut could violate the definition of an uncrossable function.

▶ **Example 19.** We construct the graph G by starting with a 4-cycle v_1, v_2, v_3, v_4, v_1 and then replacing each edge of the 4-cycle by a pair of parallel edges; thus, we have a 4-regular graph with 8 edges; we designate the following four edges as unsafe (and the other four edges are safe): both copies of edge $\{v_1, v_4\}$, one copy of edge $\{v_1, v_2\}$, and one copy of edge $\{v_3, v_4\}$. Clearly, G is a feasible instance of $(3, 1)$-FGC. On the other hand, G is infeasible for $(3, 2)$-FGC, and the cuts $\delta(\{v_1, v_2\})$ and $\delta(\{v_2, v_3\})$ are deficient. Note that the function $f : \{v_1, v_2, v_3, v_4\} \to \{0, 1\}$ that has $f(\{v_1, v_2\}) = f(\{v_2, v_3\}) = f(\{v_1\}) = f(\{v_4\}) = 1$ and $f(S) = 0$ for all other $S \subseteq V$ is not uncrossable (observe that the cuts $\delta(v_2)$ and $\delta(v_3)$ are not deficient). Moreover, observe that the minimal violated set $C = \{v_2, v_3\}$ crosses the violated set $S = \{v_1, v_2\}$.

Proof of Theorem 6. In the following, we use F to denote the set of edges picked by the algorithm at any step of the execution; we mention that our correctness arguments are valid despite this ambiguous notation; moreover, we use $\delta(S)$ rather than $\delta_F(S)$ to refer to a cut of the subgraph (V, F), where $\emptyset \neq S \subseteq V$.

Since F is a feasible edge-set for $(p, 1)$-FGC, any cut $\delta(S)$ (where $\emptyset \neq S \subseteq V$) either (i) has at least p safe edges or (ii) has at least $p + 1$ edges. Consider a node-set S that violates the requirements of the $(p, 2)$-FGC problem. We have $\emptyset \neq S \subsetneq V$ and there exist two unsafe edges $e, f \in \delta(S)$ such that $|\delta_F(S) \setminus \{e, f\}| \leq p - 1$. Since F is feasible for $(p, 1)$-FGC, we have $|\delta(S) \setminus \{e\}| \geq p$ and $|\delta(S) \setminus \{f\}| \geq p$. Thus, $|\delta_F(S)| = p + 1$. In other words, the node-sets S that need to be augmented have exactly $p + 1$ edges in $\delta(S)$, at least two of which are unsafe edges. Augmenting all such violated sets by at least one (safe or unsafe) edge will result in a feasible solution to $(p, 2)$-FGC. Let $f : 2^V \to \{0, 1\}$ be the indicator function of these violated sets. Observe that f is symmetric, that is, $f(S) = f(V \setminus S)$ for any

$S \subseteq V$; this additional property of f is useful for our arguments. We claim that f is a pliable function that satisfies property (γ), hence, we obtain an $O(1)$-approximation algorithm for $(p, 2)$-FGC, via the primal-dual method and Theorem 3.

Our proof of the following key lemma is presented in [3, Section 5].

▶ **Lemma 20.** *f is a pliable function that satisfies property (γ). Moreover, for even p, f is an uncrossable function.*

Lastly, we show that there is a polynomial-time subroutine for computing the minimal violated sets. Consider the graph (V, F). Note that size of a minimum cut of (V, F) is at least p since F is a feasible edge-set for $(p, 1)$-FGC. The violated sets are subsets $S \subseteq V$ such that $\delta(S)$ contains exactly $p+1$ edges, at least two of which are unsafe edges. Clearly, all the violated sets are contained in the family of sets S such that $\delta(S)$ is a 2-approximate min-cut of (V, F); in other words, $\{S \subsetneq V \ : \ p \leq |\delta(S)| \leq 2p\}$ contains all the violated sets. It is well known that the family of 2-approximate min-cuts in a graph can be listed in polynomial time, see [22, 28]. Hence, we can find all violated sets and all minimally violated sets in polynomial time.

Thus, we have a 20-approximation algorithm for $(p, 2)$-FGC via the primal-dual algorithm of [33] based on our results in Section 3. Furthermore, for even p, the approximation ratio is $6 (= 4 + 2)$ since the additive approximation-loss for the augmenting step is 2 when f is uncrossable (see Theorem 9). This completes the proof of Theorem 6. ◀

A Missing Proofs from Section 3

This section has several lemmas and proofs from Section 3 that are used to prove our main result, Theorem 3.

▶ **Lemma 21.** *Suppose S_1 is a witness for edge e_1 and S_2 is a witness for edge e_2 such that S_1 overlaps S_2. Then there exist S_1' and S_2' satisfying the following properties:*

(i) *S_1' is a valid witness for edge e_1, S_2' is a valid witness for edge e_2, and S_1' does not overlap S_2'.*
(ii) *$S_1', S_2' \in \{S_1, S_2, S_1 \cup S_2, S_1 \cap S_2, S_1 \setminus S_2, S_2 \setminus S_1\}$.*
(iii) *either $S_1' = S_1$ or $S_2' = S_2$.*

Proof. We perform an exhaustive case analysis to check that the lemma is true. Note that at least two of the four sets $S_1 \cup S_2, S_1 \cap S_2, S_1 \setminus S_2, S_2 \setminus S_1$ must be violated in the current iteration. We consider the following cases.

1. If $S_1 \cup S_2$ and $S_1 \cap S_2$ are violated or $S_1 \setminus S_2$ and $S_2 \setminus S_1$ are violated, then the proof of Lemma 5.2 in [33] can be applied.
2. If $S_1 \cup S_2$ and $S_1 \setminus S_2$ are violated, then consider where the end-nodes of the edges e_1 and e_2 lie. If $e_1 \in E(S_1 \setminus S_2, V \setminus (S_1 \cup S_2))$ and $e_2 \in E(S_1 \setminus S_2, S_1 \cap S_2)$, then we can set $S_1' = S_1 \cup S_2$ and $S_2' = S_2$. The other possibilities for e_1 and e_2 are handled similarly.
3. If $S_1 \cap S_2$ and $S_1 \setminus S_2$ are violated, again consider where the end-nodes of the edges e_1 and e_2 lie. If $e_1 \in E(S_1 \setminus S_2, V \setminus (S_1 \cup S_2))$ and $e_2 \in E(S_1 \setminus S_2, S_1 \cap S_2)$, then we can set $S_1' = S_1 \cap S_2$ and $S_2' = S_2$. The other possibilities for e_1 and e_2 are handled similarly.

This completes the proof of the lemma. ◀

▶ **Lemma 22.** *Suppose a set A_1 overlaps a set A_2 and a third set A_3 does not overlap A_1 nor A_2. Then A_3 does not overlap any of the sets $A_1 \cup A_2, A_1 \cap A_2, A_1 \setminus A_2, A_2 \setminus A_1$.*

Proof. Note that since A_3 does not overlap A_1 (or A_2), they are either disjoint or one contains the other. We consider the following cases.

1. Suppose $A_3 \cap A_1 = \emptyset$. Then $A_2 \not\subseteq A_3$ since $A_1 \cap A_2 \neq \emptyset$. If $A_3 \cap A_2 = \emptyset$, then $A_3 \subseteq V \setminus A_1 \cup A_2$ and we are done. Finally if $A_3 \subseteq A_2$, then $A_3 \subseteq A_2 \setminus A_1$ and we are done.
2. Suppose $A_1 \subseteq A_3$. Then $A_3 \cap A_2 \neq \emptyset$ since $A_1 \cap A_2 \neq \emptyset$. Also, $A_3 \not\subseteq A_2$ since $A_1 \not\subseteq A_2$. If $A_2 \subseteq A_3$, then $A_1 \cup A_2 \subseteq A_3$ and we are done.
3. Suppose $A_3 \subseteq A_1$. Then $A_2 \not\subseteq A_3$ since $A_2 \setminus A_1 \neq \emptyset$. If $A_3 \subseteq A_2$, then $A_3 \subseteq A_1 \cap A_2$ and we are done. Finally if $A_3 \cap A_2 = \emptyset$, then $A_3 \subseteq A_1 \setminus A_2$ and we are done. ◀

▶ **Lemma 11.** *There exists a laminar family of witness sets.*

Proof. We show that any witness family can be uncrossed and made laminar. We prove this by induction on the size of the witness family ℓ.

Base Case: Suppose $\ell = 2$, then one application of Lemma 21 is sufficient.

Inductive Hypothesis: If $S_1, \ldots, S_\ell$ are witness sets for edges $e_1, \ldots, e_\ell$ respectively with $\ell \leq k$, then, by repeatedly applying Lemma 21, one can construct witness sets $S'_1, \ldots, S'_\ell$ for the edges $e_1, \ldots, e_\ell$ respectively such that $S'_1, \ldots, S'_\ell$ is a laminar family.

Inductive Step: Consider $k+1$ witness sets $S_1, \ldots, S_{k+1}$. By the inductive hypothesis, we can uncross all the witness sets $S_1, \ldots, S_k$ to obtain witness sets $S'_1, \ldots, S'_k$ that form a laminar family. We now consider the following cases.

1. If S_{k+1} does not overlap some S'_i, say S'_1, then we can apply the inductive hypothesis to the k sets $S'_2, \ldots, S'_k, S_{k+1}$ and we obtain a laminar family of witness sets, none of which overlap S'_1 either (by Lemma 22) and so we are done.
2. Suppose S_{k+1} overlaps all the sets $S'_1, \ldots, S'_k$ and for some S'_i, say S'_1, applying Lemma 21 to the pair S'_1, S_{k+1} gives S'_1, S'_{k+1}. Then S'_1 does not overlap any of the witness sets $S'_2, \ldots, S'_{k+1}$, hence, applying the inductive hypothesis to these k sets gives us a laminar family of witness sets $S''_2, \ldots, S''_k$. By Lemma 22, S'_1 does not overlap any of the sets $S''_2, \ldots, S''_k$ and so we are done.
3. Suppose S_{k+1} overlaps all the sets $S'_1, \ldots, S'_k$ and, for every S'_i, applying Lemma 21 to the pair S'_i, S_{k+1} gives S''_i, S_{k+1}. Then after doing this for every S'_i, we end up with the witness family $S''_1, \ldots, S''_k, S_{k+1}$ with the property that S_{k+1} does not overlap any of the other sets. Applying the inductive hypothesis to the k sets $S''_1, \ldots, S''_k$ gives us a laminar family of witness sets $S'''_1, \ldots, S'''_k$. By Lemma 22, S_{k+1} does not overlap any of the sets $S'''_1, \ldots, S'''_k$ and so we are done. ◀

B Optimal Dual Solutions with Non-Laminar Supports

In this section, we describe an instance of the AugSmallCuts problem where none of the optimal dual solutions (to the dual LP given in (2.1), Section 2) have a laminar support. Recall that the connectivity requirement function f for the AugSmallCuts problem is pliable and satisfies property (γ), as seen in the proof of Theorem 4.

Consider the graph $G = (V, E)$ (shown in Figure 1 below using solid edges) which is a cycle on 4 nodes $1, 2, 3, 4$, in that order. Edge-capacities are given by $u_{12} = 3, u_{23} = 4, u_{34} = 2, u_{41} = 1$. The link-set (shown using dashed edges) is $L = \{12, 23, 34, 41\}$, a disjoint copy of E. Link-costs are given by $c_{12} = c_{23} = c_{34} = 1$ and $c_{41} = 2$.

Consider the AugSmallCuts instance that arises when we choose $\widetilde{\lambda} = 6$. The family of small cuts (with capacity strictly less than $\widetilde{\lambda}$) is given by $\bigcup_{S \in \mathcal{A}} \{S, V \setminus S\}$, where

$$\mathcal{A} = \{\{1\}, \{1,2\}, \{2,3\}, \{1,2,3\}\}.$$

The associated pliable function f satisfies $f(S) = 1$ if and only if $S \in \mathcal{A}$ or $V \setminus S \in \mathcal{A}$ holds. Observe that f is *not* uncrossable since $f(\{1,2\}) = 1 = f(\{2,3\})$, but $f(\{1,2\} \cap \{2,3\}) = f(\{2\}) = 0$ and $f(\{2,3\} \setminus \{1,2\}) = f(\{3\}) = 0$. Also note that the minimal violated set $\{2,3\}$ (w.r.t. $F = \emptyset$) crosses the violated set $\{1,2\}$.

It can be seen that there are three inclusion-wise minimal link-sets that are feasible for the above instance and these are given by

$$\mathcal{C} := \{\{12, 23, 34\}, \{12, 41\}, \{34, 41\}\}.$$

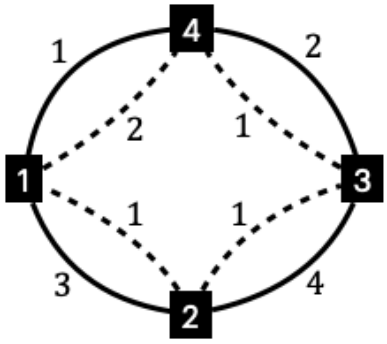

Figure 1 An instance of the AugSmallCuts problem where none of the optimal dual solutions have a laminar support.

Since each $F \in \mathcal{C}$ has cost 3, the optimal value for the instance is 3. Next, since L contains at least two links from every nontrivial cut, the vector $x \in [0,1]^L$ with $x_e = \frac{1}{2}$, $\forall e \in L$ is a feasible augmentation for the fractional version of the instance, i.e., x is feasible for the primal LP given in (2.1), Section 2. Therefore, the optimal value of the primal LP is at most $\frac{5}{2}$.

Now, consider the dual LP, which is explicitly stated below. The dual packing-constraints are listed according to the following ordering of the links: $12, 23, 34, 41$. For notational convenience, we use the shorthand y_1 to denote the dual variable $y_{\{1\}}$ corresponding to the set $\{1\}$. We use similar shorthand to refer to the dual variables of the other sets; thus, y_{234} refers to the dual variable $y_{\{2,3,4\}}$, etc.

$$
\begin{array}{lccccccccc}
\max & (y_1 + y_{234}) & + & (y_{12} + y_{34}) & + & (y_{23} + y_{14}) & + & (y_{123} + y_4) & & \\
\text{subject to:} & (y_1 + y_{234}) & & & + & (y_{23} + y_{14}) & & & \leq & 1 \\
& & & (y_{12} + y_{34}) & & & & & \leq & 1 \\
& & & & & (y_{23} + y_{14}) & + & (y_{123} + y_4) & \leq & 1 \\
& (y_1 + y_{234}) & + & (y_{12} + y_{34}) & & & + & (y_{123} + y_4) & \leq & 2 \\
& & & & & & & y & \geq & 0.
\end{array}
$$

Observe that adding all packing constraints gives $2 \cdot \sum_{S \in \mathcal{A}} (y_S + y_{V \setminus S}) \leq 5$, hence, the optimal value of the dual LP is at most $5/2$. Moreover, a feasible dual solution with objective $5/2$ must satisfy the following conditions:

$$y_1 + y_{234} = y_{23} + y_{14} = y_{123} + y_4 = \frac{1}{2} \quad \text{and} \quad y_{12} + y_{34} = 1.$$

Clearly, there is at least one solution to the above set of equations, hence, by LP duality, the optimal value of both the primal LP and the dual LP is $5/2$.

Furthermore, any optimal dual solution y^* satisfies $\max(y^*_S, y^*_{V \setminus S}) > 0$ for all $S \in \mathcal{A}$ (by the above set of equations). We conclude by arguing that for any optimal dual solution y^*, its support $\mathcal{S}(y^*) = \{S \subseteq V : y^*_S > 0\}$ is non-laminar, because some two sets $A, B \in \mathcal{S}(y^*)$ cross. Since the relation A crosses B is closed under taking set-complements (w.r.t. the ground-set V), we may assume w.l.o.g. that the support contains each set in $\mathcal{A} = \{\{1\}, \{1,2\}, \{2,3\}, \{1,2,3\}\}$. The support of y^* is not laminar because $\{1,2\}$ and $\{2,3\}$ cross.

Approximation Algorithms for Envy-Free Cake Division with Connected Pieces

Siddharth Barman

Abstract

Cake cutting is a classic model for studying fair division of a heterogeneous, divisible resource among agents with individual preferences. Addressing cake division under a typical requirement that each agent must receive a connected piece of the cake, we develop approximation algorithms for finding envy-free (fair) cake divisions. In particular, this work improves the state-of-the-art additive approximation bound for this fundamental problem. Our results hold for general cake division instances in which the agents' valuations satisfy basic assumptions and are normalized (to have value 1 for the cake). Furthermore, the developed algorithms execute in polynomial time under the standard Robertson-Webb query model.

Prior work has shown that one can efficiently compute a cake division (with connected pieces) in which the additive envy of any agent is at most 1/3. An efficient algorithm is also known for finding connected cake divisions that are (almost) 1/2-multiplicatively envy-free. Improving the additive approximation guarantee and maintaining the multiplicative one, we develop a polynomial-time algorithm that computes a connected cake division that is both $\left(\frac{1}{4} + o(1)\right)$-additively envy-free and $\left(\frac{1}{2} - o(1)\right)$-multiplicatively envy-free. Our algorithm is based on the ideas of interval growing and envy-cycle elimination.

In addition, we study cake division instances in which the number of distinct valuations across the agents is parametrically bounded. We show that such cake division instances admit a fully polynomial-time approximation scheme for connected envy-free cake division.

1 Introduction

Cake cutting is an exemplar of fair division literature [9, 22, 21]. Since the foundational work of Steinhaus, Banach, and Knaster [24], fair cake division has been extensively studied over decades, and it continues to inspire research, including algorithmic breakthroughs [4], deep mathematical connections [17, 20], and applicable variants [16]. This fair-division model captures resource-allocation domains in which a divisible, heterogeneous resource (metaphorically, the cake) needs to be fairly divided among agents with individual, distinct preferences. For instance, cake division has been studied in the context of border negotiations [9] and fair electricity division [5]. The predominant fairness notion of envy-freeness was also defined in

the cake-division context [14]. This solution concept deems a cake division to be fair if each agent values the piece assigned to her over that of any other agent, i.e., if the agents are not envious of each other.

Formally, the cake is modeled as the interval $[0, 1]$ and the cardinal preferences of the n participating agents (over pieces of the cake) are expressed via valuation functions $v_1, \ldots, v_n$; in particular, $v_i(I) \in \mathbb{R}_+$ denotes the value that agent i has for any interval $I \subseteq [0, 1]$. In this work, we address cake division under the requirement that every agent must receive a connected piece (i.e., an interval) of the cake. That is, our goal is to partition the cake $[0, 1]$ into exactly n pairwise-disjoint intervals and assign them among the n agents. This connectivity requirement is standard in literature and is motivated by practical settings wherein each agent must receive a contiguous part of the resource; consider, for instance, division of land or non-preemptive scheduling. Hence, in this setup, an envy-free (i.e., fair) division corresponds to a partition of $[0, 1]$ into n pairwise-disjoint intervals, $I_1, I_2, \ldots, I_n$, such that assigning each interval I_i to agent $i \in [n]$ results in no envy, i.e., $v_i(I_i) \geq v_i(I_j)$, for all agents $i, j \in [n]$.

The significance of envy-freeness is elevated by universal existential guarantees: under benign assumptions on agents' valuations, an envy-free cake division, in which each agent receives a connected piece, is guaranteed to exist [25, 23, 27]. Here, the elegant proof of Su [27] is considered a foundational result across all of fair division. These strong existential results, however, do not have an algorithmic counterpart. Stromquist [26] has shown that even a finite-time algorithm does not exist for computing an envy-free cake division with connected pieces; this negative result holds in a model where the valuations are specified via an (adversarial) oracle. Furthermore, it is known that, under ordinal preferences, achieving envy-freeness with connected pieces is PPAD-hard [12].

These algorithmic barriers in route to finding exact envy-free cake divisions necessitate the study of approximation guarantees. The current paper contributes to this research thread by developing algorithms for finding connected cake divisions that are approximately envy-free. In particular, this work improves the state-of-the-art additive approximation bound for this fundamental fair division problem.

Our Results and Techniques. Our algorithmic results hold for general cake division instances in which the agents' valuations satisfy basic assumptions and are normalized, such that the value for the entire cake for every agent is equal to one, i.e., $v_i([0, 1]) = 1$ for all agents $i \in [n]$. Furthermore, the developed algorithms execute in the standard Robertson-Webb query model [21].

We address both additive and multiplicative approximations of envy-freeness. Specifically, for parameter $\varepsilon \in (0, 1)$, a connected cake division $I_1, \ldots I_n$ (in which interval I_i is assigned to agent $i \in [n]$) is said to be ε-envy-free (ε-EF) iff no agent has more than ε envy towards any other agent, i.e., $v_i(I_i) \geq v_i(I_j) - \varepsilon$ for all agents $i, j \in [n]$. Analogously, an α-multiplicatively envy-free (α-mult-EF) cake division $I_1, \ldots I_n$ is one in which the envy is multiplicatively bounded within a factor of α, i.e., $v_i(I_i) \geq \alpha v_i(I_j)$ for all agents $i, j \in [n]$; here parameter $\alpha \in (0, 1]$.

Our main result is a polynomial-time algorithm that computes a cake division (with connected pieces) that is simultaneously $\left(\frac{1}{4} + c\right)$-EF and $\left(\frac{1}{2} - c'\right)$-mult-EF (Theorems 13 and 14); here, c and c' are polynomially small (in n) terms. For instance, our algorithm can be used to efficiently find a cake division that is 0.251-EF and 0.499-mult-EF.

Our result improves upon the previously best known additive approximation guarantee. Specifically, prior work of Goldberg et al. [15] provides an efficient algorithm for computing a $\frac{1}{3}$-EF cake division (with connected pieces); here, the computed allocation can leave some

agents with no cake allocated to them and, hence, incur unbounded multiplicative envy. On the multiplicative front, for a lower order term κ, Arunachaleswaran et al. [3] obtain a $\left(\frac{1}{2} - \kappa\right)$-mult-EF guarantee, in conjunction with an additive envy bound close to $\frac{1}{3}$. Therefore, for envy-free cake division, we improve the additive approximation guarantee from $\frac{1}{3}$ to (almost) $\frac{1}{4}$, while maintaining the best known multiplicative one.

Our algorithm extends the interval-growing method of [3] with the idea of bifurcating intervals (see Definition 3). Such intervals satisfy the property that if an agent i receives an interval that is bifurcating with respect to v_i, then irrespective of how the rest of the cake is assigned, agent i's envy towards others remains bounded. For the algorithm's design and analysis, we modify each agent's valuation to have a preference for bifurcating intervals. With these modified valuations, we build upon the idea of interval growing. In particular, we first obtain an allocation of (pairwise disjoint) intervals that might partially cover the entire cake, though induce bounded envy among the agents and against the unassigned intervals. Then, we use an envy-cycle-elimination idea to further allocate small pieces till at most n unassigned intervals remain. Envy-graphs and the cycle-elimination method have been extensively utilized in fair division; see, e.g., [19]. However, their use for *contiguous* cake cutting (i.e., division under the contiguity requirement) is novel. We employ cycle elimination in such a way that envy remains bounded as we allocate more and more of the cake. Finally, we have n assigned and at most n unassigned intervals. We pair up adjacent assigned and unassigned intervals to overall obtain a complete partition of the cake that has bounded envy; see Section 3.1 for a detailed description of the algorithm.

It is relevant to note the technical distinctions between the algorithm of Arunachaleswaran et al. [3] and the current one. In contrast to the prior work, the current algorithm executes with a novel modification of the valuations (to incorporate preferences towards bifurcating intervals). Moreover, the current analysis is more involved; in particular, the analysis requires multiple new lemmas and consideration of intricate cases (see, e.g., Lemmas 6 to 11 and the case analysis in the proof of Theorem 13).

Our second result addresses cake division instances in which the number of distinct valuations is bounded. Specifically, we consider instances in which, for a parameter $\varepsilon \in (0, 1)$ and across the n agents, the number of *distinct* valuations is at most $(\varepsilon n - 1)$. For such instances with bounded heterogeneity, we provide an algorithm that computes ε-EF allocations in time polynomial in n and $\frac{1}{\varepsilon}$ (Theorem 16). Note that such settings naturally generalize the case of identical valuations. Fair division algorithms under identical valuations have been developed in many contexts (beyond cake division). Our result shows that, under this natural generalization, a strong additive approximation guarantee can be obtained for connected envy-free cake division; see Section 4.[1]

Additional Related Work. Prior works in (connected) cake division have also studied improved approximation guarantees for specific valuation classes. For instance, it is shown in [7] that a connected cake division with arbitrarily small envy can be computed efficiently if the agents' value densities satisfy the monotone likelihood ratios property. Another studied valuation class is that of single-block valuations; in particular, these correspond to valuations in which the agents have a constant density over some (agent-specific) interval of cake and zero everywhere else. The work of Alijani et al. [1] provides an efficient algorithm for finding (exact) envy-free cake division under single-block valuations that satisfy an ordering property.

[1] We also detail at the end of the Section 4 that achieving multiplicative approximation bounds for envy under bounded heterogeneity is as hard as it is in the general case.

For arbitrary single-block valuations (without the ordering property), Goldberg et al. [15] obtain a $\frac{1}{4}$-EF guarantee. They also obtain NP-hardness results for connected envy-free cake division under additional constraints, such as conforming to a given cut point.

Focussing on query complexity, Brânzei and Nisan [10] show that an ε-EF cake division (with connected pieces) can be computed in a query efficient manner but the algorithm runs in time exponential in n and $\frac{1}{\varepsilon}$. By contrast, we develop polynomial-time algorithms.

The study of approximation guarantees – to bypass computational or existential barriers – is an established research paradigm in theoretical computer science. For instance, in discrete fair division, (multiplicative) approximation bounds for the maximin share has received significant attention in recent years; see [2] and multiple references therein. Also, in algorithmic game theory, approximation guarantees for Nash equilibria in two-player games have been extensively studied; see, e.g., [11, 28, 18]. Our work contributes to this thematic thread with a focus on cake division.

Non-Contiguous Cake Division. Algorithmic aspects of (exact) envy-free cake division remain challenging even without the connectivity requirement. In fact, the existence of a finite-time algorithm for noncontiguous envy-free cake division remained open until the work of Brams and Taylor [8]. For noncontiguous envy-free cake divisions, an explicit runtime bound – albeit a hyper-exponential one – was obtained in the notable work of Aziz and Mackenzie [4]. Prior works have also addressed non-contiguous envy-free cake division for special valuation classes: [1] obtains a polynomial-time algorithm for finding (exact, but not necessarily contiguous) envy-free cake divisions under single-block valuations. Also, [29] develops a polynomial-time algorithm for computing non-contiguous envy-free cake divisions under single-peaked preferences. For the non-contiguous setting, [19] provides a fully polynomial-time approximation scheme for computing approximate envy-free cake divisions.

2 Notation and Preliminaries

We consider fair division of a divisible, heterogeneous good – i.e., a cake – among n agents. The cake is modeled as the interval $[0, 1]$, and the cardinal preferences of the agents $i \in [n]$ over the cake are expressed via valuation functions v_i. In particular, $v_i(I) \in \mathbb{R}_+$ denotes the valuation that agent $i \in [n]$ has for any interval $I = [x, y] \subseteq [0, 1]$; here, $0 \leq x \leq y \leq 1$. As in prior works (see, e.g., [21]), we will address valuations $\{v_i\}_{i=1}^n$ that are (i) nonnegative: $v_i(I) \geq 0$ for all intervals $I \subseteq [0, 1]$, (ii) normalized: $v_i([0, 1]) = 1$ for all agents i, (iii) divisible: for any interval $[x, y] \subseteq [0, 1]$ and scalar $\lambda \in [0, 1]$, there exists a point $z \in [x, y]$ with the property that $v_i([x, z]) = \lambda v_i([x, y])$, and (iv) additive: $v_i(I \cup J) = v_i(I) + v_i(J)$ for any pair of disjoint intervals $I, J \subseteq [0, 1]$.

These properties ensure that for all agents $i \in [n]$ and each interval $I \subseteq [0, 1]$ we have $0 \leq v_i(I) \leq 1$. Also, note that, since the valuations v_i are divisible, they are non-atomic: $v_i([x, x]) = 0$ for all points $x \in [0, 1]$. Relying on this property, we will throughout regard, as a convention, two intervals to be disjoint even if they intersect exactly at an endpoint. Our algorithms efficiently execute in the standard Robertson-Webb query model [22], that provides access to the agents' valuations via the following queries:

- **(i)** Evaluation queries, $\mathsf{Eval}_i(x, y)$: Given points $0 \leq x \leq y \leq 1$, the oracle returns the value that agent i has for the interval $[x, y]$, i.e., returns $v_i([x, y])$.
- **(ii)** Cut queries, $\mathsf{Cut}_i(x, \nu)$: Given an initial point $x \in [0, 1]$ and a value $\nu \in (0, 1)$, the oracle returns the leftmost point $y \in [x, 1]$ with the property that $v_i([x, y]) \geq \nu$. If no such y exists, the response to the query is 1.

Allocations. The current work addresses fair cake division under the requirement that each agent must receive a connected piece. That is, we focus solely on assigning to each agent a single sub-interval of $[0,1]$. Specifically, in a cake division instance with n agents, an allocation is defined as an n-tuple of pairwise-disjoint intervals, $\mathcal{I} = (I_1, I_2, \ldots, I_n)$, where interval I_i is assigned to agent $i \in [n]$ and $\bigcup_{i=1}^{n} I_i = [0,1]$. In addition, we will use the term partial allocation to refer to an n-tuple of pairwise-disjoint intervals $\mathcal{P} = (P_1, \ldots, P_n)$ that do not necessarily cover the entire cake, $\cup_{i\in[n]} P_i \subsetneq [0,1]$. Note that, in an allocation $\mathcal{J} = (J_1, J_2, \ldots, J_n)$, partial or complete, each interval J_i is indexed to identify the agent i that owns the interval, and not how the intervals are ordered within $[0,1]$.

Furthermore, for a partial allocation $\mathcal{P} = (P_1, \ldots, P_n)$, write $\mathcal{U}_{\mathcal{P}} = \{U_1, \ldots, U_t\}$ to denote the collection of unassigned intervals that remain after the assigned ones (i.e., P_is) are removed from $[0,1]$. Formally, $\mathcal{U}_{\mathcal{P}} = \{U_1, \ldots, U_t\}$ is the minimum-cardinality collection of disjoint intervals that satisfy $\bigcup_i U_i = [0,1] \setminus \left(\bigcup_{j=1}^{n} P_j\right)$.

Approximate Envy-Freeness. The fairness notions studied in this work are defined next. An allocation $\mathcal{E} = (E_1, \ldots, E_n)$ is said to be envy free (EF) iff each agent prefers the interval assigned to her over that of any other agent, $v_i(E_i) \geq v_i(E_j)$ for all agents $i, j \in [n]$. This paper addresses both additive and multiplicative approximations of envy-freeness.

▶ **Definition 1** (ε-EF). *In a cake division instance with n agents and for a parameter $\varepsilon \in (0,1)$, an (partial) allocation $\mathcal{I} = (I_1, I_2, \ldots, I_n)$ is said to be ε-additively envy-free (ε-EF) iff $v_i(I_i) \geq v_i(I_j) - \varepsilon$, for all agents $i, j \in [n]$.*

▶ **Definition 2** (α-mult-EF). *For a parameter $\alpha \in (0,1)$, an (partial) allocation $\mathcal{I} = (I_1, I_2, \ldots, I_n)$ is said to be α-multiplicatively envy-free (α-mult-EF) iff, for all agents $i, j \in [n]$, we have $v_i(I_i) \geq \alpha\ v_i(I_j)$.*

3 Approximation Algorithm for Envy-Free Cake Division

This section develops an algorithm for efficiently computing a cake division (with connected pieces) that is $\left(\frac{1}{4} + o(1)\right)$-EF and $\left(\frac{1}{2} - o(1)\right)$-mult-EF.

For the design of the algorithm, we will use the notion of bifurcating intervals. For an agent i, a bifurcating interval X satisfies the property that, if i is assigned interval X, then one can divide the rest of the cake in any way and still agent i will have at most $1/4$ envy towards any other agent. Formally,

▶ **Definition 3** (Bifurcating Intervals). *An interval $[x,y] \subseteq [0,1]$ is said to be a bifurcating interval for an agent $i \in [n]$ iff*

$$v_i([x,y]) \geq \frac{1}{4}, \qquad v_i([0,x]) \leq \frac{1}{2}, \qquad \text{and} \quad v_i([y,1]) \leq \frac{1}{2}.$$

For each agent $i \in [n]$, we extend the valuation v_i to a function $\widehat{v}_i$ which codifies a preference towards bifurcating intervals. Formally, for each agent $i \in [n]$ and any interval $X \subseteq [0,1]$, define

$$\widehat{v}_i(X) \coloneqq \begin{cases} 1 & \text{if } X \text{ is bifurcating for } i. \\ v_i(X) & \text{if } X \text{ is not bifurcating for } i. \end{cases} \tag{1}$$

We note that, in contrast to the valuation v_i, the function $\widehat{v}_i$ is not additive.[2] However, analogous to v_i, the function $\widehat{v}_i$ is monotonic, normalized, and nonnegative. In addition, given access to $\mathsf{Eval}_i()$ queries, we can efficiently compute $\widehat{v}_i(X)$ for any interval $X \subseteq [0,1]$. We will show in the analysis that the algorithm's steps involving $\widehat{v}_i$s can be implemented efficiently, given Robertson-Webb query access to the underlying valuations. The claim below provides a bound on the value of non-bifurcating intervals.

▷ Claim 4. For any agent $i \in [n]$, if $Y \subseteq [0,1]$ is *not* a bifurcating interval, then, $\widehat{v}_i(Y) = v_i(Y) < \frac{1}{2}$.

Proof. All intervals $H \subseteq [0,1]$ of value $v_i(H) \geq \frac{1}{2}$ are bifurcating; see Definition 3 and recall that the agents' valuations are normalized, $v_i([0,1]) = 1$. Hence, for any non-bifurcating interval $Y \subseteq [0,1]$ we have $v_i(Y) < \frac{1}{2}$, i.e., $\widehat{v}_i(Y) = v_i(Y) < \frac{1}{2}$ (see equation (1)). ◁

We will also use the construct of an envy-graph. Specifically, for a partial allocation $\mathcal{P} = (P_1, \ldots, P_n)$, an envy-graph $G_{\mathcal{P}}$ is a directed graph over n vertices. Here, the vertices represent the n agents and a directed edge, from vertex i to vertex j, is included in the graph iff $\widehat{v}_i(P_i) < \widehat{v}_i(P_j)$. Envy-graphs and the cycle-elimination algorithm (detailed next) have been extensively utilized in discrete fair division; see, e.g., [19]. However, their use for *contiguous* cake cutting is novel.

We will next show that, if for any partial allocation $\mathcal{P} = (P_1, \ldots, P_n)$, the envy-graph $G_{\mathcal{P}}$ contains a cycle, then we can in fact resolve the cycle – by reassigning the intervals – and eventually obtain a partial allocation $\mathcal{Q} = (Q_1, \ldots, Q_n)$ whose envy-graph $G_{\mathcal{Q}}$ is acyclic.[3]

▶ **Lemma 5.** *Given any partial allocation $\mathcal{P} = (P_1, \ldots, P_n)$, one can reassign the intervals P_is among the agents and efficiently find another partial allocation $\mathcal{Q} = (Q_1, \ldots, Q_n)$ with the properties that*

(i) *The envy-graph $G_{\mathcal{Q}}$ is acyclic.*

(ii) *The value $\widehat{v}_i(Q_i) \geq \widehat{v}_i(P_i)$, for all agents $i \in [n]$.*

The proof of Lemma 5 is standard and, for completeness, is provided in Appendix A. Recall that, for any partial allocation $\mathcal{P} = (P_1, \ldots, P_n)$, the set $\mathcal{U}_{\mathcal{P}} = \{U_1, \ldots, U_t\}$ denotes the collection of unassigned intervals that remain after the intervals P_is are removed from $[0,1]$. Also, note that for any partial allocation $\mathcal{P} = (P_1, \ldots, P_n)$, we have $|\mathcal{U}_{\mathcal{P}}| \leq n + 1$.

3.1 Interval Growing and Cycle Elimination

Our algorithm (Algorithm 1) consists of two phases. In Phase I (Lines 2 to 6 in Algorithm 1), which we call the interval growing phase, the algorithm starts with empty intervals – i.e., $P_i = \emptyset$ for all i – and iteratively grows these intervals while maintaining bounded envy among the agents. In particular, to extend a partial allocation $\mathcal{P} = (P_1, \ldots, P_n)$, we first judiciously select an unassigned interval $U \in \mathcal{U}_{\mathcal{P}}$ and then assign an inclusion-wise minimal sub-interval of U to an agent a. The sub-interval of U and agent a are selected such that the function value, $\widehat{v}_a$, increases appropriately and, at the same time, the envy towards a (from any other agents) remains bounded. Note that, in this phase, the cake might not be allocated completely, but the invariant of bounded envy is maintained throughout. Phase I terminates with a partial allocation $\overline{\mathcal{P}} = (\overline{P}_1, \ldots, \overline{P}_n)$ under which each agent $i \in [n]$ has bounded envy towards the other agents and towards all the unassigned intervals $U \in \mathcal{U}_{\overline{\mathcal{P}}}$ (see Lemma 8).

[2] Also, the function $\widehat{v}_i$ is not divisible.

[3] Here, the reassignment of the intervals implies that there exists a permutation $\pi \in \mathbb{S}_n$ such that $Q_i = P_{\pi(i)}$ for all agents i.

Algorithm 1 Approximation Algorithm for Connected Cake Division.

Input: A cake division instance with oracle access to the valuations $\{v_i\}_{i=1}^n$ of the n agents and a fixed constant $\delta \in (0,1)$.

Output: A complete allocation $(I_1, \ldots, I_n)$.

1: Initialize partial allocation $\mathcal{P} = (P_1, \ldots, P_n) = (\emptyset, \ldots, \emptyset)$ and $\mathcal{U}_\mathcal{P} = \{[0,1]\}$.
2: **while** there exists an unassigned interval $U = [\ell, r] \in \mathcal{U}_\mathcal{P}$ and an agent $i \in [n]$ such that $\widehat{v}_i(U) \geq \widehat{v}_i(P_i) + \frac{\delta}{n}$ **do**
3: Let $C \coloneqq \left\{i \in [n] \ : \widehat{v}_i(U) \geq \widehat{v}_i(P_i) + \frac{\delta}{n}\right\}$ and, for every agent $i \in C$, set $r_i \in [\ell, r]$ to be the leftmost point such that $\widehat{v}_i([\ell, r_i]) \geq \widehat{v}_i(P_i) + \frac{\delta}{n}$.
4: Select agent $a \in \arg\min_{i \in C} \ r_i$ and update the partial allocation $\mathcal{P}$: assign $P_a \leftarrow [\ell, r_a]$ and keep the interval assignment of all other agents unchanged.
5: Update $\mathcal{U}_\mathcal{P}$ to be the collection of intervals that are left unassigned under the current partial allocation $\mathcal{P}$.
6: **end while**
7: **while** $|\mathcal{U}_\mathcal{P}| > n$ **do**
8: Update $\mathcal{P} = (P_1, \ldots, P_n)$ following Lemma 5 to ensure that the envy-graph $G_\mathcal{P}$ is acyclic.
9: Let $s \in [n]$ be a source vertex in the graph $G_\mathcal{P}$, with assigned interval $P_s = [\ell_s, r_s]$.
10: Let $\widetilde{U} = [r_s, \widetilde{r}] \in \mathcal{U}_\mathcal{P}$ be the unassigned interval that is adjacent (on the right) to P_s. {Since $|\mathcal{U}_\mathcal{P}| > n$, such an interval $\widetilde{U}$ is guaranteed to exist.}
11: Write $x \in [r_s, \widetilde{r}]$ to be the point with the property that $v_i([r_s, x]) \leq \frac{\delta}{n}$ for all agents i and this inequality is tight for at least one agent. Append $P_s \leftarrow P_s \cup [r_s, x]$. {If for all agents the value of $\widetilde{U}$ is at most $\frac{\delta}{n}$, then append $P_s \leftarrow P_s \cup \widetilde{U}$.}
12: **end while**
13: Index the unassigned intervals $U_j \in \mathcal{U}_\mathcal{P}$ such that each U_j is adjacent to a *distinct* interval P_j, for all j. {Since $|\mathcal{U}_\mathcal{P}| \leq n$, such an indexing is possible.}
14: For all agents i, set interval $I_i = P_i \cup U_i$. {If an unassigned interval is not associated with P_i, then set $I_i = P_i$.}
15: **return** allocation $\mathcal{I} = (I_1, \ldots, I_n)$.

At the end of Phase I, it is possible that the number of unassigned intervals is $n+1$. The objective of Phase II (Lines 7 to 12 in the algorithm) is to reduce the number of unassigned intervals, while maintaining bounded envy between the agents and against the unassigned intervals. Towards this, we use the cycle-elimination method (Lemma 5) to first ensure that for the maintained partial allocation $\mathcal{P}$ the envy-graph $G_\mathcal{P}$ is acyclic. Now, given that the directed graph $G_\mathcal{P}$ is acyclic, it necessarily admits a source vertex $s \in [n]$, i.e., a vertex s with no incoming edges. Furthermore, by the definition of the envy graph, we get that no agent has sufficiently high envy towards the source vertex $s \in [n]$. With this guarantee in hand, we enlarge the interval assigned to s (i.e., enlarge P_s) while maintaining bounded envy overall. Specifically, we append to P_s a piece of small enough value from the unassigned interval $\widetilde{U}$ adjacent to P_s. Since $|\mathcal{U}_\mathcal{P}| = n+1$, an unassigned interval, adjacent to P_s, is guaranteed to exist. Also, note that this extension ensures that P_s continues to be a connected piece of the cake, i.e., agent s continues to receive a single interval. Performing such updates, Phase II efficiently finds a partial allocation $\mathcal{P}$ with the property that $|\mathcal{U}_\mathcal{P}| \leq n$. Since at the end of Phase II the number of unassigned intervals is at most n, we can associate each unassigned interval $U \in \mathcal{U}_\mathcal{P}$ with a *distinct* assigned interval P_j that is adjacent to U. We merge each assigned interval P_i with the associated and adjacent unassigned interval U_i (if any) to obtain

the interval I_i for each agent $i \in [n]$. The intervals $I_1, I_2, \ldots, I_n$ completely partition the cake $[0, 1]$ and constitute the returned allocation $\mathcal{I} = (I_1, I_2, \ldots, I_n)$. In Appendix A.1, we will prove that the two phases run in polynomial time under the Robertson-Webb query model. We now establish the approximation guarantee of the Algorithm.

3.2 Approximation Guarantee

We first note a monotonicity property with respect to the function values, $\widehat{v}_i$s, satisfied during the execution of the algorithm.

▶ **Lemma 6.** *For any agent $i \in [n]$, the function values $\widehat{v}_i$ of the assigned intervals, P_is, are nondecreasing through the execution of Algorithm 1.*

Proof. To establish the monotonicity under $\widehat{v}_i$ in Phase I, consider any iteration for the first while-loop. Here, for the selected agent $a \in [n]$, the value of the assigned interval, under $\widehat{v}_a$, in fact increases and for all the other agents it continues to be the same. Hence, the lemma holds throughout Phase I. The monotonicity is also maintained during the execution of Phase II: the value under $\widehat{v}_i$ does not decrease in Line 8 (Lemma 5) or in Line 11. Therefore, the lemma stands proved. ◀

Next, we assert that, throughout the execution of the algorithm, the assigned intervals satisfy an inclusion-wise minimality property. Note that in the following lemma we evaluate agent i's assigned interval under the function $\widehat{v}_i$ and evaluate the compared interval X under the valuation v_i.

▶ **Lemma 7.** *Let $\mathcal{P}' = (P'_1, \ldots, P'_n)$ be any partial allocation considered during the execution of Algorithm 1. Then, for any two assigned intervals P'_i and $P'_j = [\ell'_j, r'_j]$ along with any strict subset $X = [\ell'_j, x] \subsetneq P'_j$ (i.e., $x < r'_j$), we have $v_i(X) < \widehat{v}_i(P'_i) + \frac{\delta}{n}$.*

Proof. We establish the lemma via an inductive argument. Indeed, the initial partial allocation $(\emptyset, \ldots, \emptyset)$ satisfies the desired property. Now, consider any iteration of the first-while loop, and write $\mathcal{P}'' = (P''_1, \ldots, P''_n)$ to be the partial allocation that gets updated (in this iteration) to $\mathcal{P}' = (P'_1, \ldots, P'_n)$. In particular, let a be the agent selected in Line 4. Note that for all the other agents $i \neq a$, the assigned interval remains unchanged, $P'_i = P''_i$. Also, the induction hypothesis implies that $\mathcal{P}''$ satisfies the lemma. Hence, for all the agents $i, j \neq a$ (whose assigned intervals have not changed), the desired property continues to hold. Furthermore, agent a receives an interval of higher function value, $\widehat{v}_a(P'_a) \geq \widehat{v}_a(P''_a) + \delta/n$. Hence, we have the lemma from agent a against any other agent j.

It remains to show that the lemma holds between P'_i and $P'_a = [\ell'_a, r'_a]$. Assume, towards a contradiction, that there exists a strict subset $X = [\ell'_a, x] \subsetneq P'_a$ such that $v_i(X) \geq \widehat{v}_i(P'_i) + \delta/n$. Since $P'_i = P''_i$ and $\widehat{v}_i(X) \geq v_i(X)$, we obtain $\widehat{v}_i(X) \geq \widehat{v}_i(P''_i) + \delta/n$. This, however, contradicts the selection criterion in Lines 3 and 4. In particular, this bound implies $r_i < r_a$ (see Line 3) and, hence, a would not be the selected agent in Line 4. Therefore, by way of contradiction, we have that the property holds with respect to P'_a as well.

The above-mentioned arguments prove that the lemma holds for all allocations considered in Phase I. Next, we show that it continues to hold through Phase II.

Consider any iteration of the second while-loop, and write $\mathcal{P}'' = (P''_1, \ldots, P''_n)$ to be the partial allocation that gets updated in this iteration. The induction hypothesis gives us that $\mathcal{P}''$ satisfies the desired property. In Line 8 the intervals are reassigned among the agents (i.e., the collection of intervals remains unchanged) and for each agent i, the value, under $\widehat{v}_i$, of the assigned interval does not decrease; see Lemma 5. Hence, the property continues

to hold after Line 8. For analyzing the rest of the iteration, let $s \in [n]$ denote the (source) agent that gets selected in Line 9 and P'_s be the updated interval for agent s; in particular, interval P'_s is obtained by appending a piece to P''_s. Since s is the only agent whose interval got updated here, the lemma continues to hold between all other agents $i, j \neq s$. Also, the property is maintained from agent s's perspective, since $\widehat{v}_s(P'_s) \geq \widehat{v}_s(P''_s)$. To complete the proof we will next show that the property is upheld between P'_i and P'_s, for any $i \in [n]$.

Note that, for agent $i \neq s$, the assigned interval remains unchanged during the current update, $P'_i = P''_i$. Furthermore, the fact that s is a source vertex gives us

$$\widehat{v}_i(P''_i) \geq \widehat{v}_i(P''_s) \geq v_i(P''_s) \tag{2}$$

The extension of P''_s to P'_s (performed in Line 11) ensures that $v_i(P'_s) \leq v_i(P''_s) + \delta/n$. Hence, inequality (2) gives us $v_i(P'_s) \leq \widehat{v}_i(P'_i) + \delta/n$. That is, there does not exist an $X \subsetneq P'_s$ with the property that $v_i(X) \geq \widehat{v}_i(P'_i) + \delta/n$. This completes the proof. ◀

The next lemma provides a bounded envy guarantee for the partial allocation $\overline{\mathcal{P}} = (\overline{P}_1, \ldots, \overline{P}_n)$ computed by Phase I. Note that in this lemma, while considering envy from agent i to agent j, we evaluate $\overline{P}_i$ with respect to $\widehat{v}_i$ and evaluate $\overline{P}_j$ under v_i.

▶ **Lemma 8.** *Let $\overline{\mathcal{P}} = (\overline{P}_1, \ldots, \overline{P}_n)$ be the partial allocation maintained by Algorithm 1 at the end of Phase* I *(i.e., at the termination of the first while-loop). Then, for all agents $i, j \in [n]$ and all unassigned intervals $U \in \mathcal{U}_{\overline{\mathcal{P}}}$, we have*

$$\widehat{v}_i(\overline{P}_i) \geq v_i(\overline{P}_j) - \frac{\delta}{n} \qquad \text{and} \qquad \widehat{v}_i(\overline{P}_i) \geq v_i(U) - \frac{\delta}{n}.$$

Proof. Fix an arbitrary agent $i \in [n]$ and consider any unassigned interval $U \in \mathcal{U}_{\overline{\mathcal{P}}}$. The execution condition of the first while-loop ensures that at termination it holds that $\widehat{v}_i(\overline{P}_i) \geq \widehat{v}_i(U) - \frac{\delta}{n} \geq v_i(U) - \frac{\delta}{n}$; the last inequality directly follows from the definition of $\widehat{v}_i$. This establishes the desired inequalities with respect to the unassigned intervals.

Next, for any assigned interval $\overline{P}_j = [\overline{\ell}_j, \overline{r}_j]$, assume, towards a contradiction, that $v_i(\overline{P}_j) > \widehat{v}_i(\overline{P}_i) + \delta/n$. Since the valuation v_i is divisible (see Section 2),[4] there exists a strict subset $X = [\overline{\ell}_j, x] \subsetneq \overline{P}_j$ with the property that $v_i(X) = \widehat{v}_i(\overline{P}_i) + \delta/n$. This, however, contradicts Lemma 7 (instantiated with $\mathcal{P}' = \overline{\mathcal{P}}$). The lemma stands proved. ◀

Next, we show that the bounded envy guarantee obtained at the end of Phase I (as stated in Lemma 8) continues to hold in Phase II.

▶ **Lemma 9.** *Let $\mathcal{P} = (P_1, \ldots, P_n)$ be the partial allocation maintained by Algorithm 1 at the end of Phase* II*. Then, for all agents $i, j \in [n]$ and all unassigned intervals $U \in \mathcal{U}_{\mathcal{P}}$, we have*

$$\widehat{v}_i(P_i) \geq v_i(P_j) - \frac{\delta}{n} \qquad \text{and} \qquad \widehat{v}_i(P_i) \geq v_i(U) - \frac{\delta}{n}.$$

Proof. Let $\overline{\mathcal{P}} = (\overline{P}_1, \ldots, \overline{P}_n)$ be the partial allocation maintained by Algorithm 1 at the end of Phase I. Note that $\mathcal{U}_{\overline{\mathcal{P}}}$ and $\mathcal{U}_{\mathcal{P}}$ denote the collection of unassigned intervals left at the end of Phase I and Phase II, respectively. We observe that, for all unassigned intervals $U \in \mathcal{U}_{\mathcal{P}}$, there exists an unassigned interval $\overline{U} \in \mathcal{U}_{\overline{\mathcal{P}}}$ such that $U \subseteq \overline{U}$. These containments

[4] Here, we invoke divisibility of v_i with factor $\alpha = \frac{\widehat{v}_i(\overline{P}_i) + \delta/n}{v_i(\overline{P}_j)} \in (0, 1)$. Also, note that, in contrast to v_i, the function $\widehat{v}_i$ is not divisible.

follow from the fact that in each iteration of the second while-loop (i.e., in Phase II) we either reassign the allocated intervals (which preserves the collection of the unassigned ones) or we enlarge a chosen assigned interval (Line 11); under such an enlargement, one of the unassigned intervals gets reduced and the others remain unchanged.

Furthermore, Lemma 6 gives us $\widehat{v}_i(P_i) \geq \widehat{v}_i(\overline{P}_i) \geq v_i(\overline{U}) - \delta/n$, for any interval $\overline{U} \in \mathcal{U}_{\overline{P}}$; here, the last inequality follows from Lemma 8. Using this bound and the above-mentioned containment of unassigned intervals we get $\widehat{v}_i(P_i) \geq v_i(U) - \delta/n$, for all $U \in \mathcal{U}_{\mathcal{P}}$. This establishes the desired inequalities with respect to the unassigned intervals.

Next, for any assigned interval $P_j = [\ell_j, r_j]$, assume, towards a contradiction, that $v_i(P_j) > \widehat{v}_i(P_i) + \delta/n$. Since the valuation v_i is divisible, there exists a strict subset $X = [\ell_j, x] \subsetneq P_j$ with the property that $v_i(X) = \widehat{v}_i(P_i) + \delta/n$. This, however, contradicts Lemma 7 (instantiated with $\mathcal{P}' = \mathcal{P}$). The lemma stands proved. ◀

The following lemma shows that, at the end of Phase I, if an agent i does not receive a bifurcating interval but some other agent j does, then j's interval cannot be bifurcating (for i) with an additional margin of $\frac{\delta}{n}$. Formally,[5]

▶ **Lemma 10.** *Let $\overline{\mathcal{P}} = (\overline{P}_1, \ldots, \overline{P}_n)$ be the partial allocation maintained by Algorithm 1 at the end of Phase* I*. If, for an agent $i \in [n]$, the assigned interval $\overline{P}_i$ is* not *bifurcating (for i), but interval $\overline{P}_j = [\overline{\ell}_j, \overline{r}_j]$ is bifurcating (for i). Then, at least one of the following inequalities holds:*

$$v_i(\overline{P}_j) < \frac{1}{4} + \frac{\delta}{n} \qquad \text{or} \qquad v_i([\overline{r}_j, 1]) > \frac{1}{2} - \frac{\delta}{n}.$$

Proof. Assume, towards a contradiction, that the bifurcating interval $\overline{P}_j = [\overline{\ell}_j, \overline{r}_j]$ has value $v_i(\overline{P}_j) \geq \frac{1}{4} + \frac{\delta}{n}$ and $v_i([\overline{r}_j, 1]) \leq \frac{1}{2} - \frac{\delta}{n}$. These properties in fact imply the existence of a strict subset $X \subsetneq \overline{P}_j$ that is bifurcating for i: write $x \in [\overline{\ell}_j, \overline{r}_j]$ to denote the leftmost point that satisfies $v_i([\overline{\ell}_j, x]) = v_i(\overline{P}_j) - \frac{\delta}{n}$ and set $X = [\overline{\ell}_j, x]$. Since valuation v_i is divisible, such a point x exists and we have $x < \overline{r}_j$. Furthermore, the lower bound on the value of $\overline{P}_j$ gives us $v_i(X) \geq \frac{1}{4}$. In addition, note that $v_i([0, \overline{\ell}_j]) \leq 1/2$, since $\overline{P}_j = [\overline{\ell}_j, \overline{r}_j]$ is bifurcating. Also, using the inequality $v_i([\overline{r}_j, 1]) \leq \frac{1}{2} - \frac{\delta}{n}$ and the additivity of the valuation v_i, we get that $v_i([x, 1]) \leq \frac{1}{2}$. Indeed, these bounds ensure that X is a strict subset of $\overline{P}_j$ and is bifurcating for agent i.

The existence of X contradicts the selection criterion in Lines 3 and 4. In particular, consider the iteration in which $\overline{P}_j$ was assigned and write P'_i to denote the interval assigned to agent i during that iteration. We note that

$$\begin{aligned} \widehat{v}_i(P'_i) &\leq \widehat{v}_i(\overline{P}_i) && \text{(via Lemma 6)} \\ &< \frac{1}{2} && (\overline{P}_i \text{ is non-bifurcating \& Claim 4}) \end{aligned}$$

On the other hand, $\widehat{v}_i(X) = 1$, for the interval X identified above. Hence, j would not be the selected agent in Line 4. This contradiction establishes the lemma. ◀

We next prove that a guarantee, analogous to Lemma 10, holds for Phase II as well.[6]

[5] Note that, in contrast to Lemmas 8 and 9, here we have an absolute bound on the value of the compared interval $\overline{P}_j$.

[6] As in Lemma 10, here we have an absolute bound on the value of the compared interval P_j.

▶ **Lemma 11.** *Let $\mathcal{P} = (P_1, \ldots, P_n)$ be the partial allocation maintained by Algorithm 1 at the end of Phase* II*. If, for an agent $i \in [n]$, the assigned interval P_i is* not *bifurcating (for i), but interval $P_j = [\ell_j, r_j]$ is bifurcating (for i). Then, at least one of the following inequalities holds:*

$$v_i(P_j) < \frac{1}{4} + \frac{\delta}{n} \qquad \text{or} \qquad v_i([r_j, 1]) > \frac{1}{2} - \frac{\delta}{n}.$$

Proof. Write $\overline{\mathcal{P}} = (\overline{P}_1, \ldots, \overline{P}_n)$ to denote the partial allocation at the end of Phase I. Note that, throughout Phase II, the algorithm either reassigns the intervals (Line 8) or appends (unassigned) pieces to them (Line 11). Hence, for the interval P_j, assigned to agent j at the end of Phase II, there exists $\overline{P}_k$, for some $k \in [n]$, such that $P_j \supseteq \overline{P}_k$.

We assume, towards a contradiction, that the bifurcating interval $P_j = [\ell_j, r_j]$ has value $v_i(P_j) \geq \frac{1}{4} + \frac{\delta}{n}$ and $v_i([r_j, 1]) \leq \frac{1}{2} - \frac{\delta}{n}$. It cannot be the case that $P_j = \overline{P}_k$ (for an interval $\overline{P}_k$ assigned at the end of Phase I), since this would contradict Lemma 10. Hence, in the remainder of the proof we address the complementary case wherein P_j was obtained by appending to an interval, say P'_s, in an iteration of the second while-loop (specifically, Line 11). Also, write P'_i to denote the interval assigned to agent i during that iteration. Lemma 6 and the fact that P_i is non-bifurcating for i (Claim 4) give us $\widehat{v}_i(P'_i) \leq \widehat{v}_i(P_i) < 1/2$. Using this inequality and the fact that s was a source agent during the iteration under consideration, we get

$$\widehat{v}_i(P'_s) \leq \widehat{v}_i(P'_i) < 1/2 \tag{3}$$

However, the assumptions on the values of $P_j = [\ell_j, r_j]$ and $[r_j, 1]$ contradict inequality (3): Let z denote the right endpoint of P'_s, i.e., $P'_s = [\ell_j, z]$. Since a piece of bounded value is appended in Line 11, we have $v_i(P'_s) \geq v_i(P_j) - \frac{\delta}{n} \geq \frac{1}{4}$. Furthermore, using the inequality $v_i([r_j, 1]) \leq \frac{1}{2} - \frac{\delta}{n}$, we obtain $v_i([z, 1]) \leq \frac{1}{2}$. In addition, the fact that $P_j = [\ell_j, r_j]$ is a bifurcating interval gives us $v_i([0, \ell_j)) \leq \frac{1}{2}$, i.e., the value to the left of $P'_s = [\ell_j, z]$ is at most $1/2$. These observations imply that P'_s is a bifurcating interval for i; in particular, $\widehat{v}_i(P'_s) = 1$. This bound contradicts inequality (3) and completes the proof. ◀

Using Lemma 9, we next obtain a relevant envy bound for the allocation $\mathcal{I}$ returned by the algorithm.

▶ **Lemma 12.** *The allocation $\mathcal{I} = (I_1, \ldots, I_n)$ computed by Algorithm 1 satisfies $v_i(I_i) \geq \frac{1}{2} v_i(I_j) - \frac{\delta}{n}$, for all agents $i, j \in [n]$.*

Proof. Write $\mathcal{P} = (P_1, \ldots, P_n)$ to denote the partial allocation of the algorithm at the end of Phase II. The execution condition of the second while-loop ensures that $|\mathcal{U}_{\mathcal{P}}| \leq n$. Also, at the end of the algorithm, for each unassigned interval $U \in \mathcal{U}_{\mathcal{P}}$, we select a distinct and adjacent interval P_j and associate U with P_j. In particular, let U_j be the unassigned interval associated with P_j. If P_j is not associated with any unassigned interval, then set $U_j = \emptyset$. Indeed, $I_j = P_j \cup U_j$ is a connected piece of the cake, i.e., an interval.

For any agent $i \in [n]$, if interval I_i is bifurcating, then $v_i(I_i) \geq \frac{1}{4}$. Furthermore, any other assigned interval I_j is either completely to the left of I_i or to the right of I_i. In either case, by the definition of bifurcating intervals, we have $v_i(I_j) \leq \frac{1}{2}$. Hence, for agents i that receive a bifurcating interval I_i, we have the stated inequality, $v_i(I_i) \geq \frac{1}{2} v_i(I_j)$.

It remains to show that the lemma holds for agents i for whom I_i is not bifurcating. For such agents, the interval $P_i \subseteq I_i$ is also non-bifurcating and, hence, $v_i(P_i) = \widehat{v}_i(P_i)$. Therefore,

$$v_i(I_i) \geq v_i(P_i) \geq v_i(P_j) - \frac{\delta}{n} \quad \text{and} \quad v_i(I_i) \geq v_i(P_i) \geq v_i(U_j) - \frac{\delta}{n} \quad \text{(via Lemma 9)}$$

Summing we get

$$2v_i(I_i) \geq v_i(P_j) + v_i(U_j) - \frac{2\delta}{n} = v_i(I_j) - \frac{2\delta}{n} \qquad \text{(since } v_i \text{ is additive)}$$

Hence, we obtain the stated inequality, $v_i(I_i) \geq \frac{1}{2}v_i(I_j) - \frac{\delta}{n}$. This completes the proof. ◀

We now establish the main result of this section.

▶ **Theorem 13.** *Given any cake division instance – with Robertson-Webb query access to the valuations of the n agents – and parameter $\delta \in (0, 1)$, Algorithm 1 computes a connected cake division (i.e., an allocation) $\mathcal{I} = (I_1, \ldots, I_n)$ that is $\left(\frac{1}{4} + \frac{2\delta}{n}\right)$-EF. The algorithm executes in time that is polynomial in n and $\frac{1}{\delta}$.*

Proof. Fix any agent $i \in [n]$. We establish the theorem by considering three complementary and exhaustive cases, based on the interval I_i (assigned to agent i):
Case 1: Interval I_i is bifurcating,
Case 2: Value $v_i(I_i) < \frac{1}{4}$,
Case 3: Interval I_i is not bifurcating and $v_i(I_i) \geq \frac{1}{4}$.

In Case 1, since interval I_i is bifurcating for agent i, we have $v_i(I_i) \geq \frac{1}{4}$ and, for any other interval I_j (either to the left of I_i or to its right), we have $v_i(I_j) \leq \frac{1}{2}$. Therefore, in this case, the stated approximation bound on envy holds, $v_i(I_i) \geq v_i(I_j) - \frac{1}{4}$.

In Case 2, value $v_i(I_i) < \frac{1}{4}$. Note that, Lemma 12 gives us $v_i(I_i) \geq \frac{1}{2}v_i(I_j) - \frac{\delta}{n}$, for any other agent $j \in [n]$. Multiplying both sides of this inequality by 2 and simplifying we obtain

$$v_i(I_i) \geq v_i(I_j) - v_i(I_i) - \frac{2\delta}{n} \geq v_i(I_j) - \frac{1}{4} - \frac{2\delta}{n} \qquad \text{(since } v_i(I_i) < \tfrac{1}{4}\text{)}$$

Therefore, in Case 2 as well, for agent i the envy is additively at most $\left(\frac{1}{4} + \frac{2\delta}{n}\right)$.

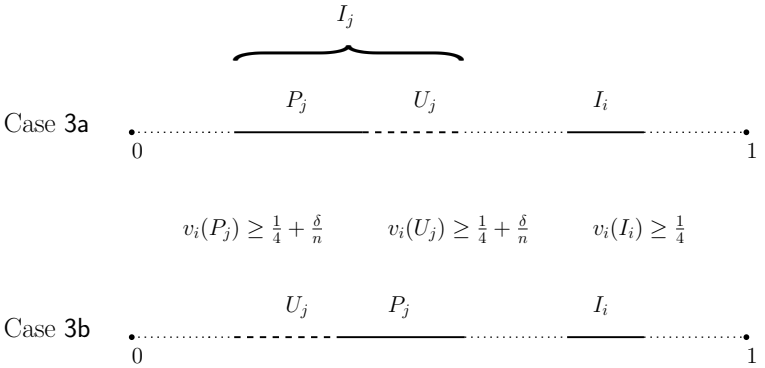

Figure 1 Placement of intervals P_j and U_j in Case 3.

Finally, in Case 3, interval I_i is not bifurcating and $v_i(I_i) \geq \frac{1}{4}$. Write $\mathcal{P} = (P_1, \ldots, P_n)$ to denote the partial allocation at the end of Phase II and recall that $I_k = P_k \cup U_k$, for each agent $k \in [n]$ and the associated unassigned interval $U_k \in \mathcal{U}_{\mathcal{P}}$. For analyzing this case, assume, towards a contradiction, that there exists an interval I_j that violates the stated approximate envy-freeness bound, i.e.,

$$v_i(I_j) > v_i(I_i) + \frac{1}{4} + \frac{2\delta}{n}. \tag{4}$$

Since, in the current case, $v_i(I_i) \geq \frac{1}{4}$, inequality (4) reduces to $v_i(I_j) > \frac{1}{2} + \frac{2\delta}{n}$. We will further show that for interval I_j the composing sub-intervals P_j and U_j are each of value (under v_i) at least $\frac{1}{4} + \frac{\delta}{n}$. Towards this, note that, in the current case, since I_i is not bifurcating for i, neither is $P_i \subseteq I_i$. Furthermore,

$$\begin{aligned} v_i(I_i) &\geq v_i(P_i) && (v_i \text{ is monotonic}) \\ &= \widehat{v}_i(P_i) && (\text{since } P_i \text{ is not bifurcating for } i) \\ &\geq v_i(P_j) - \frac{\delta}{n} && (5) \end{aligned}$$

The last inequality follows from Lemma 9. A similar application of the lemma also gives us

$$v_i(I_i) \geq v_i(U_j) - \frac{\delta}{n} \tag{6}$$

Inequalities (4), (5), and (6) imply that the values of both P_j and U_j are at least $\frac{1}{4} + \frac{\delta}{n}$. Otherwise, say $v_i(P_j) < \frac{1}{4} + \frac{\delta}{n}$. Then,

$$v_i(I_j) = v_i(P_j) + v_i(U_j) < \frac{1}{4} + \frac{\delta}{n} + v_i(U_j) \leq v_i(I_i) + \frac{1}{4} + \frac{2\delta}{n} \qquad (\text{via inequality (6)})$$

Since the last inequality contradicts assumption (4), we have $v_i(P_j) \geq \frac{1}{4} + \frac{\delta}{n}$. Similarly, $v_i(U_j) \geq \frac{1}{4} + \frac{\delta}{n}$.

As mentioned previously, $v_i(I_j) > \frac{1}{2} + \frac{2\delta}{n}$. Hence, the values to the left and to the right of $I_j = [\ell_j, r_j]$ are upper bounded as follows:[7] $v_i([0, \ell_j]) \leq \frac{1}{2} - \frac{2\delta}{n}$ and $v_i([r_j, 1]) \leq \frac{1}{2} - \frac{2\delta}{n}$.

For the subsequent analysis, we also assume that interval I_j is on the left of I_i (see Figure 1); the proof for the other configuration (of I_j being to the right of I_i) follows analogously. Now, there are two sub-cases to consider:

Case 3a: Interval P_j is to the left of U_j (i.e., U_j lies between P_j and I_i).

Case 3b: Interval P_j is to the right of U_j (i.e., P_j lies between U_j and I_i).

In Case 3a, we note that the interval $U_j \in \mathcal{U}_{\mathcal{P}}$ is bifurcating for agent i: As observed above, $v_i(U_j) \geq \frac{1}{4} + \frac{\delta}{n}$ and the value (in the cake) to the right of U_j is equal to $v_i([r_j, 1]) \leq \frac{1}{2} - \frac{2\delta}{n}$. In addition, the value to the left of U_j is at most $1 - (v_i(U_j) + v_i(I_i)) \leq 1 - \frac{1}{4} - \frac{1}{4} - \frac{\delta}{n} = \frac{1}{2} - \frac{\delta}{n}$; interval I_i is to the right to I_j and, hence, to the right of U_j. Hence, $U_j \in \mathcal{U}_{\mathcal{P}}$ is bifurcating for agent i.

Also, the design of Phase II ensures that, for the interval U_j, there exists an unassigned interval $\overline{U} \in \mathcal{U}_{\overline{\mathcal{P}}}$ such that $\overline{U} \supseteq U_j$; here $\overline{\mathcal{P}} = (\overline{P}_1, \ldots, \overline{P}_n)$ denotes the partial allocation at the end of Phase I. Since U_j is bifurcating for i, so is $\overline{U}$. By contrast, in the current case (Case 3), the interval P_i is not bifurcating for i and, hence, neither is $\overline{P}_i$ (Lemma 6). That is, $\widehat{v}_i(\overline{P}_i) < \frac{1}{2} < 1 = \widehat{v}_i(\overline{U})$. The bound, however, contradicts the termination of the first while-loop. Therefore, by way of contradiction, we get that assumption (4) cannot hold in Case 3a. This completes the analysis of this sub-case.

In Case 3b, we note that the interval P_j is bifurcating for agent i, with a margin of $\frac{\delta}{n}$: As observed above, $v_i(P_j) \geq \frac{1}{4} + \frac{\delta}{n}$ and the value to the right of P_j is equal to $v_i([r_j, 1]) \leq \frac{1}{2} - \frac{2\delta}{n}$. In addition, the value to the left of P_j is at most $1 - (v_i(P_j) + v_i(I_i)) \leq 1 - \frac{1}{4} - \frac{1}{4} - \frac{\delta}{n} = \frac{1}{2} - \frac{\delta}{n}$. The existence of such a bifurcating interval P_j contradicts Lemma 11. Hence, even in Case 3b, we must have $v_i(I_j) \leq v_i(I_i) + \frac{1}{4} + \frac{2\delta}{n}$, i.e., the stated bound on envy holds.

This completes the analysis for all the cases, and the theorem stands proved. ◀

[7] Recall that the value of the entire cake is normalized, $v_i([0, 1]) = 1$.

Complementing the additive envy-freeness guarantee obtained in Theorem 13, the next result establishes that, in the computed allocation $\mathcal{I}$, the envy is within a factor of $(2+c)$, where parameter $c \in (0,1)$ is polynomially small (in n).

▶ **Theorem 14.** *Given any cake division instance – with Robertson-Webb query access to the valuations of the n agents – and parameter $c \in (0,1)$, we can compute (in time polynomial in n and $1/c$) a connected cake division (i.e., an allocation) $\mathcal{I} = (I_1, \ldots, I_n)$ that is $\frac{1}{2+c}$-mult-EF.*

Proof. The theorem directly follows from Lemma 12. In particular, we execute Algorithm 1 with parameter $\delta = \frac{c}{8}$, for a sufficiently small $c \in (0,1)$,[8] and note that, for the computed allocation $\mathcal{I}$, Lemma 12 gives us $v_i(I_i) \geq \frac{1}{2} v_i(I_j) - \frac{\delta}{n} = \frac{1}{2} v_i(I_j) - \frac{c}{8n}$, for agents $i, j \in [n]$. Summing over j, we obtain

$$n\ v_i(I_i) \geq \frac{1}{2} \sum_{j=1}^{n} v_i(I_j) - \frac{c}{8} = \frac{1}{2} - \frac{c}{8} \tag{7}$$

The last equality follows from the fact that $I_1, \ldots, I_n$ constitute a complete partition of the cake, with value $v_i([0,1]) = 1$. Since constant $c \leq 1$, inequality (7) reduces to $v_i(I_i) \geq \frac{1}{4n}$, for all agents $i \in [n]$. Therefore, the bound obtained in Lemma 12 can be expressed as

$$v_i(I_i) \geq \frac{1}{2} v_i(I_j) - \frac{c}{8n} \geq \frac{1}{2} v_i(I_j) - \frac{c}{2} v_i(I_i).$$

Simplifying we obtain $(2+c)\, v_i(I_i) \geq v_i(I_j)$, for all agents $i, j \in [n]$. Therefore, the computed allocation is $\frac{1}{2+c}$-mult-EF ◀

4 An ε-EF Algorithm under Bounded Heterogeneity

This section addresses cake division instances in which, for a parameter $\varepsilon \in (0,1)$ and across the n agents, the number of distinct valuations is at most $(\varepsilon n - 1)$. Our algorithm (Algorithm 2) for finding ε-EF allocations in such instances in detailed next.

We first show in Lemma 15 below that the collection of intervals computed by Algorithm 2 cover the entire cake. We will then use this lemma to establish the approximate envy-freeness guarantee in Theorem 16.

▶ **Lemma 15.** *Given any cake division instance in which, across the n agents, the number of distinct valuations is at most $(\varepsilon n - 1)$, Algorithm 2's output $\mathcal{I} = (I_1, \ldots, I_n)$ is a complete allocation, i.e., I_is are pairwise disjoint and $\cup_{i \in [n]} I_i = [0,1]$.*

Proof. By construction, the set of intervals $\mathcal{F}$ populated in Line 4 of Algorithm 2 are pairwise disjoint and cover the entire cake. We will show that the number of intervals in $\mathcal{F}$ is at most n, i.e., $|\mathcal{F}| \leq n$. Since the assigned intervals, I_is, are selected from the set $\mathcal{F}$ (see the for-loop in the algorithm), the cardinality bound implies that no interval in $\mathcal{F}$ remains unassigned. Hence, $\cup_{i \in [n]} I_i = [0,1]$. Also, given that the intervals in $\mathcal{F}$ are pairwise disjoint, so are the I_is. Therefore, $\mathcal{I} = (I_1, \ldots, I_n)$ is a complete allocation.

We complete the proof by establishing that $|\mathcal{F}| \leq n$. Towards this it suffices to show that $|Z| \leq n+1$; see Line 4 and note that $|\mathcal{F}| = |Z| - 1$. In Line 2, for each agent $i \in [n]$, we consider $T+1$ cut points $0 = x_0^i < x_1^i < x_2^i < \ldots < x_{T-1}^i < x_T^i = 1$. The end points of the cake, 0 and 1, are considered for every agent. Moreover, for any two agents, $i, j \in [n]$, with

[8] With this parameter choice, the algorithm executes in time that is polynomial in n and $1/c$.

Algorithm 2 ε-EF under bounded heterogeneity.

Input: A cake division instance with oracle access to the valuations $\{v_i\}_{i=1}^n$ of the n agents along with parameter $\varepsilon \in (0,1)$.
Output: A complete allocation $(I_1, \ldots, I_n)$.

1: Set T to be the smallest integer such that $T\varepsilon \geq 1$, i.e., $T \coloneqq \lceil \frac{1}{\varepsilon} \rceil$.
2: For each agent $i \in [n]$, let $0 = x_0^i < x_1^i < x_2^i < \ldots < x_{T-1}^i < x_T^i = 1$ be the collection of $(T+1)$ cut points that satisfy $v_i([x_{t-1}^i, x_t^i]) = \varepsilon$, for all $1 \leq t \leq T-1$, and $v_i([x_{T-1}^i, x_T^i]) \leq \varepsilon$.
3: Let Z be the union of these cut points $Z \coloneqq \bigcup_{i\in[n]} \{x_0^i, x_1^i, \ldots, x_{T-1}^i, x_T^i\}$
$\{Z$ is not a multiset, i.e., multiple instances of same cut point are not repeated in $Z.\}$
4: Index the points in $Z = \{z_0, z_1, z_2, \ldots, z_r\}$ such that $0 = z_0 < z_1 < z_2 < \ldots < z_r = 1$ and define the collection of intervals $\mathcal{F} \coloneqq \left\{[z_t, z_{t+1}]\right\}_{t=0}^{r-1}$
5: **for** agents $i = 1$ to n **do**
6: If $\mathcal{F} = \emptyset$, then set interval $I_i = \emptyset$. Otherwise, if $\mathcal{F} \neq \emptyset$, then set $I_i = \arg\max_{F\in\mathcal{F}} v_i(F)$ and update $\mathcal{F} \leftarrow \mathcal{F} \setminus \{I_i\}$.
7: **end for**
8: **return** allocation $\mathcal{I} = (I_1, \ldots, I_n)$.

identical valuations, $v_i = v_j$, even the remaining $(T-1)$ points are the same: $x_t^i = x_t^j$ for all $1 \leq t \leq T-1$. Since the number of distinct valuations is at most $(\varepsilon n - 1)$, there are at most $(\varepsilon n - 1)(T-1)$ cut points in Z that are strictly between 0 and 1. Including the endpoints of the cake in the count, we get $|Z| \leq (\varepsilon n - 1)(T-1) + 2 \leq (\varepsilon n - 1)\frac{1}{\varepsilon} + 2$. The last inequality follows from the definition of T; in particular, $T - 1 < \frac{1}{\varepsilon}$. Simplifying we obtain $|Z| \leq n - \frac{1}{\varepsilon} + 2 \leq n + 1$; recall that $\varepsilon \leq 1$. Therefore, $|\mathcal{F}| \leq n$ and the lemma stands proved. ◀

The following theorem establishes that Algorithm 2 finds an allocation $\mathcal{I} = (I_1, \ldots, I_n)$ that satisfies $v_i(I_i) \geq v_i(I_j) - \varepsilon$ for all agents $i, j \in [n]$.

▶ **Theorem 16.** *Given any cake division instance in which, across the n agents, the number of distinct valuations is at most $(\varepsilon n - 1)$, Algorithm 2 (with Robertson-Webb query access to the valuations) computes an ε-EF allocation in polynomial time.*

Proof. The runtime analysis of the algorithm is direct. Also, via Lemma 15, we have that the the returned tuple $\mathcal{I} = (I_1, \ldots, I_n)$ is indeed a complete allocation.

For proving that the algorithm achieves an ε-EF guarantee, consider any agent $i \in [n]$ and interval $I_j = [z_t, z_{t+1}]$, where z_t and z_{t+1} are successive points in the set Z; see Line 4. If $I_j = \emptyset$, then in fact i does not envy j. We will show that $v_i(I_j) \leq \varepsilon$ and, hence, obtain the desired bound: $v_i(I_i) \geq v_i(I_j) - \varepsilon$.

For agent i, write x_s^i to be the largest (rightmost) cut point considered in Line 2 that satisfies $x_s^i \leq z_t$. In particular, $x_{s+1}^i > z_t$. Note that the set Z (see Line 3) contains all the points $x_0^i, x_1^i, \ldots, x_{T-1}^i, x_T^i$; in particular, $x_{s+1}^i \in Z$. In addition, z_t and z_{t+1} are two successive points in Z. Hence, we have $z_{t+1} \leq x_{s+1}^i$ and the interval $I_j = [z_t, z_{t+1}] \subseteq [x_s^i, x_{s+1}^i]$. By construction, $v_i([x_s^i, x_{s+1}^i]) \leq \varepsilon$ and, hence, $v_i(I_j) \leq \varepsilon$. This bound on the valuation of interval I_j implies that the computed allocation is ε-EF. The theorem stands proved. ◀

Note that the algorithm might assign some agents $i \in [n]$ an interval of value of zero; in particular, $I_i = \emptyset$. Imposing the requirement that each agent $i \in [n]$ receives an interval of nonzero value (to i) renders the problem as hard as finding an ε-EF allocation in general cake

division instances (without bounded heterogeneity). To see this, consider any cake division instance (which might not satisfy the bounded heterogeneity condition). Append to the cake another unit length interval and include $\lceil \frac{n+2}{\varepsilon} \rceil$ dummy agents that have identical valuation confined to the appended interval. This new instance satisfies bounded heterogeneity. Now, if each agent in the constructed instance receives an interval of nonzero value, then the appended interval must have been divided among the dummy agents and the underlying cake $[0, 1]$ among the original agents. This way we obtain an ε-EF allocation for the original instance. Furthermore, note that an α-mult-EF guarantee, for any $\alpha > 0$, implies that each agent receives an interval of nonzero value. Therefore, achieving multiplicative approximation bounds for envy under bounded heterogeneity is as hard as the general case.

▶ Remark 17. The discretization method used in Algorithm 2 has been utilized in prior works as well; see [10] and [19]. The relevant insight obtained here is the difference between additive and multiplicative approximations: While one can efficiently achieve an ε-additive approximation under bounded heterogeneity, establishing any multiplicative guarantee is as hard as solving the problem in complete generality.

5 Conclusion and Future Work

Algorithmically, connected envy-free cake division is a challenging and equally intriguing problem at the core of fair division. The proof of existence of envy-free cake divisions (with connected pieces) does not lend itself to efficient (approximation) algorithms and, at the same time, negative results – that rule out, say, a polynomial-time approximation scheme (PTAS) – are not known either. In this landscape, the current work improves upon the previously best-known approximation guarantee for connected envy-free cake division. We develop a computationally efficient algorithm that finds a connected cake division that is simultaneously $(1/4 + o(1))$-EF and $(1/2 - o(1))$-mult-EF. We also show that specifically for instances with bounded heterogeneity, an ε-EF division can be computed in time polynomial in n and $1/\varepsilon$.

In addition to the patent problem of efficiently finding ε-EF connected cake divisions, developing ε-EF algorithms for special valuation classes (such as single-block and single-peaked valuations) is a relevant direction of future work. Inapproximability results – similar to the ones recently obtained for ε-consensus halving [13] – are also interesting.

A Missing Proofs from Section 3

Here, we restate and prove Lemma 5.

▶ **Lemma 5.** *Given any partial allocation $\mathcal{P} = (P_1, \ldots, P_n)$, one can reassign the intervals P_is among the agents and efficiently find another partial allocation $\mathcal{Q} = (Q_1, \ldots, Q_n)$ with the properties that*

(i) *The envy-graph $G_{\mathcal{Q}}$ is acyclic.*

(ii) *The value $\widehat{v}_i(Q_i) \geq \widehat{v}_i(P_i)$, for all agents $i \in [n]$.*

Proof. If, for given partial allocation $\mathcal{P} = (P_1, \ldots, P_n)$, the envy-graph $G_{\mathcal{P}}$ is already acyclic, then we directly obtain the lemma by setting $\mathcal{Q} = \mathcal{P}$. Hence, in the remainder of the proof we consider the case wherein $G_{\mathcal{P}}$ is cyclic.

Write $C = i_1 \to i_2 \to \ldots \to i_k \to i_1$ to denote a cycle in $G_{\mathcal{P}}$. To obtain a new partial allocation $\mathcal{P}' = (P'_1, \ldots, P'_n)$, we reassign the intervals as follows: for all agents j not in the cycle (i.e., $j \notin \{i_1, i_2, \ldots, i_k\}$), set $P'_j = P_j$. Furthermore, for all the agents i_t in the cycle C, with $1 \leq t < k$, we set $P'_{i_t} = P_{i_{t+1}}$ and $P'_{i_k} = P_{i_1}$. That is, each agent in the cycle receives the interval assigned to its successor in the cycle. This reassignment ensures that, for all agents $i \in [n]$, we have $\widehat{v}_i(P'_i) \geq \widehat{v}_i(P_i)$; recall that a directed edge (i, j) is included in the graph $G_{\mathcal{P}}$ iff $\widehat{v}_i(P_i) < \widehat{v}_i(P_j)$.

We will now show that the number of edges in the envy-graph $G_{\mathcal{P}'}$ is strictly smaller than the number of edges in $G_{\mathcal{P}}$. Hence, repeated elimination of cycles leads to an allocation $\mathcal{Q}$ that satisfies the lemma. Note that the collection of intervals assigned in the allocation $\mathcal{P}'$ is the same as the collection of intervals in $\mathcal{P}$. Also, the out-degree of any vertex i in $G_{\mathcal{P}}$ (or in $G_{\mathcal{P}'}$) is equal to the number of bundles P_js (or P'_js) have value (under $\widehat{v}_i$) strictly greater than i's value (again, under $\widehat{v}_i$) for her own bundle. These observations imply that for all agents not in the cycle C, the out-degree is the same in $G_{\mathcal{P}}$ and $G_{\mathcal{P}'}$. Moreover, for all agents i_t in the cycle C, we have $\widehat{v}_{i_t}(P'_{i_t}) > \widehat{v}_{i_t}(P_{i_t})$. Hence, the out-degree of any such agent i_t in $G_{\mathcal{P}}$ is strictly smaller than its out-degree in $G_{\mathcal{P}}$. Therefore, the number of edges in $G_{\mathcal{P}'}$ is strictly smaller than the ones in $G_{\mathcal{P}}$. This strict reduction in the number of edges implies that after a polynomial number of cycle eliminations we obtain an allocation $\mathcal{Q}$ for which $G_{\mathcal{Q}}$ is acyclic and we have $\widehat{v}_i(Q_i) \geq \widehat{v}_i(P_i)$, for all agents $i \in [n]$. The lemma stands proved. ◀

A.1 Runtime Analysis of Algorithm 1

We begin by noting that, given Robertson-Webb query access to the underlying valuation v_is, we can answer cut and evaluation queries for the functions $\widehat{v}_i$ (see equation (1)) in polynomial time. That is, given points $0 \leq x \leq y \leq 1$, we can find $\widehat{v}_i([x, y])$ in polynomial time. Also, given a point $x \in [0, 1]$ and value $\nu \in [0, 1]$, we can efficiently compute the leftmost point y (if one exists) that satisfies $\widehat{v}_i([x, y]) \geq \nu$.

▷ Claim 18. For any agent $i \in [n]$, given Robertson-Webb query access to the valuation v_i, we can answer cut and evaluation queries with respect to the function $\widehat{v}_i$ in polynomial time.

Proof. We first address the evaluation query for $\widehat{v}_i$. Given interval $[x, y] \subseteq [0, 1]$, we use Eval_i to obtain the following three values: $v_i([x, y])$, $v_i([0, x])$, and $v_i([y, 1])$. These three values tell us whether $[x, y]$ is a bifurcating interval for agent i; see Definition 3. If $[x, y]$ is a bifurcating interval, then we have $\widehat{v}_i([x, y]) = 1$. Otherwise, $\widehat{v}_i([x, y]) = v_i([x, y])$.

Now, we consider the cut query for $\widehat{v}_i$. Given a point $x \in [0, 1]$, and a value $\nu \in [0, 1]$, we identify two candidate points y_1 and y_2 and set $y \coloneqq \min\{y_1, y_2\}$ as the leftmost point that satisfies $\widehat{v}_i([x, y]) \geq \nu$. The first candidate point is defined as $y_1 \coloneqq \mathsf{Cut}_i(x, \nu)$, i.e., y_1

is the leftmost point that satisfies $v_i([x, y_1]) = \nu$. The definition of $\widehat{v}_i$ (see equation (1)) implies that $\widehat{v}_i([x, y_1]) \geq v_i([x, y_1)] = \nu$. Still, there could be a point y_2 to the left of y_1 such that the interval $[x, y_2]$ is bifurcating for i and, hence, $\widehat{v}_i([x, y_2]) \geq \nu$. Therefore, the second candidate y_2 is computed by finding the smallest bifurcating interval, if one exists, starting at x. Towards this, we first use the query $\mathsf{Eval}_i(0, x)$ to ensure that $v_i([0, x]) \leq \frac{1}{2}$. If the interval $[0, x]$ is of value more than $1/2$, then we set $y_2 = 1$. In case $v_i([0, x]) \leq \frac{1}{2}$, we set $y_2 \coloneqq \max\{\mathsf{Cut}_i(x, 0.25), \mathsf{Cut}_i(0, 0.5)\}$. Finally, we return the minimum of y_1 and y_2 as the answer y to the cut query for $\widehat{v}_i$.

Overall, we get that both the cut and the evaluation queries for $\widehat{v}_i$ can be answered in polynomial time. This completes the proof. ◁

We now prove that the algorithm executes in polynomial time.

▶ **Lemma 19.** *Given a fixed constant $\delta \in \left(0, \frac{1}{4}\right)$ and any cake division instance with (Robertson-Webb) query access to the valuations of the n agents, Algorithm 1 computes an allocation in time that is polynomial in n and $\frac{1}{\delta}$.*

Proof. We will first establish the time complexity of Phase I of the algorithm. Note that, in every iteration of this phase (i.e., in every iteration of the while-loop between Lines 2 and 6), for some agent $a \in [n]$, the value $\widehat{v}_a(P_a)$ increases additively by at least $\frac{\delta}{n}$; see Lines 3 and 4. Since the functions $\widehat{v}_i$s are monotonic and upper bounded by 1, the first while-loop in the algorithm iterates at most $\frac{n^2}{\delta}$ times. We next show that each iteration of this while-loop can be implemented in polynomial time and, hence, obtain that overall Phase I executes in polynomial time. Note that the execution condition of the while-loop (Line 2) can be evaluated efficiently, since the evaluation query under $\widehat{v}_i$s can be answered in polynomial time (Claim 18). Similarly, the candidate set C in Line 3 can be computed efficiently. Finding the points r_is in Line 3 entails answering cut queries for the functions $\widehat{v}_i$s and this too can be implemented efficiently (Claim 18). Therefore, all the steps in the while-loop can be implemented efficiently, and we get that Phase I terminates in polynomial time.

For Phase II and each maintained partial allocation $\mathcal{P} = (P_1, \ldots, P_n)$, consider the potential $\varphi(\mathcal{P}) \coloneqq \sum_{i=1}^{n} \sum_{j=1}^{n} v_i(P_j)$. In each iteration of the second while-loop (Lines 7 to 12), the assigned region of the cake (i.e., $\cup_{i \in [n]} P_i$) monotonically increases. Indeed, while updating a partial allocation, the intervals might get reassigned among the agents, however, the union $\cup_{i \in [n]} P_i$ increases in each iteration of the second while-loop. Furthermore, in every iteration, for at least one agent i and the selected interval P_s (see Line 11), the value increases by $\frac{\delta}{n}$.[9] Hence, in each iteration, the potential φ increases by at least $\frac{\delta}{n}$. Also, note that the potential is upper bounded by n and, hence, the second while-loop iterates at most $\frac{n^2}{\delta}$ times. Since all the steps in each iteration of the loop can be implemented in polynomial time – including the envy cycle elimination one (Lemma 5) – we get that Phase II itself executes in polynomial time.

The final merging of the intervals takes linear time. This, overall, establishes the polynomial-time complexity of the algorithm. ◀

[9] If the unassigned interval $\widetilde{U}$, considered in Line 11, is of value less than $\frac{\delta}{n}$ for all agents $i \in [n]$, then after that update the number of unassigned intervals (i.e., $|\mathcal{U}_{\mathcal{P}}|$) strictly decreases. Hence, after such an update, the while-loop terminates.

Cumulative Memory Lower Bounds for Randomized and Quantum Computation

Paul Beame

Abstract

Cumulative memory – the sum of space used per step over the duration of a computation – is a fine-grained measure of time-space complexity that was introduced to analyze cryptographic applications like password hashing. It is a more accurate cost measure for algorithms that have infrequent spikes in memory usage and are run in environments such as cloud computing that allow dynamic allocation and de-allocation of resources during execution, or when many multiple instances of an algorithm are interleaved in parallel.

We prove the first lower bounds on cumulative memory complexity for both sequential classical computation and quantum circuits. Moreover, we develop general paradigms for bounding cumulative memory complexity inspired by the standard paradigms for proving time-space tradeoff lower bounds that can only lower bound the maximum space used during an execution. The resulting lower bounds on cumulative memory that we obtain are just as strong as the best time-space tradeoff lower bounds, which are very often known to be tight.

Although previous results for pebbling and random oracle models have yielded time-space tradeoff lower bounds larger than the cumulative memory complexity, our results show that in general computational models such separations cannot follow from known lower bound techniques and are not true for many functions.

Among many possible applications of our general methods, we show that any classical sorting algorithm with success probability at least $1/\mathrm{poly}(n)$ requires cumulative memory $\tilde{\Omega}(n^2)$, any classical matrix multiplication algorithm requires cumulative memory $\Omega(n^6/T)$, any quantum sorting circuit requires cumulative memory $\Omega(n^3/T)$, and any quantum circuit that finds k disjoint collisions in a random function requires cumulative memory $\Omega(k^3n/T^2)$.

1 Introduction

For some problems, algorithms can use additional memory for faster running times or additional time to reduce memory requirements. While there are different kinds of tradeoffs between time and space, the most common complexity metric for such algorithms is the maximum time-space (TS) product. This is appropriate when a machine must allocate an

algorithm's maximum space throughout its computation. However, recent technologies like AWS Lambda [15] suggest that in the context of cloud computing, space can be allocated to a program only as it is needed. When using such services, analyzing the average memory used per step leads to a more accurate picture than measuring the maximum space.

Cumulative memory (CM), the sum over time of the space used per step of an algorithm, is an alternative notion of time-space complexity that is more fair to algorithms with rare spikes in memory. Cumulative memory complexity was introduced by Alwen and Serbinenko [12] who devised it as a way to analyze time-space tradeoffs for "memory hard functions" like password hashes. Since then, lower and upper bounds on the CM of problems in structured computational models using the black pebble game have been extensively studied, beginning with the work of [12, 7, 32, 10, 9, 8]. Structured models via pebble games are natural in the context of the random oracle assumptions that are common in cryptography. By carefully interweaving their memory-intensive steps, authors of these papers devise algorithms for cracking passwords that compute many hashes in parallel using only slightly more space than is necessary to compute a single hash. While such algorithms can use parallelism to amortize costs and circumvent proven single instance TS complexity lower bounds, their cumulative memory only scales linearly with the number of computed hashes. Strong CM results have also been shown for the black-white pebble game and used to derive related bounds for resolution proof systems [11].

The ideas used for these structured models yield provable separations between CM and TS complexity in pebbling and random oracle models. The key question that we consider is whether or not the same applies to general models of computation without cryptographic or black-box assumptions: Are existing time-space tradeoff lower bounds too pessimistic for a world where cumulative memory is more representative of a computation's cost?

Our Results

The main answer we provide to this question is negative for both classical and quantum computation: We give *generic methods* that convert existing paradigms for obtaining time-space tradeoff lower bounds involving worst-case space to new lower bounds that replace the time-space product by cumulative space, immediately yielding a host of new lower bounds on cumulative memory complexity. With these methods, we show how to extend virtually all known proofs for time-space tradeoffs to equivalent lower bounds on cumulative memory complexity, implying that there cannot be cumulative memory savings for these problems. Our results, like those of existing time-space tradeoffs, apply in models in which arbitrary sequential computations may be performed between queries to a read-only input. Our lower bounds also apply to randomized and quantum algorithms that are allowed to make errors.

Classical computation. We focus on lower bound paradigms that apply to computations of multi-output functions $f : D^n \to R^m$. Borodin and Cook [22] introduced a method for proving time-space tradeoff lower bounds for such functions that takes a property such as the following: for some $K = K(R, n)$, constant γ, and distribution μ on D^n:

(*) For any partial assignment τ of $k \leq \gamma m$ output values over R and any restriction (i.e., partial assignment) π of $h = h(k, n)$ coordinates on D^n,

$$\Pr_{x \sim \mu}[f(x) \text{ is consistent with } \tau \mid x \text{ is consistent with } \pi] \leq K^{-k}.$$

and derives a lower bound of the following form:

Table 1 All CM bounds match the TS lower bound when considering RAM computation or quantum circuits. The symbol * indicates that the result requires additional assumptions.

Problem	TS Lower Bound	Source	Matching CM Bound
Ranking, Sorting	$\Omega(n^2/\log n)$	[22]	Corollary 4.4
Unique Elements, Sorting	$\Omega(n^2)$	[16]	Corollary 4.14

Quantum k disjoint collisions	$\Omega(k^3 n/T^2)$	[27]	Corollary 4.16
Quantum Boolean Matrix-Mult	$\Omega(n^5/T)$	[29]	Full paper [18]*

▶ **Proposition 1.1** ([22]). *Assume that Property (*) holds for $f : D^n \to R^m$ with $\gamma > 0$ constant. Then, $T\ (S + \log_2 T)$ is $\Omega(m\ h(S/\log_2 K, n) \log K)$.*

In particular, since $S \geq \log_2 n$ is essentially always required, if we have the typical case that $h(k, n) = k^{\Delta}\ h_1(n)$ for some function $h_1(n)$ then this says that $T \cdot S^{1-\Delta}$ is $\Omega(m\ h_1(n)\ \log^{1-\Delta} K)$ or, equivalently, that $\max(S, \log n)$ is $\Omega([(m\ h_1(n)/T]^{1/(1-\Delta)} \log K)$. As a simplified example of our new general paradigm, we prove the following analog for cumulative complexity:

▶ **Theorem 1.2.** *Suppose that Property (*) holds for $f : D^n \to R^m$ with $h(k, n) = k^{\Delta} h_1(n)$ and $\gamma > 0$ constant. If $T \log_2 T$ is $o(m\ h_1(n) \log K)$ then any algorithm computing f requires cumulative memory $\Omega\left(\left[(m\ h_1(n))^{1/(1-\Delta)} \log K\right]/T^{\Delta/(1-\Delta)}\right)$.*

We note that this bound corresponds exactly to the bound on the product of time and space from Borodin-Cook method. The full version of our general theorem for randomized computation (Theorem 4.8) is inspired by an extension by Abrahamson [4] of the Borodin-Cook paradigm to average case complexity.

Our full paper ([18]) also shows how the paradigms for the best time-space tradeoff lower bounds for single-output Boolean functions, which are based on the densities of *embedded rectangles* where these functions are constant, can be extended to yield cumulative memory bounds.

Quantum computation. We develop an extension of our general approach that applies to quantum computation as well. In this case Property (*) and its extensions that we use for our more general theorem must be replaced by statements about quantum circuits with a small number of queries. In this case, we first generalize the quantum time-space tradeoff for sorting proven in [29], which requires that the time order in which output values are produced must correspond to the sorted order, to a matching cumulative memory complexity bound of $\Omega(n^3/T)$ that works for any fixed time-ordering of output production, yielding a more general lower bound. (For example, an algorithm may be able to determine the median output long before it determines the other outputs.) We then show how an analog of our classical general theorem can be applied to extend to paradigms for quantum time-space tradeoffs to cumulative memory complexity bounds for other problems.

A summary of our results for both classical and quantum complexity is given in Table 1.

Previous work

Memory hard functions and cumulative memory complexity. Alwen and Serbinenko [12] introduced parallel cumulative (memory) complexity as a metric for analyzing the space footprint required to compute *memory hard functions (MHFs)*, which are functions designed to require large space to compute. Most MHFs are constructed using hashgraphs [26] of DAGs whose output is a fixed length string and their proofs of security are based on pebbling arguments on these DAGs while assuming access to truly random hash functions for their complexity bounds [12, 21, 32, 8, 10, 20]. (Also see our full paper [18] for their use in separating CM and TS complexity.) Recent constructions do not require random hash functions; however, they still rely on cryptographic assumptions [25, 14].

Classical time-space tradeoffs. While these were originally studied in restricted pebbling models similar to those considered to date for cumulative memory complexity [35, 23], the gold-standard model for time-space tradeoff analysis is that of unrestricted branching programs, which simultaneously capture time and space for general sequential computation. Following the methodology of Borodin and Cook [22], who proved lower bounds for sorting, many other problems have been analyzed (e.g., [37, 2, 3, 16, 30]), including universal hashing and many problems in linear algebra [4]. (See [34, Chapter 10] for an overview.) A separate methodology for single-output functions, introduced in the context of restricted branching programs [24, 31], was extended to general branching programs in [17], with further applications to other problems [5] including multi-precision integer multiplication [33] and error-correcting codes [28] as well as over Boolean input domains [6, 19]. Both of these methods involve breaking the program into blocks to analyze the computation under natural distributions over the inputs based on what happens at the boundaries between blocks.

Quantum time-space tradeoffs. Similar blocking strategies can be applied to quantum circuits to achieve time-space trade-offs for multi-output functions. In [29] the authors use direct product theorems to prove time-space tradeoffs for sorting and Boolean matrix multiplication. They also proved somewhat weaker lower bounds for computing matrix-vector products for fixed matrices A; those bounds were extended in [13] to systems of linear inequalities. However, both of these latter results apply to computations where the fixed matrix A defining the problem depends on the space bound and, unlike the case of sorting or Boolean matrix multiplication, do not yield a fixed problem for which the lower bound applies at all space bounds. More recently [27] extended the recording query technique of Zhandry in [38] to obtain time-space lower bounds for the k-collision problem and match the aforementioned result for sorting.

Our methods

At the highest level, we employ part of the same paradigms previously used for time-space tradeoff lower bounds. Namely breaking up the computations into blocks of time and analyzing properties of the branching programs or quantum circuits based on what happens at the boundaries between time blocks. However, for cumulative memory complexity, those boundaries cannot be at fixed locations in time and their selection needs to depend on the space used in these time steps.

Further, in many cases, the time-space tradeoff lower bound needs to set the lengths of those time blocks in a way that depends on the specific space bound. When extending the ideas to bound cumulative memory usage, there is no single space bound that can be used

throughout the computation; this sets up a tricky interplay between the choices of boundaries between time blocks and the lengths of the time blocks. Because the space usage within a block may grow and shrink radically, even with optimal selection of block boundaries, the contribution of each time block to the overall cumulative memory may be significantly lower than the time-space product lower bound one would obtain for the individual block.

We show how to bound any loss in going from time-space tradeoff lower bounds to cumulative memory lower bounds in a way that depends solely on the bound on the lengths of blocks as a function h_0 of the target space bound (cf. Lemma 4.7). For many classes of bounding functions we are able to bound the loss by a constant factor, and we are able show that it is always at most an $O(\log n)$ factor loss. If this bounding function h_0 is non-constant, we also need to bound the optimum way for the algorithm to allocate its space budget for producing the require outputs throughout its computation. This optimization again depends on the bounding function h_0. This involves minimizing a convex function based on h_0 subject to a mix of convex and concave constraints, which is not generally tractable. However, assuming that h_0 is nicely behaved, we are able to apply specialized convexity arguments (cf. Lemma 4.10) which let us derive strong lower bounds on cumulative memory complexity.

Road map. We give the overall definitions in Section 2, including a review of the standard definitions of the work space used by quantum circuits. In Section 3, we give our lower bound for quantum sorting algorithms which gives a taste of the issues involved for our general theorems. In Section 4, we give the general theorems that let us convert the Borodin-Cook-Abrahamson paradigm for multi-output functions to cumulative memory lower bounds for classical randomized algorithms; that section also contains the corresponding theorems for quantum lower bounds and statements of some sample applications for our general results. Appendix A contains the arguments that bound the optimum allocations of cumulative space budgets to time steps. Our full paper [18] contains more details, a conditional separation between CM and TS complexity, detailed applications of the general theorems we present here, and our bounds for single-output functions.

2 Preliminaries

Cumulative memory is an abstract notion of time-space complexity that can be applied to any model of computation with a natural notion of space. Here we will use branching programs and quantum circuits as concrete models, although our results generalize to any reasonable model of computation.

Branching Programs. A branching programs with input $\{x_1, \ldots, x_n\} \in D^n$ is defined using a rooted DAG in which each non-sink vertex is labeled with an $i \in [n]$ and has $|D|$ outgoing edges that correspond to possible values of x_i. Each edge is optionally labeled by some number of output statements expressed as pairs (j, o_j) where $j \in [m]$ is an output index and $o_j \in R$ (if outputs are to be ordered) or simply $o_j \in R$ (if outputs are to be unordered). Evaluation starts at the root v_0 and follows the appropriate labels of the respective x_i. We consider branching programs P that contain $T + 1$ layers where the outgoing edges from nodes in each layer t are all in layer $t + 1$. We impose no restriction on the query pattern of the branching program or when it can produce parts of the output. The *time* of the branching program is $T(P) = T$. The *space* of the branching program is $S(P) = \max_t \log_2 |L_t|$ where L_t is the set of nodes in layer t. Observe that in the absence of any limit on its space, a branching program could be a decision tree; hence the minimum time for branching programs

to compute a function f is its *decision tree complexity*. The *time-space* (product) used by the branching program is $TS(P) = T(P)S(P)$. The *cumulative memory* used by the branching program is $CM(P) = \sum_t \log_2 |L_t|$.

Branching programs are very general, and simultaneously model time and space for sequential computation. In particular they model time and space for random-access off-line multitape Turing machines and random-access machines (RAMs) when time is unit-cost, space is log-cost, and the input and output are read-only and write-only respectively. Branching programs are much more flexible than these models since they can make arbitrary changes to their storage in a single step.

Quantum Circuits. We also consider quantum circuits $\mathcal{C}$ classical read-only input $X = x_1, \ldots, x_n$ that can be queried using an XOR query oracle. As is normal in circuit models, each output wire is associated with a fixed position in the output sequence, independent of the input. As shown in Figure 1 following [29], we abstract an arbitrary quantum circuit $\mathcal{C}$ into layers $\mathcal{C} = \{L_1, \ldots, L_T\}$ where layer L_t starts with the t-th query Q to the input and ends with the start of the next layer. During each layer, an arbitrary unitary transformation V gets applied which can express an arbitrary sub-circuit involving input-independent computation. The sub-circuit/transformation V outputs S_t qubits for use in the next layer in addition to some qubits that are immediately measured in the standard basis, some of which are treated as classical write-only output. The time of $\mathcal{C}$ is lower bounded by the number of layers T and we say that the space of layer L_t is S_t. Observe that to compute a function f, T must be at least the *quantum query complexity* of f since that measure corresponds the above circuit model when the space is unbounded. Note that the cumulative memory of a circuit is lower-bounded by the sum of the S_t. For convenience we define S_0, the space of the circuit before its first query, to be zero. Thus we only consider the space after the input is queried.

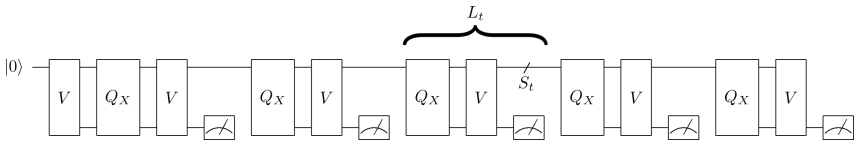

Figure 1 The abstraction of a quantum circuit into layers.

3 Quantum cumulative memory complexity of sorting

As an illustrative example, we first show that the quantum cumulative memory complexity of sorting is $\Omega(n^3/T)$, matching the TS complexity bounds given in [29, 27]. This involves the quantum circuit model which, as we have noted, produces each output position at a predetermined input-independent layer. We restrict our attention to circuits that output all elements in the input in some fixed rank order. While our proof is inspired by the time-space lower bound of [29], it can be easily adapted to follow the proof in [27] instead. We start by constructing a probabilistic reduction from the k-threshold problem to sorting.

▶ **Definition 3.1.** *In the* k-threshold problem *we receive an input* $X = x_1, \ldots, x_n$ *where* $x_i \in \{0, 1\}$. *We want to accept iff there are at least* k *distinct values for* i *where* $x_i = 1$.

▶ **Proposition 3.2** (Theorem 13 in [29]). *For every* $\gamma > 0$ *there is an* $\alpha > 0$ *such that any quantum* k*-threshold circuit with at most* $T \leq \alpha\sqrt{kn}$ *queries and with perfect soundness must have completeness* $\sigma \leq e^{-\gamma k}$ *on inputs with Hamming weight* k.

▶ **Lemma 3.3.** *Let $\gamma > 0$. Let n be sufficiently large and $\mathcal{C}(X)$ be a quantum circuit with input $X = x_1, \ldots, x_n$. There is a $\beta < 1$ depending only on γ such that for all $k \leq \beta^2 n$ and $R \subseteq \{n/2+1, \ldots, n\}$ where $|R| = k$, if $\mathcal{C}(X)$ makes at most $\beta\sqrt{kn}$ queries, then the probability that $\mathcal{C}(X)$ can correctly output all k pairs (x_i, r_j) where $r_j \in R$ and x_i is the r_j-th smallest element of X is at most $e^{(1-\gamma)k-1}$. If R is a contiguous set of integers, then the probability is at most $e^{-\gamma k}$.*

A version of this lemma was first proved in [29] with the additional assumption that the set of output ranks R is a contiguous set of integers; this was sufficient to show that any quantum circuit that produces its sorted output in sorted time order requires that T^2S is $\Omega(n^3)$. The authors stated that their proof can be generalized to any fixed rank ordering, but the generalization is not obvious. We generalize their lemma to non-contiguous R, which is sufficient to obtain an $\Omega(n^3/T)$ lower bound on the cumulative complexity of sorting independent of the time order in which the sorted output is produced.

Proof of Lemma 3.3. Choose α as the constant for γ in Proposition 3.2 and let $\beta = \sqrt{2}\alpha/6$. Let $\mathcal{C}$ be a circuit with at most $\beta\sqrt{kn}$ layers that outputs the k correct pairs (x_i, r_j) with probability p. Let $R = \{r_1, \ldots r_k\}$ where $r_1 < r_2 < \ldots < r_k$. We describe our construction of a circuit $\mathcal{C}'(X)$ solving the k-threshold problem on inputs $X = x_1, \ldots, x_{n/2}$ with exactly k ones in terms of a function $f : [n/2] \to R$. Given f, we re-interpret the input as follows: we replace each x_i with $x'_i = f(i)x_i$, add k dummy values of 0, and add one dummy value of j for each $j \in \{n/2+1, \ldots, n\} \setminus R$. Doing this gives us an input $X' = x'_1, \ldots, x'_n$ that has $n/2$ zeroes. If we assume that f is 1-1 on the k ones of X, then the image of the ones of X will be R and there will be precisely one element of X' for each $j \in \{n/2+1, \ldots, n\}$. Therefore the element of rank $j > n/2$ in X' will have value j, and hence the rank $r_1, \ldots, r_k$ elements of X' will be the images of precisely those elements of X with $x_i = 1$.

To obtain perfect soundness, we cannot rely on the output of $\mathcal{C}(X')$ and must be able to check that each of the output ranks was truly mapped to by a distinct one of X. For each element x_i of X we simply append its index i as $\log_2 n$ low order bits to its image x'_i and append an all-zero bit-vector of length $\log_2 n$ to each dummy value to obtain input X''. Doing so will not change the ranks of the elements in X', but will allow recovery of the k indices that should be the ones in X. In particular, circuit $\mathcal{C}'(X)$ will run $\mathcal{C}(X'')$ and then for each output x''_j with low order bits i, $\mathcal{C}'(X)$ will query x_i, accepting if and only if all of those $x_i = 1$. More precisely, since the mapping from each x_i to the corresponding x''_i is only a function of f, x_i, and i, as long as $\mathcal{C}'(X)$ has an explicit representation of f, it can simulate each query of $\mathcal{C}(X'')$ with two oracle queries to X. Since $\mathcal{C}'$ has at most

$$2\beta\sqrt{kn} + k \leq 3\beta\sqrt{kn} \leq \alpha\sqrt{kn/2}$$

layers, by Proposition 3.2, it can only accept with probability $\leq e^{-\gamma k}$ on inputs with k ones.

We now observe that for each fixed X with exactly k ones, for a randomly chosen function $f : [n/2] \to R$, the probability that f is 1-1 on the ones of X' is exactly $k!/k^k \geq e^{1-k}$. Therefore $\mathcal{C}'(X)$ will give the indices of the k ones in X with probability[1] at least $p \cdot e^{1-k}$. However, this probability must be at most $e^{-\gamma k}$, so we can conclude that $p \leq e^{(1-\gamma)k-1}$. In the event that R is a contiguous set of integers, observe that any choice for the function f will make X'' have the ones of X become ranks $r_1, \ldots, r_k$. So the probability of finding the ones is at least $p \leq e^{-\gamma k}$. ◀

[1] Note that though this is exponentially small in k it is still sufficiently large compared to the completeness required in the lower bound for the k-threshold problem.

By setting k and γ appropriately, Lemma 3.3 gives a useful upper bound on the number of fixed ranks successfully output by any $\beta\sqrt{Sn}$ query quantum circuit that has access to S qubits of input dependent initial state. To handle input-dependent initial state, we will need to use the following proposition.

▶ **Proposition 3.4** ([1]). *Let $\mathcal{C}$ be a quantum circuit, ρ be any S qubit (possibly mixed) state, and I be the S qubit maximally mixed state. If $\mathcal{C}$ with initial state ρ produces some output $\mathcal{O}$ with probability p, then $\mathcal{C}$ with initial state I produces $\mathcal{O}$ with probability at least $p/2^{2S}$.*

This allows us to bound the overall progress made by any short quantum circuit.

▶ **Lemma 3.5.** *There is a constant $\beta > 0$ such that, for any fixed set of $S \leq \beta^2 n$ ranks that are greater than $n/2$, the probability that any quantum circuit $\mathcal{C}$ with at most $\beta\sqrt{Sn}$ queries and S qubits of input-dependent initial state correctly produces the outputs for these S ranks is at most $1/e$.*

Proof. Choose β as the constant when γ is $1+\ln(4)$ in Lemma 3.3. Applying Proposition 3.4 to the bound in Lemma 3.3 gives us that a quantum circuit with S qubits of input-dependent state can produce a fixed set of $k \leq \beta^2 n$ outputs larger than median with a probability at most $2^{2S}e^{(1-\gamma)k-1}$. Since $\gamma = 1+\ln(4)$ setting $k = S$ gives that this probability is $\leq 1/e$. ◀

▶ **Theorem 3.6.** *When n is sufficiently large, any quantum circuit $\mathcal{C}$ for sorting a list of length n with success probability at least $1/e$ and at most T layers that produces its sorted outputs in any fixed time order requires cumulative memory that is $\Omega(n^3/T)$.*

Proof. We partition $\mathcal{C}$ into blocks with large cumulative memory that can only produce a small number of outputs. We achieve this by starting at last unpartitioned layer and finding a suitably low space layer before it so that we can apply Lemma 3.5 to upper bound the number of correct outputs that can be produced in that block with a success probability of at least $1/e$. Let β be the constant from Lemma 3.5 and $k^*(t)$ be the least non-negative integer value of k such that the interval:

$$I(k,t) = \left[t - \frac{\beta}{2}(2^{k+1}-1)\sqrt{n}, t - \frac{\beta}{2}(2^k-1)\sqrt{n}\right]$$

contains some t' such that $S_{t'} \leq 4^k - 1$. We recursively define our blocks as follows. Let ℓ be the number of blocks generated by this method. The final block $\mathcal{C}_\ell$ starts with the first layer $t_{\ell-1} \in I(k^*(T), T)$ where $S_{t_{\ell-1}} \leq 4^{k^*(T)} - 1$ and ends with layer $t_\ell = T$. Let t_i be the first layer of block $\mathcal{C}_{i+1}$. Then the block $\mathcal{C}_i$ starts with the first layer $t_{i-1} \in I(k^*(t_i), t_i)$ where $S_{t_{i-1}} \leq 4^{k^*(t_i)} - 1$ and ends with t_i. See Figure 2 for an illustration of our partitioning. Since $S_0 = 0$ we know that $k^*(t) \leq \log(T)$. Likewise since $S_t > 0$ when $t > 0$, for all $t > \frac{\beta}{2}\sqrt{n}$ we know that $0 < k^*(t) \leq \log(T)$.

Block $\mathcal{C}_i$ starts with less than $4^{k^*(t_i)}$ qubits of initial state and has length at most $\beta 2^{k^*(t_i)}\sqrt{n}$; so by Lemma 3.5, if $4^{k^*(t_i)} \leq \beta^2 n$, the block $\mathcal{C}_i$ can output at most $4^{k^*(t_i)}$ inputs with failure probability at most $1/e$. Additionally $\mathcal{C}_i$ has at least $\frac{\beta}{2}2^{k^*(t_i)-1}\sqrt{n}$ layers so

$$\sum_{i=1}^{\ell} \frac{\beta}{4} 2^{k^*(t_i)}\sqrt{n} \leq T \tag{1}$$

and each of these layers has at least $4^{k^*(t_i)-1}$ qubits[2], so the cumulative memory of $\mathcal{C}_i$ is at

[2] This may not hold for $\mathcal{C}_1$ with length less than $\frac{\beta}{2}\sqrt{N}$, but Lemma 3.3 gives us that this number of layers is insufficient to find a fixed rank input with probability at least $1/e$. Thus we can omit such a block from our analysis.

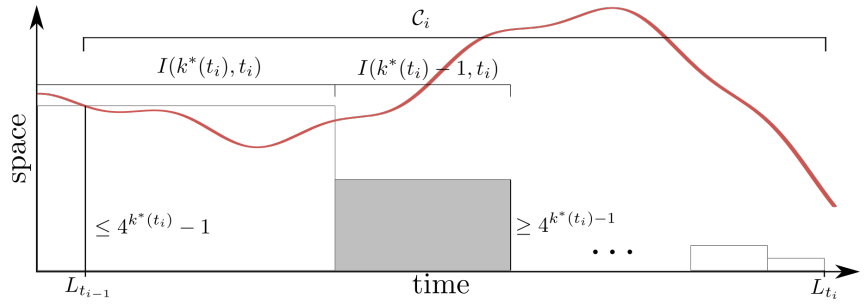

Figure 2 How we define the block $\mathcal{C}_i$ that ends at layer L_{t_i}. The red line is a plot of $\mathcal{C}$'s space over time. The grey layers are the ones used to lower bound the cumulative memory complexity of $\mathcal{C}_i$, as each of these layers uses at least $4^{k^*(t_i)-1}$ qubits and the length of this interval is $\frac{\beta}{2}2^{k^*(t_i)-1}\sqrt{n}$.

least $\frac{\beta}{2}2^{3k^*(t_i)-3}\sqrt{n}$ so

$$CM(\mathcal{C}) \geq \sum_{i=1}^{\ell} \frac{\beta}{2}2^{3k^*(t_i)-3}\sqrt{n}. \tag{2}$$

We now have two possibilities: If we have some i such that $4^{k^*(t_i)} > \beta^2 n$, the cumulative memory of $\mathcal{C}_i$ alone is at least $\beta^4 n^2/16$ which is $\Omega(n^2)$ and hence $\mathcal{C}$ has cumulatively memory $\Omega(n^3/T)$ since $T \geq n$. Otherwise, since we require that the algorithm is correct with probability at least $1/e$, each block $\mathcal{C}_i$ can produce at most $4^{k^*(t_i)}$ outputs. Since our circuit must output all $n/2$ elements larger than the median, we know $\sum_{i=1}^{\ell} 4^{k^*(t_i)} \geq n/2$. For convenience we define $w_i = 2^{k^*(t_i)}$ which allows us to express the constraints as

$$CM(\mathcal{C}) \geq \frac{\beta}{16}\sqrt{n}\sum_{i=1}^{\ell} w_i^3 \quad \text{and} \quad \frac{\beta}{4}\sqrt{n}\sum_{i=1}^{\ell} w_i \leq T \quad \text{and} \quad \sum_{i=1}^{\ell} w_i^2 \geq n/2. \tag{3}$$

Minimizing $\sum_{i=1}^{\ell} w_i^3$ is a non-convex optimization problem and can instead be solved using

$$\text{Minimize} \quad \sum_{i=1}^{\ell} x_i^3 \quad \text{subject to} \quad \sum_{i=1}^{\ell} x_i^2 \geq \xi \quad \text{and} \quad \sum_{i=1}^{\ell} x_i \leq \xi \quad \text{and} \quad \forall i, x_i \geq 0, \tag{4}$$

for $x_i = \frac{8T}{\beta n^{3/2}} w_i$ and $\xi = \frac{32T^2}{\beta^2 n^2}$. Lemma A.1 from Appendix C shows that for non-negative x_i with $\sum x_i \leq \sum x_i^2$, we have $\sum x_i^2 \leq \sum x_i^3$. Thus $\sum x_i^3 \geq \xi$ and applying the variable substitution gives us: $\sum_{i=1}^{\ell} w_i^3 \geq \frac{\beta n^{5/2}}{16T}$. Plugging this into Equation (3) gives us the bound: $CM(\mathcal{C}) \geq \frac{\beta^2 n^3}{256T}$ and hence the cumulative memory of $\mathcal{C}$ is $\Omega(n^3/T)$. ◀

4 General methods for proving cumulative memory lower bounds

Our method involves adapting techniques previously used to prove tradeoff lower bounds on worst-case time and worst-case space. We show that the same properties that yield lower bounds on the product of time and space in the worst case can also be used to produce nearly identical lower bounds on cumulative memory. To do so, we first revisit the standard approach to such time-space tradeoff lower bounds.

The standard method for time-space tradeoff lower bounds for multi-output functions

Consider a multi-output function f on D^n where the output $f(x)$ is either unordered (the output is simply a set of elements from R) or ordered (the output is a vector of elements from R). Then $|f(x)|$ is either the size of the set or the length of the vector of elements. The standard method for obtaining an ordinary time-space tradeoff lower bounds for multi-output functions on D-way branching programs is the following:

The part that depends on f. Choose a suitable probability distribution μ on D^n, often simply the uniform distribution on D^n and then:

(A) Prove that $\Pr_{x\sim\mu}[|f(x)| \geq m] \geq \alpha$.

(B) Prove that for all $k \leq m'$ and any branching program B of height $\leq h'(k,n)$, the probability for $x \sim \mu$ that B produces at least k correct output values of f on input x is at most $C \cdot K^{-k}$ for some m', h', $K = K(R,n)$, and constant C independent of n.

Observe that under any distribution μ, a branching program with ordered outputs that makes no queries can produce k outputs that are all correct with probability at least $|R|^{-k}$, so the bound in (B) shows that, roughly, up to the difference between K and $|R|$ there is not much gained by using a branching program of height h.

The generic completion. In the following outline we omit integer rounding for readability.

- Let $S' = S + \log_2 T$ and suppose that

$$S' \leq m' \log_2 K - \log_2(2C/\alpha). \tag{5}$$

- Let $k = [S' + \log_2(2C/\alpha)]/\log_2 K$, which is at most m' by hypothesis on S', and define $h(S',n) = h'(k,n)$.
- Divide time T into $\ell = T/h$ blocks of length $h = h(S',n)$.
- The original branching program can be split into at most $T \cdot 2^S = 2^{S'}$ sub-branching programs of height $\leq h$, each beginning at a boundary node between layers. By Property (B) and a union bound, for $x \sim \mu$ the probability that at least one of these $\leq 2^{S'}$ sub-branching programs of height at most h produces k correct outputs on input x is at most $2^{S'} \cdot C \cdot K^{-k} \leq \alpha/2$ by our choice of k.
- Under distribution μ, by (A), with probability at least α, an input $x \sim \mu$ has some block of time where at least $m/\ell = m \cdot h(S',n)/T$ outputs of f must be produced on input x.
- If $m \cdot h(S',n)/T \leq k$, this can occur for at most an $\alpha/2$ fraction of inputs under μ. Therefore we have $m \cdot h(S',n)/T > k = [S' + \log_2(2C/\alpha)]/\log_2 K$ and hence since $h(S',n) \geq h(S,n)$, combining with Equation (5), we have

$$T \cdot (S + \log_2 T) = T \cdot S' \geq \min\left(m\ h(S,n),\ m'\ n'\right)\ \log_2 K - \log_2(C/\alpha) \cdot T$$

where $n' \leq n$ is the decision tree complexity of f and hence a lower bound on T.

▶ Remark 4.1. Though it will not impact our argument, for many instances of the above outline, the proof of Property (B) is shown for a decision tree of the same height by proving an analog for the conditional probability along each path in the decision tree separately; this will apply to the tree as a whole since the paths are followed by disjoint inputs, so Property (B) follows from the alternative property below:

(B') For any partial assignment τ of $k \leq m'$ output values over R and any restriction (i.e., partial assignment) π of $h'(k,n)$ coordinates within D^n,

$$\Pr_{x\sim\mu}[f(x) \text{ is consistent with } \tau \mid x \text{ is consistent with } \pi] \leq C \cdot K^{-k}.$$

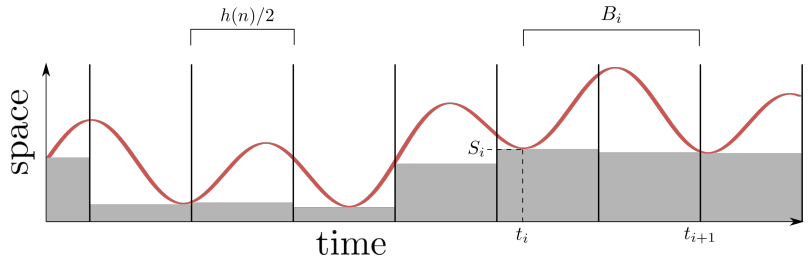

Figure 3 Our generic method for choosing blocks when $h(k,n) = h(n)$. The area marked in grey corresponds to the cumulative memory lower bound we obtain.

Observe that Property (B') is only a slightly more general version of Property (*) from the introduction where $C = 1$, m' is arbitrary, and h' is used instead of h.

▶ Remark 4.2. The above method still gives lower bounds for many multi-output functions $g : D^N \to R^M$ that have individual output values that are easy to compute or large portions of the input space on which they are easy to compute. The bounds follow by applying the method to some subfunction f of g given by $f(x) = \Pi_O(g(x,\pi))$ where π is a partial assignment to the input coordinates and Π_O is a projection onto a subset O of output coordinates. In the subsequent discussions we ignore this issue, but the idea can be applied to all of our lower bound methods.

A general extension to cumulative memory bounds

To give a feel for the basic ideas of the method, we first show this for a simple case. Observe that, other than the separate bound on time, the lower bound on cumulative memory usage we prove in this case is asymptotically identical to the bound achieved for the product of time and worst-case space using the standard outline.

▶ **Theorem 4.3.** *Let $c > 0$. Suppose that properties (A) and (B) apply for $h'(k,n) = h(n)$, $m' = m$, and $\alpha = C = 1$. If $T \log_2 T \le \frac{m\ h(n)\ \log_2 K}{6(c+1)}$ then the cumulative memory used in computing $f : D^n \to R^m$ in time T with success probability at least T^{-c} is at least $\frac{1}{6}\, m\ h(n) \log_2 K$.*

Proof. Fix a deterministic branching program P of length T computing f. Rather than choosing fixed blocks of height $h = h(n)$, layers of nodes at a fixed distance from each other, and a fixed target of k outputs per block, we choose the block boundaries depending on the properties of P and the target k depending on the property of the boundary layer chosen.

Let $H = \lfloor h(n)/2 \rfloor$. We break P into $\ell = \lceil T/H \rceil$ time segments of length H working backwards from step T so that the first segment may be shorter than the rest. We let $t_1 = 0$ and for $1 < i \le \ell$ we let $t_i = \arg\min\{\ |L_t| \ :\ T - (\ell - i + 1) \cdot H \le t < T - (\ell - i) \cdot H\ \}$ be the time step with the fewest nodes among all time steps $t \in [T - (\ell - i + 1) \cdot H, T - (\ell - i) \cdot H]$.

The i-th time block of P will be between times t_i and t_{i+1}. Observe that by construction $|t_{i+1} - t_i| \le h(n)$ so each block has length at most $h(n)$. This construction is shown in Figure 3 Set $S_i = \log_2 |L_{t_i}|$ so that L_{t_i} has at 2^{S_i} nodes. By definition of each t_i, the cumulative memory used by P,

$$CM(P) \ge \sum_{i=1}^{\ell} S_i \cdot H. \tag{6}$$

(Note that since $S_1 = 0$, it does not matter that the first segment is shorter than the rest[3].)

[3] This simplifies some calculations and is the prime reason for starting the time segment boundaries at T.

We now define the target k_i for the number of output values produced in each time block to be the smallest integer such that $K^{-k_i} \leq 2^{-S_i}/T^{c+1}$. That is,

$$k_i = \lceil (S_i + (c+1)\log_2 T)/\log_2 K \rceil.$$

For $x \sim \mu$, for each $i \in [\ell]$ and each sub-branching program B rooted at some node in L_{t_i} and extending until time t_{i+1}, by our choice of k_i and Property (B), if $k_i \leq m$, the probability that B produces at least k_i correct outputs on input x is at most $2^{-S_i}/T^{c+1}$. Therefore, by a union bound, for $x \sim \mu$ the probability that P produces at least k_i correct outputs in the i-th time block on input x is at most $|L_{t_i}| \cdot 2^{-S_i}/T^{c+1} = 1/T^{c+1}$. Therefore, if each $k_i \leq m$, the probability for $x \sim \mu$ that there is some i such that P produces at least k_i correct outputs on input x during the i-th block is at most $\ell/T^{c+1} < T^c$ and the probability for $x \sim \mu$ that P produces at most $\sum_{i=1}^{\ell}(k_i - 1)$ correct outputs in total on input x is $> 1 - 1/T^c$.

If each $k_i \leq m$, since P must produce m correct outputs on $x \in D^n$ with probability at least $1/T^c$, we must have $\sum_{i=1}^{\ell}(k_i - 1) \geq m$. On the other hand, if some $k_i > m$ we have the same bound. Using our definition of k_i we have $\sum_{i=1}^{\ell}[(S_i + (c+1)\log_2 T)]/\log_2 K] \geq m$ or $\sum_{i=1}^{\ell}(S_i + (c+1)\log_2 T) \geq m \cdot \log_2 K$. Plugging in the bound (6) on the cumulative memory and the value of ℓ, it implies that $CM(P)/H + (c+1)\lceil T/H \rceil \cdot \log_2 T \geq m \cdot \log_2 K$ or that $CM(P) + (c+1)T\log_2 T \geq \frac{1}{3}\ m \cdot h(n) \cdot \log_2 K$, where the 3 on the right rather than a 2 allows us to remove the ceiling. Therefore either

$$T\log_2 T > \frac{m \cdot h(n) \cdot \log_2 K}{6(c+1)} \qquad \text{or} \qquad CM(P) \geq \frac{1}{6}\ m\ h(n)\ \log_2 K. \qquad \blacktriangleleft$$

Simple applications. This simple case of our general theorem is sufficient to obtain many tight new lower bounds on cumulative memory complexity including the following (full proofs are in [18]):

▶ **Corollary 4.4.** *Producing the ranks (positions of each input in the sorted order) or sorting n integers from $[n^2]$ requites CMC that is $\Omega(n^2/\log_2 n)$.*

▶ **Corollary 4.5.** *For many fixed (random or explicit) $n \times n$ matrices A, computing Ax over a finite field $\mathbb{F}$ requires CMC that is $\Omega(n^2 \log |\mathbb{F}|)$.*

Corollary 4.4 uses property (B) for ranking with $m' = h'(k,n) = \Theta(n)$, $C = 1$, $K = 2^{\Theta(1/\log n)}$ proven in [22, Lemma 1]. Corollary 4.5 uses property (B') with $m' = h'(k,n) = cn$, for $0 < c \leq 1/2$, $C = 1$, and $K = |\mathbb{F}|^c$ proven in [4, Theorem 4.6].

Full general theorem. In the general version of our theorem there are a number of additional complications, most especially because the branching program height limit $h(k,n)$ in Property (B) *can depend on* k, the target for the number of outputs produced. This forces the lengths of the blocks and the space used at the boundaries between blocks to depend on each other in a quite delicate way. In order to discuss the impact of that dependence and state our general theorem, we need the following definition.

▶ **Definition 4.6.** *Given a non-decreasing function $p : \mathbb{R} \to \mathbb{R}$ with $p(1) = 1$, we define $p^{-1} : \mathbb{R} \to \mathbb{R} \cup \{\infty\}$ by $p^{-1}(R) = \min\{j \mid p(j) \geq k\}$. We also define the* loss, *$\mathcal{L}_p$, of p by*

$$\mathcal{L}_p(n) = \min_{1 \leq k \leq p(n)} \frac{\sum_{j=1}^{k} p^{-1}(j)}{k \cdot p^{-1}(k)}.$$

▶ **Lemma 4.7.** *The following hold for every non-decreasing function $p : \mathbb{R} \to \mathbb{R}$ with $p(1) = 1$:*

(a) $1/p(n) \le \mathcal{L}_p(n) \le 1$.

(b) *If p is a polynomial function $p(s) = s^{1/c}$ then $\mathcal{L}_p(n) > 1/2^{c+1}$.*

(c) *For any $c > 1$, $\mathcal{L}_p(n) \ge \min_{1 \le s \le n} \dfrac{p(s) - p(s/c)}{cp(s)}$.*

(d) *We say that p is* nice *if it is differentiable and there is an integer $c > 1$ such that for all x, $p'(cx) \ge p'(x)/c$. If p is nice then $\mathcal{L}_p(n)$ is $\Omega(1/\log_2 n)$. This is tight for p with $p(s) = 1 + \log_2 s$.*

We prove this technical lemma in the full paper [18]. Here is our full general theorem.

▶ **Theorem 4.8.** *Let $c > 0$. Suppose that function f defined on D^n has properties (A) and (B) with α that is $1/n^{O(1)}$ and m' that is $\omega(\log_2 n)$. For $s > 0$, define $h(s, n)$ to be $h'(k, n)$ for $k = s/\log_2 K$. Suppose that $h(s, n) = h_0(s)\, h_1(n)$ with $h_0(1) = 1$ and h_0 is constant or a differentiable function such that $s/h_0(s)$ is increasing and concave. Define $S^* = S^*(T, n)$ by*

$$S^*/h_0(S^*) = (m\ h_1(n)\ \log_2 K)\,/6T.$$

(a) *Either $T \log_2(2CT^{c+1}/\alpha) > \dfrac{1}{6}\, m\ h_1(n)\ \log_2 K$, which implies that T is $\Omega(\frac{m\ h_1(n)\ \log K}{\log n})$, or the cumulative memory used by a randomized branching program in computing f in time T with error $\varepsilon \le \alpha(1 - 1/(2T^c))$ is at least*

$$\frac{1}{6}\, \mathcal{L}_{h_0}(n \log_2 |D|) \cdot \min\left(m\ h(S^*(T, n), n),\ 3m'\ h'(m'/2, n)\right) \cdot \log_2 K.$$

(b) *Further any randomized random-access machine computing f in time T with error $\varepsilon \le \alpha(1 - 1/(2T^c))$ requires cumulative memory*

$$\Omega\left(\mathcal{L}_{h_0}(n \log_2 |D|) \cdot \min\left(m\ h(S^*(T, n), n),\ m'\ h'(m'/2, n)\right) \cdot \log_2 K\right).$$

Before we give the proof of the theorem, we note that by Lemma 4.7, in the case that h_0 is constant or $h_0(s) = s^{\Delta}$ for some constant $\Delta > 0$, which together account for all existing applications we are aware of, the function $\mathcal{L}_{h_0}$ is lower bounded by a constant. In the latter case, h_0 is differentiable, has $h_0(s) = 1$, and the function $s/h_0(s) = s^{1-\Delta}$ is increasing and concave so it satisfies the conditions of our theorem. By using $\alpha = 1$, $m' = m$, and $C = 1$ with h from Property (*) in place of h' in Property (B'), Theorem 4.8 yields Theorem 1.2.

More generally, the value S^* in the statement of this theorem is at least a constant factor times the value of S used in the generic time-space tradeoff lower bound methodology. Therefore, the cumulative memory lower bound in Theorem 4.8 for random-access machines is close to the lower bound on the product of time and space using standard methods.

Proof of Theorem 4.8. We prove both (a) and (b) directly for branching programs, which can model random-access machines, and will describe the small variation that occurs in the case that the branching program in question comes from a random-access machine. To prove these properties for randomized branching programs, by Yao's Lemma [36] it suffices to prove the properties for deterministic branching programs that have error at most ε under distribution μ. Fix a (deterministic) branching program P of length T computing f with error at most ε under distribution μ. Without loss of generality, P has maximum space usage at most $S^{max} = n \log_2 |D|$ space since there are at most $|D^n|$ inputs.

Let $H = \lfloor h_1(n)/2 \rfloor$. We break P into $\ell = \lceil T/H \rceil$ time segments of length H working backwards from step T so that the first segment may be shorter than the rest. We then choose a sequence of *candidates* for the time steps in which to begin new blocks, as follows: We let $\tau_1 = 0$ and for $1 < i \le \ell$ we let

$$\tau_i = \arg\min\{\ |L_t|\ :\ T - (\ell - i + 1) \cdot H \le t < T - (\ell - i) \cdot H\ \}$$

be the time step with the fewest nodes among all time steps $t \in [T-(\ell-i+1)\cdot H, T-(\ell-i)\cdot H]$. Set $\sigma_i = \log_2 |L_{\tau_i}|$ so that L_{τ_i} has at 2^{σ_i} nodes. This segment contributes at least $\sigma_i \cdot H$ to the cumulative memory bound of P.

To choose the beginning t_{i^*} of the last time block[4]. we find the smallest k such that $h_0(\sigma_{\ell-k+1}) < k$. Such a k must exist since h_0 is a non-decreasing non-negative function, $h_0(1) = 1$ and $\sigma_1 = 0 < 1$. We now observe that the length of the last block is at most $k \cdot H$ which by choice of k is less than $h(\sigma_{\ell-k+1}, n)$ and hence we have satisfied the requirements for Property (B) to apply at each starting node of the last time block.

By our choice of each τ_i, the cumulative memory used in the last k segments is at least $\sum_{j=1}^{k} \sigma_{\ell+1-j} \cdot H$. Further, since k was chosen as smallest with the above property, we know that for every $j \in [k-1]$ we have $h_0(\sigma_{\ell-j+1}) \geq j$ Hence we have $\sigma_{\ell-j+1} \geq h_0^{-1}(j)$ and we get a cumulative memory bound for the last k segments of at least

$$(\sigma_{\ell-k+1} + \sum_{j=1}^{k-1} h_0^{-1}(j)) \cdot H. \tag{7}$$

▷ Claim 4.9. $\sigma_{\ell-k+1} + \sum_{j=1}^{k-1} h_0^{-1}(j) \geq \mathcal{L}_{h_0}(S^{max}) \cdot \sigma_{\ell-k+1} \cdot k$.

Proof of Claim. Observe that it suffices to prove the claim when we replace $\sigma_{\ell-k+1}$, which appears on both sides, by a larger quantity. In particular, we show how to prove the claim with $h_0^{-1}(k)$ instead, which is larger since $h_0(\sigma_{\ell-k+1}) < k$. But this follows immediately since by definition $\mathcal{L}_{h_0}(S^{max}) \leq \frac{\sum_{j=1}^{k} h_0^{-1}(j)}{k \cdot h_0^{-1}(k)}$, which is equivalent to what we want to prove. ◁

Write $S_{i^*} = \sigma_{\ell-k+1}$. By the claim, the cumulative memory contribution associated with the last block beginning at t_{i^*} is at least $\mathcal{L}_{h_0}(S^{max}) \cdot S_{i^*} \cdot h_0(S_{i^*})H$.

We repeat this in turn to find the time step for the beginning of the next block from the end, t_{i^*-1}. One small difference now is that there is a last partial segment of height at most H from the beginning of segment containing t_{i^*} to layer t_{i^*}. However, this only adds at most $h_1(n)/2$ to the length of the segment which still remains well within the height bound of $h(S_{i^*-1}, n) = h_0(S_{i^*-1})h_1(n)$ for Property (B) to apply.

Repeating this back to the beginning of the branching program we obtain a decomposition of the branching program into some number i^* of blocks, the i-th block beginning at time step t_i with 2^{S_i} nodes, height between $h_0(S_i)H$ and $h_0(S_i)H + H \leq 2h_0(S_i)H$, and with an associated cumulative memory contribution in the i-th block of $\geq \mathcal{L}_{h_0}(S^{max}) \cdot S_i \cdot h_0(S_i)H$. (This is correct even for the partial block starting at time $t_1 = 0$ since $S_1 = 0$.) Since we know that $i^* \leq \ell$, for convenience, we also define $S_i = 0$ for $i^* + 1 \leq i \leq \ell$. Then, by definition

$$CM(P) \geq \mathcal{L}_{h_0}(S^{max}) \cdot \left(\sum_{i=1}^{i^*} S_i \cdot h_0(S_i) \right) \cdot H = \mathcal{L}_{h_0}(S^{max}) \cdot \left(\sum_{i=1}^{\ell} S_i \cdot h_0(S_i) \right) \tag{8}$$

$$\text{and} \qquad \sum_{i=1}^{\ell} h_0(S_i) \leq T/H. \tag{9}$$

As in the previous argument for the simple case, for $i \leq i^*$, we define the target k_i for the number of output values produced in each time block to be the smallest integer such that $C\dot{K}^{-k_i} \leq 2^{-S_i}\alpha/(2T^{c+1})$. That is, $k_i = \lceil (S_i + \log_2(2CT^{c+1}/\alpha))/\log_2 K \rceil$.

[4] Since we are working backwards from the end of the branching program and we do not know how many segments are included in each block, we don't actually know this index until things stop with $t_1 = 0$

If $k_i > m'$ for some i, then $S_i \geq m' \cdot \log_2 K - \log_2(2CT^{c+1}/\alpha) \geq (m' \log_2 K)/2$ since m' is $\omega(\log n)$ and $1/\alpha$ and T are $n^{O(1)}$. Therefore $h_0(S_i) \geq h'(m'/2, n)$ and hence

$$CM(P) \geq \frac{1}{2}\,\mathcal{L}_{h_0}(S^{max}) \cdot m' \cdot h'(m'/2, n) \cdot \log_2 K$$

Suppose instead that $k_i \leq m'$ for all $i \leq i^*$. Then, for $x \sim \mu$, for each $i \in [i^*]$ and each sub-branching program B rooted at some node in L_{t_i} and extending until time t_{i+1}, by our choice of k_i and Property (B), the probability that B produces at least k_i correct outputs on input x is at most $\alpha \cdot 2^{-S_i}/(2T^{c+1})$. Therefore, by a union bound, for $x \sim \mu$ the probability that P produces at least k_i correct outputs in the i-th time block on input x is at most

$$|L_{t_i}| \cdot \alpha \cdot 2^{-S_i}/(2T^{c+1}) = \alpha/(2T^{c+1})$$

and hence the probability for $x \sim \mu$ that there is some i such that P produces at least k_i correct outputs on input x during the i-th block is at most $\ell \cdot \alpha/(2T^{c+1}) < \alpha/(2T^c)$. Therefore, the probability for $x \sim \mu$ that P produces at most $\sum_{i=1}^{\ell}(k_i - 1)$ correct outputs in total on input x is $> 1 - \alpha/(2T^c)$.

Since, by Property (A) and the maximum error it allows, P must produce at least m correct outputs with probability at least $\alpha - \epsilon \geq \alpha - \alpha(1 - 1/(2T^c)) = \alpha/(2T^c)$ for $x \sim \mu$, we must have $\sum_{i=1}^{i^*}(k_i - 1) \geq m$. Using our definition of k_i we obtain

$$\sum_{i=1}^{i^*}(S_i + \log_2(2CT^{c+1}/\alpha)) \geq m \log_2 K.$$

This is the one place in the proof where there is a distinction between an arbitrary branching program and one that comes from a random access machine.

We first start with the case of arbitrary branching programs: Note that $i^* \leq \ell = \lceil T/H \rceil = \lceil T/\lfloor h_1(n)/2 \rfloor \rceil$. Suppose that $T \log_2(2CT^{c+1}/\alpha) \leq \frac{1}{6}\, m \cdot h_1(n) \cdot \log_2 K$. Then, even with rounding, we obtain $\sum_{i=1}^{i^*} S_i \geq \frac{1}{2}\, m \log_2 K$.

Unlike an arbitrary branching program that may do non-trivial computation with sub-logarithmic S_i, a random-access machine with even one register requires at least $\log_2 n$ bits of memory (just to index the input for example) and hence $S_i + \log_2(2CT^{c+1}/\alpha)$ will be $O(S_i)$, since T is at most polynomial in n and $1/\alpha$ is at most polynomial in n by assumption. Therefore we obtain that $\sum_{i=1}^{i^*} S_i$ is $\Omega(m \log_2 K)$ without the assumption on T.

In the remainder we continue the argument for the case of arbitrary branching programs and track the constants involved. The same argument obviously applies for programs coming from random-access machines with slightly different constants that we will not track. In particular, since $S_i = 0$ for $i > i^*$ we have

$$\sum_{i=1}^{\ell} S_i \geq \frac{1}{2}\, m \cdot \log_2 K. \tag{10}$$

From this point we need to do something different from the argument in the simple case because the lower bound on the total cumulative memory contribution is given by Equation (8) and is not simply $\sum_{i=1}^{\ell} S_i \cdot H$. Instead, we combine Equation (10) and Equation (9) using the following technical lemma that we prove in Appendix A.

▶ **Lemma 4.10.** *Let $p : \mathbb{R}^{\geq 0} \to \mathbb{R}^{\geq 0}$ be a differentiable function such that $q(x) = x/p(x)$ is a concave increasing function of x. For $x_1, x_2, \ldots \in \mathbb{R}^{\geq 0}$, if $\sum_i x_i \geq K$ and $\sum_i p(x_i) \leq L$ then $\sum_i x_i p(x_i) \geq q^{-1}(K/L) \cdot L$.*

In our application of Lemma 4.10, $p = h_0$, $K = \frac{1}{2}\, m \cdot \log_2 K$, and $L = T/H$. Let S^* be the solution to $\frac{S^*}{h_0(S^*)} = K/L = \frac{m \cdot H \cdot \log_2 K}{2T} \geq \frac{m \cdot h_1(n) \log_2 K}{6T}$. Then Lemma 4.10 implies that $\sum_{i=1}^{\ell} S_i \cdot h_0(S_i) \geq S^* \cdot T/H = \frac{1}{2}, m \cdot h_0(S^*) \cdot \log_2 K$. and hence

$$CM(P) \geq \mathcal{L}_{h_0}(S^{max}) \cdot \frac{1}{2}\, m \cdot h_0(S^*) \cdot H \cdot \log_2 K \geq \frac{1}{6}\, \mathcal{L}_{h_0}(S^{max}) \cdot m \cdot h(S^*, n) \cdot \log_2 K$$

since $H = \lfloor h_1(n)/2 \rfloor$ and $h(S^*, n) = h_0(S^*) \cdot h_1(n)$. ◀

In the special case that $h_0(s) = s^{\Delta}$ (and indeed for any nice function h_0), there is an alternative variant of the above in which one breaks up time into exponentially growing segments starting with time step T. We used that alternative approach in Section 3.

▶ Remark 4.11. If we restrict our attention to $o(m' \log K)$-space bounded computation, then each $k_i \leq m'$ and the cumulative memory bound for a branching program in Theorem 4.8 becomes $\frac{1}{6}\, \mathcal{L}_{h_0}(n \log_2 |D|) \cdot m \cdot h(S^*(T, n), n) \cdot \log_2 K$. And the bound for RAM cumulative memory becomes $\Omega\left(\mathcal{L}_{h_0}(n \log_2 |D|) \cdot m \cdot h(S^*(T, n), n) \cdot \log_2 K\right)$.

Generic method for quantum time-space tradeoffs

Quantum circuit time-space lower bounds have the same general structure as their classical branching program counterparts. They require a lemma similar to (B) that gives an exponentially small probability of producing k outputs with a small number of queries.

▶ **Lemma 4.12** (Quantum generic property). *For all $k \leq m'$ and any quantum circuit $\mathcal{C}$ with at most $h'(k, n)$ layers, there exists a distribution μ such that when $x \sim \mu$, the probability that $\mathcal{C}$ produces at least k correct output values of $f(x)$ is at most $C \cdot K^{-k}$.*

Such lemmas have historically been proving using direct product theorems [29, 13] or the recording query technique [27]. Quantum time-space tradeoffs use the same blocking strategy as branching programs; however, they cannot use union bounds to account for input-dependent state at the start of a block. Instead, Proposition 3.4 lets us apply Lemma 4.12 to blocks in the middle of a quantum circuit. The 2^{2S} factor in Proposition 3.4 means that a quantum time-space or cumulative memory lower bound is half of what you would expect from a classical bound. Since a quantum circuit requires $\log_2 n$ qubits to make a query, we know that the space between layers is always at least $\log_2 n$ and

$$T \cdot S \text{ is } \Omega\left(\min\{m\ h'(S, n), m'\ Q(f)\} \cdot \log_2 K\right)$$

where $Q(f)$ is the bounded-error quantum query complexity of f.

Generic method for quantum cumulative complexity bounds

Our generic argument can just as easily be applied to quantum lower bounds for problems where we have an instance of Lemma 4.12 using Proposition 3.4 to bound the number of outputs produced even with initial input-dependent state. Quantum circuits require at least $\log_2 n$ qubits to hold the query index so the bounds derived are like those from Theorem 4.8(b).

▶ **Corollary 4.13.** *Let $c > 0$. Suppose that function f defined on D^n satisfies generic Lemma 4.12 with m' that is $\omega(\log_2 n)$. For $s > 0$, let $h(s, n) = h'(s/\log_2 K, n)$. Let $h(s, n) = h_0(s)h_1(n)$ where $h_0(1) = 1$ and h_0 is constant or a differentiable function where $s/h_0(s)$ is increasing and concave. Let S^* be defined by:*

$$S^*/h_0(S^*) = (m\ h_1(n)\ \log_2 K)\,/6T.$$

The CM used by a quantum circuit that computes f in time T with error $\varepsilon \leq (1 - 1/(2T^c))$ is

$$\geq \frac{1}{6}\,\mathcal{L}_{h_0}(n \log_2 |D|) \cdot \min\{m\ h(S^*, n),\ 3m'\ h'(m'/2, n)\} \cdot \log_2 K.$$

If the circuit uses $o(m' \log K)$ qubits, the CMC instead is $\frac{1}{6}\,\mathcal{L}_{h_0}(n \log_2 |D|) \cdot m \cdot h(S^*, n) \cdot \log_2 K$.

Full general applications. Some applications of our full general theorem generalizing classical and quantum time-space product lower bounds are the following (full proofs are in [18]):

▶ **Corollary 4.14.** *The CMC for listing all uniquely occurring elements or sorting n integers from $[n]$ is $\Omega(n^2)$.*

▶ **Corollary 4.15.** *Matrix multiplication for $n \times n$ matrices over finite field $\mathbb{F}$ requires classical CMC that is $\Omega((n^6 \log |\mathbb{F}|)/T)$.*

▶ **Corollary 4.16.** *For every $m \geq n$, finding k disjoint collisions in a random function from $[m]$ to $[n]$ requires quantum CMC that is $\Omega(k^3 n/T^2)$.*

Corollary 4.14 uses properties (A) and (B) for unique elements with $h'(k, n) = n/4$, $m' = n/4$, $m = n/(2e)$, $\alpha = 1/(2e - 1)$, $K = 1/(2 \ln N)$ and $C = 1$ that follow from [16, Lemmas 2, 3]. Corollary 4.15 uses properties (A) and (B') with $h'(k, n) = \Theta(n\sqrt{k})$, $m' = m = n^2$, $\alpha = 1$, $K = |\mathbb{F}|^{\Theta(1)}$ and $C = d^2$. as proven in [4, Theorem 7.1]. Corollary 4.16 uses Lemma 4.12 with $h'(k, n) = \Theta(k^{2/3} n^{1/3}), m' = m = k$, and $C = K = 2$ which follow from [27, Theorem 9].

A Optimizations

In this section we prove general optimization lemmas that allow us to derive worst-case properties of the allocation of branching program layers into blocks.

▶ **Lemma A.1.** *For non-negative reals $x_1, x_2, \ldots$ if $\sum_i x_i \le \sum_i x_i^2$ then $\sum_i x_i^3 \ge \sum_i x_i^2$.*

Proof. Without loss generality we remove all x_i that are 0 or 1 since they contribute the same amount to each of $\sum_i x_i$, $\sum_i x_i^2$, and $\sum_i x_i^3$. Therefore every x_i satisfies $0 < x_i < 1$ or it satisfies $x_i > 1$. We rename those x_i with $0 < x_i < 1$ by y_i and those x_i with $x_i > 1$ by z_j.

Then $\sum_i x_i \le \sum_i x_i^2$ can be rewritten as $\sum_i y_i(1-y_i) \le \sum_j z_j(z_j-1)$, and both quantities are positive. Let y^* be the largest value < 1 and z^* be the smallest value > 1. Thus:

$$\sum_i (y_i^2 - y_i^3) = \sum_i y_i^2(1-y_i) \le \sum_i y^* y_i(1-y_i) = y^* \sum_i y_i(1-y_i) \le y^* \sum_j z_j(z_j-1)$$
$$< z^* \sum_j z_j(z_j-1) = \sum_j z^* z_j(z_j-1) \le \sum_j z_j^2(z_j-1) = \sum_j (z_j^3 - z_j^2).$$

Rewriting gives $\sum_i y_i^2 + \sum_j z_j^2 < \sum_i y_i^3 + \sum_j z_j^3$, or $\sum_i x_i^3 > \sum_i x_i^2$, as required. ◀

The following is a generalization of the above to all differentiable functions $p : \mathbb{R}^{\ge 0} \to \mathbb{R}^{\ge 0}$ such that $s/p(s)$ is a concave increasing function of s.

▶ **Lemma 4.10.** *Let $p : \mathbb{R}^{\ge 0} \to \mathbb{R}^{\ge 0}$ be a differentiable function such that $q(x) = x/p(x)$ is a concave increasing function of x. For $x_1, x_2, \ldots \in \mathbb{R}^{\ge 0}$, if $\sum_i x_i \ge K$ and $\sum_i p(x_i) \le L$ then $\sum_i x_i p(x_i) \ge q^{-1}(K/L) \cdot L$.*

Proof. By hypothesis, $\sum_i (x_i - Kp(x_i)/L) \geq 0$. Observe that $s - Kp(s)/L$ is an increasing function of s since $s/p(s)$ is an increasing function of s that is 0 precisely when $s = q^{-1}(K/L)$. Since all x_i with $x_i = q^{-1}(K/L)$ evaluate to 0 in the sum, we can rewrite it as

$$\sum_{x_i > q^{-1}(K/L)} (x_i - Kp(x_i)/L) \geq \sum_{x_i < q^{-1}(K/L)} (Kp(x_i)/L - x_i)\,, \tag{11}$$

where each of the summed terms is positive. For $x_i \neq q^{-1}(K/L)$, define

$$f(x_i) = x_i \cdot \frac{p(x_i) - q^{-1}(K/L) \cdot L/K}{x_i - Kp(x_i)/L}.$$

Observe that for $x_i = q^{-1}(K/L)$ the denominator is 0 and the numerator equals $p(x_i) - x_i \cdot L/K$ which is also 0. For $x_i > q^{-1}(K/L)$ both the numerator and denominator are positive and for $x_i < q^{-1}(K/L)$ both the numerator and denominator are negative. Hence $f(x_i)$ is non-negative for every $x_i \neq q^{-1}(K/L)$. The following claim holds because of the concavity of q; its proof is in the full paper [18].

▷ Claim A.2. If q is a convex differentiable function, we can complete f to a (non-decreasing) continuous function of x with $f'(x) \geq 0$ for all x with $0 < x \neq q^{-1}(K/L)$

We now have the tools we need. Let x^*_- be the largest $x_i < q^{-1}(K/L)$ and x^*_+ be the smallest $x_i > q^{-1}(K/L)$. Then we have $f(x^*_+) \geq f(x^*_-)$ and

$$\begin{aligned}
&\sum_{x_i > q^{-1}(K/L)} \left(x_i\ p(x_i) - q^{-1}(K/L) \cdot L/K \cdot x_i\right) \\
&\qquad = \sum_{x_i > q^{-1}(K/L)} f(x_i) \cdot (x_i - Kp(x_i)/L) \\
&\qquad \geq \sum_{x_i > q^{-1}(K/L)} f(x^*_+) \cdot (x_i - Kp(x_i)/L) \\
&\qquad \geq f(x^*_-) \sum_{x_i > q^{-1}(K/L)} (x_i - Kp(x_i)/L) \\
&\qquad \geq f(x^*_-) \sum_{x_i < q^{-1}(K/L)} (Kp(x_i)/L - x_i) \qquad \text{by Equation (11)} \\
&\qquad \geq \sum_{x_i < q^{-1}(K/L)} f(x_i) \cdot (Kp(x_i)/L - x_i) \\
&\qquad = \sum_{x_i < q^{-1}(K/L)} \left(q^{-1}(K/L) \cdot L/K \cdot x_i - x_i\ p(x_i)\right).
\end{aligned}$$

Adding back the terms where $x_i = q^{-1}(K/L)$, which have value 0, and rewriting we obtain

$$\sum_i \left(x_i\ p(x_i) - q^{-1}(K/L) \cdot L/K \cdot x_i\right) \geq 0.$$

Therefore we have

$$\sum_i x_i\ p(x_i) \geq q^{-1}(K/L) \cdot L/K \cdot \sum_i x_i \geq q^{-1}(K/L) \cdot (L/K) \cdot K = q^{-1}(K/L) \cdot L. \qquad \blacktriangleleft$$

Dynamic Averaging Load Balancing on Arbitrary Graphs

Abstract

In this paper we study dynamic averaging load balancing on general graphs. We consider infinite time and dynamic processes, where in every step new load items are assigned to randomly chosen nodes. A matching is chosen, and the load is averaged over the edges of that matching. We analyze the discrete case where load items are indivisible, moreover our results also carry over to the continuous case where load items can be split arbitrarily. For the choice of the matchings we consider three different models, random matchings of linear size, random matchings containing only single edges, and deterministic sequences of matchings covering the whole graph. We bound the discrepancy, which is defined as the difference between the maximum and the minimum load. Our results cover a broad range of graph classes and, to the best of our knowledge, our analysis is the first result for discrete and dynamic averaging load balancing processes. As our main technical contribution we develop a drift result that allows us to apply techniques based on the effective resistance in an electrical network to the setting of dynamic load balancing.

1 Introduction

Parallel and distributed computing is ubiquitous in science, technology, and beyond. Key to the performance of a distributed system is the efficient utilization of resources: in order to obtain a substantial speed-up it is of utmost importance that all processors have to handle the same amount of work. Unfortunately, many practical applications such as finite element

simulations are highly "irregular", and the amount of load generated on some processors is much larger than the amount of load generated on others. We therefore investigate *load balancing* to redistribute the load. Efficient load balancing schemes have a plenitude of applications, including high performance computing [34], cloud computing [27], numerical simulations [26], and finite element simulations [29].

In this paper we consider *neighborhood* load balancing on arbitrary graphs with n nodes, where the nodes balance their load in each step only with their direct neighbors. We assume *discrete* load items as opposed to *continuous* (or *idealized*) load items which can be broken into arbitrarily small pieces. We study *infinite* and *dynamic* processes where new load items are generated in every step.

We consider two different settings. In the *synchronous* setting m load items are generated on randomly chosen nodes. Then a matching is chosen and the load of the nodes is balanced (via weighted averaging) over the edges of that matching. Here we further distinguish between two matching models. We consider the *random matching model* where linear-size matchings are randomly chosen, and the *balancing circuit model* where the graph is divided deterministically into $d_{\max}$ many matchings. Here $d_{\max}$ is the maximum degree of any node. In the *asynchronous model* exactly one load item is generated on a randomly chosen node. In turn, the node chooses one of its edges at random and balances its load with the corresponding neighbor. This model can be regarded as a variant of the synchronous model where the randomly chosen matching has size one. It was introduced by [2] where the authors show results for cycles assuming continuous load. Our goal is to bound the so-called *discrepancy*, which is defined as the maximal load of any node minus the minimal load of any node.

The assumption that load items initially arrive at uniformly random nodes is a limitation of the model. However, we believe this to be a good starting point for further investigations into the behavior of load balancing methods in dynamic settings.

Results in a Nutshell. In this paper we present bounds on the expected discrepancy and bounds that hold with high probability for the three models introduced above. Our bounds for the synchronous model with balancing circuits hold for arbitrary graphs G, the bounds for the asynchronous model and the synchronous model with random matchings hold for regular graphs G only. For the asynchronous model and the model with random matchings our bounds on the discrepancy are expressed in terms of hitting times of a standard random walk on G, as well as in terms of the spectral gap of the Laplacian of G. For the synchronous model with balancing circuits we express our bounds in terms of the *global divergence*. This can be thought of as a measure of the convergence speed of the Markov chains modeling a random walk on G. However, it does not directly measure the speed of convergence of the chain. It accounts for the time period in which the chain keeps a given distance from the stationary (and uniform) distribution. In physics terminology, it is a measure of total *absement*, which is the time-integral of displacement.

For all three infinite processes our bounds on the discrepancy hold at an arbitrary point of time as long as the system is initially empty. Otherwise, the bounds hold after an initial time period, its length is a function of the initial discrepancy. In the following we give some exemplary results assuming that the system is initially empty and $m = n$. For the synchronous model with random matchings and the asynchronous model we can bound the discrepancy by $\mathcal{O}(\sqrt{n}\log(n))$ for *any* regular graph G. Our results show a polylogarithmic bound on the discrepancy for all regular graphs with a hitting time at most $\mathcal{O}(n \operatorname{poly}\log(n))$ (e.g., the two-dimensional torus or the hypercube). In all models we can bound the discrepancy

Table 1 Asymptotic upper bounds on the discrepancy in specific graph classes.

Graph	$\text{SBAL}(\mathcal{D}_{\text{RM}}(G), 1, m)$	$\text{SBAL}(\mathcal{D}_{\text{BC}}(G), 1, m)$	$\text{ABAL}(\mathcal{D}_{\text{A}}(G), 1)$
d-regular graph (const. d)	$\log(n) + \sqrt{m \cdot \log(n)}$	$\log(n) + \sqrt{m \cdot \log(n)}$	$\sqrt{n \cdot \log(n)}$
cycle C_n	$\log(n) + \sqrt{m \cdot \log(n)}$	$\log(n) + \sqrt{m \cdot \log(n)}$	$\sqrt{n \cdot \log(n)}$
2-D torus	$\log(n) + \sqrt{m/n} \cdot \log^{3/2}(n)$	$(1 + \sqrt{m/n}) \cdot \log(n)$	$\log^{3/2}(n)$
r-D torus (const. $r \geq 3$)	$(1 + \sqrt{m/n}) \cdot \log(n)$	$\log(n) + \sqrt{m/n \cdot \log(n)}$	$\log(n)$
hypercube	$(1 + \sqrt{m/n}) \cdot \log(n)$	$(1 + \sqrt{m/n}) \cdot \log(n)$	$\log(n)$
expander	$\log n + \sqrt{m/n \cdot \log(n)}$	$\log n + \sqrt{\zeta / \lambda(\mathbf{R})} \cdot \sqrt{m/n \cdot \log n}$	$\log(n)$

by $\mathcal{O}(\sqrt{n \log(n)})$ for arbitrary constant-degree regular graphs. For the full results we refer the reader to Theorem 3.1, Theorem 4.1, and Theorem 5.1. We show an overview of our bounds on the discrepancy for specific graph classes in Table 1. The corresponding results are formally derived and can be found in the full version.

All bounds presented in this paper also hold for the corresponding continuous processes without rounding. The authors of [2] consider the asynchronous process on cycles in the continuous setting where the load items can be divided into arbitrary small pieces. They bound the expected discrepancy, showing that $\mathbb{E}[\text{disc}(G)] = \mathcal{O}(\sqrt{n} \log(n))$ for a cycle G with n nodes. In contrast, we improve that bound for the cycle to $\mathcal{O}(\sqrt{n \log(n)})$, both in expectation and with high probability.

Our main analytical vehicle is a drift theorem that bounds the tail of the sum of a non-increasing sequence of random variables. Our drift theorem adapts known drift results from the literature, similarly to the Variable Drift Theorem in [23].

1.1 Related Work

There is a vast body of literature on iterative load balancing schemes on graphs where nodes are allowed to balance (or average) their load with neighbors only. One distinguishes between *diffusion* load balancing where the nodes balance their load with all neighbors at the same time and the *matching model* (or *dimension exchange*) model where the edges which are used for the balancing form a matching. In the latter model every resource is only involved in one balancing action per step, which greatly facilitates the analysis.

In this overview we only consider theoretical results and, as it is beyond the scope of this work to provide a complete survey, we focus on results for discrete load balancing. For results about continuous load balancing see, for example, [14, 22]. There are also many results in the context of balancing schemes where not the resources try to balance their load but the tokens (acting as selfish players) try to find a resource with minimum load. See [16] for a comprehensive survey about selfish load balancing and [1, 21, 11] for some recent results. Another related topic is token distribution where nodes do not balance their entire load with neighbors but send only single tokens over to neighboring nodes with a smaller load. See [18, 5, 30] for the static setting and [4] for the dynamic setting.

Discrete Models. The authors of [28] give the first rigorous result for discrete load balancing in the diffusion model. They assume that the number of tokens sent along each edge is obtained by rounding down the amount of load that would be sent in the continuous case. Using this approach they establish that the discrepancy is at most $O(n^2)$ after $O(\log(Kn))$ steps, where K is the initial discrepancy. Similar results for the matching model are shown in [19]. While always rounding down may lead to quick stabilization, the discrepancy tends to be quite large, a function of the diameter of the graph. Therefore, the authors of [32] suggest to use randomized rounding in order to get a better approximation of the continuous case. They show results for a wide class of diffusion and matching load balancing protocols and introduce the so-called *local divergence*, which aggregates the sum of load differences over all edges in all rounds. The authors prove that the local divergence gives an upper bound on the maximum deviation between the continuous and discrete case of a protocol. In [17] the authors show several results for a randomized protocol with rounding in the matching model. For complete graphs their results show a discrepancy of $\mathcal{O}(n\sqrt{\log n})$ after $\Theta(\log(Kn))$ steps. Later, [7] extended some of these results to the diffusion model. In [33] the authors show that the number of rounds needed to reach constant discrepancy is w.h.p. bounded by a function of the spectral gap of the relevant mixing matrix and the initial discrepancy. In [8] the authors propose a very simple potential function technique to analyze discrete diffusion load balancing schemes, both for discrete and continuous settings. In [9] the authors investigate a load balancing process on complete graphs. In each round a pair of nodes is selected uniformly at random and completely balance their loads up to a rounding error of ± 1.

The authors of [12] study load balancing via matchings assuming random placement of the load items. The initial load distribution is sampled from exponentially concentrated distributions (including the uniform, binomial, geometric, and Poisson distributions). The authors show that in this setting the convergence time is smaller than in the worst case setting. Regardless of the graph's topology, the discrepancy decreases by a factor of $\sqrt[4]{t}$ within t synchronous rounds. Their approach of using concentration inequalities to bound the discrepancy (in terms of the squared 2-norm of the columns of the matrices underlying the mixing process) strongly influenced our approach.

Dynamic Models. There are far fewer results for the *dynamic* diffusion models where new loads enter the system over time. In [2] the authors study a model similar to our asynchronous model. In each step one load item is allocated to a chosen node. In the same step, the chosen node picks a random neighbor, and the two nodes balance their loads by averaging them (continuous model). The authors show that the expected discrepancy is bounded by $\mathcal{O}(\sqrt{n}\log n)$, as well as a lower bound on the square of the discrepancy of $\Omega(n)$. The authors of [3] consider load balancing via matchings in a dynamic model where the load is, in every step, distributed by an adversary. They show the system is stable for sufficiently limited adversaries. They also give some upper bounds on the maximum load for the somewhat more restricted adversary. The authors of [10] consider discrete dynamic diffusion load balancing on arbitrary graphs. In each step up to n load items are generated on arbitrary nodes (the allocation is determined by an adversary). Then the nodes balance their load with each neighbor and finally one load item is deleted from every non-empty node. The authors show that the system is stable, which means that the total load remains bounded over time (as a function of n alone and independently of the time t).

In the *graphical balanced allocations* setting, the initial allocation of a load item is constrained to a randomly chosen edge of a graph, but load items cannot be moved after allocation (in contrast to our setting). For d-regular graphs, Peres, Talwar, and Wieder [31]

show that for the greedy algorithm which allocates the load item to the lower-loaded node at the edge, with the edge distribution being uniform, the discrepancy is in $\mathcal{O}(\log(n)d/\varepsilon)$ with high probability, where ε is the edge expansion of the graph. In fact, they show a more general result in terms of distributions over arbitrary subsets of nodes. Furthermore, Bansal and Feldheim [6] give a non-greedy algorithm using some non-local information that achieves a discrepancy in $\mathcal{O}((d/k)\log^4(n)\log(\log(n)))$ for k-edge-connected d-regular graphs, as well as a lower bound for the graphical balanced allocation setting stating that the discrepancy is in $\Omega(d/k + \log(n))$ with constant probability at any given time for any allocation strategy.

2 Balancing Models and Notation

We consider the following class of dynamic load balancing processes on d-regular graphs G with n nodes $V(G) = [n]$. Each process is modeled by a Markov chain $(\vec{X}(t))_{t\in\mathbb{N}_0}$, where the *load vector* $\vec{X}(t) = (X_i(t))_{i\in[n]} \in \mathbb{R}^n$ is the *state* of the process at the end of step t, and $X_i(t)$ is the load of node i at time t. We measure a load vector's imbalance by the discrepancy $\operatorname{disc}(\vec{x})$, which is the difference between the maximum load and the minimum load $\operatorname{disc}(\vec{x}) := \max_{i\in[n]} x_i - \min_{j\in[n]} x_j$.

We consider two balancing processes, the synchronous process SBal and the asynchronous process ABal. Both processes are parameterized by a *balancing parameter* β determining the balancing speed and a matching distribution $\mathcal{D}(G)$. For SBal, $\mathcal{D}(G)$ is a distribution over linear-sized matchings of G. For ABal, $\mathcal{D}(G)$ is a distribution over edges of G. SBal is additionally parameterized by the number of load items $m \in \mathbb{N}^+$ allocated in each round. ABal allocates only one new load item per step.

Synchronous Processes. The synchronous process $\text{SBal}(\mathcal{D}(G), \beta, m)$ works as follows. The process first allocates m items to randomly chosen nodes. Then it uses the matching distribution $\mathcal{D}(G)$ to determine the matching which is applied. Finally it balances the load over the edges of the matching (see Process $\text{Bal}(\mathbf{m}, \beta)$ described below). The parameter $\beta \in (0, 1]$ controls the fraction of the load difference that is sent over an edge in a step.

For the synchronous process SBal we consider two families of matching distributions, random matchings $(\mathcal{D}_{\text{RM}}(G))$ and balancing circuits $(\mathcal{D}_{\text{BC}}(G))$. $\mathcal{D}_{\text{RM}}(G)$ is generated according to the following method described in [19]. In essence, in a first step, nodes mark edges independently with probability $1/(8d)$, so that each edge is marked independently with probability $1/(4d) - 1/(16d^2) = \Theta(1/d)$ (as it can be marked from either end); in a second step, marked edges which are not incident to any other marked edge are selected for the matching. In expectation, the resulting matching has a size which is linear in the number of nodes; we refer to [19] for a more detailed description.

We will use capital $\mathbf{M}$ for randomly chosen matchings. The analysis for the random matching model can be found in Section 3. In the *balancing circuit model* we assume G is covered by ζ fixed matchings $\mathbf{m}(1), \ldots, \mathbf{m}(\zeta)$. $\mathcal{D}_{\text{BC}}(G)$ deterministically chooses matchings in periodic manner such that in step t the matching $\mathbf{m}(t) = \mathbf{m}(t \bmod \zeta)$ is chosen. We will use small $\mathbf{m}$ for deterministically chosen matchings. The analysis for the balancing circuit model can be found in Section 4.

Asynchronous Process. The asynchronous process $\text{ABal}(\mathcal{D}(G), \beta)$ works as follows. The process first uses $\mathcal{D}(G)$ to generate a matching, this time containing one edge only. The distribution we consider, $\mathcal{D}_{\text{A}}(G)$, first chooses a node i uniformly at random and then it chooses one of the nodes' edges (i, j) uniformly at random. Finally one new token is assigned

to either node i or j and then the edge (i, j) is used for balancing (see $\textsc{Bal}(\mathbf{m}, \beta)$). Note that for $\textsc{ABal}(\mathcal{D}_{\mathrm{A}}(G), \beta)$ the load allocation heavily depends on the edges which are used for balancing. This makes the analysis for this model quite challenging. In contrast, in $\textsc{SBal}(\mathcal{D}_{\mathrm{A}}(G), \beta, m)$ the load allocation and the balancing are independent. Note that in the case of d-regular graphs $\mathcal{D}_{\mathrm{A}}(G)$ is equivalent to the uniform distribution over all edges or to choosing a random matching of size one. We analyze the asynchronous model in Section 5.

$\textsc{SBal}(\mathcal{D}(G), \beta, m)$: In each round $t \in \mathbb{N}^+$:

1. Allocate m discrete, unit-sized load items to the nodes uniformly and independently at random. Define $\ell_i(t)$ as the number of tokens assigned to node i.
2. Sample a matching $\mathbf{M}(t)$ according to $\mathcal{D}(G)$.
3. Balance with $\textsc{Bal}(\mathbf{M}(t), \beta)$ applied to $X_i(t) := X_i(t) + \ell_i(t)$, $i \in \{1, \dots n\}$.

$\textsc{ABal}(\mathcal{D}(G), \beta)$: In each round $t \in \mathbb{N}^+$:

1. Select an edge $\{i, j\}$ according to $\mathcal{D}(G)$.
2. Allocate a single unit-size load item to either node i or j with a probability of $1/2$. I.e., with prob. $1/2$ set $\ell_i(t) = 1$ and $\ell_k = 0$ for all $k \neq i$, otherwise set $\ell_j(t) = 1$ and $\ell_k = 0$ for all $k \neq j$.
3. Balance with $\textsc{Bal}(\mathbf{M}(t), \beta)$ applied to $X_i(t) := X_i(t) + \ell_i(t)$, where $\mathbf{M}(t)$ includes just the edge $\{i, j\}$.

$\textsc{Bal}(\mathbf{m}, \beta)$: For each edge $\{i, j\}$ in the matching $\mathbf{m}$ balance loads of i and j:

1. Assume w.l.o.g. that $X_i(t) \geq X_j(t)$.
2. Let $p = \frac{\beta \cdot (X_i(t) - X_j(t))}{2} - \left\lfloor \frac{\beta \cdot (X_i(t) - X_j(t))}{2} \right\rfloor$.
3. Then, node i sends $L_{i,j}$ load items to node j where

$$L_{i,j} := \begin{cases} \left\lceil \frac{\beta \cdot (X_i(t) - X_j(t))}{2} \right\rceil, & \text{with probability } p, \\ \left\lfloor \frac{\beta \cdot (X_i(t) - X_j(t))}{2} \right\rfloor, & \text{with probability } 1 - p. \end{cases}$$

In the idealized setting, where the load is continuously divisible, a load of $\beta(X_i(t) - X_j(t))/2$ is sent from node i to node j.

2.1 Notation

We are given an arbitrary graph $G = (V, E)$ with n nodes. We mainly assume that G is regular and write d for the node degree. Recall that the process is modeled by a Markov chain $(\vec{X}(t))_{t \in \mathbb{N}}$, where $\vec{X}(t) = (X_i(t))_{i \in [n]} \in \mathbb{R}^n$ is the *load vector* at the end of step t, and $X_i(t)$ is the load of node i at time t. We write $\ell_i(t)$ for the number of load items allocated to node i in step t and define $\vec{\ell}(t) = (\ell_i(t))_{i \in [n]}$. We will use upper case letters such as $X_i(t)$ and $\mathbf{M}(t)$ to denote random variables and random matrices and lower case letters (like $x_i(t)$, $\mathbf{m}(t)$) for fixed outcomes. If clear from the context we will omit t from a random variable.

We model the idealized balancing step in round t by multiplication with a matrix $\mathbf{M}^{\beta}(t) \in \mathbb{R}^{n \times n}$ given by

$$\mathbf{M}^{\beta}_{i,j}(t) := \begin{cases} 1, & \text{if } i = j \text{ and } i \text{ is not matched at time } t, \\ 1 - \beta/2, & \text{if } i = j \text{ and } i \text{ is matched at time } t, \\ \beta/2, & \text{if } i \text{ and } j \text{ are matched at time } t, \\ 0, & \text{otherwise.} \end{cases}$$

We will omit the parameter β if it is clear from context. With slight abuse of notation we use the same symbol $\mathbf{M}(t)$ for the matching itself and the associated balancing matrix and refer to both as just "matchings". Furthermore, we write $E(\mathbf{M}(t))$ for their edges. For the product of all matching matrices from time t_1 to time t_2 we write

$$\mathbf{M}^{[t_1,t_2]} \coloneqq \mathbf{M}(t_2) \cdot \mathbf{M}(t_2-1) \cdot \dots \cdot \mathbf{M}(t_1+1) \cdot \mathbf{M}(t_1),$$

where for $t_1 > t_2$ we consider this to be the identity matrix. We generally refer to these matrices as *mixing matrices*. Moreover, we write $\mathbf{M}^{[t]}$ for the sequence of matching matrices $(\mathbf{M}(\tau))_{\tau\in[t]}$ and analogously $\mathbf{m}^{[t]}$ for a fixed sequence of matching matrices $(\mathbf{m}(\tau))_{\tau\in[t]}$. We will write $\mathbf{M}_{k,\cdot}$ for the vector forming the kth row of the matrix $\mathbf{M}$ (which we often treat as a column vector despite it being a row).

In the balancing circuit model we define the *round matrix* $\mathbf{R} \coloneqq \mathbf{m}^{[1,\zeta]}$ as the product of the matching matrices forming a complete period of the balancing circuit. Note that ζ has no relation to the minimum or maximum degree, although we may assume w.l.o.g. that each edge is covered by at least one of the matchings. We write $\lambda(\mathbf{R})$ for the spectral gap of the round matrix $\mathbf{R}$, i.e., for the difference between the largest two eigenvalues of $\mathbf{R}$.

We write $\vec{\varepsilon}(t) \in \mathbb{R}^n$ for the vector of additive rounding errors in round t. Then $\varepsilon_k(t)$ is the difference between the load at node k after step t and the load at node k after step t in an idealized scheme where loads are arbitrarily divisible.

Putting all of this together we can express the load vector at the end of step $t \in \mathbb{N}^+$ as

$$\vec{X}(t) = \mathbf{M}(t) \cdot \left(\vec{X}(t-1) + \vec{\ell}(t)\right) + \vec{\varepsilon}(t). \tag{1}$$

We write $\mathrm{t_{hit}}(\mathrm{G})$ for the *hitting time* of G, which is the maximum expected time it takes for a standard random walk on G (i.e., the walk moves to a neighbor chosen uniformly at random in each step) to reach a given node i from a given node j, with the maximum taken over all such pairs of nodes. We write $\mathrm{t^*_{hit}}(\mathrm{G})$ for the *edge hitting time* of G, which is defined like the hitting time, except that the maximum is taken over adjacent nodes only. We write $\mathbf{L}(G)$ for the normalized Laplacian matrix of a graph G. For regular graphs it may be defined as $\mathbf{L}(G) \coloneqq \mathbf{I} - \mathbf{A}(G)/d$, where $\mathbf{A}(G)$ is the adjacency matrix of G. Writing $\lambda_0 \le \lambda_1 \le \ldots \le \lambda_{n-1}$ for the real eigenvalues of $\mathbf{L}(G)$, we let $\lambda(\mathbf{L}(G)) \coloneqq \lambda_1 - \lambda_0$ be the spectral gap of the Laplacian of G.

3 Random Matching Model

In this section we analyze the process $\textsc{SBal}(\mathcal{D}_{\mathrm{RM}}(G), \beta, m)$ for d-regular graphs G, where the matching distribution $\mathcal{D}_{\mathrm{RM}}(G)$ is generated by the algorithm given in [19]. Note that the result (as well as the results for the two other models) holds at any point of time t if the system is initially empty. Furthermore, we can show the same results in the idealized setting where load items can be divided into arbitrarily small pieces (see [2]). For more details we refer the reader to the paragraph directly after Equation (3).

▶ **Theorem 3.1.** *Let G be a d-regular graph and define $T(G) \coloneqq \min\left\{\frac{\mathrm{t_{hit}}(\mathrm{G})}{n}\cdot\log(n), \sqrt{\frac{d}{\lambda(\mathbf{L}(G))}}, \frac{1}{\lambda(\mathbf{L}(G))}\right\}$. Let $\vec{X}(t)$ be the state of process $\mathrm{SBAL}(\mathcal{D}_{RM}(G), \beta, m)$ at time t with $\mathrm{disc}(\vec{X}(0)) =: K \ge 1$. There exists a constant $c > 0$ such that for all $t \ge c \cdot \log(K \cdot n)/(\lambda(\mathbf{L}(G)) \cdot \beta)$ it*

holds w.h.p.[1] *and in expectation*

$$\operatorname{disc}(\vec{X}(t)) = \mathcal{O}\left(\log(n)\cdot\left(1+\sqrt{\frac{m}{n}\cdot\frac{\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})}{n}}\right)+\sqrt{\frac{\log(n)}{\beta}\cdot\frac{m}{n}\cdot T(G)}\right).$$

Proof. We first expand the recurrence of Equation (1) (cf. [32]). After one step we get

$$\begin{aligned}\vec{X}(t) &= \mathbf{M}(t)\cdot\left(\vec{X}(t-1)+\vec{\ell}(t)\right)+\vec{\varepsilon}(t)\\ &= \mathbf{M}(t)\cdot\Big(\underbrace{\left(\mathbf{M}(t-1)\cdot\left(\vec{X}(t-2)+\vec{\ell}(t-1)\right)+\vec{\varepsilon}(t-1)\right)}_{\vec{X}(t-1)}+\vec{\ell}(t)\Big)+\vec{\varepsilon}(t)\\ &= \mathbf{M}^{[t-1,t]}\cdot\vec{X}(t-2)+\sum_{\tau=t-1}^{t}\mathbf{M}^{[\tau,t]}\cdot\vec{\ell}(\tau)+\sum_{\tau=t-1}^{t}\mathbf{M}^{[\tau+1,t]}\cdot\vec{\varepsilon}(\tau)\end{aligned}$$

We repeatedly expand this form up to the beginning of the process and get

$$\vec{X}(t) = \underbrace{\mathbf{M}^{[1,t]}\cdot\vec{X}(0)}_{\vec{I}(t)}+\underbrace{\sum_{\tau=1}^{t}\mathbf{M}^{[\tau,t]}\cdot\vec{\ell}(\tau)}_{\vec{D}(t)}+\underbrace{\sum_{\tau=1}^{t}\mathbf{M}^{[\tau+1,t]}\cdot\vec{\varepsilon}(\tau)}_{\vec{R}(t)}. \tag{2}$$

We write $\vec{I}(t)$, $\vec{D}(t)$, and $\vec{R}(t)$ for the three terms as indicated. Note that in general these terms are vectors of real numbers. The sum $\vec{I}(t)+\vec{D}(t)$ can be regarded as the contribution of an idealized process, where $\vec{I}(t)$ is the contribution of the initial load and $\vec{D}(t)$ is the contribution of the dynamically allocated load. Thus, $\vec{R}(t)$ is the deviation between the idealized process without rounding and the discrete process described in Section 2.

To bound the discrepancy $\operatorname{disc}(\vec{X}(t))$ of the load vector $\vec{X}(t)$ at time t, we use the fact that the discrepancy is sub-additive, i.e., that $\operatorname{disc}(\vec{x}+\vec{y})\le\operatorname{disc}(\vec{x})+\operatorname{disc}(\vec{y})$. Hence, to bound $\operatorname{disc}(\vec{X}(t))$, we individually bound the discrepancies of the three terms in Equation (2) and get

$$\operatorname{disc}(\vec{X}(t)) \le \operatorname{disc}(\vec{I}(t))+\operatorname{disc}(\vec{D}(t))+\operatorname{disc}(\vec{R}(t)). \tag{3}$$

If the system is initially empty, then $\operatorname{disc}(\vec{I}(t))=0$. Moreover, in the idealized setting without rounding $\operatorname{disc}(\vec{R}(t))=0$. Techniques to bound the first term $\operatorname{disc}(\vec{I}(t))$ and the last term $\operatorname{disc}(\vec{R}(t))$ are well-established. We state the corresponding results in Lemma 3.2 and Lemma 3.3 directly below the proof of our theorem. The main part of the proof is to bound $\operatorname{disc}(\vec{D}(t))$, which will be done in Section 3.1.

Let now $\gamma>1$. First, it follows from Lemma 3.2 that for all $t\ge c\cdot\log(K\cdot n)/(\lambda(\mathbf{L}(G))\cdot\beta)$ we have $\operatorname{disc}(\vec{I}(t))\le 1$ with probability at least $1-n^{-\gamma}$. Second, it follows from Lemma 3.4 that $\operatorname{disc}(\vec{R}(t))\le 2\sqrt{\gamma\log(n)/\beta}$ with probability at least $1-3\cdot n^{-\gamma+1}$. Third, it follows from Lemma 3.3 that

$$\operatorname{disc}(\vec{D}(t)) = \mathcal{O}\left(\gamma\log(n)\cdot\left(1+\sqrt{\frac{m}{n}\cdot\frac{\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})}{n}}\right)+\sqrt{\frac{\gamma\log(n)}{\beta}\cdot\frac{m}{n}\cdot T(G)}\right)$$

with probability at least $1-2\cdot n^{-\gamma+1}$. The statement of the theorem therefore follows from a union bound over the statements of Lemma 3.2, Lemma 3.3, and Lemma 3.4. The bound on expectation follows analogously from the linearity of expectation and the bounds on the expected discrepancies in the aforementioned lemmas. ◀

[1] The expression *with high probability (w.h.p.)* denotes a probability of at least $1-n^{-\Omega(1)}$.

Intuitively, Lemma 3.2 states that the contribution of the initial load to the discrepancy is insignificant if t is large enough. We generalize the analysis of Theorem 1 [32] (or Theorem 2.9 in [33]) to establish a bound on the discrepancy of the initial load as a function of β. We prove it in the full version.

▶ **Lemma 3.2** (Memorylessness Property). *Let G be a d-regular graph. Let $K = \operatorname{disc}(\vec{X}(0))$. Then there exists a constant $c > 0$ such that for all $\gamma > 0$ and $t \in \mathbb{N}$ with $t \geq t_0(\gamma) := c \cdot \max\{\gamma \log(n), \log(K \cdot n)\} \cdot \frac{1}{\lambda(\mathbf{L}(G)) \cdot \beta}$ we get with probability at least $1 - n^{-\gamma}$ and in expectation*

$$\operatorname{disc}(\vec{I}(t)) \leq 1.$$

The next lemma bounds $\operatorname{disc}(\vec{R}(t))$, the discrepancy contribution of cumulative rounding errors. Note that this result does not just hold for the random matching model, but for all the three models that we consider in this paper. In the proof of the lemma we extend then results of Theorem 3.6 in [33] (which is based on work in [7]) to establish a bound as a function of β. We prove it in the full version.

▶ **Lemma 3.3** (Insignificance of Rounding Errors). *Let G be an arbitrary graph. Then for all $\gamma > 1$, $t \in \mathbb{N}$, and $k \in [n]$ we get with probability at least $1 - 2n^{-\gamma+1}$ and in expectation*

$$\operatorname{disc}(\vec{R}(t)) \leq 2 \cdot \sqrt{\gamma \log(n)/\beta}.$$

To bound $\operatorname{disc}(\vec{D}(t))$, the discrepancy contribution of dynamically allocated load items we apply the next lemma. It is in fact the core of our work. We prove it in Section 3.1.

▶ **Lemma 3.4** (Contribution of Dynamically Allocated Load). *Let G be a d-regular graph. Define $T(G) := \min\left\{\mathrm{t}_{\mathrm{hit}}(\mathrm{G}) \cdot \log n/n, \sqrt{d/\lambda(\mathbf{L}(G))}, 1/\lambda(\mathbf{L}(G))\right\}$. Then for all $\gamma > 1$ and $t \in \mathbb{N}$ we get with probability at least $1 - 3n^{-\gamma+1}$ and in expectation*

$$\operatorname{disc}(\vec{D}(t)) = \mathcal{O}\left(\gamma \log(n) \cdot \left(1 + \sqrt{\frac{m}{n} \cdot \frac{\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})}{n}}\right) + \sqrt{\frac{\gamma \log(n)}{\beta} \cdot \frac{m}{n} \cdot T(G)}\right).$$

3.1 Bounding the Contribution of Dynamically Allocated Load

In this section we prove Lemma 3.4. Some of the proofs are omitted and can be found in full version. As a first step, we bound $\operatorname{disc}(\vec{D}(t))$ using the *global divergence* $\Upsilon(\mathbf{M}^{[t]})$, which is defined over a sequence of matching matrices $\mathbf{M}^{[t]}$ as

$$\Upsilon(\mathbf{M}^{[t]}) := \max_{k \in [n]} \Upsilon_k(\mathbf{M}^{[t]}), \quad \text{where} \quad \Upsilon_k(\mathbf{M}^{[t]}) := \sqrt{\sum_{\tau=1}^{t} \left\| \mathbf{M}^{[\tau,t]}_{k,\cdot} - \frac{\vec{1}}{n} \right\|_2^2}.$$

The global divergence can be regarded as a measure of the convergence speed of a random walk that uses the matching matrices as transition probabilities. In [17, 33, 7] the authors use a related notion which they call the *local p-divergence*, also defined on a sequence of matchings $\mathbf{m}^{[t]}$. The difference lies in the fact that the global divergence, essentially, measures differences between nodes' values and a global average, while the local divergence measures differences between neighboring nodes. To show Lemma 3.4 we first observe the following.

▶ **Observation 3.5.** *It holds that* $\operatorname{disc}(\vec{D}(t)) \leq 2 \cdot \max_{k \in [n]} |D_k(t) - t \cdot m/n|$.

Next we consider a fixed node k and show a concentration inequality on $D_k(t)$ in terms of $\Upsilon_k(\mathbf{m}^{[t]})$, where $\mathbf{m}^{[t]}$ is the sequence of matchings applied by our process (Lemma 3.6). Note that in the lemma we assume the matchings are fixed and the randomness is due to the random load placement only. Hence, the lemma directly applies to $\mathcal{D}_{\mathrm{BC}}(G)$. Afterwards, we bound the global divergence of the random sequence of matchings, $\Upsilon_k(\mathbf{M}^{[t]})$ in terms of a notion of "goodness" of the used matching distribution $\mathcal{D}$, for the random sequence of matchings (Lemma 3.9), and then bound the "goodness" of the distribution $\mathcal{D}_{\mathrm{RM}}(G)$ used in the random matching model (Lemma 3.10). We start with a bound on the deviation of $D_k(t)$ from the average load $t \cdot m/n$ in terms of $\Upsilon(\mathbf{m}^{[t]})$.

▶ **Lemma 3.6** (Load Concentration). *Let $\mathbf{m}^{[t]}$ be an arbitrary sequence of matchings. Then for all $\gamma > 0$, $t \in \mathbb{N}$, and $k \in [n]$ we get with probability at most $2 \cdot n^{-\gamma}$*

$$\left| D_k(t) - t \cdot \frac{m}{n} \right| \geq \frac{4}{3} \cdot \gamma \log(n) + \sqrt{8\gamma \log(n) \cdot \frac{m}{n}} \cdot \Upsilon_k(\mathbf{m}^{[t]}).$$

Proof. Our goal is to decompose $D_k(t)$ into a sum of independent random variables. Recall that we assume that the matching matrices are fixed and all randomness is due to the random choices of the load items. This will enable us to apply a concentration inequality to this sum. For the decomposition observe that $\vec{D}(t) = \sum_{\tau=1}^{t} \mathbf{m}^{[\tau,t]} \cdot \vec{\ell}(\tau)$, where $\vec{\ell}(\tau)$ is the random load vector corresponding to the m load items allocated at time τ. So the kth coordinate of $\vec{D}(t)$ is $D_k(t) = \sum_{\tau=1}^{t} \sum_{w \in [n]} \mathbf{m}_{k,w}^{[\tau,t]} \cdot \ell_w(\tau)$. We define the indicator random variable $B(\tau, j, w)$ for $\tau \in [t], j \in [m]$ and $w \in [n]$ as

$$B(\tau, j, w) \coloneqq \begin{cases} 1, & \text{if the } j\text{-th load item of step } \tau \text{ is allocated to node } w, \\ 0, & \text{otherwise.} \end{cases}$$

Note that for fixed τ and j we have $\sum_{w \in [n]} B(\tau, j, w) = 1$, $\mathbb{P}[B(\tau, j, w) = 1] = 1/n$ and $\mathbb{E}[B(\tau, j, w)] = 1/n$. Observe that $\ell_w(\tau)$, the load allocated to node w at step τ, can be expressed as $\sum_{j \in [m]} B(\tau, j, w)$. Merging this with the value of $D_k(t)$ gives

$$D_k(t) = \sum_{\tau=1}^{t} \sum_{w \in [n]} \mathbf{m}_{k,w}^{[\tau,t]} \cdot \left(\sum_{j \in [m]} B(\tau, j, w) \right) = \sum_{\tau=1}^{t} \sum_{j \in [m]} \underbrace{\left(\sum_{w \in [n]} \left(\mathbf{m}_{k,w}^{[\tau,t]} \cdot B(\tau, j, w) \right) \right)}_{=: C_k(\tau, j)}.$$

For a fixed $\tau \in [t]$ and $j \in [m]$ we define $C_k(\tau, j) \coloneqq \sum_{w \in [n]} \mathbf{m}_{k,w}^{[\tau,t]} \cdot B(\tau, j, w)$. This random variable measures the contribution of j-th load item of round τ to $D_k(t)$. Note that the load items are allocated independently from each other. Since $\mathbf{m}^{[\tau,t]}$ are fixed matrices, then $C_k(\tau, j)$ and $C_k(\tau', j')$ are independent for all τ and τ' and $j \neq j'$. To apply the concentration inequality Theorem 3.4 in [13], we need to show that $C_k(\tau, j) \leq 1$ and compute an upper bound on $\mathrm{Var}[C_k(\tau, j)]$. Showing the first condition is easy since exactly one of the indicator random variables $B(\tau, j, w)$ is one and $\mathbf{m}_{k,w}^{[\tau,t]}$ has a value between zero and one.

It remains to consider the variance of $C_k(\tau, j)$. First note that by linearity of expectation

$$\mathbb{E}[C_k(\tau, j)] = \mathbb{E}\left[\sum_{w \in [n]} \left(\mathbf{m}_{k,w}^{[\tau,t]} \cdot B(\tau, j, w) \right) \right] = \sum_{w \in [n]} \mathbf{m}_{k,w}^{[\tau,t]} \cdot \mathbb{E}[B(\tau, j, w)] = \sum_{w \in [n]} \mathbf{m}_{k,w}^{[\tau,t]} \cdot \frac{1}{n} = \frac{1}{n},$$

where the last equality follows form the fact that $\mathbf{m}^{[\tau,k]}$ is doubly stochastic. Now we get

$$\begin{aligned}\mathrm{Var}[C_k(\tau,j)] &= \mathbb{E}\Big[(C_k(\tau,j)-\mathbb{E}[C_k(\tau,j)])^2\Big] = \mathbb{E}\left[\Big(\Big(\sum_{w\in[n]} \mathbf{m}^{[\tau,t]}_{k,w}\cdot B(\tau,j,w)\Big)-\frac{1}{n}\Big)^2\right]\\ &= \sum_{w'\in[n]}\frac{1}{n}\cdot\left(\mathbf{m}^{[\tau,t]}_{k,w'}-\frac{1}{n}\right)^2 = \frac{1}{n}\cdot\left\|\mathbf{m}^{[\tau,t]}_{k,\cdot}-\frac{\vec{1}}{n}\right\|_2^2,\end{aligned}$$

where we used that for each τ and each j exactly one of the $B(\tau,j,w)$ is one and all others are zero, and each of the n possible cases has uniform probability.

Recall that $C_k(\tau,j)$ and $C_k(\tau',j')$ are independent for all τ,τ' and $j\neq j'$. Hence we get

$$\begin{aligned}\mathrm{Var}\left[\sum_{\tau=1}^{t}\sum_{j\in[m]}C_k(\tau,j)\right] &= \sum_{\tau=1}^{t}\sum_{j\in[m]}\mathrm{Var}[C_k(\tau,j)] = \frac{1}{n}\cdot\sum_{\tau=1}^{t}\sum_{j\in[m]}\left\|\mathbf{m}^{[\tau,t]}_{k,\cdot}-\frac{\vec{1}}{n}\right\|_2^2\\ &= \frac{m}{n}\cdot\Big(\Upsilon_k(\mathbf{m}^{[t]})\Big)^2,\end{aligned}$$

where the final equality uses the definition of the global divergence $\Upsilon_k(\mathbf{m}^{[t]})$. Applying Theorem 3.4 in [13] with $M=1$ and $X=D_k(t)=\sum_{\tau=1}^{t}\sum_{j\in[m]}C_k(\tau,j)$ with $\lambda = 2\gamma\log(n)/3+\Upsilon_k(\mathbf{m}^{[t]})\cdot\sqrt{2\gamma m/n}$ results in

$$\mathbb{P}\left[D_k(t)-t\cdot\frac{m}{n}\geq\frac{2}{3}\cdot\gamma\log(n)+\sqrt{2\gamma\log(n)\cdot\frac{m}{n}}\cdot\Upsilon_k(\mathbf{m}^{[t]})\right]\leq n^{-\gamma}.$$

The lower bound can be established using Theorem 4.1 in [13] (with $a_i=0$ and $M=1$). Via a union bound we get

$$\mathbb{P}\left[\left|D_k(t)-t\cdot\frac{m}{n}\right|\geq\frac{4}{3}\cdot\gamma\log(n)+\sqrt{8\gamma\log(n)\cdot\frac{m}{n}}\cdot\Upsilon_k(\mathbf{m}^{[t]})\right]\leq 2\cdot n^{-\gamma}.$$ ◀

To bound the global divergence of the matching sequence used by the process we use two potential functions. The *quadratic node potential* $\Phi(\vec{x})$ is given by

$$\Phi(\vec{x}) \coloneqq \sum_{i\in[n]}(x_i-\overline{x})^2,\quad \text{where}\quad \overline{x}\coloneqq\frac{1}{n}\cdot\sum_{j\in[n]}x_j.$$

For a set of edges S on the nodes $[n]$ and a vector $\vec{x}\in\mathbb{R}^n$, the *quadratic edge potential* is

$$\Psi_S(\vec{x}) \coloneqq \sum_{\{i,j\}\in S}(x_i-x_j)^2.$$

We may also write $\Psi_G\coloneqq\Psi_{E(G)}$ whenever G is a graph, and $\Psi_{\mathbf{M}}\coloneqq\Psi_{E(\mathbf{M})}$ whenever $\mathbf{M}$ is a matching matrix. The following observation relates the drop of node potential to the edge potential in terms of β.

▶ **Observation 3.7.** *Let $\mathbf{M}^\beta$ be a matching matrix with parameter $\beta\in(0,1]$. Then for any $\vec{x}\in\mathbb{R}^n$ we have $\Phi(\vec{x})-\Phi(\mathbf{M}^\beta\cdot\vec{x}) = \frac{1-(1-\beta)^2}{2}\cdot\Psi_{E(\mathbf{M}^\beta)}(\vec{x})$.*

We now define a notion of a matching distribution being *good*. In Lemma 3.9 below we show that the notion is sufficient for showing that matching sequences generated from such distributions have bounded global divergence. Note that the "goodness" of a distribution does not depend on β but on graph properties and the random choices with which the matchings are chosen. Hence, we assume $\beta=1$.

▶ **Definition 3.8.** *Assume G is an arbitrary d-regular graph. Let $g\colon \mathbb{R}_0^+ \to \mathbb{R}^+$ be an increasing function and let $\sigma^2 > 1$. Then a matching distribution $\mathcal{D}(G)$ is (g, σ^2)-*good *if the following conditions hold for $\mathbf{M}^1 \sim \mathcal{D}(G)$ and all stochastic vectors $\vec{x} \in \mathbb{R}^n$.*

1. $\Phi(\vec{x}) - \mathbb{E}[\Phi(\mathbf{M}^1 \cdot \vec{x})] \geq g(\Phi(\vec{x}))$.
2. $\mathrm{Var}[\Phi(\mathbf{M}^1 \cdot \vec{x})] \leq (\sigma^2 - 1) \cdot \big(\Phi(\vec{x}) - \mathbb{E}[\Phi(\mathbf{M}^1 \cdot \vec{x})]\big)^2$.

It remains to show two results. First, assuming a matching distribution is (g, σ^2)-good, the global divergence of a matching sequence generated by that distribution can be bounded in terms of g and σ (Lemma 3.9). Second, we have to calculate a function g_G and the values of σ_G for which the matching distribution $\mathcal{D}_{\mathrm{RM}}(G)$ is (g_G, σ_G^2)-good (see Lemma 3.10).

▶ **Lemma 3.9** (Global Divergence)**.** *Assume G is an arbitrary graph. Let $g\colon \mathbb{R}_0^+ \to \mathbb{R}^+$ be an increasing function, $\sigma^2 > 1$, and $\beta \in (0, 1]$. Let $\mathbf{M}^{[t]} = (\mathbf{M}^\beta(\tau))_{\tau=1}^t$ be an i.i.d. sequence of matching matrices generated by $\mathcal{D}(G)$ and assume $\mathcal{D}(G)$ is a (g, σ^2)-good matching distribution. Then for all $\gamma > 0$ and $k \in [n]$ we get with probability at least $1 - n^{-\gamma}$*

$$\Big(\Upsilon_k(\mathbf{M}^{[t]})\Big)^2 \leq 8\sigma^2(\gamma \log(n) + \log(8\sigma^2)) + \frac{2}{\beta} \cdot \int_0^1 \frac{x}{g(x)}\,\mathrm{d}x.$$

▶ **Lemma 3.10.** *Assume G is an arbitrary d-regular graph. Let*

$$g_G(x) \coloneqq \frac{1}{16d} \cdot \max\left\{d \cdot \lambda(\mathbf{L}(G)) \cdot x, \frac{x^2}{\mathrm{Res}(G)}, \frac{4}{27} \cdot x^3\right\} \text{ and } \sigma_G^2 = 32 \cdot (\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})\,/n) + 5.$$

Then $\mathcal{D}_{RM}(G)$ is (g_G, σ_G^2)-good.

Proof. First, note that the function $g_G(x)$ is increasing in x. Applying the first part of Lemma 3.11 (see below) we get that for any vector $\vec{x} \in \mathbb{R}^n$ it holds that

$$\Phi(\vec{x}) - \mathbb{E}\big[\Phi(\mathbf{M}^1 \cdot \vec{x})\big] \geq \frac{1}{16d} \cdot \Psi_G(\vec{x}).$$

From the first two statements of Lemma 3.12 (stated behind Lemma 3.12) we see that for $\mathbf{M}^1 \sim \mathcal{D}_{\mathrm{RM}}(G)$ and all stochastic vectors $\vec{x} \in \mathbb{R}^n$

$$\Psi_G(\vec{x}) \geq \max\left\{d \cdot \lambda(\mathbf{L}(G)) \cdot \Phi(\vec{x}), \frac{\Phi(\vec{x})^2}{\mathrm{Res}(G)}, \frac{4}{27} \cdot \Phi(\vec{x})^3\right\}.$$

Hence,

$$\Phi(\vec{x}) - \mathbb{E}\big[\Phi(\mathbf{M}^1 \cdot \vec{x})\big] \geq \frac{1}{16d} \cdot \max\left\{d \cdot \lambda(\mathbf{L}(G)) \cdot \Phi(\vec{x}), \frac{\Phi(\vec{x})^2}{\mathrm{Res}(G)}, \frac{4}{27} \cdot \Phi(\vec{x})^3\right\},$$

and as a consequence, $\Phi(\vec{x}) - \mathbb{E}[\Phi(\mathbf{M}^1 \cdot \vec{x})] \geq g_G(\Phi(\vec{x}))$ by the definition of g_G.

It remains to check the second condition of Definition 3.8 with our claimed value σ_G^2. Inserting its value as stated in the lemma, the condition requires that

$$\mathrm{Var}[\Phi(\mathbf{M}^1 \cdot \vec{x})] \leq (32(\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})\,/n) + 5 - 1) \cdot \big(\Phi(\vec{x}) - \mathbb{E}[\Phi(\mathbf{M}^1 \cdot \vec{x})]\big)^2,$$

which is given in the second part of Lemma 3.11 (see below). ◀

In Lemma 3.11 we first relate the drop of Φ to the quadratic edge potential Ψ. In the second part we bound the variance of the potential drop as a function of the edge hitting time.

▶ **Lemma 3.11.** *Let G be a d-regular graph, let $\mathbf{M}^1 \sim \mathcal{D}_{RM}(G)$, and let $\vec{x} \in \mathbb{R}^n$, then*

1. $\Phi(\vec{x}) - \mathbb{E}\big[\Phi(\mathbf{M}^1 \cdot \vec{x})\big] \geq \frac{1}{16d} \cdot \Psi_G(\vec{x})$.
2. $\mathrm{Var}\big[\Phi(\mathbf{M}^1 \cdot \vec{x})\big] \leq (32 \cdot (\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})/n) + 4) \cdot \big(\Phi(\vec{x}) - \mathbb{E}\big[\Phi(\mathbf{M}^1 \cdot \vec{x})\big]\big)^2$.

In Lemma 3.12 we relate the size of the quadratic edge potential Ψ_G to the second-largest eigenvalue of $\mathbf{L}(G)$, effective resistances of G and node potential. To state it, we need some additional definitions. For any two nodes i and j of the graph G, $\mathrm{Res}(i,j)$ is the *effective resistance* (or *resistive distance*) between i and j in G (see Chapter 9 in [24] for a definition, and refer to further details and properties can also be found in [15] and [25, Section 4]; note that in our case, all edges have unit weight). Furthermore, we write $\mathrm{Res}(G)$ for the *resistive diameter* of G, i.e., the largest resistive distance between any pair of nodes in G, and write $\mathrm{Res}^*(G)$ for the maximum effective resistance between any pair of nodes adjacent in G. I.e., $\mathrm{Res}(G) \coloneqq \max_{i,j\in[n]} \mathrm{Res}(i,j)$ and $\mathrm{Res}^*(G) \coloneqq \max_{\{i,j\}\in E(G)} \mathrm{Res}(i,j)$. The first part of the following lemma was previously shown in [19, 33].

▶ **Lemma 3.12.** *Let $\vec{x} \in \mathbb{R}^n$, and let G be a connected d-regular graph.*

1. $\Psi_G(\vec{x}) \geq d \cdot \lambda(\mathbf{L}(G)) \cdot \Phi(\vec{x})$.
2. *If $\vec{x}$ is stochastic, then* $\Psi_G(\vec{x}) \geq \max\left\{\frac{1}{\mathrm{Res}(G)} \cdot \Phi(\vec{x})^2, \frac{4}{27} \cdot \Phi(\vec{x})^3\right\}$
3. $\max_{\{i,j\}\in E(G)} (x_i - x_j)^2 \leq \mathrm{Res}^*(G) \cdot \Psi_G(\vec{x})$.

Proof of Lemma 3.4

Proof. Define $g_G(x) = \frac{1}{16d} \cdot \max\{d \cdot \lambda(\mathbf{L}(G)) \cdot x, x^2/\mathrm{Res}(G), 4x^3/27\}$ and let $\sigma_G^2 \coloneqq 32 \cdot (\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})/n) + 5$. Then by Lemma 3.10 the matching distribution $\mathcal{D}_{\mathrm{RM}}(G)$ is (g_G, σ_G^2)-good. By Lemma 3.9 we have for all $t \in \mathbb{N}$, $k \in [n]$

$$\mathbb{P}\left[\left(\Upsilon_k(\mathbf{M}^{[t]})\right)^2 \leq 8\sigma_G^2((\gamma+1)\log(n) + \log(8\sigma_G^2)) + \frac{1}{\beta} \cdot \int_0^1 \frac{x}{g_G(x)}\,\mathrm{d}x\right] \geq 1 - n^{-(\gamma+1)}.$$

To bound $\Upsilon_k(\mathbf{M}^{[t]})$ we use the following two claims, which we prove in the full version.

▷ Claim 3.13. It holds that $\int_0^1 x/g_G(x)\,\mathrm{d}x = \mathcal{O}(T(G))$.

▷ Claim 3.14. For any d-regular graph G it holds that $\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})/n \geq 1/2$.

Together we get from Claim 3.13 and Claim 3.14 that with probability at least $1 - n^{-(\gamma+1)}$

$$\left(\Upsilon_k(\mathbf{M}^{[t]})\right)^2 = \mathcal{O}\left(\frac{\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})}{n} \cdot \left(\gamma\log(n) + \log\left(\frac{\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})}{n}\right)\right) + \frac{T(G)}{\beta}\right). \tag{4}$$

Since $\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G}) = \mathcal{O}(n^3)$ (Proposition 10.16 in [24]), $\log(\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})/n) = \mathcal{O}(\log n)$, and $\gamma > 1$,

$$\Upsilon_k(\mathbf{M}^{[t]}) = \mathcal{O}\left(\sqrt{\gamma\log(n) \cdot \frac{\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})}{n} + \frac{T(G)}{\beta}}\right) = \mathcal{O}\left(\sqrt{\gamma\log(n) \cdot \frac{\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})}{n}} + \sqrt{\frac{T(G)}{\beta}}\right).$$

Now Lemma 3.6 states that for any fixed sequence of matching matrices $\mathbf{m}^{[t]}$, with probability at least $1 - 2n^{-(\gamma+1)}$ it holds that

$$\left|D_k(t) - t \cdot \frac{m}{n}\right| = \mathcal{O}\left(\gamma\log(n) + \sqrt{\gamma\log(n) \cdot \frac{m}{n}} \cdot \Upsilon_k(\mathbf{m}^{[t]})\right). \tag{5}$$

Applying a union bound over all $k \in [n]$, Equation (4) and Equation (5) hold for all k with probability at least $1 - 3n^{-\gamma}$. Hence, for all $k \in [n]$

$$\left|D_k(t) - t \cdot \frac{m}{n}\right| = \mathcal{O}\left(\gamma \log(n) + \sqrt{\gamma \log(n) \cdot \frac{m}{n}} \cdot \left(\sqrt{\gamma \log(n) \cdot \frac{\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})}{n}} + \sqrt{\frac{T(G)}{\beta}}\right)\right)$$
$$= \mathcal{O}\left(\gamma \log(n) \cdot \left(1 + \sqrt{\frac{m}{n} \cdot \frac{\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})}{n}}\right) + \sqrt{\frac{(\gamma+1)\log(n)}{\beta} \cdot \frac{m}{n} \cdot T(G)}\right).$$

The high-probability bound now follows from Observation 3.5. The corresponding bound on $\mathbb{E}[\mathrm{disc}(\vec{D}(t)]$ follows readily; see the full version for details. ◀

4 Balancing Circuit Model

Here we assume $\beta = 1$. Recall that we assume G is covered by ζ fixed matchings $\mathbf{m}(1), \ldots, \mathbf{m}(\zeta)$. The matching distribution $\mathcal{D}_{\mathrm{BC}}(G)$ then deterministically chooses the matching $\mathbf{m}(t) = \mathbf{m}(t \bmod \zeta)$ in step t. The round matrix is defined as $\mathbf{R} := \mathbf{m}^{[1,\zeta]}$. Thus, for a sequence of matchings $\mathbf{m}^{[t]}$ the global divergence is $\Upsilon(\mathbf{m}^{[t]}) := \max_{k\in[n]} \sqrt{\sum_{\tau=1}^{t} \left\|\mathbf{m}^{[\tau,t]}_{k,\cdot} - 1/n\right\|_2^2}$. The next theorem provides an upper bound on the discrepancy for this model. Note that the following theorem holds for arbitrary graphs, while Theorem 3.1 only holds for d-regular graphs.

▶ **Theorem 4.1.** *Let G be an arbitrary graph and let $\vec{X}(t)$ be the state of process $SB_{AL}(\mathcal{D}_{BC}(G), 1, m)$ at time t with $\mathrm{disc}(\vec{X}(0)) =: K$. For all $t \in \mathbb{N}$ with $t \geq \frac{\zeta}{\lambda(\mathbf{R})} \cdot (\ln(K \cdot n))$ it holds w.h.p. and in expectation*

$$\mathrm{disc}(\vec{X}(t)) = \mathcal{O}\Big(\log(n) + \sqrt{m/n} \cdot \Upsilon(\mathbf{m}^{[t]}) \cdot \sqrt{\log(n)}\Big).$$

Proof. The proof follows the same line as the proof Theorem 3.1, which is proved via Lemma 3.2, Lemma 3.4, and Lemma 3.3 bounding $\vec{I}(t), \vec{D}(t)$, and $\vec{R}(t)$, respectively. Lemma 3.2 is replaced by Lemma 4.2 below. Lemma 3.2 can also be applied to the balancing circuit model since it only requires that the subgraph used for balancing is a matching.

It remains to replace Lemma 3.3. Since the matching matrices are fixed this time the proof is much simpler. The proof of Lemma 3.6 carries to over to this model giving us a bound on $|D_k(t) - tm/n|$ for $k \in [n]$ with probability at least $1 - 2 \cdot n^{-\gamma}$. Applying the union bound over all nodes $k \in [n]$, together with Observation 3.5 (stating that $\mathrm{disc}(\vec{D}(t)) \leq 2 \cdot \max_{k\in[n]} |D_k(t) - t \cdot m/n|$), gives a bound on $\mathrm{disc}(\vec{D}(t))$ which holds with probability at least $1 - 2 \cdot n^{\gamma+1}$. ◀

▶ **Lemma 4.2** (Memorylessness Property). *For all $t \in \mathbb{N}$ with $t \geq \zeta/\lambda(\mathbf{R}) \cdot (\ln(K \cdot n))$ it holds that $\mathrm{disc}(\vec{I}(t)) \leq 2$.*

Proof. Since $\Phi(\vec{x}) \leq K^2 \cdot n$ it follows from Lemma 2 in [20] that

$$\Phi\left(\mathbf{m}^{[1,t]} \cdot \vec{x}\right) \leq (1 - \lambda(\mathbf{R}))^{2\lfloor t \rfloor/\zeta} \cdot \Phi(\vec{x}) \leq (1 - \lambda(\mathbf{R}))^{2\lfloor t \rfloor/\zeta} \cdot K^2 \cdot n \leq e^{-2\lfloor t \rfloor \cdot \lambda(\mathbf{R})/\zeta + 2\ln(Kn)}.$$

Setting $t \geq (\zeta/\lambda(\mathbf{R})) \cdot (\ln(Kn))$ gives $\Phi\left(\mathbf{m}^{[1,t]} \cdot \vec{x}\right) \leq 1$ which implies that $\mathrm{disc}(\vec{I}(t) \leq 2$. ◀

Note that a similar statement was shown in [32, 33, 7].

The next theorem provides a lower bound on the discrepancy for this model. The proof can be found in the full version.

▶ **Theorem 4.3.** *Let G be an arbitrary graph and let $\vec{X}(t)$ be the state of process $SBAL(\mathcal{D}_{BC}(G), 1, m)$ at time t. Then for all $t \in \mathbb{N}$ and $m \geq 4n \cdot \log(n)/\Upsilon(\mathbf{m}^{[t]})$ it holds with constant probability*

$$\operatorname{disc}(\vec{X}(t)) = \Omega\Big(\sqrt{m/n} \cdot \Upsilon(\mathbf{m}^{[t]})\Big).$$

5 Asynchronous Model

The following is our main theorem for the asynchronous model. The bounds provided by Theorem 5.1 for the asynchronous model differ from those in Theorem 3.1 for the random matching model in two details. First, the lower bound on the balancing time is larger by a factor of n. This is due to the fact that the asynchronous model balances across just one edge per round in contrast to $\Theta(n)$ edges in the random matching model. Second, the upper bound on $\operatorname{disc}(\vec{X}(t))$ is much simpler. Note, however that setting $m = n$ in Theorem 3.1 and further simplifying the result by using $\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})/n = \Omega(1)$ (see also Claim 3.14 in the proof of Lemma 3.4) results in the same asymptotic bound as in Theorem 5.1.

▶ **Theorem 5.1.** *Let G be a d-regular graph and define $T(G) := \min\left\{\frac{\mathrm{t}_{\mathrm{hit}}(\mathrm{G})}{n} \cdot \log(n), \sqrt{\frac{d}{\lambda(\mathbf{L}(G))}}, \frac{1}{\lambda(\mathbf{L}(G))}\right\}$. Let $\vec{X}(t)$ be the state of process $ABAL(\mathcal{D}_A(G), \beta)$ at time t with $\operatorname{disc}(\vec{X}(0)) =: K \geq 1$. There exists a constant $c > 0$ such that for all $t \geq c \cdot n \cdot \log(K \cdot n)/(\lambda(\mathbf{L}(G)) \cdot \beta)$ it holds w.h.p. and in expectation*

$$\operatorname{disc}(\vec{X}(t)) = \mathcal{O}\left(\log(n)\sqrt{\frac{\mathrm{t}^*_{\mathrm{hit}}(\mathrm{G})}{n}} + \sqrt{\frac{\log(n)}{\beta} \cdot T(G)}\right).$$

Proof Sketch of Theorem 5.1. The proof of the theorem follows along the same lines at the proof of Theorem 3.1. However, there are some major differences. Most importantly, the proof of Lemma 3.6 (giving a concentration bound on $D_k(t)$ in terms of the global divergence of the sequence of matching matrices) can not be applied for ABAL. The proof heavily relies on the fact that the load allocation and the matching edges are chosen independently from each other, which is certainly not the case for ABAL. In the full version, we carefully analyze the dependency using a stronger concentration inequality. In addition, we also have to re-calculate the function g_G and σ_G to show that the matching distribution used by $\mathcal{D}_{\mathrm{A}}$ is (g_G, σ_G^2)-good. ◀

6 Drift Result

In our analysis we use the following tail bound for the sum of a non-increasing sequence of random variables with variable negative drift. The proof uses established methods from drift analysis. In particular, it relies one techniques found in the proof of the Variable Drift Theorem in [23]. We prove it in the full version.

▶ **Theorem 6.1.** *Let $(X(t))_{t\geq 0}$ be a non-increasing sequence of discrete random variables with $X(t) \in \mathbb{R}_0^+$ for all t with fixed $X(0) = x_0$. Assume there exists an increasing function $h\colon \mathbb{R}_0^+ \to \mathbb{R}^+$ and a constant $\sigma > 0$ such that the following holds. For all $t \in \mathbb{N}$ and all $x > 0$ with $\mathbb{P}[X(t) = x] > 0$*

1. $\mathbb{E}[X(t+1) \mid X(t) = x] \leq x - h(x)$,
2. $\operatorname{Var}[X(t+1) \mid X(t) = x] \leq \sigma \cdot (\mathbb{E}[X(t+1) \mid X(t) = x] - x)^2$.

Then the following statements hold.

1. *For all* $\delta \in (0,1)$ *and any arbitrary but fixed* t

$$\mathbb{P}\left[\int_{X(t)}^{x_0} \frac{1}{h(\varphi)}\,\mathrm{d}\varphi \leq (1-\delta)t\right] \leq \exp\left(-\frac{\delta^2 t}{2(\sigma+1)}\right).$$

2. *For all* $\delta \in (0,1)$ *and* $p \in (0,1)$ *we define* $t_0 \coloneqq \frac{2(\sigma+1)}{\delta^2}\left(-\log(p) + \log\left(\frac{2(\sigma+1)}{\delta^2}\right)\right)$. *Then*

$$\mathbb{P}\left[\sum_{t=t_0+1}^{\infty} X(t) \leq \frac{1}{1-\delta} \cdot \int_0^{x_0} \frac{\varphi}{h(\varphi)}\mathrm{d}\varphi\right] \geq 1-p.$$

7 Conclusions and Open Problems

In this paper we analyze discrete load balancing processes on graphs. As our main contribution we bound the discrepancy that arises in dynamic load balancing in three models, the random matching model, the balancing circuit model, and the asynchronous model. Our results for the random matching model and the asynchronous model hold for d-regular graphs, while our analysis for the balancing circuit model applies to arbitrary graphs.

To the best of our knowledge our results constitute the first discrepancy bounds for discrete, dynamic balancing processes on general graphs. Furthermore, our results improve the work by Alistarh et al. [2] who prove that the expected discrepancy is bounded by $\sqrt{n}\log(n)$ in the (arguably simpler) continuous asynchronous process $\textsc{ABal}^{(\mathrm{cont})}(\mathcal{D}_{\mathrm{A}}(G),1)$. We improve their bound to $\sqrt{n\log(n)}$ and additionally show that it holds with high probability. We conjecture that our results are tight, up to polylogarithmic factors. However, showing tight upper and lower bounds remains an open problem.

One interesting feature of our bound on the discrepancy is the scaling with the parameter β: decreasing it linearly only increases the bound on the discrepancy by a square root factor. This means for sufficiently small β, the expected amount of load transferred per edge and round is constant.

Open Problems. We are confident that our results carry over to arbitrary graphs (as opposed to regular graphs), provided that there exists a lower bound on the probability p_{min} with which an edge is used for balancing. However, to show bounds on the discrepancy one has to overcome fundamental problems such as the bias introduced by high-degree nodes. Analyzing the behavior for more general load arrival distributions is also an interesting but likely challenging open problem. More avenues for generalization are the deletion of load over time as well as varying the amount of load generated in each round dynamically.

Another interesting open question is whether the results carry over to a model where the amount of load that may be transmitted over an edge in each step is bounded by a constant. If only a single load item can be transferred per edge and step the problem is similar to the token distribution problem (see, for example, [5]).

Finally, we believe that one can also adapt our analysis to variant of a graphical balls-into-bins process. The process works as follows. In each step an edge (i,j) is sampled uniformly at random. W.l.o.g. assume that the load of i is smaller than the load of j by an additive term Δ. Then a biased coin is tossed showing heads with probability $p \coloneqq \min\{1,(1+\beta\cdot\Delta)/2\}$ and tails otherwise, where β is a suitably chosen and non-constant parameter. If the coin hits heads one item is allocated to i and otherwise to j. A formal analysis of this allocation process (as well as of other, related balls-into-bins processes) is beyond the scope of our paper and remains an open problem.

Abstract

Search trees on trees (STTs) generalize the fundamental binary search tree (BST) data structure: in STTs the underlying search space is an arbitrary tree, whereas in BSTs it is *a path*. An optimal BST of size n can be computed for a given distribution of queries in $\mathcal{O}(n^2)$ time [Knuth, Acta Inf. 1971] and *centroid* BSTs provide a nearly-optimal alternative, computable in $\mathcal{O}(n)$ time [Mehlhorn, SICOMP 1977].

By contrast, optimal STTs are not known to be computable in polynomial time, and the fastest constant-approximation algorithm runs in $\mathcal{O}(n^3)$ time [Berendsohn, Kozma, SODA 2022]. Centroid trees can be defined for STTs analogously to BSTs, and they have been used in a wide range of algorithmic applications. In the unweighted case (i.e., for a uniform distribution of queries), the centroid tree can be computed in $\mathcal{O}(n)$ time [Brodal, Fagerberg, Pedersen, Östlin, ICALP 2001; Della Giustina, Prezza, Venturini, SPIRE 2019]. These algorithms, however, do not readily extend to the weighted case. Moreover, no approximation guarantees were previously known for centroid trees in either the unweighted or weighted cases.

In this paper we revisit centroid trees in a general, weighted setting, and we settle both the algorithmic complexity of constructing them, and the quality of their approximation. For constructing a weighted centroid tree, we give an *output-sensitive* $\mathcal{O}(n \log h) \subseteq \mathcal{O}(n \log n)$ time algorithm, where h is the height of the resulting centroid tree. If the weights are of polynomial complexity, the running time is $\mathcal{O}(n \log \log n)$. We show these bounds to be optimal, in a general decision tree model of computation. For approximation, we prove that the cost of a centroid tree is at most *twice* the optimum, and this guarantee is best possible, both in the weighted and unweighted cases. We also give tight, fine-grained bounds on the approximation-ratio for bounded-degree trees and on the approximation-ratio of more general α-centroid trees.

1 Introduction

Search trees on trees (STTs) are a far-reaching generalization of binary search trees (BSTs), modeling the exploration of tree-shaped search spaces. Given an undirected tree $\mathcal{T}$, an STT on $\mathcal{T}$ is a tree rooted at an arbitrary vertex r of $\mathcal{T}$, with subtrees built recursively on the components resulting after removing r from $\mathcal{T}$, see Figure 1 for an example. BSTs correspond to the special case where the underlying tree $\mathcal{T}$ is a *path*.

STTs and, more generally, search trees on graphs arise in several different contexts and have been studied under different names: *tubings* [14], *vertex rankings* [20, 8, 23], *ordered colorings* [35], *elimination trees* [43, 49, 2, 9]. STTs have been crucial in many algorithmic applications, e.g., in pattern matching and counting [24, 37, 27], cache-oblivious data structures [4, 25], tree clustering [26], geometric visibility [30], planar point location [29], distance oracles [16]. They arise in matrix factorization (e.g., see [22, § 12]), and have also been related to the competitive ratio in certain online hitting set problems [23].

Similarly to the setting of BSTs, a natural goal is to find an STT in which the expected depth of a vertex is as small as possible; we refer to such a tree as an *optimal tree*, noting that it is not necessarily unique. This optimization task can be studied both for the uniform probability distribution over the vertices, and for the more general case of an arbitrary distribution given as input. We refer to the first as the *unweighted* and the second as the *weighted* problem.

For BSTs, both the unweighted and the weighted problems are well-understood. In the unweighted case, a simple balanced binary tree achieves the optimum. In the weighted case, an optimal tree on n vertices can be found in time $\mathcal{O}(n^2)$ by Knuth's algorithm [36], a textbook example of dynamic programming. No faster algorithm is known in general, although Larmore's algorithm [40] achieves better bounds under certain regularity assumptions on the weights; for example, if the probability assigned to each vertex is $\Omega(1/n)$, then the optimum can be found in time $\mathcal{O}(n^{1.591})$.

By contrast, the complexity of computing an optimal STT is far less understood. Even in the unweighted case, no polynomial-time algorithm is known, and the problem is not known to be NP-hard even with arbitrary weights. Recently, a PTAS was given for the weighted problem [7], but its running time for obtaining a $(1+\varepsilon)$-approximation of the optimal STT is $\mathcal{O}(n^{1+2/\varepsilon})$, which is prohibitive for reasonably small values of ε. Note that the apparently easier problem of minimizing the *maximum depth* of a vertex, i.e., computing the *treedepth* of a tree, can be solved in linear time by Schäffer's algorithm [50], and treedepth itself has many algorithmic applications, e.g., see [47, § 6,7].

Centroid trees. Given the relatively high cost of computing optimal binary search trees, research has turned already half a century ago to efficient approximations. Mehlhorn has shown [44, 45] that a simple BST that can be computed in $\mathcal{O}(n)$ time closely approximates the optimum. More precisely, both the optimum cost and the cost of the obtained tree are in $[H/\log(3), H+1]$, where H is the binary entropy of the input distribution.[1] Alternatively, the cost can be upper bounded by $\texttt{OPT} + \log(\texttt{OPT}) + \log e$, where $\texttt{OPT}$ is the cost of the optimal tree. Observe that this means that the approximation ratio gets arbitrarily close to 1 as $\texttt{OPT}$ goes to infinity.[2]

[1] All logarithms in this paper are base 2.

[2] Results for BSTs are sometimes presented in a more general form, where the input distribution also accounts for *unsuccessful searches*, i.e., it may assign non-zero probabilities to the *gaps* between neighboring vertices and outside the two extremes. Extending such a model to STTs is straightforward, but perhaps less natural in the case of general trees, we therefore omit it for the sake of simplicity, and consider only successful searches.

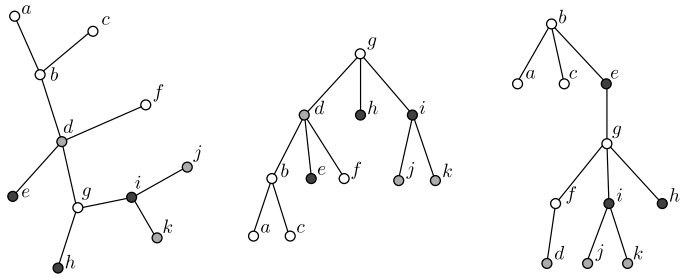

Figure 1 (*Left.*) Tree $\mathcal{T}$. (*Middle.*) Centroid tree of $\mathcal{T}$. (*Right.*) A different STT on $\mathcal{T}$. Colors indicate weights (probabilities), $w(e) = w(h) = w(i) = 0.15$, $w(d) = w(j) = w(k) = 0.10$, and all other vertices have weight 0.05. Observe that the centroid tree is (in this example) unique.

The BST that achieves the above guarantees is built by recursively picking roots such as to make the weights of the left and right subtrees "as equal as possible". This is a special case of a *centroid tree*, defined as follows. Given a tree $\mathcal{T}$, a *centroid* of $\mathcal{T}$ is a vertex whose removal from $\mathcal{T}$ results in components with weight *at most half* of the total weight of $\mathcal{T}$. A centroid tree is built by iteratively finding a centroid and recursing on the components resulting after its removal. See Figure 1 for an example.

The fact that an (unweighted) centroid always exists was already shown in the 19-th century by C. Jordan [34]. We sketch the easy, constructive argument that also shows the existence of a weighted centroid: start at an arbitrary vertex of $\mathcal{T}$ and, as long as the current vertex is not a centroid, move one edge in the direction of the component with largest weight. It is not hard to see that the procedure succeeds, visiting each vertex at most once.

A straightforward implementation of the above procedure finds an unweighted centroid tree in $\mathcal{O}(n \log n)$ time. This running time has been improved to $\mathcal{O}(n)$ by carefully using data structures [11, 28]. The run-time guarantees however, do not readily generalize from the unweighted to the weighted setting. Intuitively, the difficulty lies in the fact that in the weighted case, the removal of a centroid vertex may split the tree in a very unbalanced way, leaving up to $n - 1$ vertices in one component. Thus, a naive recursive approach will take $\Theta(n^2)$ time in the worst case.

Most algorithmic applications of STTs, including those mentioned before, rely on centroid trees. It is therefore surprising that nothing appears to be known about how well the centroid tree approximates the optimal STT in either the unweighted or weighted cases. In this paper we prove that the centroid tree is a 2-approximation of the optimal STT, and that the factor 2 is, in general, best possible, both in the unweighted and weighted settings. As our main result, we also show a more precise bound on the approximation ratio of centroid trees, in terms of the maximum degree of the underlying tree $\mathcal{T}$.[3]

Before stating our results, we need a few definitions. Consider an undirected, unrooted tree $\mathcal{T}$ given as input, together with a *weight function* $w : V(\mathcal{T}) \to \mathbb{R}_{\geq 0}$. For convenience, for any subgraph $\mathcal{H}$ of $\mathcal{T}$, we denote $w(\mathcal{H}) = \sum_{x \in V(\mathcal{H})} w(x)$. (To interpret the weights as probabilities, we need the condition $w(\mathcal{T}) = 1$. It is, however, often convenient to relax this requirement and allow arbitrary non-negative weights, which is the approach we will take.)

[3] In their recent paper on dynamic STTs, Bose, Cardinal, Iacono, Koumoutsos, and Langerman [10] remark that the ratio between the costs of the centroid- and optimal trees may be unbounded. In light of our results, this observation is erroneous. It is true, however, that a centroid tree built using the uniform distribution may be far from the optimum w.r.t. a different distribution.

A *search tree* on $\mathcal{T}$ is a rooted tree T with vertex set $V(\mathcal{T})$ whose root is an arbitrary vertex $r \in V(\mathcal{T})$. The children of r in T are the roots of search trees built on the connected components of the forest $\mathcal{T} - r$. A tree consisting of a single vertex admits only itself as a search tree. It follows from the definition that for all x, the subtree T_x of T rooted at x induces a connected subgraph $\mathcal{T}[V(T_x)]$ of $\mathcal{T}$, and moreover, T_x is a search tree on $\mathcal{T}[V(T_x)]$.

The *cost* of a search tree T on $\mathcal{T}$ is $\texttt{cost}_w(T) = \sum_{x \in V(T)} w(x) \cdot \texttt{depth}_T(x)$, where the depth of the root is taken to be 1. The *optimum cost* $\texttt{OPT}(\mathcal{T}, w)$ is the minimum of $\texttt{cost}_w(T)$ over all search trees T of $\mathcal{T}$.

A vertex $v \in V(\mathcal{T})$ is a *centroid* if for all components $\mathcal{H}$ of $\mathcal{T} - v$, we have $w(\mathcal{H}) \leq w(\mathcal{T})/2$. A search tree T of $\mathcal{T}$ is a *centroid tree* if vertex x is a centroid of $\mathcal{T}[V(T_x)]$ for all $x \in V(\mathcal{T})$. In general, the centroid tree is not unique, and centroid trees of the same tree can have different costs.[4] We denote by $\texttt{cent}(\mathcal{T}, w)$ the *maximum* cost of a centroid tree of $(\mathcal{T}, w)$, with weight function w.

We can now state our approximation guarantee for centroid trees.

▶ **Theorem 1.** *Let $\mathcal{T}$ be a tree, $w : V(\mathcal{T}) \to \mathbb{R}_{\geq 0}$, and $m = w(\mathcal{T})$. Then*

$$\texttt{cent}(\mathcal{T}, w) \leq 2 \cdot \texttt{OPT}(\mathcal{T}, w) - m.$$

We show that this result is optimal, including in the additive term. Moreover, the constant factor 2 cannot be improved even for unweighted instances.

▶ **Theorem 2.**

(i) *For every $\varepsilon > 0$ there is a sequence of instances $(\mathcal{T}_n, w_n)$ with $w_n(\mathcal{T}_n) = 1$, and for every centroid tree C_n of $(\mathcal{T}_n, w_n)$*

$$\texttt{cost}_{w_n}(C_n) \geq 2 \cdot \texttt{OPT}(\mathcal{T}_n, w_n) - 1 - \varepsilon.$$

(ii) *There is a sequence of instances $(\mathcal{T}_n, w_n)$, where w_n is the uniform distribution on $V(\mathcal{T}_n)$, and for every centroid tree C_n of $(\mathcal{T}_n, w_n)$*

$$\lim_{n \to \infty} \frac{\texttt{cost}_{w_n}(C_n)}{\texttt{OPT}(\mathcal{T}_n, w_n)} = 2.$$

In both cases $\lim_{n \to \infty} \texttt{OPT}(\mathcal{T}_n, w_n) = \infty$.

Note that the fact that $\lim_{n \to \infty} \texttt{OPT}(\mathcal{T}_n, w_n) = \infty$ in Theorem 2 establishes that the *asymptotic* approximation ratio is 2. By this we mean that every bound of the form $\texttt{cent} \leq c \cdot \texttt{OPT} + o(\texttt{OPT})$ must have $c \geq 2$.

We next show a stronger guarantee when the underlying tree has bounded degree.

▶ **Theorem 3.** *Let $\mathcal{T}$ be a tree, $w : V(\mathcal{T}) \to \mathbb{R}_{\geq 0}$, and let Δ be the* maximum degree *of $\mathcal{T}$. Then*

$$\texttt{cent}(\mathcal{T}, w) \leq \left(2 - \frac{1}{2^\Delta}\right) \cdot \texttt{OPT}(\mathcal{T}, w).$$

We complement this result by two lower bounds. The first establishes the tightness of the approximation ratio. The second shows a (slightly smaller) lower bound on the approximation ratio for instances where $\texttt{OPT}$ is unbounded.

[4] Consider, for instance the two different centroid trees of a path on four vertices, with weights $(0.2, 0.3, 0.2, 0.3)$.

▶ **Theorem 4.** *Let $\Delta \geq 3$ be integer.*

(i) *There is a sequence of instances $(\mathcal{T}_n, w_n)$ such that $\mathcal{T}_n$ has maximum degree at most Δ, and for every centroid tree C_n of $(\mathcal{T}_n, w_n)$*

$$\lim_{n\to\infty} \frac{\texttt{cost}_{w_n}(C_n)}{\texttt{OPT}(\mathcal{T}_n, w_n)} = 2 - \frac{1}{2^\Delta}.$$

(ii) *There is a sequence of instances $(\mathcal{T}_n, w_n)$ such that $\mathcal{T}_n$ has maximum degree at most Δ, $\lim_{n\to\infty} \texttt{OPT}(\mathcal{T}_n, w_n) = \infty$, $w_n(\mathcal{T}_n) = 1$, and for every centroid tree C_n of $(\mathcal{T}_n, w_n)$*

$$\texttt{cost}_{w_n}(C_n) \geq \left(2 - \frac{4}{2^\Delta}\right) \cdot \texttt{OPT}(\mathcal{T}_n, w_n) - 1.$$

We remark that Theorem 4(i) does not exclude the possiblity of a bound of the form $\texttt{cent} \leq c \cdot \texttt{OPT} + o(\texttt{OPT})$, where $c < 2 - \frac{1}{2^\Delta}$, as here $\texttt{OPT}(\mathcal{T}_n, w_n)$ is bounded. Part (ii), however, establishes that a bound of the form $\texttt{cent} \leq c \cdot \texttt{OPT} + o(\texttt{OPT})$ must have $c \geq 2 - \frac{4}{2^\Delta}$. We leave open the problem of closing the gap in the asymptotic approximation ratio in terms of Δ.

Computing centroid trees. On the algorithmic side, we show that the weighted centroid tree can be computed in $\mathcal{O}(n \log n)$ time. Previously, the fastest known constant-approximation algorithm [7] took $\mathcal{O}(n^3)$ time (similarly achieving an approximation ratio of 2). The main step of our algorithm, finding the weighted centroid of a tree, is achievable in $\mathcal{O}(\log n)$ time, assuming that the underlying tree is stored in a *top tree* data structure [1]. Iterating this procedure in combination with known algorithms for *constructing* and *splitting* top trees yields the algorithm that runs in $\mathcal{O}(n \log n)$ time. As our main algorithmic result, we also develop an improved, *output-sensitive* algorithm, with running time $\mathcal{O}(n \log h)$, where h is the height of the resulting centroid tree, yielding a running time $\mathcal{O}(n \log \log n)$ in the typical case when the height is $\mathcal{O}(\log n)$.

▶ **Theorem 5.** *Let $\mathcal{T}$ be a tree on n vertices and w be a weight function. We can compute a centroid tree of $(\mathcal{T}, w)$ in time $\mathcal{O}(n \log h)$, where h is the height of the computed centroid tree.*

One may ask whether the weighted centroid tree can be computed in linear time, similarly to the unweighted centroid tree, or to the weighted centroid BST. We show that, assuming a general decision tree model of computation, this is not possible, and the algorithm of Theorem 5 is optimal for all n and h (up to a constant factor). Our lower bound on the running time applies, informally, to any deterministic algorithm in which the input weights affect program flow in the form of binary decisions, involving arbitrary computable functions.

More precisely, consider a tree $\mathcal{T}$ on n vertices. We say that a *binary decision tree $D_\mathcal{T}$ solves $\mathcal{T}$* for a class of weight functions $\mathcal{W}$ mapping $V(\mathcal{T})$ to $\mathbb{R}_{\geq 0}$, if the leaves of $D_\mathcal{T}$ are search trees on $\mathcal{T}$, every branching of $D_\mathcal{T}$ is of the form "$f(w)>0$?" for some computable function $f : \mathcal{W} \to \{-1, +1\}$, and for every weight function $w \in \mathcal{W}$, starting from the root of $D_\mathcal{T}$ and following branchings down the tree, we reach a leaf T of $D_\mathcal{T}$ that is a valid centroid tree for $(\mathcal{T}, w)$. The height of $D_\mathcal{T}$ is then a lower bound on the worst-case running time.

▶ **Theorem 6.** *Let $h \geq 3$ and $n \geq h + 1$ be integers. Then there is a tree $\mathcal{T}$ on at most n vertices and a class $\mathcal{W}$ of weight functions on $V(\mathcal{T})$ such that for every $w \in \mathcal{W}$, every centroid tree of $(\mathcal{T}, w)$ has height h, and every binary decision tree that solves $\mathcal{T}$ for $\mathcal{W}$ has height $\Omega(n \log h)$.*

We can nonetheless improve the running time, when the weights are restricted in certain (natural) ways. We define the *spread* σ of a weight function w as the ratio between the total weight $w(\mathcal{T})$, and the smallest *non-zero* weight of a vertex. As we show, $\mathcal{O}(n \log h) \subseteq \mathcal{O}(n \log\log(\sigma + n))$ and therefore, when $\sigma \in n^{\mathcal{O}(1)}$ (for instance, if the weights are integers stored in RAM words), we obtain a running time of $\mathcal{O}(n \log\log n)$.

When many vertices have zero weight, we obtain further improvements, e.g., if only $\mathcal{O}(n/\log n)$ of the weights are non-zero, we can compute a centroid tree in $\mathcal{O}(n)$ time, even if the height h is large. The precise statement of these refined bounds and the discussion of their optimality are available in the full version of this paper [6].

Approximate centroid trees. Finally, we consider the approximation guarantees of a generalized form of centroid trees. Let us call a vertex v of a tree $\mathcal{T}$ an α-centroid, for $0 \leq \alpha \leq 1$, if $w(\mathcal{H}) \leq \alpha \cdot w(\mathcal{T})$, for all components $\mathcal{H}$ of $\mathcal{T} - v$. An α-centroid tree is an STT in which every vertex x is an α-centroid of its subtree $\mathcal{T}[V(T_x)]$.

Observe that the standard centroid tree is a $\frac{1}{2}$-centroid tree, and all STTs are 1-centroid trees. Also note that an α-centroid is a β-centroid for all $\beta \geq \alpha$ and that the existence of an α-centroid is not guaranteed for $\alpha < \frac{1}{2}$ (consider a single edge with the two endpoints having the same weight). On the other hand, an α-centroid for $\alpha < \frac{1}{2}$, if it exists, is unique, and therefore the α-centroid tree is also unique. To see this, consider an α-centroid c that splits $\mathcal{T}$ into components $\mathcal{T}_1, \ldots, \mathcal{T}_k$. If an alternative α-centroid c' were in component $\mathcal{T}_i$, then its removal would yield a component containing all vertices in $\mathcal{T} - V(\mathcal{T}_i)$, of weight at least $(1-\alpha) \cdot w(\mathcal{T}) > \alpha \cdot w(\mathcal{T})$.

Denote by $\texttt{cent}^\alpha(\mathcal{T}, w)$ the maximum cost of an α-centroid tree of $(\mathcal{T}, w)$, or 0 if no α-centroid tree exists. We refine our guarantee from Theorem 1 to approximate centroid trees:

▶ **Theorem 7.** *Let $\mathcal{T}$ be a tree, $w : V(\mathcal{T}) \to \mathbb{R}_{\geq 0}$, $m = w(\mathcal{T})$. We have*

$$(i)\quad \texttt{cent}^\alpha(\mathcal{T}, w) \leq \frac{1}{1-\alpha} \cdot \texttt{OPT}(\mathcal{T}, w) - \frac{\alpha}{1-\alpha} m, \qquad \text{for } \alpha \in (0, 1),$$

$$(ii)\quad \texttt{cent}^\alpha(\mathcal{T}, w) \leq \frac{1}{2-3\alpha} \cdot \texttt{OPT}(\mathcal{T}, w) - \frac{3\alpha - 1}{2-3\alpha} m, \qquad \text{for } \alpha \in \left[\frac{1}{3}, \frac{1}{2}\right].$$

Note that the second bound is a strengthening of the first when $\alpha < \frac{1}{2}$. In particular, for $\alpha \leq \frac{1}{3}$, it implies that an α-centroid tree is *optimal*, if it exists.

We show that the result is tight when $\alpha \geq \frac{1}{2}$ by proving a matching lower bound.

▶ **Theorem 8.** *For every $\alpha \in [\frac{1}{2}, 1)$ there is a sequence of instances $(\mathcal{T}_n, w_n)$ with $\lim_{n\to\infty} \texttt{OPT}(\mathcal{T}_n, w_n) = \infty$, $w_n(\mathcal{T}_n) = 1$ and*

$$\texttt{cent}^\alpha(\mathcal{T}_n, w_n) \geq \frac{1}{1-\alpha} \cdot \texttt{OPT}(\mathcal{T}_n, w_n) - \frac{\alpha}{1-\alpha}.$$

Note that if $\alpha > \frac{1}{2}$, we cannot prove such a lower bound for *all* α-centroid trees of $(\mathcal{T}_n, w_n)$ (as in Theorem 2), since a $\frac{1}{2}$-centroid tree exists and has stronger approximation guarantees according to Theorem 1.

Finally, we argue that every optimal STT is a $\frac{2}{3}$-centroid tree. A special case of this result (for BSTs) was shown by Hirschberg, Larmore, and Molodowitch [32], who also showed that the ratio $\frac{2}{3}$ is tight (in the special case of BSTs, and thus, also for STTs).

▶ **Theorem 9.** *Let T be an optimal STT of $(\mathcal{T}, w)$. Then, T is a $\frac{2}{3}$-centroid tree of $(\mathcal{T}, w)$.*

Structure of the paper. In this extended abstract we omit some of the proofs, discussions, and technical details which are included in the full paper [6]. In Section 2 we state a number of results needed in the proofs. The general upper and lower bounds on the approximation ratio of centroid trees (Theorems 1 and 2) are proved in Section 3. These results can be seen as a warm-up towards the fine-grained bounds on the approximation ratio of centroid trees (Theorems 3 and 4), which we prove in Section 4. The algorithmic results (Theorem 5) are discussed in Section 5, with the details of the output-sensitive algorithm, the lower bounds (Theorem 6), and further extensions available in the full paper. Results on α-centroids (Theorems 7, 8, and 9) are proved in the full paper. In Section 6 we conclude with open questions.

Related work. Different models of searching in trees have also been considered, e.g., the one where we query edges instead of vertices [3, 39, 46, 48], with connections to searching in posets [42, 31]. In the edge-query setting, Cicalese, Jacobs, Laber and Molinaro [17, 18] study the problem of minimizing the average search time of a vertex, and show this to be an NP-hard problem [17]. They also show that an "edge-centroid" tree (in their terminology, a greedy algorithm) gives a 1.62-approximation of the optimum [18].

STTs generalize BSTs, therefore it is natural to ask to what extent the theory developed for BSTs can be extended to STTs. Defining a natural *rotation* operation on STTs, Bose, Cardinal, Iacono, Koumoutsos, and Langerman [10] develop an $O(\log\log n)$ competitive dynamic STT, analogously to Tango BSTs [19]. In a similar spirit, Berendsohn and Kozma [7] generalize Splay trees [51] to STTs. The rotation operation on STTs naturally leads to the definition of *tree associahedra*, a combinatorial structure that extends the classical associahedron defined over BSTs or other Catalan-structures. Properties of tree- and more general graph associahedra have been studied in [14, 21, 15, 12, 13, 5].

Searching in trees and graphs has also been motivated with applications, including file system synchronisation [3, 46], software testing [3, 46], asymmetric communication protocols [38], VLSI layout [41], and assembly planning [33].

2 Preliminaries

Given a graph G, we denote by $V(G)$ its set of vertices, by $E(G)$ its set of edges, and by $\mathbb{C}(G)$ its set of connected components. If $v \in V(G)$, denote by $N_G(v)$ the set of neighbors of v in G, and $\deg_G(v) = |N_G(v)|$. For $S \subseteq V(G)$, denote by $G[S]$ the subgraph of G induced by S, and for brevity, $G - v = G[V(G) - \{v\}]$, and $G - S = G[V(G) - S]$.

The following observation is straightforward.

▶ **Observation 10.** *Let T be a search tree on $\mathcal{T}$, $w : V(\mathcal{T}) \to \mathbb{R}_{\geq 0}$, $m = w(\mathcal{T})$ and $r = \mathtt{root}(T)$. For each component $\mathcal{H} \in \mathbb{C}(\mathcal{T} - r)$, denote by $T_{\mathcal{H}}$ the subtree of T rooted at the unique child of r in $\mathcal{H}$. Then*

$$\mathtt{cost}_w(T) = m + \sum_{\mathcal{H} \in \mathbb{C}(\mathcal{T}-r)} \mathtt{cost}_w(T_{\mathcal{H}}) \geq m + \sum_{\mathcal{H} \in \mathbb{C}(\mathcal{T}-r)} \mathtt{OPT}(\mathcal{H}, w).$$

Projection of a search tree. For a rooted tree T and a vertex $v \in V(T)$, we denote by $\mathtt{Path}_T(v)$ the set of vertices on the path in T from $\mathtt{root}(T)$ to v, including both endpoints. Our upper bounds require the following notion of *projection* of a search tree.

▶ **Theorem 11.** *Let T be a search tree on $\mathcal{T}$ and $\mathcal{H}$ a connected subgraph of $\mathcal{T}$. There is a unique search tree $T|_{\mathcal{H}}$ on $\mathcal{H}$ such that for every $v \in V(\mathcal{H})$,*

$$\texttt{Path}_{T|_{\mathcal{H}}}(v) = \texttt{Path}_T(v) \cap V(\mathcal{H}).$$

▶ **Definition 12** (Projection)**.** *Let T be a search tree on $\mathcal{T}$ and $\mathcal{H}$ a connected subgraph of $\mathcal{T}$. We call $T|_{\mathcal{H}}$, whose existence is established by Theorem 11, the projection of T to $\mathcal{H}$.*

Tie-breaking. Our lower bounds require the following tie-breaking procedure.

▶ **Lemma 13.** *Let $\mathcal{T}$ be a tree, $w : V(\mathcal{T}) \to \mathbb{R}_{\geq 0}$ a weight function and let C be a centroid tree of $(\mathcal{T}, w)$. For every $\varepsilon > 0$ there exists a weight function $w' : V(\mathcal{T}) \to \mathbb{R}_{\geq 0}$ such that C is the unique centroid tree of $(\mathcal{T}, w')$ and $\|w' - w\|_\infty < \varepsilon$.*

Centroid and median. A certain concept of a *median vertex* of a tree has been used previously in the literature. If $\mathcal{T}$ is a tree with positive vertex weights and positive edge weights, then the median of $\mathcal{T}$ is the vertex v minimizing the quantity $\sum_{u \neq v} w(u) \cdot d(u, v)$. Here $w(u)$ is the weight of the vertex u, and $d(u, v)$ is the distance from u to v, i.e., the sum of the edge weights on the path from u to v. We show that if all edge-weights are 1, then medians are precisely centroids.

▶ **Lemma 14.** *Let $\mathcal{T}$ be a graph and w be a weight function on $V(\mathcal{T})$. For each $u \in V(\mathcal{T})$, define $W(u) = \sum_{v \in V(\mathcal{T})} d_{\mathcal{T}}(u, v) \cdot w(v)$, where $d_{\mathcal{T}}(u, v)$ denotes the number of edges on the path from u to v in $\mathcal{T}$. Then $c \in V(\mathcal{T})$ is a centroid of $(\mathcal{T}, w)$ if and only if $W(c)$ is minimal.*

Proofs to Theorem 11 and Lemmas 13 and 14 are available in the full paper [6].

3 Approximation guarantees for general trees

In this section we prove the general upper bound and lower bounds the approximation quality of centroid trees. We start with the upper bound.

▶ **Theorem 1.** *Let $\mathcal{T}$ be a tree, $w : V(\mathcal{T}) \to \mathbb{R}_{\geq 0}$, and $m = w(\mathcal{T})$. Then*

$$\texttt{cent}(\mathcal{T}, w) \leq 2 \cdot \texttt{OPT}(\mathcal{T}, w) - m.$$

We prove the following lemma.

▶ **Lemma 15.** *Let c be a centroid of $(\mathcal{T}, w)$ and $m = w(\mathcal{T})$. Then*

$$\texttt{OPT}(\mathcal{T}, w) \geq \frac{m}{2} + \frac{w(c)}{2} + \sum_{\mathcal{H} \in \mathbb{C}(\mathcal{T} - c)} \texttt{OPT}(\mathcal{H}, w). \tag{1}$$

Proof. Let T be an arbitrary search tree on $\mathcal{T}$. We will show that $\texttt{cost}_w(T)$ is at least the right hand side of Equation (1).

Denote $r = \texttt{root}(T)$. If $r = c$, using Observation 10, we have

$$\texttt{cost}_w(T) \geq m + \sum_{\mathcal{H} \in \mathbb{C}(\mathcal{T} - c)} \texttt{OPT}(\mathcal{H}, w),$$

which implies the claim. Assume therefore that $r \neq c$. Denote by $\mathcal{H}^*$ the connected component of $\mathcal{T} - c$ where r is. The contribution of vertices of $\mathcal{H}^*$ to $\texttt{cost}_w(T)$ is at least $\texttt{cost}_w(T|_{\mathcal{H}^*})$. For $\mathcal{H} \in \mathbb{C}(\mathcal{T} - c)$, $\mathcal{H} \neq \mathcal{H}^*$ and $v \in V(\mathcal{H})$, we have $\texttt{Path}_T(v) \supseteq \{r\} \cup \texttt{Path}_{T|_{\mathcal{H}}}(v)$, therefore

the contribution of vertices of every $\mathcal{H} \neq \mathcal{H}^*$ is at least $w(\mathcal{H}) + \texttt{cost}_w(T|_{\mathcal{H}})$. Finally, the contribution of c is at least $2w(c)$, since both $c, r \in \texttt{Path}_T(c)$. Summing the contributions of all the vertices, we get

$$\begin{aligned}\texttt{cost}_w(T) &\geq 2w(c) + \texttt{cost}_w(T|_{\mathcal{H}^*}) + \sum_{\mathcal{H}\neq\mathcal{H}^*} (w(\mathcal{H}) + \texttt{cost}_w(T|_{\mathcal{H}})) \\ &\geq m - w(\mathcal{H}^*) + w(c) + \sum_{\mathcal{H}} \texttt{OPT}(\mathcal{H}, w) \\ &\geq \frac{m}{2} + w(c) + \sum_{\mathcal{H}} \texttt{OPT}(\mathcal{H}, w),\end{aligned}$$

where the last inequality follows from c being a centroid. ◀

Proof of Theorem 1. The proof is by induction on the number of vertices. When $|V(\mathcal{T})| = 1$ we have

$$2 \cdot \texttt{OPT}(\mathcal{T}, w) - m = 2m - m = m = \texttt{cent}(\mathcal{T}, w), \quad \text{as required.}$$

Assume $|V(\mathcal{T})| > 1$. Let C be a centroid tree on $\mathcal{T}$ and $c = \texttt{root}(C)$. Using Observation 10 and the induction hypothesis we have:

$$\begin{aligned}\texttt{cost}_w(C) &\leq m + \sum_{\mathcal{H}\in\mathbb{C}(\mathcal{T}-c)} \texttt{cent}(\mathcal{H}, w) \\ &\leq m + \sum_{\mathcal{H}\in\mathbb{C}(\mathcal{T}-c)} (2 \cdot \texttt{OPT}(\mathcal{H}, w) - w(\mathcal{H})) \\ &= w(c) + 2 \cdot \sum_{\mathcal{H}\in\mathbb{C}(\mathcal{T}-c)} \texttt{OPT}(\mathcal{H}, w),\end{aligned}$$

therefore it is enough to show that

$$w(c) + 2 \cdot \sum_{\mathcal{H}\in\mathbb{C}(\mathcal{T}-c)} \texttt{OPT}(\mathcal{H}, w) \leq 2 \cdot \texttt{OPT}(\mathcal{T}, w) - m,$$

which is just a re-arrangement of Lemma 15. This concludes the proof. ◀

Next, we prove the lower bounds on the approximation quality of centroid trees, showing the tightness of Theorem 1. We note that in the *edge-query model* of search trees a 2-approximation was shown in [18] using techniques similar to those in the proof of Theorem 1. In contrast to that result, however, our approximation guarantee is best possible.

▶ **Theorem 2.**

(i) *For every $\varepsilon > 0$ there is a sequence of instances $(\mathcal{T}_n, w_n)$ with $w_n(\mathcal{T}_n) = 1$, and for every centroid tree C_n of $(\mathcal{T}_n, w_n)$*

$$\texttt{cost}_{w_n}(C_n) \geq 2 \cdot \texttt{OPT}(\mathcal{T}_n, w_n) - 1 - \varepsilon.$$

(ii) *There is a sequence of instances $(\mathcal{T}_n, w_n)$, where w_n is the uniform distribution on $V(\mathcal{T}_n)$, and for every centroid tree C_n of $(\mathcal{T}_n, w_n)$*

$$\lim_{n\to\infty} \frac{\texttt{cost}_{w_n}(C_n)}{\texttt{OPT}(\mathcal{T}_n, w_n)} = 2.$$

In both cases $\lim_{n\to\infty} \texttt{OPT}(\mathcal{T}_n, w_n) = \infty$.

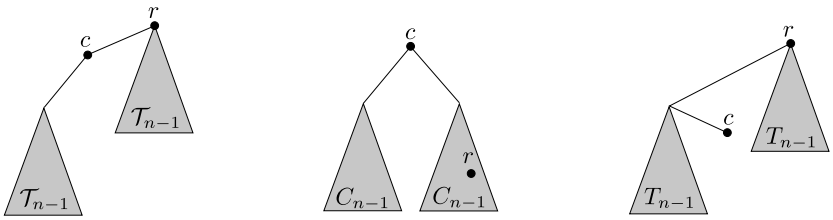

Figure 2 Illustration of the proof of Theorem 2(i). Vertex r is the root of $\mathcal{T}_n$. (*Left.*) The underlying tree $\mathcal{T}_n$. (*Middle.*) The entroid tree C_n of $\mathcal{T}_n$. (*Right.*) The search tree T_n.

As the proofs of both parts of Theorem 2 use the same construction with only slightly different analyses, we prove here only part (i). The proof of part (ii) appears in the full paper [6].

We proceed by constructing a sequence $(\mathcal{T}_n, w_n)$ such that for *some* centroid tree C_n,

$$\texttt{cost}_{w_n}(C_n) \geq 2 \cdot \texttt{OPT}(\mathcal{T}_n, w_n) - 1.$$

Using Lemma 13, we can then add an arbitrarily small perturbation to w_n to make C_n the *unique* centroid tree. (Observe that for every search tree T, $\texttt{cost}_w(T)$ is continuous in w, therefore so is $\texttt{OPT}(\mathcal{T}, w)$.)

The sequence $(\mathcal{T}_n, w_n)$ is constructed recursively as follows. For the sake of the construction we view $\mathcal{T}_n$ as a rooted tree. The base case $\mathcal{T}_0$ is a tree with a single vertex v and $w_0(v) = 1$. For $n > 0$, take two copies $(\mathcal{A}, w_\mathcal{A})$ and $(\mathcal{B}, w_\mathcal{B})$ of $(\mathcal{T}_{n-1}, w_{n-1})$. Connect the roots of $\mathcal{A}$ and $\mathcal{B}$ to a new vertex c. Finally, set $\texttt{root}(\mathcal{T}_n) = \texttt{root}(\mathcal{A})$ (see Figure 2). We define w_n as follows. (observe that $w_n(\mathcal{T}_n) = 1$, by induction on n.)

$$w_n(v) = \begin{cases} 0, & v = c \\ \frac{1}{2} w_\mathcal{A}(v), & v \in V(\mathcal{A}) \\ \frac{1}{2} w_\mathcal{B}(v), & v \in V(\mathcal{B}). \end{cases}$$

Let C_n denote the search tree on $\mathcal{T}_n$ obtained by setting c as the root and recursing. Observe that C_n is a centroid tree of $(\mathcal{T}_n, w_n)$.

▶ **Lemma 16.** *The following hold*

(a) $\texttt{cost}_{w_n}(C_n) = n + 1$,

(b) $\lim_{n\to\infty} \texttt{OPT}(\mathcal{T}_n, w_n) = \infty$.

Proof. Let $c_n = \texttt{cost}_{w_n}(C_n)$. Clearly, $c_0 = 1$. Assume $n > 0$. Let $C_\mathcal{A}$ and $C_\mathcal{B}$ be search trees on $\mathcal{A}$ and $\mathcal{B}$ respectively, each a copy of C_{n-1}. By construction of C_n we have

$$c_n = 1 + \frac{1}{2}\texttt{cost}_{w_\mathcal{A}}(C_\mathcal{A}) + \frac{1}{2}\texttt{cost}_{w_\mathcal{B}}(C_\mathcal{B}) = 1 + c_{n-1},$$

and (a) follows by induction.

Using (a) and Theorem 1, part (b) follows:

$$\texttt{OPT}(\mathcal{T}_n, w_n) \geq \frac{c_n + 1}{2} = \frac{n}{2} + 1 \to \infty. \qquad \blacktriangleleft$$

Next, in order to bound $\texttt{OPT}(\mathcal{T}_n, w_n)$ from above, we construct a sequence of search trees T_n on $\mathcal{T}_n$. For $n = 0$, tree T_0 is a single vertex. Assume $n > 0$. Let $\mathcal{A}$, $\mathcal{B}$, and c be as in the definition of $\mathcal{T}_n$. Let $T_\mathcal{A}$ and $T_\mathcal{B}$ be search trees over $\mathcal{A}$ and $\mathcal{B}$ respectively, each a copy of T_{n-1}. Denote $r_\mathcal{A} = \texttt{root}(\mathcal{A})$ and $r_\mathcal{B} = \texttt{root}(\mathcal{B})$. Tree T_n is obtained by adding an edge from $r_\mathcal{A}$ to $r_\mathcal{B}$ and an edge from $r_\mathcal{B}$ to c, and setting $\texttt{root}(T_n) = r_\mathcal{A}$.

▶ **Lemma 17.** $\texttt{cost}_{w_n}(T_n) = \frac{n}{2} + 1$.

Proof. Denote $t_n = \texttt{cost}_{w_n}(T_n)$. Clearly $t_0 = 1$. Assume $n > 0$. The contribution of vertices of $\mathcal{A}$ to t_n is exactly $\frac{1}{2}\texttt{cost}_{w_\mathcal{A}}(T_\mathcal{A}) = \frac{t_{n-1}}{2}$. Since r is an ancestor of all vertices in $\mathcal{B}$, the contribution of these vertices to t_n is exactly $\frac{1}{2}(1 + \texttt{cost}_{w_\mathcal{B}}(T_\mathcal{B})) = \frac{1+t_{n-1}}{2}$. Summing the contribution of all vertices, we get $t_n = t_{n-1} + \frac{1}{2}$ and the claim follows. ◀

Proof of Theorem 2(i). By Lemma 17, $\texttt{OPT}(\mathcal{T}_n, w_n) \leq \frac{n}{2} + 1$. Together with Lemma 16, the claim follows. ◀

4 Approximation guarantees for trees with bounded degrees

In this section we show the upper and lower bounds on the approximation quality of centroid trees when the underlying tree $\mathcal{T}$ has bounded degree. We start with the upper bound.

▶ **Theorem 3.** *Let $\mathcal{T}$ be a tree, $w : V(\mathcal{T}) \to \mathbb{R}_{\geq 0}$, and let Δ be the* maximum degree *of $\mathcal{T}$. Then*

$$\texttt{cent}(\mathcal{T}, w) \leq \left(2 - \frac{1}{2^\Delta}\right) \cdot \texttt{OPT}(\mathcal{T}, w).$$

For simplicity, in what follows we omit the weight function w from notations.

▶ **Lemma 18.** *Let C be a centroid tree of $\mathcal{T}$ such that $\texttt{cost}(C) = \texttt{cent}(\mathcal{T})$. Let $P = (v_0, v_1, \ldots, v_p)$ be any path in C. Then*

$$\texttt{cent}(\mathcal{T}) \leq \left(2 - \frac{1}{2^p}\right) m + \sum_{\mathcal{H} \in \mathbb{C}(\mathcal{T} - P)} \texttt{cent}(\mathcal{H}).$$

Proof. By induction on p. For $p = 0$ we have

$$\texttt{cent}(\mathcal{T}) = m + \sum_{\mathcal{H} \in \mathbb{C}(\mathcal{T} - v_0)} \texttt{cent}(\mathcal{H}), \quad \text{as required.}$$

Assume now $p > 0$. Denote by $\tilde{\mathcal{T}}$ the connected component of $\mathcal{T} - v_0$ where v_1 is. Denote $\tilde{P} = (v_1, \ldots, v_p)$, and $\tilde{m} = w(\tilde{\mathcal{T}})$. Observe that $\tilde{m} \leq m/2$ and that $\mathbb{C}(\mathcal{T} - P) = \mathbb{C}(\tilde{\mathcal{T}} - \tilde{P}) \uplus (\mathbb{C}(\mathcal{T} - v_0) - \{\tilde{\mathcal{T}}\})$. By the induction hypothesis we have

$$\texttt{cent}(\tilde{\mathcal{T}}) \leq \left(2 - \frac{1}{2^{p-1}}\right) \tilde{m} + \sum_{\mathcal{H} \in \mathbb{C}(\tilde{\mathcal{T}} - \tilde{P})} \texttt{cent}(\mathcal{H}), \quad \text{therefore}$$

$$\begin{aligned}
\texttt{cent}(\mathcal{T}) &= m + \texttt{cent}(\tilde{\mathcal{T}}) + \sum_{\substack{\mathcal{H} \in \mathbb{C}(\mathcal{T} - v_0) \\ \mathcal{H} \neq \tilde{\mathcal{T}}}} \texttt{cent}(\mathcal{H}) \\
&\leq m + \left(2 - \frac{1}{2^{p-1}}\right) \tilde{m} + \sum_{\mathcal{H} \in \mathbb{C}(\tilde{\mathcal{T}} - \tilde{P})} \texttt{cent}(\mathcal{H}) + \sum_{\substack{\mathcal{H} \in \mathbb{C}(\mathcal{T} - v_0) \\ H \neq \tilde{\mathcal{T}}}} \texttt{cent}(\mathcal{H}) \\
&\leq m + \left(2 - \frac{1}{2^{p-1}}\right) \frac{m}{2} + \sum_{\mathcal{H} \in \mathbb{C}(\mathcal{T} - P)} \texttt{cent}(\mathcal{H}) \\
&= \left(2 - \frac{1}{2^p}\right) m + \sum_{\mathcal{H} \in \mathbb{C}(\mathcal{T} - P)} \texttt{cent}(\mathcal{H}), \quad \text{as required.}
\end{aligned}$$

◀

Proof of Theorem 3. The proof is by induction on $|V(\mathcal{T})|$. Let T be any search tree on $\mathcal{T}$. We will show that $\texttt{cent}(\mathcal{T}) \leq \left(2 - \frac{1}{2^\Delta}\right)\texttt{cost}(T)$.

Denote $r = \texttt{root}(T)$. Let C be a centroid tree on $\mathcal{T}$ with $\texttt{cost}(C) = \texttt{cent}(\mathcal{T})$. Denote by $v_0, v_1, \ldots, v_d = r$ the vertices along the path to r in C. Denote $\mathcal{T}_i = \mathcal{T}[V(C_{v_i})]$. Observe that $r \in V(\mathcal{T}_d) \subseteq \cdots \subseteq V(\mathcal{T}_0) = V(\mathcal{T})$. For $i < d$, denote by $\mathcal{K}_i$ the connected component of $\mathcal{T} - r$ where v_i is. Denote by s_i the unique child of r in T such that $s_i \in V(\mathcal{K}_i)$, i.e., $V(T_{s_i}) = V(\mathcal{K}_i)$. Finally, denote by p the minimal i for which one of the following holds:

1. $v_i = r$, i.e., $i = d$,
2. $s_i \in V(\mathcal{T}_{i+1})$, or
3. there exists $j < i$ such that $\mathcal{K}_j = \mathcal{K}_i$, i.e., $s_j = s_i$.

Note that from the third condition above it follows that $p \leq \Delta$. Denote $P = (v_0, \ldots, v_p)$. We will prove the following.

▷ Claim 19.

$$\texttt{cost}(T) \geq m + \sum_{\mathcal{H} \in \mathbb{C}(\mathcal{T} - P)} \texttt{cost}(T|_{\mathcal{H}}).$$

Assume for now that Claim 19 holds. Using Lemma 18, the fact that $p \leq \Delta$, the induction hypothesis and Claim 19, we have

$$\begin{aligned}
\texttt{cent}(\mathcal{T}) &\leq \left(2 - \frac{1}{2^p}\right) m + \sum_{\mathcal{H} \in \mathbb{C}(\mathcal{T} - P)} \texttt{cent}(\mathcal{H}) \\
&\leq \left(2 - \frac{1}{2^\Delta}\right) m + \sum_{\mathcal{H} \in \mathbb{C}(\mathcal{T} - P)} \left(2 - \frac{1}{2^\Delta}\right) \texttt{cost}(T|_{\mathcal{H}}) \\
&\leq \left(2 - \frac{1}{2^\Delta}\right) \texttt{cost}(T).
\end{aligned}$$

◀

Proof of Claim 19. The proof breaks into cases according to the defining condition of p.

Case 1. Assume $v_p = r$. For every $\mathcal{H} \in \mathbb{C}(\mathcal{T} - P)$ and $v \in V(\mathcal{H})$ we have $\texttt{Path}_T(v) \supseteq \{r\} \uplus \texttt{Path}_{T|_{\mathcal{H}}}(v)$. The contribution of such v to $\texttt{cost}(T)$ is therefore at least $w(v)(1 + |\texttt{Path}_{T|_{\mathcal{H}}}(v)|)$. The contribution of each v_i to $\texttt{cost}(T)$ is at least $w(v_i)$. Summing the contribution of all vertices yields the required result. See Figure 3.

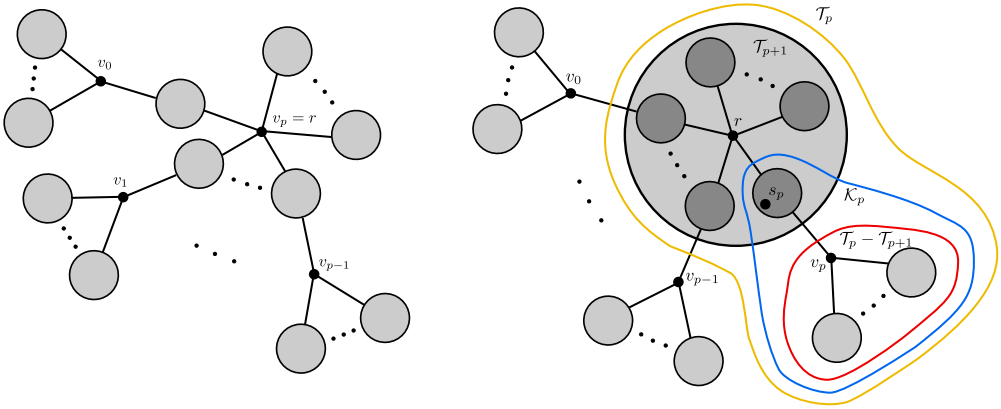

Figure 3 Illustration of the proof of Claim 19. Connected components of $\mathcal{T} - P$ are represented by light gray circles. (*Left.*) Case 1. (*Right.*) Case 2. Vertices in $\mathcal{T} - \mathcal{T}_p$ have r as ancestor. Vertices in $\mathcal{T}_p - \mathcal{T}_{p+1}$ have both r and s_p as ancestors.

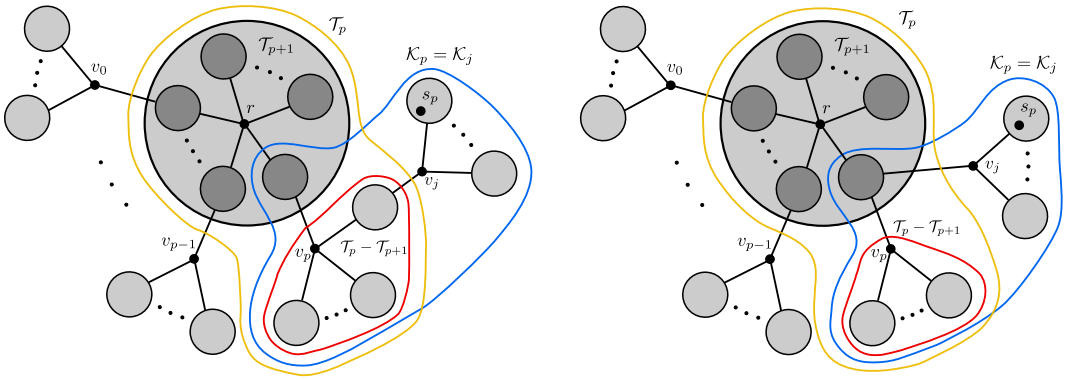

Figure 4 Case 3 in the proof of Claim 19. (*Left.*) Sub-case where v_p is in the path in $\mathcal{T}$ between r and v_j. (*Right.*) Complementary sub-case. Connected components of $\mathcal{T} - P$ are represented by light gray circles. In both sub-cases, vertices in $\mathcal{T}_p - \mathcal{T}_{p+1}$ have both r and s_p as ancestors.

Case 2. Assume $s_p \in V(\mathcal{T}_{p+1})$. Denote by $\mathbb{C}_1$ the set of connected components of $\mathcal{T} - P$ that are not contained in $\mathcal{T}_p$. Denote $\mathbb{C}_2 = \mathbb{C}(\mathcal{T} - P) - \mathbb{C}_1$ (see Figure 3). For every $\mathcal{H} \in \mathbb{C}_1$, if $v \in V(\mathcal{H})$, then $\texttt{Path}_T(v) \supseteq \{r\} \cup \texttt{Path}_{T|_\mathcal{H}}(v)$. Therefore the contribution of vertices in $V(\mathcal{T} - \mathcal{T}_p)$ to $\texttt{cost}(T)$ is at least

$$m - w(\mathcal{T}_p) + \sum_{\mathcal{H} \in \mathbb{C}_1} \texttt{cost}(T|_\mathcal{H}). \tag{2}$$

For vertices $v \in V(\mathcal{T}_p - \mathcal{T}_{p+1})$ we have $\{r, s_p\} \subseteq \texttt{Path}_T(v)$. Therefore, using the fact that $w(\mathcal{T}_p - \mathcal{T}_{p+1}) \geq \frac{w(\mathcal{T}_p)}{2}$, the contribution of vertices in $V(\mathcal{T}_p)$ to $\texttt{cost}(T)$ is at least

$$2 \cdot w(\mathcal{T}_p - \mathcal{T}_{p+1}) + \sum_{\mathcal{H} \in \mathbb{C}_2} \texttt{cost}(T|_\mathcal{H}) \geq w(\mathcal{T}_p) + \sum_{\mathcal{H} \in \mathbb{C}_2} \texttt{cost}(T|_\mathcal{H}). \tag{3}$$

Summing Equation (2) and Equation (3) yields the required result.

Case 3. Assume that there is a $j < p$ such that $\mathcal{K}_p = \mathcal{K}_j$. Since p is minimal, we further assume that Case 2 did not occur for indices smaller that p. In particular, $s_p = s_j \notin V(\mathcal{T}_p)$. As in Case 2, the contribution of vertices in $\mathcal{T} - \mathcal{T}_p$ to $\texttt{cost}(T)$ is at least as in Equation (2). We have $r \notin V(\mathcal{T}_p - \mathcal{T}_{p+1})$ and $v_p \in V(\mathcal{T}_p - \mathcal{T}_{p+1}) \cap V(\mathcal{K}_p) \neq \emptyset$, therefore, since $\mathcal{T}_p - \mathcal{T}_{p+1}$ is connected, $V(\mathcal{T}_p - \mathcal{T}_{p+1}) \subseteq V(\mathcal{K}_p)$ (see Figure 4). It follows that vertices in $\mathcal{T}_p - \mathcal{T}_{p+1}$ have both r and s_p as ancestors. Since $w(\mathcal{T}_p - \mathcal{T}_{p+1}) \geq \frac{w(\mathcal{T}_p)}{2}$, the contribution of vertices in $\mathcal{T}_p$ is at least as in Equation (3). As in Case 2, the result follows by summing Equation (2) and Equation (3). ◁

We now proceed to the lower bounds.

▶ **Theorem 4.** *Let $\Delta \geq 3$ be integer.*

(i) *There is a sequence of instances $(\mathcal{T}_n, w_n)$ such that $\mathcal{T}_n$ has maximum degree at most Δ, and for every centroid tree C_n of $(\mathcal{T}_n, w_n)$*

$$\lim_{n \to \infty} \frac{\texttt{cost}_{w_n}(C_n)}{\texttt{OPT}(\mathcal{T}_n, w_n)} = 2 - \frac{1}{2^\Delta}.$$

(ii) *There is a sequence of instances $(\mathcal{T}_n, w_n)$ such that $\mathcal{T}_n$ has maximum degree at most Δ, $\lim_{n \to \infty} \texttt{OPT}(\mathcal{T}_n, w_n) = \infty$, $w_n(\mathcal{T}_n) = 1$, and for every centroid tree C_n of $(\mathcal{T}_n, w_n)$*

$$\texttt{cost}_{w_n}(C_n) \geq \left(2 - \frac{4}{2^\Delta}\right) \cdot \texttt{OPT}(\mathcal{T}_n, w_n) - 1.$$

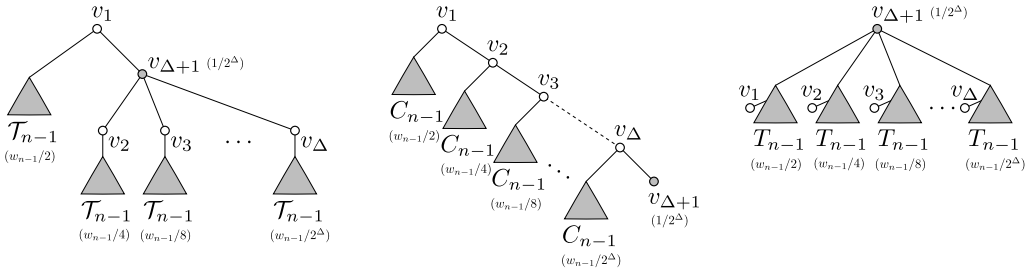

Figure 5 Illustration of Theorem 4(i). (*Left.*) The underlying tree $\mathcal{T}_n$. (*Middle.*) The centroid tree C_n. (*Right.*) The search tree T_n.

Part (i). As in the proof of Theorem 2, it will suffice to prove Theorem 4(i) for *some* centroid tree C_n. Using Lemma 13, we can then add arbitrarily small perturbation to w_n, making C_n the unique centroid tree.

The sequence $(\mathcal{T}_n, w_n)$ of Theorem 4(i) is constructed recursively as follows. For the sake of the construction we regard $\mathcal{T}_n$ as a rooted tree. $\mathcal{T}_0$ is simply a single vertex v (which is the root) and $w_0(v) = 1$. For $n > 0$, $\mathcal{T}_n$ is constructed from Δ copies of $\mathcal{T}_{n-1}$ and $\Delta + 1$ additional vertices, $v_1, \ldots, v_{\Delta+1}$, as shown in Figure 5 (left). The i'th copy of $\mathcal{T}_{n-1}$ gets the weight function $w_{n-1}/2^i$. We set $w_n(v_i) = 0$ for $1 \le i \le \Delta$ and $w_n(v_{\Delta+1}) = 1/2^\Delta$. Finally, we set $\mathrm{root}(\mathcal{T}_n) = v_1$. By induction, $\mathcal{T}_n$ has maximal degree Δ and w_n is a distribution on $V(\mathcal{T}_n)$.

Let C_n be a search tree on $\mathcal{T}_n$ defined recursively as follows. Connect the vertices $v_1, \ldots, v_{\Delta+1}$ to form a path and set v_1 as the root of C_n. Continue recursively on each connected component of $\mathcal{T} - \{v_1, \ldots, v_{\Delta+1}\}$. (See Figure 5 (middle).) Observe that C_n is a centroid tree of $(\mathcal{T}_n, w_n)$.

▶ **Lemma 20.** *For all n,*

$$\mathtt{cost}_{w_n}(C_n) = 2^{\Delta+1} - 1 - (2^{\Delta+1} - 2)\left(1 - \frac{1}{2^\Delta}\right)^n. \tag{4}$$

Proof. Denote $c_n = \mathtt{cost}_{w_n}(C_n)$. Clearly $c_0 = 1$ as required. Let $n > 0$. For each i, the subtree of all the descendants of v_i in C_n has weight $1/2^{i-1}$. Therefore

$$c_n = \sum_{i=1}^{\Delta+1} \frac{1}{2^{i-1}} + \sum_{i=1}^{\Delta} \frac{1}{2^i} c_{n-1} = 2 - \frac{1}{2^\Delta} + \left(1 - \frac{1}{2^\Delta}\right) c_{n-1}.$$

It is straightforward to verify that the right hand side of Equation (4) is the solution to the recursive formula above. ◀

In order to upper bound $\mathtt{OPT}(\mathcal{T}_n, w_n)$ we construct recursively a search tree T_n on $\mathcal{T}_n$. For $n > 0$, T_n is constructed by setting $v_{\Delta+1}$ as root and attaching to it Δ copies of T_{n-1}. The vertices $v_1, \ldots, v_\Delta$ are finally attached as leaves of T_n, each at its unique valid place. See Figure 5 (right).

▶ **Lemma 21.** *For all n,*

$$\mathtt{cost}_{w_n}(T_n) = 2^\Delta - 2^\Delta \left(1 - \frac{1}{2^\Delta}\right)^{n+1}. \tag{5}$$

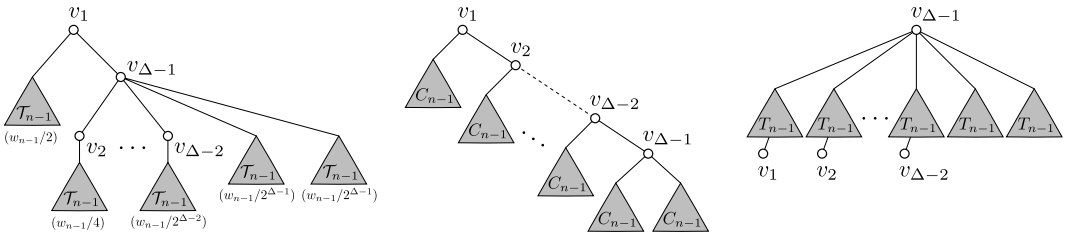

Figure 6 An illustration of Theorem 4(ii). (*Left.*) The underlying tree $\mathcal{T}_n$. (*Middle.*) The centroid tree C_n. (*Right.*) The search tree T_n.

Proof. Denote $t_n = \texttt{cost}_{w_n}(T_n)$. We have $t_0 = 1$. For $n > 0$, t_n obeys the recursive relation

$$t_n = 1 + \sum_{i=1}^{\Delta} \frac{1}{2^i} t_{n-1} = 1 + \left(1 - \frac{1}{2^\Delta}\right) t_{n-1},$$

of which the right hand side of Equation (5) is the solution. ◀

Proof of Theorem 4(i). Using Lemma 20 and Lemma 21,

$$\frac{\texttt{cost}_{w_n}(C_n)}{\texttt{OPT}(\mathcal{T}_n, w_n)} \geq \frac{\texttt{cost}_{w_n}(C_n)}{\texttt{cost}_{w_n}(T_n)} \to 2 - \frac{1}{2^\Delta}.$$ ◀

Observe that, as discussed in Section 1, $\texttt{OPT}(\mathcal{T}_n, w_n)/w_n(\mathcal{T}_n)$ is bounded.

Part (ii). To prove Theorem 4(ii), we repeat the recursive construction of Theorem 4(i) with a slight modification. As before, $\mathcal{T}_0$ is a tree with a single vertex. For $n > 0$, $(\mathcal{T}_n, w_n)$ is constructed from Δ weighted copies of $(\mathcal{T}_{n-1}, w_{n-1})$ and $\Delta - 1$ additional vertices, $v_1, \ldots, v_{\Delta-1}$, each with weight 0, as shown in Figure 6 (left). We set $\texttt{root}(\mathcal{T}_n) = v_1$.

As before, the search tree C_n is defined by connecting the vertices $v_1, \ldots, v_{\Delta-1}$ to a path, setting v_1 as root and recursing on the remaining connected component. Observe that C_n is a centroid tree of $(\mathcal{T}_n, w_n)$. (See Figure 6 (middle).) The search tree T_n is defined by setting $v_{\Delta-1}$ as root, attaching to it Δ copies of T_{n-1}, then adding the vertices $v_1, \ldots, v_{\Delta-2}$ as leaves, each at its unique valid place. See Figure 6 (right).

▶ **Lemma 22.** *For all n,*
(a) $\texttt{cost}_{w_n}(C_n) = \left(2 - \frac{4}{2^\Delta}\right) \cdot n + 1$,
(b) $\texttt{cost}_{w_n}(T_n) = n + 1$.

The proof follows an analysis similar to that of Lemma 20 and Lemma 21.

Proof. Denote $c_n = \texttt{cost}_{w_n}(C_n)$ and $t_n = \texttt{cost}_{w_n}(T_n)$. Clearly $c_0 = t_0 = 1$. For $n > 0$ we have

$$c_n = \sum_{i=1}^{\Delta-1} \frac{1}{2^{i-1}} + \sum_{i=1}^{\Delta-2} \frac{1}{2^i} c_{n-1} + 2\frac{1}{2^{\Delta-1}} c_{n-1} = 2 - \frac{4}{2^\Delta} + c_{n-1}, \quad \text{and}$$

$$t_n = \sum_{i=1}^{\Delta-2} \frac{1}{2^i}(t_{n-1} + 1) + 2\frac{1}{2^{\Delta-1}}(t_{n-1} + 1) = 1 + t_{n-1},$$

and the lemma follows by induction. ◀

Proof of Theorem 4(ii). The fact that $\lim_{n\to\infty} \texttt{OPT}(\mathcal{T}_n, w_n) = \infty$ follows from Lemma 22 and Theorem 3 (or Theorem 1). Using Lemma 22 again, we have

$$\texttt{cost}_{w_n}(C_n) \geq \left(2 - \frac{4}{2^\Delta}\right) \texttt{OPT}(\mathcal{T}_n, w_n) - 1 + \frac{4}{2^\Delta}.$$

Using Lemma 13, for each n we can add small enough perturbation to w_n such that C_n is the unique centroid tree and the claimed bound holds. ◀

5 Computing centroid trees

In this section, we show how to compute centroid trees using the *top tree* framework of Alstrup, Holm, de Lichtenberg, and Thorup [1]. *Top trees* are a data structure used to maintain dynamic forests under insertion and deletion of edges. Most importantly, they expose a simple interface that allows the user to maintain information in the trees of the forest. For this, the user only needs to implement a small number of internal operations.

Alstrup et al. in particular show how to maintain the *median* of trees in $\mathcal{O}(\log n)$ per operation, see Section 2 for the definition of the median. As mentioned before, if all edge-weights are 1, then medians are precisely centroids (see Lemma 14).

▶ **Theorem 23** ([1, Theorem 3.6]). *We can maintain a forest with positive vertex weights on n vertices under the following operations:*

- *Add an edge between two given vertices u, v that are not in the same connected component;*
- *Remove an existing edge;*
- *Change the weight of a vertex;*
- *Retrieve a pointer to the tree containing a given vertex;*
- *Find the centroid of a given tree in the forest.*

Each operation requires $\mathcal{O}(\log n)$ time. A forest without edges and with n arbitrarily weighted vertices can be initialized in $\mathcal{O}(n)$ time.

Note that Theorem 23 only admits *positive* vertex weights, whereas we allowed zero-weight vertices. We show how to handle this problem in the full paper [6].

We now show how to use Theorem 23 to construct a centroid tree in $\mathcal{O}(n \log n)$ time.

▶ **Theorem 24.** *Given a tree $\mathcal{T}$ on n vertices and a positive weight function w, we can compute a centroid tree of $(\mathcal{T}, w)$ in $\mathcal{O}(n \log n)$ time.*

Proof. First build a top tree on $\mathcal{T}$ by adding the edges one-by-one, in $\mathcal{O}(n \log n)$ time. Then, find the centroid c, and remove each incident edge. Then, recurse on each newly created tree (except for the one containing only c). The algorithm finds each vertex precisely once and removes each edge precisely once, for a total running time of $\mathcal{O}(n \log n)$. ◀

Output-sensitive algorithm. We improve the algorithm given above to run in time $\mathcal{O}(n \log h)$, where n is the number of vertices in $\mathcal{T}$ and h is the height of the computed centroid tree.

The main idea of the algorithm is inspired by the linear-time algorithm for *unweighted* centroids by Della Giustina, Prezza, and Venturini [28], with a number of further technical challenges. Instead of building a top tree on the whole tree $\mathcal{T}$, we first split $\mathcal{T}$ into connected subgraphs of size roughly h, and build a top tree on each component. Contracting each component into a single vertex yields *super-vertices* in a *super-tree*. Each search for a centroid consists of a global search and a local search: We first find the super-vertex containing the

centroid, then we find the centroid within that super-vertex. After finding the centroid, we remove it, which may split up the super-vertex into multiple super-vertices with a top tree each, and also may split the super-tree into a super-forest. Finally, we recurse on each component of the super-forest.

It can be seen that the total number of top tree operations needed is $\mathcal{O}(n)$. Since the top trees each contain only h vertices, a top tree operation takes $\mathcal{O}(\log h)$ time, for a total of $\mathcal{O}(n \log h)$. Detailed description and analysis of the algorithm, as well as the matching lower bound, appear in the full paper [6].

6 Conclusions

We showed that the average search time in a centroid tree is larger by at most a factor of 2 than the smallest possible average search time in an STT and that this bound is tight. We also showed that centroid trees can be computed in $\mathcal{O}(n \log h)$ time where h is the height of the centroid tree. Perhaps the most intriguing question is to determine whether the problem of computing an optimal STT is in P. A secondary goal would be to achieve an approximation ratio better than 2 in near linear time. (The running time of the STT's of Berendsohn and Kozma [7] degrade as $\mathcal{O}(n^{2k+1})$ for a $\left(1 + \frac{1}{k}\right)$-approximation.) As for centroid trees, a remaining question is whether they can be computed in $\mathcal{O}(n)$ time whenever the spread of the weight function is $\sigma \in \mathcal{O}(n)$.

A special case in which high quality approximation can be efficiently found is when an α-centroid tree exists for $\alpha < \frac{1}{2}$. This case can be recognized and handled in near linear time using our algorithm. (Observe that an α-centroid tree for $\alpha < \frac{1}{2}$ is also the unique $\frac{1}{2}$-centroid tree.) Theorem 7(ii) gives strong approximation guarantees for this case, yielding the *optimum* when $\alpha \leq \frac{1}{3}$. It is an interesting question whether the bounds can be improved for α in the range $\left(\frac{1}{3}, \frac{1}{2}\right)$, i.e., whether Theorem 7(ii) is tight.

A small gap remains in the exact approximation ratio of centroid trees when $\mathcal{T}$ has maximum degree Δ and `OPT` is unbounded, i.e., between the upper bound $(2 - \frac{1}{2^\Delta})$ of Theorem 3 and the lower bound $(2 - \frac{4}{2^\Delta})$ of Theorem 4(ii).

Improved Product-State Approximation Algorithms for Quantum Local Hamiltonians

Thiago Bergamaschi
Department of Computer Science, University of California, Berkeley, CA, USA

Abstract

The ground state energy and the free energy of Quantum Local Hamiltonians are fundamental quantities in quantum many-body physics, however, it is QMA-Hard to estimate them in general. In this paper, we develop new techniques to find classical, additive error product-state approximations for these quantities on certain families of Quantum k-Local Hamiltonians. Namely, those which are either dense, have low threshold rank, or are defined on a sparse graph that excludes a fixed minor, building on the methods and the systems studied by Brandão and Harrow, Gharibian and Kempe, and Bansal, Bravyi and Terhal.

We present two main technical contributions. First, we discuss a connection between product-state approximations of local Hamiltonians and combinatorial graph property testing. We develop a series of *weak Szemerédi regularity* lemmas for k-local Hamiltonians, built on those of Frieze and Kannan and others. We use them to develop *constant time* sampling algorithms, and to characterize the "vertex sample complexity" of the Local Hamiltonian problem, in an analog to a classical result by Alon, de la Vega, Kannan and Karpinski. Second, we build on the information-theoretic product-state approximation techniques by Brandão and Harrow, extending their results to the free energy and to an asymmetric graph setting. We leverage this structure to define families of algorithms for the free energy at low temperatures, and new algorithms for certain sparse graph families.

1 Introduction

The mean-field approximation is a popular heuristic in quantum many-body physics, in which product-states are used as an ansatz for generic quantum states. The low-energy states of quantum systems may be highly entangled objects, and possibly exponentially more complex than simple (unentangled) product states. This often makes computing properties of these low-energy states classically intractable. From a complexity-theoretic point of view, the mean-field approach casts these quantum problems that are in the complexity class QMA [34], into problems in NP, since product-states have a polynomial-size description and can act as classical, efficiently verifiable certificates. However, in the absence of a hardness-of-approximation result for QMA [1, 6, 2, 29] and assuming QMA≠NP, it is generally unknown if the ground states of quantum systems can even have "good" approximations with succinct classical descriptions, let alone if we can compute or approximate them efficiently.

In this work, we develop a series of classical algorithms to efficiently find mean-field approximations for quantum systems described by *local Hamiltonians*, and we develop new techniques to show that good mean-field approximations exist for fairly general classes of

these systems. A local Hamiltonian corresponds to a sparse matrix $H \in \mathbb{C}^{d^n \times d^n}$ which is exponentially large in the number n of quantum particles (or qu$d$its), and can be described as a sum over "local" terms $H = \sum_{e \in E} h_e$ defined by some hypergraph $G = ([n], E)$. H is said to be k-local if each hyperedge $e \in E$ is a k-tuple of vertices in $[n]$, and is said to have "bounded" interaction strengths if the operator norm $\|h_e\|_\infty$ is at most a constant independent of n for each hyperedge in E[1].

It is well known that the existence of product-state approximations to H is very sensitive to the structure of the underlying interaction graph G. In a seminal result, Brandão and Harrow [15] proved that so long as H has bounded interaction strengths, and is defined on a graph G of high degree or small expansion, then there exists a product state which approximates the ground state energy of H up to an additive error $\epsilon \cdot m$ (scaling with the number of edges or "interactions" m of H). Their results can be interpreted as rigorous proofs of accuracy of the mean-field approximation to the ground state energy of certain systems, and they opened the door to classical approximation schemes to find these "good" mean-field solutions efficiently. One of the main focuses of this work is to relax certain assumptions on the structure of the interaction graphs G, to extend the scope of their algorithms and existence statements.

The second main focus of this work is to study the structure and classical computation of properties of quantum systems in thermal equilibrium. The Helmholtz Free Energy $F(\beta)$ of a Quantum Local Hamiltonian H at a given temperature β^{-1} arises as an approximate counting analog to the ground state energy, as it reveals the degeneracy of the ground state (the number of QMA witnesses), the density of states of the Hamiltonian, as well as the existence of phase transitions. Quantitatively, $F(\beta)$ can be described as the optimum of a maximum entropy program:

$$F(\beta) \equiv \min_{\rho \geq 0,\ \mathrm{Tr}\rho = 1} f(\rho) = \min_{\rho \geq 0,\ \mathrm{Tr}\rho = 1} \mathrm{Tr}[H\rho] - S(\rho)/\beta \tag{1}$$

where the optimizer $\rho \propto e^{-\beta H}$ of the program above is called the Gibbs state of H. The computational complexity, and in particular the hardness of approximation of $F(\beta)$ is similarly not comprehensively understood. While QMA-Hard to estimate in general due to a reduction to the "low temperature" limit, and exactly computable in polynomial time using a #P oracle [19], it would seem there is much to uncover regarding the computational tradeoffs between error and temperature [16].

1.1 Our Main Contributions

In this section we overview our main contributions, which we present formally and in more detail in section 2.2.

Rigorous Mean-Field Approximations and Guarantees in NP

Our first contributions concern improvements and extensions to the existence statements by Brandão and Harrow [15]. Their methods had roots in the information-theoretic techniques by [39] and [10], developed in the context of approximating CSPs using the Lasserre Heirarchy. Informally, we show how to use their self-decoupling arguments to construct mixed states which are tensor products of single-particle mixed states, which approximate the Free Energy up to an additive error. We view these results as rigorous proofs of accuracy for the mean-field

[1] Please refer to section 2.1 for more background on local Hamiltonians and Schatten norms.

approximation to the Free Energy of Quantum Local Hamiltonians, and they imply that approximating the Free Energy of dense Hamiltonians up to an extensive error (scaling with the number of edges) is in NP.

▶ **Theorem 1.** *Fix $k, d = O(1)$, and an inverse temperature β. Let $H = \sum_{e \in E} h_e$ be a k-Local Hamiltonian on n qudits of local dimension d, and m interactions each of strength $\|h_e\|_\infty \leq 1$. Then, there exists a product state σ_β such that*

$$F \leq f(\sigma_\beta) = Tr[H\sigma_\beta] - S(\sigma_\beta)/\beta \leq F + O(n^{\frac{k-1}{3}} m^{2/3}) \tag{2}$$

That is, σ_β is an $O(n^{\frac{k-1}{3}} m^{2/3})$ additive error approximation to the Free Energy of H.

Note that when $k = 2$ (Hamiltonians on Graphs), the error becomes $O(n^{1/3}m^{2/3}) = O(m/D^{1/3})$, which recovers Brandão and Harrow's [15] result in terms of the *average* degree $D = m/n$ of the graph.

We emphasize two important points about the result above. First and foremost, the existence of approximations to $F(\beta)$ in NP implies that we can now use classical approximation schemes to search for optimal mean-field approximations to the free energy, and they will also be good additive approximations to the "entangled value" of $F(\beta)$. As we later discuss, this enables us to import practically all the previous machinery of approximation schemes for the ground state energy, to the Free Energy, developing novel algorithms for many quantum systems and improving on recent results by Bravyi et al. [16].

The second point of emphasis is that the result above holds at all temperatures β^{-1}. In this fashion, we are able to bypass the "low temperature bottleneck" of many approximation schemes for the Free Energy which constrain approaches in previous work, such as the polynomial interpolation method [11, 27] or Markov Chain Monte Carlo methods. We present a comprehensive comparison with previous work and the scope of our techniques for thermal systems in section 2.3.

Hamiltonian Regularity Lemmas and Approximation Algorithms

From an algorithmic point of view, our main contribution is a connection between product state approximations and graph property testing. We discuss quantum analogs of the *weak Szemerédi regularity lemmas* for dense graphs, hyper-graphs and low-threshold rank graphs [22, 3, 23], developed in the context of additive approximation schemes for Max-Cut and Max-kCSPs. At their heart lies a powerful combinatorial characterization of these systems, Szemerédi's celebrated regularity lemma [42], which states that dense graphs can be approximately decomposed into unions of complete bipartite graphs. We develop natural, constructive generalizations of these results for Quantum Local Hamiltonians, by combining our new product state approximations with multi-coloured versions of known weak regularity results, leading to improved approximation algorithms and novel structural characterizations of local Hamiltonians. Our central result in this vein is an additive error approximation scheme for dense k-Local Hamiltonians, which runs in *constant time*:

▶ **Theorem 2.** *Fix $d, k = O(1)$, $\epsilon > 0$, and let $H = \sum_e h_e$ be a k-Local Hamiltonian on n qudits of local dimension d and bounded strength interactions $\|h_e\|_\infty \leq 1$. Then, there exists a randomized algorithm which runs in time $2^{poly(1/\epsilon)}$, and with probability .99 returns an estimate for the ground state energy of H accurate up to an additive error of $\epsilon \cdot n^k$.*

We report our sampling algorithms, including that in theorem 2, in the *probe model of computation* introduced by Goldreich et al. [26]. In a nutshell, the time complexity measured above corresponds to the number of queries to a description of H, see section 2.1 for more details.

Our simplest algorithm is remarkably clean to describe, and is based on the "Vertex Sample Complexity' result for Max-kCSPs by Alon et al. [3]: Given a Hamiltonian H, sample a uniformly random subset of qudits $Q \subset [n]$ of certain constant size $|Q| = q = \text{poly}(1/\epsilon)$, and let H_Q be the $d^q \times d^q$ matrix corresponding to the restriction to the interactions of H contained entirely in Q. Then, exactly diagonalize the (constant-sized) $d^q \times d^q$ matrix H_Q, and output its lowest eigenvalue multiplied by $(n/q)^k$. For small constant $d, k, \epsilon > 0$, it is clear that this approach requires just a constant number of queries to H. The challenge, of course, lies in proving that this estimate corresponds to a $\epsilon \cdot n^k$ additive error estimate to the true ground state energy of the original Hamiltonian H.

In the body, we show how these ideas can be used to develop improvements in runtime from $n^{\text{poly}(1/\epsilon)}$ to $\text{poly}(n, 1/\epsilon) + 2^{\text{poly}(1/\epsilon)}$ or just $2^{\text{poly}(1/\epsilon)}$ for a wide range of problems on Quantum Local Hamiltonians, such as approximation schemes for the ground state energy, the Free Energy, and for Hamiltonians defined on low threshold rank graphs.

2 Technical Overview

2.1 Background and Notation

Linear Algebra and Matrix Norms. Given an $w \times w$ matrix A we refer to $\|A\|_p$ as the Schatten p-norm of A (the L_p norm of the singular values of A), and we refer to $|A|_p$ as the L_p norm of the w^2-dimensional vectorization of A. The graph decompositions are phrased in terms of the *cut norm* $\|A\|_C$ introduced by [22], defined by

$$A^+ = \max_{S_1, S_2 \subseteq [w]} \sum_{i \in S_1, j \in S_2} A_{ij} \text{ and } \|A\|_C = \max(A^+, (-A)^+) \tag{3}$$

where we have $\|A\|_C \leq \|A\|_{\infty \to 1} = \sup_{x \neq 0} \frac{|Ax|_1}{|x|_\infty} \leq 4 \cdot \|A\|_C$.

Asymptotic Notation. For any function $f(n)$ we refer to the asymptotic notation $\tilde{O}(f(n)) = O(f(n)\text{polylog}(f(n))) \leq c_1 \cdot f(n) \log^{c_2} f(n)$ for a choice of real positive constants c_1, c_2.

Local Hamiltonians. We denote a k-Local Hamiltonian on n qudits of local dimension d via a $d^n \times d^n$ Hermitian matrix, which can be expressed as a sum of local interactions $H = \sum_{e \in E} h_e$. By "local", we simply mean that each summand $h_e = H_e \otimes \mathbb{I}_{V \setminus e}$ acts non-trivially only on k particles at a time, as indicated by each k-tuple $e = (u_1 \cdots u_k)$ in a set of hyper-edges E. In this manner, we can specify any Local Hamiltonian "instance" simply by specifying the $d^k \times d^k$ submatrices of each local term. If $d, k = O(1)$, then the input has a polynomial-sized description in n. For notational convenience, we often omit the trivial support $\mathbb{I}_{V \setminus e}$. The ground state energy and the ground state of H are its minimum eigenvalue and corresponding eigenvector, and the *variational* minimum energy of H is the minimum energy of H among all product states $\min_{\rho = \otimes \rho_u} \text{Tr}[H \otimes_u \rho_u]$ with $\rho_u \in \mathbb{C}^{d \times d}$ and $\rho_u \geq 0, \text{Tr}_u[\rho_u] = 1$.

Interaction Graphs. We refer to the "Interaction Graph" $G = ([n], E)$ of a 2-Local Hamiltonian H as the graph with undirected edges $e = (u, v) \in E$ whenever the particles u, v interact non-trivially in H. That is, whenever the spectral norm is non-zero $\|H_e\|_\infty \neq 0$. By expressing each $d^2 \times d^2$ Hermitian matrix $H_{u,v} = \sum_{i,j \in [d^2]} H^{i,j}_{u,v} \cdot \sigma^i_u \otimes \sigma^j_v$ in an orthogonal basis decomposition, and grouping all the interactions with the same basis i, j, we refer to the i, j "Pauli Graph" as the subgraph of G induced on all the *directed* edges $e = (u, v)$ with

non-zero $H^{i,j}_{u,v} = d^{-2}\mathrm{Tr}[H_{u,v}\sigma^i_u \otimes \sigma^j_v]$, with weighted adjacency matrix $J^{ij} = \{H^{i,j}_{u,v}\}_{u,v\in[n]}$. We note that the matrices J^{ij} are degenerate, since $J^{ij} = (J^{ji})^T$, but we often brush over this issue via a handshaking argument. If we are given a density matrix $\rho = \otimes\rho_u$ which is a product of single qudit density matrices with a basis decomposition $\rho_u = d^{-1}\sum_i \alpha^i_u \cdot \sigma^i$, then the energy of ρ, $\mathrm{Tr}[H\rho]$ is a polynomial over the real variables α:

$$\sum_{(u,v)\in E} \mathrm{Tr}[H_{u,v}\rho_u\otimes\rho_v] = d^{-2}\sum_{(u,v)\in E}\sum_{i,j\in[d^2]} H^{i,j}_{u,v}\alpha^i_u\cdot\alpha^j_v = (2d^2)^{-1}\sum_{i,j\in[d^2]}\sum_{u\neq v\in[n]} J^{ij}_{uv}\alpha^i_u\cdot\alpha^j_v \quad (4)$$

Model of Computation. We report our sampling algorithms in the *probe model of computation* introduced by [26] in the context of graph property testing. That is, we assume we can sample a uniformly random vertex or hyper-edge in $O(1)$ time (or "probes"). Formally, fixed a k-Local Hamiltonian "instance" $H = \sum_{e\in E} H_e \otimes \mathbb{I}_{V\setminus e}$, for any k-tuple of vertices/hyper-edge $e = (u_1 \cdots u_k), u_i \in [n]$, we assume we can query the (constant-sized) $d^k \times d^k$ sub-matrix H_e in $O(1)$ time. We emphasize that since our goal is often a sublinear time algorithm, we always enforce that our algorithms output estimates for the energy (or free energy), and *implicit* descriptions of product states. If requested, these implicit descriptions can always be expanded into n-qudit product states in an additional $\mathrm{poly}(n, 1/\epsilon)$ time.

2.2 Our Results

Approximation Guarantees in NP

The first of our results are rigorous proofs of accuracy of the mean-field approximation on Quantum k-Local Hamiltonians. We argue the existence of product states, or products of single-particle mixed states, which provide additive error approximations to the ground state energy and the free energy of these systems. We build on the information-theoretic techniques by Brandão and Harrow [15], presenting an extension to the free energy and modestly refining their techniques on generic (hyper-) graphs.

▶ **Theorem 3.** *Fix $k, d = O(1)$. Let $H = \sum_{e\in E} h_e$ be a k-Local Hamiltonian on n qudits of local dimension d, and m interactions each of strength $\|h_e\|_\infty \leq 1$. Then, there exists a product state $|\psi\rangle = \otimes_{u\in[n]}|\psi_u\rangle, |\psi_u\rangle \in \mathbb{C}^d$ such that*

$$\langle\psi|H|\psi\rangle \leq \min_\phi \langle\phi|H|\phi\rangle + O(n^{\frac{k-1}{3}}m^{2/3}) \quad (5)$$

In the body, we prove more general versions of the theorem above sensitive to the matrix of interaction strengths of H. Theorem 3 matches the previous results in [15] whenever the Hamiltonian is defined on D-regular or dense graphs $m = \Omega(n^k)$, and generalizes their statements to just depend on the number of edges m. In the setting of Theorem 3, whenever $m = \Omega(n^{k-1}/\epsilon^3)$, approximating the ground state energy of H up to additive error $\epsilon \cdot m$ is in the complexity class NP, as the product state has a polynomial size description and acts as a classical witness. While these optimal product states may still be NP-Hard to find in the worst case, there are many examples where one can approximate these solutions efficiently.

To extend both these information-theoretic ideas and algorithmic applications to the free energy, we need further insights on the structure of these product state approximations. We discuss[2] how the "entanglement-breaking" procedure of [15], not only approximately

[2] In section B of the full version.

preserves the energy, but in fact also increases the entropy as well. When applied to the Gibbs state, we show one can carefully extract a tensor product of single particle mixed-states which is a good approximation to the free energy. We formalize this statement in Theorem 4,

▶ **Theorem 4.** *Fix $k, d = O(1)$, and an inverse temperature β. Let $H = \sum_{e\in E} h_e$ be a k-Local Hamiltonian on n qudits of local dimension d, and m interactions each of strength $\|h_e\|_\infty \leq 1$. Then, there exists a product state $\sigma_\beta = \otimes_{u\in[n]}\sigma_u, \sigma_u \in \mathbb{C}^{d\times d}$ such that*

$$f(\sigma_\beta) = Tr[H\sigma_\beta] - S(\sigma_\beta)/\beta \leq F + O(n^{\frac{k-1}{3}} m^{2/3}) \tag{6}$$

We emphasize that the statement above implies a product state approximation exists at all temperatures β^{-1} (and recovers the ground state approximation at $T = 0$), and moreover uses very little of the underlying graph structure apart from the *average* dense condition.

Hamiltonian Weak Regularity Lemmas

We develop an approach to designing approximations algorithms for Local Hamiltonians based on *weak Szemerédi regularity lemmas*, which are approximate decompositions to graphs, matrices, and tensors [42, 22, 3, 23].

The idea behind this construction lies in a powerful tool in extremal combinatorics. In his celebrated regularity lemma, Szemerédi [42] proved that any dense graph can be approximated by a union of a constant number of complete bipartite graphs. However, the number of partitions grew very fast with the intended quality of approximation. Frieze and Kannan [22] developed a constructive decomposition under a weaker notion of approximation, what they refered to as a "weak" regularity lemma. Concretely, they prove that any real $n \times n$ matrix with bounded entries can be decomposed into a sum of $O(1/\epsilon^2)$ cut matrices (complete bipartite graphs), up to an error $\epsilon \cdot n^2$ in the cut norm. Moreover, [22] proved that one can in fact construct such a "cut decomposition" implicitly in time polynomial in $1/\epsilon$, which enabled them to devise constant time sampling-based approximation schemes for many problems on dense graphs.

We define a natural adaptation of their results to a quantum setting, by constructing an approximate decomposition H_D of a Local Hamiltonian H which is a sum over complete, bipartite, sub-Hamiltonians. The structure of H_D can be understood as a "multi-colored" matrix cut decomposition, as essentially we apply the cut decomposition by [22] to each term in a basis decomposition of H. For concreteness, let $H = \sum_{u,v} h_{u,v}$ be a 2-Local Hamiltonian on qubits, and let us consider re-writing its Pauli basis decomposition below. We suppress the identity terms $\otimes \mathbb{I}_{V\setminus\{u,v\}}$ on the qubits that each interaction acts trivially on.

$$H = \sum_{(u,v)\in E} h_{u,v} = \sum_{(u,v)\in E} \sum_{i,j\in\{I,X,Y,Z\}} h^{i,j}_{u,v}\sigma^i_u \otimes \sigma^j_v = \sum_{i,j\in\{I,X,Y,Z\}} \sum_{u<v} h^{i,j}_{u,v}\sigma^i_u \otimes \sigma^j_v \tag{7}$$

We associate each pair of indices $i, j \in \{I, X, Y, Z\}$ to a color, and consider the $n \times n$ real valued weighted adjacency matrix $J^{ij} = \{h^{i,j}_{u,v}\}_{u,v\in[n]}$ of the i, j "Pauli Graph". By applying the cut decomposition by [22] to each of these 16 matrices J^{ij}, we construct an approximate decomposition of H into roughly $16 \cdot O(1/\epsilon^2)$ complete bipartite sub-Hamiltonians. In this context, a "complete bipartite sub-Hamiltonian" is defined by two Pauli matrices, (say, X, Y), two subsets $S, T \subset [n]$ (which, for now, we assume to be disjoint), and an interaction strength $\alpha \in \mathbb{R}$, and can be expressed as $\alpha \sum_{u\in S, v\in T} X_u \otimes Y_v$.

In the body we argue that the approximation guarantees in the cut norm are precisely what we need to ensure that for any product state $\sigma = \otimes_u \sigma_u$, the energy of σ under H or H_D are close: $\mathrm{Tr}[H\sigma] \approx \mathrm{Tr}[H_D\sigma]$. By further combining this product state regularity with our asymmetric product state approximations, we prove a stronger property on the spectra of H_D:

▶ **Lemma 5** (Informal). *Fix $d, k = O(1)$ and a constant $\epsilon > 0$, and let $H = \sum_e h_e$ be a k-Local Hamiltonian on n qudits of local dimension d and m interactions of strength bounded by $\|h_e\|_\infty \leq 1$. Then, there exists a decomposition $H_D = \sum_i^s D^{(i)}$ of H into $s = O(1/\epsilon^2)$ complete bipartite sub-Hamiltonians such that*

$$\|H - H_D\|_\infty \leq \epsilon \cdot n^{k/2} m^{1/2} \tag{8}$$

Additive Error Approximation Schemes

Leveraging the structure of the Hamiltonian regularity (lemma 5) in combination with the product state approximation toolkit enables us to devise a series of approximation schemes for Quantum Local Hamiltonians. We follow the ideas of [22, 3, 23] in establishing LP relaxations to Max Cut and other Max CSPs, and we develop an SDP relaxation scheme for finding the minimal energy product state of a Local Hamiltonian. These ideas enable us to devise an efficient additive error approximation scheme for dense Hamiltonians,

▶ **Theorem 6** (Theorem 2, restatement). *Fix $d, k = O(1)$ and $\epsilon > 0$. Let $H = \sum_e h_e$ be a k-Local Hamiltonian on n qudits of local dimension d, and m interactions of bounded strength $\|h_e\|_\infty \leq 1$. There exists a randomized algorithm which runs in time $2^{\tilde{O}(1/\epsilon^{2k-2})}$ in the probe model of computation, and with probability .99 computes an estimate for the ground state energy of H accurate up to an additive error of $\epsilon \cdot n^{k/2}\sqrt{m}$.*

We note that $n^{k/2}\sqrt{m} \geq m$, and thus in polynomial or sublinear time this approximation scheme only provides a non-trivial guarantee when the hyper-graph is dense, $m = \Omega(n^k/\log^c n)$ for some small positive constant c. However, it provides an improvement over the $n^{O(1/\epsilon^2)}$ time algorithms by [24] and [15] in this additive error regime. On the other hand, a simple explicit variant of this result provides a sub-exponential time approximation algorithm whenever $m = \omega(n^{k-1}\log n)$:

▶ **Theorem 7.** *In the context of Theorem 2, there exists a randomized algorithm which runs in time $\tilde{O}(n^k) \cdot 2^{\tilde{O}(n^k/\epsilon^2 m)}$ and with high probability computes an estimate for the ground state energy of H accurate up to an additive error of $\epsilon \cdot m$.*

Concretely, the key idea behind these relaxations is that for any product state $\sigma = \otimes_u \sigma_u$, the energy of σ on the cut decomposition H_D is a simple function of the average magnetization of a small number of subsets of the n qudits. To illustrate how this enables a relaxation scheme, consider a single complete bipartite sub-Hamiltonian, such as $H_{S,T} = \sum_{u\in S, v\in T} X_u \otimes Y_v$. The energy of σ on $H_{S,T}$ is

$$\mathrm{Tr}[H_{S,T}\sigma] = \sum_{u\in S, v\in T} \mathrm{Tr}_{u,v}[X_u\sigma_u \otimes Y_v\sigma_v] = \left(\sum_{u\in S} \mathrm{Tr}[X_u\sigma_u]\right) \cdot \left(\sum_{v\in T} \mathrm{Tr}[Y_v\sigma_v]\right), \tag{9}$$

simply the product of the average X direction magnetization of $S \subset [n]$ with the average Y magnetization of T. If we fix a "guess" $r, c \in [-n, n]$, one can introduce affine constraints on the single particle density matrices σ_u, constraining their average magnetizations to lie within a $\pm\gamma \cdot n$ range of the guess r, c:

$$r - \gamma \cdot n \leq \sum_{u \in S} \mathrm{Tr}[X_u \sigma_u] \leq r + \gamma \cdot n, \tag{10}$$

$$c - \gamma \cdot n \leq \sum_{v \in T} \mathrm{Tr}[Y_v \sigma_v] \leq c + \gamma \cdot n. \tag{11}$$

Then, we are guaranteed that any product state σ which is feasible for the constraints above must have energy in a range around the guess: $|\mathrm{Tr}[H_{S,T}\sigma] - r \cdot c| \leq (2 \cdot \gamma + \gamma^2) \cdot n^2$. In this manner, one can discretize over the space of "guesses" (r, c) and define an overlapping set of convex constraints on the description of the product states σ, such that every product state is feasible for at least one set of constraints. Approximating the ground state energy among product states ultimately reduces to checking the feasibility of a constant number of SDPs, one for each guess of r, c, and outputting whichever gives us the smallest energy estimate.

Using the techniques by [23], we can extend these insights to the setting of symmetric 2-Local Hamiltonians defined on graphs of low threshold rank. They proved that the weak regularity results of [22] could be extended to low-threshold rank graphs, by constructing a cut decomposition of a low rank approximation to the normalized adjacency matrix of these graphs. While in the appendix we formalize approximation algorithms for generic symmetric Hamiltonians (on low threshold rank graphs), perhaps the most faithful extension of this result to the quantum setting would be its application to approximating the Quantum Max Cut [25, 37, 36, 38]. Given an undirected graph $G = (V, E)$, the "Quantum Max-Cut" corresponds to the maximum eigenvalue of the Hamiltonian

$$H = \frac{1}{2} \sum_{e \in E} \left(\mathbb{I}_u \otimes \mathbb{I}_v - X_u \otimes X_v - Y_u \otimes Y_v - Z_u \otimes Z_v \right) \otimes \mathbb{I}_{V \setminus \{u,v\}} \tag{12}$$

If A is the adjacency matrix of G and D the diagonal matrix of degrees, the δ-SOS threshold rank $t_\delta(A)$ of A is the number of eigenvalues of the normalized adjacency matrix $D^{-1/2}AD^{-1/2}$ which are outside of the range $[-\delta, \delta]$. We prove

▶ **Theorem 8.** *Fix $\epsilon, \delta > 0$. Let $G = (V, E)$ be a graph on n vertices and m edges with adjacency matrix A and threshold rank $t \equiv t_{\epsilon/2}(A)$. Then, there exists an algorithm which finds an $\epsilon \cdot m + O(n^{1/3}m^{2/3})$ additive error approximation to the Quantum Max Cut of G in time poly$(n, 1/\epsilon, t) + 2^{\tilde{O}(t/\epsilon^2)}$.*

For instance, sparse D-regular random graphs have $\Theta(D^{-1/2})$-SOS threshold rank 1. In this manner, for any constant ϵ and if $D = \Omega(1/\epsilon^3)$, then one can compute an $\epsilon \cdot m$ approximation to the Quantum Max Cut of a D-regular random graph in polynomial time.

A series of works [30, 31, 32] showed that the matrix weak regularity lemma [22] could be used to approximate the free energy of Ising Models, and to give interesting structural results on the quality of the mean-field approximation and the "vertex sample complexity" of these systems. They observed that the maximum entropy program subject to the linear relaxation constraints described above, reveals properties of the Gibbs distribution and enables an additive error approximation to the free energy at all temperatures. By combining these ideas with the Hamiltonian regularity Lemma 5 and Theorem 4 on product state approximations to the free energy, we develop a series of additive error approximation schemes for the free energy of Quantum Local Hamiltonians. The first of which is a constant time approximation scheme, which provides an additive error guarantee in a low temperature regime.

▶ **Theorem 9.** *Fix $k, d = O(1)$, and $\epsilon, \delta > \omega(n^{-1/(2k-2)})$ and an inverse temperature $\beta > 0$, and let H be a k-Local Hamiltonian on n qudits of local dimension d and m bounded strength interactions. Then, there exists an algorithm that runs in time $2^{\tilde{O}(\epsilon^{2-2k})} \cdot O(\delta^{-2})$ in the probe model of computation, that returns an estimate to the free energy accurate up to an additive error of $\epsilon n^{k/2} m^{1/2} + \delta n/\beta$ and is correct with probability .99.*

We emphasize that the free energy is a convex program regularized by temperature, and thereby our approximation schemes often incur a tradeoff between combinatorial errors and thermal (temperature dependent) errors. In the low temperature regime, whenever $\beta = \Omega(n^{1-k/2} m^{-1/2})$, the algorithm above recovers the behavior of the ground state energy approximation scheme, and is largely temperature independent. However, as the temperature increases and surpasses the threshold, the leading source of error becomes the thermal error $\delta n/\beta$. In our second algorithm, we show that an explicit approach significantly improves this thermal error dependence, at the cost of a polynomial runtime.

▶ **Theorem 10.** *Fix $k, d = O(1)$, and $\epsilon, \delta > 0$ and an inverse temperature $\beta > 0$, and let H be a k-Local Hamiltonian on n qudits of local dimension d and m bounded strength interactions. Then, there exists an algorithm that runs in time $2^{\tilde{O}(\epsilon^{-2})} \cdot \tilde{O}(n^k \log 1/\delta)$, that returns an estimate to the free energy accurate up to an additive error of $\epsilon n^{k/2} m^{1/2} + \delta n/\beta$ and is correct with high probability.*

The Vertex Sample Complexity

The Regularity Lemma Lemma 20 enables us to derive an insightful structural statement for Local Hamiltonians. Namely, the definition of a "vertex sample complexity" for Local Hamiltonians of bounded interaction strengths, in an analogy to the vertex sample complexity of Max-kCSPs of [3] and [4]. They showed that the restriction of any Max-kCSP to a uniformly random sample of $\text{poly}(1/\epsilon)$ variables, sufficed to estimate the maximum number of satisfiable clauses up to an additive error of $\epsilon \cdot n^k$. We develop a generalization of this result to Quantum Local Hamiltonians, by combining the Hamiltonian regularity lemma with some extensions to the proof techniques by [3] to SDPs.

▶ **Theorem 11.** *Fix $d, k = O(1)$ and $\epsilon > 0$, and let H be a k-local Hamiltonian on n qudits of local dimension d and m bounded interaction strengths. Let $Q \subset [n]$ be a uniformly random sample of $q = \Omega(\epsilon^{-6} \log 1/\epsilon)$ of those qudits, and let H_Q be the sum of interactions with support contained entirely in Q. Then, with probability 0.99,*

$$\left| \min_{\rho} Tr[H\rho] - \frac{n^k}{q^k} \min_{\rho_Q} Tr[H_Q \rho_Q] \right| \leq \epsilon \cdot n^k \tag{13}$$

We rely crucially on the guarantee of product state approximations to Quantum Local Hamiltonians in this regime of additive error. Indeed, one of the directions of the statement above is quite intuitive for both classical and quantum systems: If the ground state energy of H is low, then the ground state energy of the restriction H_Q can't be much higher than the estimate. This is since the reduced density matrix $\rho_Q = \text{Tr}_{V \setminus Q}[\psi]$ of the ground state ψ of H, probably also has low energy $\text{Tr}[H_Q \rho_Q] \approx \frac{q^2}{n^2} \cdot \text{Tr}[H\psi]$, and the true ground state energy of H_Q can only be lower than that.

In the converse, however, lies an interesting "semi-classical" characterization of this additive error regime. Note that if the ground state energy of H is "high", then in particular there doesn't exist any product states with low energy on H. Using the proof techniques in [3], we show this implies the existence of a certain succinctly describable classical certificate

to this product-state "infeasibility", which we sample from to prove the absence of product states with low energy on H_Q. Here is where we require the product state approximations of Theorem 3: for sufficiently large Q, the absence of low energy product states for H_Q must imply a high ground state energy for H_Q. In this sense, the ground state energy of H_Q can't be much lower than its estimate either.

As a straightforward corollary to this structural result, now we can easily devise an algorithm which provides an additive error guarantee by exactly diagonalizing the Hamiltonian H_Q on $q = \tilde{O}(\epsilon^{-6})$ vertices in time $2^{\tilde{O}(1/\epsilon^6)}$. However, we can in fact do slightly better, simply by applying the additive error, product state approximation algorithm by [24] to the subsample:

▶ **Corollary 12.** *Fix $d, k = O(1)$ and $\epsilon > 0$, and let H be a k-Local Hamiltonian on n qudits of local dimension d and m bounded interaction strengths. There exists a randomized algorithm which runs in time $2^{\tilde{O}(\epsilon^{-2})}$, and with probability .99 outputs an estimate to the ground state energy accurate up to an additive error of $\epsilon \cdot n^k$.*

Aside from the improved dependence on k in the exponent, this result may seem to only subtly differ from that in Theorem 2. However, we emphasize that Theorem 2 requires an exponential number in $1/\epsilon$ of samples of vertices, whereas Theorem 11 guarantees a polynomial number suffices.

Approximation Schemes on Graphs that exclude a Fixed Minor

Finally, we develop novel singly-exponential time algorithms for sparse, 2-Local Hamiltonians defined on graphs that exclude a fixed minor. Formally, the family of h-minor free graphs are all the graphs G that can not produce another (smaller) graph h, by deleting edges and vertices and by contracting edges [41]. Planar graphs, and bounded genus graphs (such as toriods) are among the interesting special cases of these classes. Our approach builds on previous work by [9] and [15] on planar graphs, using more general combinatorial decompositions [21] and improving on their "quantum-to-classical" mappings. We show how such 2-Local Hamiltonians can be approximately understood as classical Max k-CSPs defined on the high degree vertices in the graph, and develop a dynamic programming algorithm to solve it using a simple hyper-dimensional version of a tree decomposition. Our first result for these systems is a classical algorithm to approximate the ground state energy in time singly exponential in $\text{poly}(1/\epsilon)$,

▶ **Theorem 13.** *Fix $\epsilon > 0$. Let H be a 2-Local Hamiltonian defined on n qubits and $m = \Theta(n)$ bounded strength interactions of norm < 1, configured on an h-minor free graph $G = (V, E)$ where the minor is constant size $|h| = O(1)$. Then, we can approximate the ground state energy of H up to additive error $\epsilon \cdot n$, in time poly$(n) + n \cdot 2^{poly(1/\epsilon)}$.*

We build on these ideas by combining them with our information-theoretic techniques for the free energy of quantum systems, to construct novel algorithms for the free energy of these classes of sparse graphs at low temperatures as well.

▶ **Theorem 14.** *Fix $\epsilon > 0$ and an inverse temperature β. Let H be a 2-Local Hamiltonian on n qubits and $m = \Theta(n)$ bounded strength interactions of norm < 1, configured on an h-minor free graph $G = (V, E)$ where the minor is constant size $|h| = O(1)$. Then, we can approximate the the free energy $F(\beta)$ of H up to additive error $\epsilon \cdot n$, in time poly$(n) + n \cdot \max(2, \beta^{-1})^{poly(1/\epsilon)}$, respectively.*

2.3 Related Work

Classical Approximation Schemes for QMA Complete Problems

While the systematic study of approximation algorithms to QMA-Complete problems is still emerging, there are a number of works we would like to highlight on the topic. [9] developed classical approximation schemes for ground state energies of classical and Quantum 2-Local Hamiltonians configured on planar graphs (of bounded degree, in the quantum case). They leveraged Baker's technique [8] and structural properties of planar graphs to approximately decompose the Hamiltonian into non-interacting partitions, which then could be analyzed by exact diagonalization, or dynamic programming. [24] were among the first to construct an approximation algorithm for the k-Local Hamiltonian Problem. They argued that product states can provide a d^{-k+1}-relative factor approximations to the ground state energy of k-Local Hamiltonians defined on qu$d$its, similarly to how Max Cut admits a $1/2$ multiplicative approximation. They then developed an approximation algorithm for the variational problem of finding the minimal energy product state of a given Local Hamiltonian H. It constructs a product state that provides an (extensive) $\epsilon \cdot n^k$ additive approximation to the ground state energy, in runtime $n^{O(\epsilon^{-2} \log 1/\epsilon)}$. Their approach was based on an adaptation of a classical technique, the "exhaustive sampling method" by [7] to the quantum setting, developed in the context of approximating Max Cut on dense graphs.

Later, [15] developed information-theoretic techniques to argue the existence of product state approximations to the the ground state energy. More precisely, they show that so long as H is *everywhere dense* ($\Omega(n^{k-1})$ minimum degree), has bounded expansion, or is clustered into regions of sub-volume law entanglement entropy, there exist product states that provide *additive error* approximations to the minimum energy. Leveraging their information-theoretic statements, they turned the algorithm of [24] into a PTAS for the ground state energy, albeit only meaningful when the number of interactions $m = \Omega(n^k)$. Additionally, they devise approximation schemes for Quantum Hamiltonians defined on generic planar graphs (not just those of bounded degree), solving an open problem posed by [9]. Their key insight was what we refer to as a "high-low degree" technique, in which one could consider a product state over all vertices of degree larger than some tunable cutoff Δ, and a generic (entangled) quantum state over the hilbert space of the low-degree particles, while incurring only a small error to the ground state energy. It is worthwhile to raise however, that the runtime of the resulting algorithm is triply-exponential in $1/\epsilon$, where the algorithm returns an $\epsilon \cdot n$ additive approximation.

More recently, in the context of *relative error* approximation schemes, [28] showed that one can find a product state within a relative error of l of the ground state of a traceless k-Local Hamiltonian of bounded norm, where l is the maximum degree of the underlying hyper-graph. [18] devised a $O(\log n)$ multiplicative approximation scheme to the ground state energy of 2-Local traceless Hamiltonians by rounding the solutions of SDPs to product states.

Classical Approximation Schemes for the Free Energy of Quantum Systems

Our results also contribute to a rich literature of classical techniques for thermal quantum systems. Perhaps the most well known of these techniques are the Quantum Monte Carlo methods, which approximate the quantum partition function of a quantum system to that of a classical spin system, which in turn is approximated via Markov chain Monte Carlo methods. Despite the enormous practical success of these techniques, rigorous proofs of convergence have only been presented in certain restricted systems [17, 13, 20], and they generically

are efficient only in the high temperature limit. Another high-temperature technique is the polynomial interpolation method [11, 27], based on a Taylor expansion of the partition function in the high temperature limit. Although both of these approaches are only provably efficient either on restricted classes of systems (such as substochastic Hamiltonians) and/or in the high temperature limit (typically β is a constant, or at most $O(\log n)$), they provide quite strong notions of approximation. In fact, they generally provide $(1+\epsilon)$ multiplicative approximations to the partition function (which translates to an ϵ additive approximation to the free energy), while in this paper we only attempt *extensive*, additive, $\epsilon \cdot m$ error approximations to the free energy.

By approaching the problem via this weaker notion of error, it is possible to devise approximation schemes in a much wider range of temperatures. A recent result by [16] presented an algorithm that estimates the free energy of dense Local Hamiltonians, also building on the information-theoretic techniques by [15]. Their approach is based on a quantum generalization to a classical correlation rounding approach by [40], and their algorithm finds a $\epsilon \cdot n^2$ additive approximation to the free energy of 2-Local Hamiltonians, in runtime $n^{O(\epsilon^{-2})}$.

Comparison to Previous Work

To conclude our introduction we summarize our algorithmic improvements in constrast to previous known constructions for the quantum systems studied. In table 1 below we label the Hamiltonians, and runtime and accuracy guarantees of the additive error approximation schemes in previous work for the systems we consider. In table 2, we present our results for these same systems.

For simplicity, unless otherwise stated we concern ourselves with Quantum Local Hamiltonians of bounded interaction strengths $\|H_e\|_\infty \leq 1$ on n qubits and m interactions. In both tables, we refer to a "low threshold rank" Hamiltonian as having constant ϵ-SOS threshold rank of its interaction graph. With the exception of the recent work by [16], all the results in table 1 concern ground state energy approximation schemes.

Table 1 A summary of previous algorithms for related Quantum Systems.

Result	System/Context	Accuracy	Runtime
[24]	k-local Hamiltonians	$\epsilon \cdot n^k$	$n^{\tilde{O}(\epsilon^{-2})}$
[15]	Low Threshold Rank Hamiltonians	$\epsilon \cdot \sum_{e\in E} \|H_e\|_\infty$	$n^{O(\epsilon^{-1})}$
[16]	Free Energy of 2-local Hamiltonians	$\epsilon \cdot n^2 + \delta \cdot n/\beta$	$n^{\tilde{O}(\epsilon^{-2})} \cdot O(\log 1/\delta)$
[9]	Planar Graphs of bounded degree Δ	$\epsilon \cdot \sum_{e\in E} \|H_e\|_\infty$	$n^{O(1)} \cdot 2^{2^{\mathrm{poly}(\Delta,\epsilon^{-1})}}$
[15]	Planar Graphs	$\epsilon \cdot \sum_{e\in E} \|H_e\|_\infty$	$n^{O(1)} \cdot 2^{2^{2^{\mathrm{poly}(\epsilon^{-1})}}}$

We remark* that the runtime results for k-local Hamiltonians are reported in the probe model [26], and thus may seem apriori incomparable to more standard model runtimes. However, we emphasize that we can easily convert between models by suitably pre-processing the input Hamiltonian and underlying Graph. For instance, if we are allowed query access to the input Hamiltonian in time $O(1)$, and arithmetic operations on entries of H take time $O(1)$, *but* sampling a random element of $[n]$ takes time $O(\log n)$, then the algorithm of theorem 11 outputs an estimate to the ground state energy in total time $O(\mathrm{poly}(1/\epsilon) \cdot \log n + 2^{\mathrm{poly}(1/\epsilon)})$ -

Table 2 The main algorithms in this work.

System	Context	Accuracy	Runtime*
k-local Hamiltonians	G.S. Energy	$\epsilon \cdot n^k$	$2^{\text{poly}(\epsilon^{-1})}$
	Free Energy	$\epsilon \cdot n^k + \delta \cdot n/\beta$	$2^{\text{poly}(\epsilon^{-1})} \cdot O(\delta^{-2})$
Low Threshold Rank Quantum Max Cut	Maximum Eigenvalue	$\epsilon \cdot m + O(n^{1/3}m^{2/3})$	$(n/\epsilon)^{O(1)} + 2^{\tilde{O}(1/\epsilon^2)}$
h-Minor Free Graphs of bounded degree Δ	G.S. Energy	$\epsilon \cdot n$	$n^{O(1)} + n \cdot 2^{\text{poly}(\Delta, \epsilon^{-1})}$
	Free Energy		
h-Minor Free Graphs	G.S. Energy	$\epsilon \cdot n$	$n^{O(1)} + n \cdot 2^{\text{poly}(\epsilon^{-1})}$
	Free Energy		$n^{O(1)} + n \cdot \max(2, \beta^{-1})^{\text{poly}(\epsilon^{-1})}$

as we only require a $\text{poly}(1/\epsilon)$ number of sampled vertices. On the other hand, if don't have query access to the description of H, simply spending initial $O(d^{2k}(n+m)) = O(n+m)$ preprocessing time to read out the description of H is sufficient to reduce the setting to the previous one, assuming $d, k = O(1)$.

3 Discussion

We conclude this work by raising some open problems. The first of which is a curious gap between the quality of the mean field approximation to classical and Quantum Local Hamiltonians. To contrast our results to those in the classical setting, [14, 12, 30, 32] studied the quality of the mean-field approximation to classical spin glass models with generic interaction matrices. The work of [32] culminated in the result that the mean-field approximation is within an additive error of $O(n^{2/3}m^{1/3})$ of the free energy, a strictly better dependence on the number of interactions than our upper bound, $O(n^{1/3}m^{2/3})$. As both these results have roots in the information-theoretic techniques by [39], it seems intriguing to ask whether there is some deeper structure. A possible direction would be to combine the regularity insights with the correlation rounding techniques, as in [32]. However, there remain certain technical obstacles to approaching the free energy of quantum systems with the regularity lemma, namely analyzing the matrix exponential of the cut decomposition H_D.

Another interesting problem is to improve the weak regularity results for "low threshold rank" Hamiltonians (Such as theorem 8 and section G of the full version). While we are able to devise approximation schemes based on graph regularity for a range of Hamiltonians whose interaction graphs have low threshold rank, we are unable to provide an actual construction of an approximate Hamiltonian H'. It would also be interesting to see whether the coarsest partition technique could be lifted to be applied to more general low threshold rank Hamiltonians, as opposed to relying on the high degree of symmetry of the Quantum Max Cut.

Finally, while the focus of this paper is on product-state approximations, the author considers it to be an outstanding open problem whether one can devise entangled ansatz's for classical approximations schemes to quantum problems. For examples, see [33, 5, 35], who devised low-depth quantum circuits which perform slightly better than the best product state on certain Hamiltonians.

4 Organization

In the appendix, we present a proof of the Hamiltonian regularity lemma 20, and, for readability, defer to the full version (`https://arxiv.org/abs/2210.08680`) our information-theoretic statements and algorithms.

A The Hamiltonian Regularity Lemma

Let us begin by reviewing the cut decomposition of [22]. The key intuition behind their result is the notion that dense graphs can be roughly viewed as a sum of complete bipartite sub-graphs between subsets of vertices in the graph. Each of these bipartite sub-graphs is essentially a "cut" in the graph, hence the name.

▶ **Definition 15.** *Given two sets $S, T \subset [n]$ and a number $d \in \mathbb{R}$, the $n \times n$ cut matrix $D = CUT(S, T, d)$ is defined by $D_{u,v} = d \cdot \delta_{u \in S} \delta_{v \in T}$.*

▶ **Definition 16.** *A "cut decomposition" expresses a real matrix J as the sum*

$$J = \sum_{k=0}^{s} D^{(k)} + W \tag{14}$$

where each $D^{(k)}$ is a cut matrix defined on sets $R_k, L_k \subset [n]$, and of weight d_k. Such a decomposition is said to have width s, coefficient length $(\sum d_k^2)^{1/2}$, and error $\|W\|_{\infty \to 1}$.

The main result of [22] is precisely an algorithm to efficiently find such a decomposition:

▶ **Theorem 17** ([22])**.** *Let J be an arbitrary real matrix and fix a constant $\epsilon > 0$. Then there exists a cut decomposition of width $O(\epsilon^{-2})$, coefficient length $O(\|J\|_F/n)$, error at most $\epsilon n \|J\|_F$, and such that $\|W\|_F \leq \|J\|_F$. Moreover, with probability $1 - \delta$ said decomposition can be found implicitly in time $2^{\tilde{O}(\epsilon^{-2})}/\delta^2$, and explicitly in time $\tilde{O}(n^2/\epsilon^4) + 2^{\tilde{O}(\epsilon^{-2})}/\delta^2$.*

▶ Remark 18. The key point of the cut decomposition is that the number of cuts only depends on the quality of the approximation, not the size of the graph.

Perhaps the main tool we introduce in this work is a generalization of this result to the quantum setting. We exploit the fact that quantum density matrices and quantum Hamiltonians can be expressed in a Pauli basis, to reduce the problem of decomposing Hamiltonians into that of a "multi-colored" cut decomposition. For simplicity, here we discuss the case of 2-Local Hamiltonians, on qudits of local dimension $d = 2^{d'}$ which is a power of 2, and defer further generalizations to the appendix.

Let $H = \sum H_e$ be 2-local Hamiltonian defined on n qudits, and define $\mathbb{P}_{\log d} = \{\mathbb{I}, X, Y, Z\}^{\otimes \log d}$ be the set of Pauli operators acting on a single qudit. Any operator $h_{u,v}$ acting on the Hilbert space of 2 qudits can be decomposed into basis of $\mathbb{P}_{\log d} \otimes \mathbb{P}_{\log d}$:

$$H_{uv} = \sum_{i,j \in [d^2]} h_{uv}^{ij} \sigma_i^u \otimes \sigma_j^v \tag{15}$$

Where the h_{uv}^{ij} are all real coefficients. Group the coefficients of the interactions defined on the same Pauli matrices i, j into an interaction matrix $J^{ij} = \{h_{uv}^{ij}\}_{u,v}$, i.e., a matrix for each of d^4 "colors". We note that this essentially defines $O(d^4)$ different weighted adjacency matrices. Now, let us apply the regularity lemma of [22] on each of the colored interaction/adjacency matrices J^{ij} above. By construction, for each pair (i, j) one can express

$$J^{ij} = \sum_{k=1}^{s} D^{ijk} + W^{ij} \equiv D^{ij} + W^{ij} \tag{16}$$

Where $D^{ijk} = CUT(R^{ijk}, L^{ijk}, d^{ijk})$ are the s cut matrices of the interaction $i, j \in [d^2]$, defined on partitions $\{R^{ijk}, L^{ijk}\}$ of the vertex set of the graph, and real constants d^{ijk}, for $k \in [s]$. We can thereby define the cut decomposition H_D of the Hamiltonian H to be the edges of the D^{ijk} *crossing* any such cut:

$$\text{The Hamiltonian Cut Decomposition: } H_D = \frac{1}{2}\sum_{\substack{i,j\in[d^2]\\k\in[s]}}\sum_{\substack{u\in R^{ijk}\\v\neq u, v\in L^{ijk}}} D^{ijk}_{uv}\sigma^u_i\otimes\sigma^v_j\otimes\mathbb{I}_{V\setminus\{u,v\}} \quad (17)$$

where we appropriately order the tensor product such that $u < v$ and add a factor of $1/2$ via a handshaking argument. More importantly, we filter out the diagonal entries D^{ijk}_{uu}, since the cuts S, T returned by the cut decomposition in Theorem 17 need not be disjoint, and Local Hamiltonians can't have "self-edges" in a basis decomposition. While unfortunately we no longer can interpret the interaction graph of H_D as an exact sum of complete bipartite sub-Hamiltonians, fortunately, we will later recover this interpretation in an approximate sense.

We dedicate the rest of this section to proving two interesting properties of H_D. First, we argue that the energy of any product state $\rho = \otimes_{u\in V}\rho_u$ is close, whether in H or H_D, arising from the combinatorial structure of the decomposition. Then, we leverage our product state approximation toolkit, to argue that H_D is in fact close to H in the spectral norm $\|H - H_D\|_\infty$.

▶ **Theorem 19.** *Let $H = \sum_{u,v} H_{u,v}$ be a 2-Local Hamiltonian defined on qudits of local dimension $d = 2^{d'} = O(1)$, let $J_{uv} = \|H_{uv}\|_\infty$ be the matrix of interaction strengths, and let H_D be the Hamiltonian cut decomposition of H of width $s = O(\epsilon^{-2})$. Then, for all product states $\rho = \otimes_{u\in V}\rho_u$,*

$$|Tr[(H - H_D)\rho]| \leq \epsilon n\|J\|_F \quad (18)$$

Moreover, with probability $1 - \delta$ said decomposition can be found implicitly in time $2^{\tilde{O}(\epsilon^{-2})}/\delta^2$, and explicitly in time $\tilde{O}(n^2/\epsilon^4) + 2^{\tilde{O}(\epsilon^{-2})}/\delta^2$

Proof. By restricting our attention to product states, we are able to essentially decouple the "colors" (different Pauli terms) in the Cut Decomposition.

$$\left|\mathrm{Tr}[(H - H_D)\rho]\right| = \left|\sum_{u<v}\sum_{i,j}(h^{ij}_{uv} - D^{ij}_{uv})\mathrm{Tr}[\sigma^i_u\otimes\sigma^j_v\rho]\right| = \quad (19)$$

$$= \left|\frac{1}{2}\sum_{i,j}\sum_{u\neq v} W^{ij}_{uv}\mathrm{Tr}[\sigma^i_u\rho_u]\mathrm{Tr}[\sigma^j_v\rho_v]\right| \leq \sum_{i,j}\left|\sum_{u\neq v} W^{ij}_{uv}\mathrm{Tr}[\sigma^i_u\rho_u]\mathrm{Tr}[\sigma^j_v\rho_v]\right| = \quad (20)$$

$$= \sum_{i,j}\left|\sum_v\left(\sum_{u:u\neq v} W^{ij}_{uv}\mathrm{Tr}[\sigma^i_u\rho_u]\right)\mathrm{Tr}[\sigma^j_v\rho_v]\right| \leq \sum_{i,j}\sum_v\left|\sum_u W^{ij}_{uv}\mathrm{Tr}[\sigma^i_u\rho_u]\right| + \sum_{i,j}\sum_v|W^{ij}_{vv}| \leq \quad (21)$$

$$\leq \sum_{ij}\left(\|W^{ij}\|_{\infty\to 1} + n\cdot\max_v|W^{ij}_{vv}|\right), \quad (22)$$

where we re-introduced the diagonal terms to obtain the $\infty \to 1$ norm. From Theorem 17 we can pick a width $s = O(d^8\epsilon^{-2}) = O(\epsilon^{-2})$ s.t. $\|W^{ij}\|_{\infty\to 1} \leq \epsilon n\|J^{ij}\|_F/d^4$. Finally, the original interation graph has no diagonal elements ($J^{ij}_{vv} = 0$), and thus the Cauchy-Schwartz inequality tells us the diagonal entries of D^{ij} are bounded: $|W^{ij}_{vv}| = |J^{ij}_{vv} - D^{ij}_{vv}| \leq \sum_k|d^{ijk}| \leq s^{1/2}\cdot(\sum(d^{ijk})^2)^{1/2} \leq s^{1/2}\cdot\|J^{ij}\|_F/n$. The observation $\|J^{ij}\|_F \leq \|J\|_F$ and assuming $\epsilon^{-2} = o(n)$ concludes the proof. ◀

By combining the product state cut decomposition above with our results on product state approximations in theorem 3 and in section B of the full version, we can extend our results to entangled states as well.

▶ **Lemma 20** (The Hamiltonian Weak Regularity Lemma)**.** *In the context of Theorem 19,* $\|H - H_D\| \leq \epsilon \cdot n \|J\|_F$.

Proof. By Schatten norm duality, there exists a normalized state ψ^* s.t.

$$\|H - H_D\|_\infty = \max_\psi |\mathrm{Tr}[(H - H_D)\psi]| = |\mathrm{Tr}[(H - H_D)\psi^*]| \tag{23}$$

We now apply the product state approximation Theorem 3 on the state ψ^* and Hamiltonian $H' = H - H_D$, to argue there exists a separable state σ s.t.

$$|\mathrm{Tr}[(H - H_D)(\psi^* - \sigma)]| \leq \epsilon n \|J\|_F / 2 \tag{24}$$

where we observe that if J' is the matrix of interaction strengths of $H' = H - H_D$, then $\|J'\|_1 \leq n\|J'\|_F$ (Cauchy-Schwartz) and $\|J'\|_F \leq \sum_{i,j \in [d^2]} \|W^{ij}\|_F \leq O(d^4 \|J\|_F)$ by means of a triangle inequality and the guarantees on W in Theorem 17. Since σ is separable, we can appropriately pick the width $s = O(\epsilon^{-2})$ in Theorem 19 to guarantee

$$|\mathrm{Tr}[(H - H_D)\sigma]| \leq \epsilon n \|J\|_F / 2 \tag{25}$$

and thereby via the triangle inequality:

$$\|H - H_D\|_\infty \leq |\mathrm{Tr}[(H - H_D)(\psi^* - \sigma)]| + |\mathrm{Tr}[(H - H_D)\sigma]| \leq \epsilon n \|J\|_F \tag{26}$$

◀

Using the existing technology of matrix regularity lemmas, in the full version we present extensions to the result above for Local Hamiltonians defined on hyper-graphs and for graphs of low threshold rank.

Sublinear Time Eigenvalue Approximation via Random Sampling

Abstract

We study the problem of approximating the eigenspectrum of a symmetric matrix $\mathbf{A} \in \mathbb{R}^{n \times n}$ with bounded entries (i.e., $\|\mathbf{A}\|_\infty \leq 1$). We present a simple sublinear time algorithm that approximates all eigenvalues of $\mathbf{A}$ up to additive error $\pm\epsilon n$ using those of a randomly sampled $\tilde{O}\left(\frac{\log^3 n}{\epsilon^3}\right) \times \tilde{O}\left(\frac{\log^3 n}{\epsilon^3}\right)$ principal submatrix. Our result can be viewed as a concentration bound on the complete eigenspectrum of a random submatrix, significantly extending known bounds on just the singular values (the magnitudes of the eigenvalues). We give improved error bounds of $\pm\epsilon\sqrt{\text{nnz}(\mathbf{A})}$ and $\pm\epsilon\|\mathbf{A}\|_F$ when the rows of $\mathbf{A}$ can be sampled with probabilities proportional to their sparsities or their squared ℓ_2 norms respectively. Here $\text{nnz}(\mathbf{A})$ is the number of non-zero entries in $\mathbf{A}$ and $\|\mathbf{A}\|_F$ is its Frobenius norm. Even for the strictly easier problems of approximating the singular values or testing the existence of large negative eigenvalues (Bakshi, Chepurko, and Jayaram, FOCS '20), our results are the first that take advantage of non-uniform sampling to give improved error bounds. From a technical perspective, our results require several new eigenvalue concentration and perturbation bounds for matrices with bounded entries. Our non-uniform sampling bounds require a new algorithmic approach, which judiciously zeroes out entries of a randomly sampled submatrix to reduce variance, before computing the eigenvalues of that submatrix as estimates for those of $\mathbf{A}$. We complement our theoretical results with numerical simulations, which demonstrate the effectiveness of our algorithms in practice.

1 Introduction

Approximating the eigenvalues of a symmetric matrix is a fundamental problem – with applications in engineering, optimization, data analysis, spectral graph theory, and beyond. For an $n \times n$ matrix, all eigenvalues can be computed to high accuracy using direct eigendecomposition in $O(n^\omega)$ time, where $\omega \approx 2.37$ is the exponent of matrix multiplication [14, 2]. When just a few of the largest magnitude eigenvalues are of interest, the power method and other iterative Krylov methods can be applied [39]. These methods repeatedly multiply the matrix of interest by query vectors, requiring $O(n^2)$ time per multiplication when the matrix is dense and unstructured.

For large n, it is desirable to have even faster eigenvalue approximation algorithms, running in $o(n^2)$ time – i.e., sublinear in the size of the input matrix. Unfortunately, for general matrices, no non-trivial approximation can be computed in $o(n^2)$ time: without reading $\Omega(n^2)$ entries, it is impossible to distinguish with reasonable probability if all entries (and hence all eigenvalues) are equal to zero, or if there is a single pair of arbitrarily large entries at positions (i, j) and (j, i), leading to a pair of arbitrarily large eigenvalues. Given this, we seek to address the following question:

Under what assumptions on a symmetric $n \times n$ input matrix, can we compute non-trivial approximations to its eigenvalues in $o(n^2)$ time?

It is well known that $o(n^2)$ time eigenvalue computation is possible for highly structured inputs, like tridiagonal or Toeplitz matrices [26]. For sparse or structured matrices that admit fast matrix vector multiplication, one can compute a small number of the largest in magnitude eigenvalues in $o(n^2)$ time using iterative methods. Through the use of robust iterative methods, fast top eigenvalue estimation is also possible for matrices that admit fast *approximate* matrix-vector multiplication, such as kernel similarity matrices [25, 27, 4]. Our goal is to study simple, sampling-based sublinear time algorithms that work under much weaker assumptions on the input matrix.

1.1 Our Contributions

Our main contribution is to show that a very simple algorithm can be used to approximate *all eigenvalues* of any symmetric matrix with *bounded entries*. In particular, for any $\mathbf{A} \in \mathbb{R}^{n \times n}$ with maximum entry magnitude $\|\mathbf{A}\|_\infty \leq 1$, sampling an $s \times s$ principal submatrix $\mathbf{A}_S$ of $\mathbf{A}$ with $s = \tilde{O}\left(\frac{\log^3 n}{\epsilon^3}\right)$ and scaling its eigenvalues by n/s yields a $\pm\epsilon n$ additive error approximation to all eigenvalues of $\mathbf{A}$ with good probability.[1] This result is formally stated below, where $[n] \stackrel{\text{def}}{=} \{1, \ldots, n\}$.

▶ **Theorem 1** (Sublinear Time Eigenvalue Approximation). *Let $\mathbf{A} \in \mathbb{R}^{n \times n}$ be symmetric with $\|\mathbf{A}\|_\infty \leq 1$ and eigenvalues $\lambda_1(\mathbf{A}) \geq \ldots \geq \lambda_n(\mathbf{A})$. Let $S \subseteq [n]$ be formed by including each index independently with probability s/n as in Algorithm 1. Let $\mathbf{A}_S$ be the corresponding principal submatrix of $\mathbf{A}$, with eigenvalues $\lambda_1(\mathbf{A}_S) \geq \ldots \geq \lambda_{|S|}(\mathbf{A}_S)$.*

For all $i \in [|S|]$ with $\lambda_i(\mathbf{A}_S) \geq 0$, let $\tilde{\lambda}_i(\mathbf{A}) = \frac{n}{s} \cdot \lambda_i(\mathbf{A}_S)$. For all $i \in [|S|]$ with $\lambda_i(\mathbf{A}_S) < 0$, let $\tilde{\lambda}_{n-(|S|-i)}(\mathbf{A}) = \frac{n}{s} \cdot \lambda_i(\mathbf{A}_S)$. For all other $i \in [n]$, let $\tilde{\lambda}_i(\mathbf{A}) = 0$. If $s \geq \frac{c \log(1/(\epsilon\delta)) \cdot \log^3 n}{\epsilon^3 \delta}$, for large enough constant c, then with probability $\geq 1 - \delta$, for all $i \in [n]$, $\lambda_i(\mathbf{A}) - \epsilon n \leq \tilde{\lambda}_i(\mathbf{A}) \leq \lambda_i(\mathbf{A}) + \epsilon n$.

[1] Here and throughout, $\tilde{O}(\cdot)$ hides logarithmic factors in the argument. Note that by scaling, our algorithm gives a $\pm\epsilon n \cdot \|\mathbf{A}\|_\infty$ approximation for any $\mathbf{A}$.

See Figure 1 for an illustration of how the $|S|$ eigenvalues of $\mathbf{A}_S$ are mapped to estimates for all n eigenvalues of $\mathbf{A}$. Note that the principal submatrix $\mathbf{A}_S$ sampled in Theorem 1 will have $O(s) = \tilde{O}\left(\frac{\log^3 n}{\epsilon^3 \delta}\right)$ rows/columns with high probability. Thus, with high probability, the algorithm reads just $\tilde{O}\left(\frac{\log^6 n}{\epsilon^6 \delta^2}\right)$ entries of $\mathbf{A}$ and runs in $\text{poly}(\log n, 1/\epsilon, 1/\delta)$ time. Standard matrix concentration bounds imply that one can sample $O\left(\frac{s \log(1/\delta)}{\epsilon^2}\right)$ random entries from the $O(s) \times O(s)$ random submatrix $\mathbf{A}_S$ and preserve its eigenvalues to error $\pm \epsilon s$ with probability $1 - \delta$ [1]. See Appendix F of [10] for a proof. This can be directly combined with Theorem 1 to give improved sample complexity:

▶ **Corollary 2** (Improved Sample Complexity via Entrywise Sampling). *Let $\mathbf{A} \in \mathbb{R}^{n \times n}$ be symmetric with $\|\mathbf{A}\|_\infty \leq 1$ and eigenvalues $\lambda_1(\mathbf{A}) \geq \ldots \geq \lambda_n(\mathbf{A})$. For any $\epsilon, \delta \in (0,1)$, there is an algorithm that reads $\tilde{O}\left(\frac{\log^3 n}{\epsilon^5 \delta}\right)$ entries of $\mathbf{A}$ and returns, with probability at least $1 - \delta$, $\tilde{\lambda}_i(\mathbf{A})$ for each $i \in [n]$ satisfying $|\tilde{\lambda}_i(\mathbf{A}) - \lambda_i(\mathbf{A})| \leq \epsilon n$.*

Observe that the dependence on δ in Theorem 1 and Corollary 2 can be improved via standard arguments: running the algorithm with failure probability $\delta' = 2/3$, repeating $O(\log(1/\delta))$ times, and taking the median estimate for each $\lambda_i(\mathbf{A})$. This guarantees that the algorithm will succeed with probability at most $1 - \delta$ at the expense of a $\log(1/\delta)$ dependence in the complexity.

We note that our $\pm \epsilon n$ error guarantee is particularly useful in applications where the matrix $\mathbf{A}$ has low stable rank and the top eigenvalues have magnitude scaling roughly with n. Low stable rank is a common feature of real-life data matrices [47], including classes of bounded entry matrices, such as kernel similarity matrices [18] and adjacency matrices of power law graphs [36].

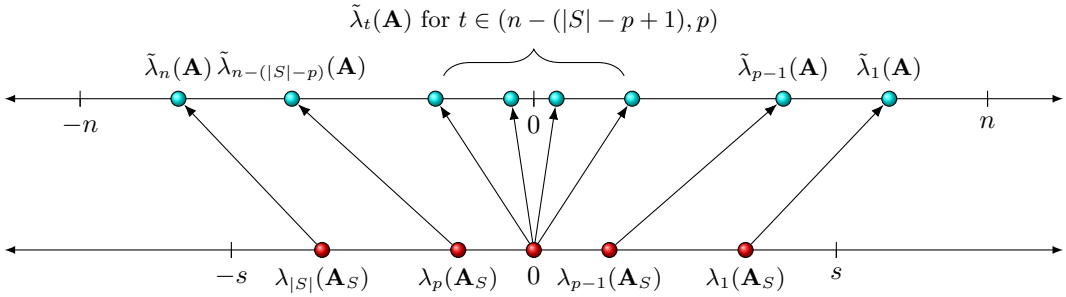

Figure 1 Alignment of eigenvalues in Thm. 1 and Algo. 1. We illustrate how the eigenvalues of $\mathbf{A}_S$, scaled by $\frac{n}{s}$, are used to approximate all eigenvalues of $\mathbf{A}$. If $\mathbf{A}_S$ has $p-1$ positive eigenvalues, they are set to the top $p-1$ eigenvalue estimates. Its $|S| - p + 1$ negative eigenvalues are set to the bottom eigenvalue estimates. All remaining eigenvalues are simply approximated as zero.

Comparison to known bounds. Theorem 1 can be viewed as a concentration inequality on the full eigenspectrum of a random principal submatrix $\mathbf{A}_S$ of $\mathbf{A}$. This significantly extends prior work, which was able to bound just the spectral norm (i.e., the magnitude of the top eigenvalue) of a random principal submatrix [38, 44]. Bakshi, Chepurko, and Jayaram [5] recently identified developing such full eigenspectrum concentration inequalities as an important step in expanding our knowledge of sublinear time property testing algorithms for bounded entry matrices.

Standard matrix concentration bounds [22] can be used to show that the *singular values* of $\mathbf{A}$ (i.e., the magnitudes of its eigenvalues) are approximated by those of a $O\left(\frac{\log n}{\epsilon^2}\right) \times O\left(\frac{\log n}{\epsilon^2}\right)$ random submatrix (see Appendix G of [10]) with independently sampled rows and columns. However, such a random matrix will not be symmetric or even have real eigenvalues in general, and thus no analogous bounds were previously known for the eigenvalues themselves.

Lower Bounds. Recently, Bakshi, Chepurko, and Jayaram [5] studied the closely related problem of testing positive semidefiniteness in the bounded entry model. They show how to test whether the minimum eigenvalue of $\mathbf{A}$ is either greater than 0 or smaller than $-\epsilon n$ by reading just $\tilde{O}(\frac{1}{\epsilon^2})$ entries. They show that this result is optimal in terms of query complexity, up to logarithmic factors. Like our approach, their algorithm is based on random principal submatrix sampling. Our eigenvalue approximation guarantee strictly strengthens the testing guarantee – given $\pm\epsilon n$ approximations to all eigenvalues, we immediately solve the testing problem. Thus, our query complexity is tight up to a $\text{poly}(\log n, 1/\epsilon)$ factor. It is open if our higher sample complexity is necessary to solve the harder full eigenspectrum estimation problem. See Section 1.4 for further discussion.

Improved bounds for non-uniform sampling. Our second main contribution is to show that, when it is possible to efficiently sample rows/columns of $\mathbf{A}$ with probabilities proportional to their sparsities or their squared ℓ_2 norms, significantly stronger eigenvalue estimates can be obtained. In particular, letting $\text{nnz}(\mathbf{A})$ denote the number of nonzero entries in $\mathbf{A}$ and $\|\mathbf{A}\|_F$ denote its Frobenius norm, we show that sparsity-based sampling yields eigenvalue estimates with error $\pm\epsilon\sqrt{\text{nnz}(\mathbf{A})}$ and norm-based sampling gives error $\pm\epsilon\|\mathbf{A}\|_F$. See Theorems 3 and 4 for formal statements. Observe that when $\|\mathbf{A}\|_\infty \leq 1$, its eigenvalues are bounded in magnitude by $\|\mathbf{A}\|_2 \leq \|\mathbf{A}\|_F \leq \sqrt{\text{nnz}(\mathbf{A})} \leq n$. Thus, Theorems 3 and 4 are natural strengthenings of Theorem 1. Row norm-based sampling (Theorem 4) additionally removes the bounded entry requirement of Theorems 1 and 3.

As discussed in Section 1.3.1, sparsity-based sampling can be performed in sublinear time when $\mathbf{A}$ is stored in a slightly augmented sparse matrix format, or when $\mathbf{A}$ is the adjacency matrix of a graph accessed in the standard graph query model of the sublinear algorithms literature [23]. Norm-based sampling can also be performed efficiently with an augmented matrix format, and is commonly studied in randomized and "quantum-inspired" algorithms for linear algebra [19, 43].

▶ **Theorem 3** (Sparse Matrix Eigenvalue Approximation). *Let $\mathbf{A} \in \mathbb{R}^{n\times n}$ be symmetric with $\|\mathbf{A}\|_\infty \leq 1$ and eigenvalues $\lambda_1(\mathbf{A}) \geq \ldots \geq \lambda_n(\mathbf{A})$. Let $S \subseteq [n]$ be formed by including the i^{th} index independently with probability $p_i = \min\left(1, \frac{s\,\text{nnz}(\mathbf{A}_i)}{\text{nnz}(\mathbf{A})}\right)$ as in Algorithm 2 of [10]. Here $\text{nnz}(\mathbf{A}_i)$ is the number of non-zero entries in the i^{th} row of $\mathbf{A}$. Let $\mathbf{A}_S$ be the corresponding principal submatrix of $\mathbf{A}$, and let $\tilde{\lambda}_i(\mathbf{A})$ be the estimate of $\lambda_i(\mathbf{A})$ computed from $\mathbf{A}_S$ as in Algorithm 2 of citebhattacharjee2021sublinear. If $s \geq \frac{c\log^8 n}{\epsilon^8\delta^4}$, for large enough constant c, then with probability $\geq 1-\delta$, for all $i \in [n]$, $|\tilde{\lambda}_i(\mathbf{A}) - \lambda_i(\mathbf{A})| \leq \epsilon\sqrt{\text{nnz}(\mathbf{A})}$.*

▶ **Theorem 4** (Row Norm Based Matrix Eigenvalue Approximation). *Let $\mathbf{A} \in \mathbb{R}^{n\times n}$ be symmetric and eigenvalues $\lambda_1(\mathbf{A}) \geq \ldots \geq \lambda_n(\mathbf{A})$. Let $S \subseteq [n]$ be formed by including the i^{th} index independently with probability $p_i = \min\left(1, \frac{s\|\mathbf{A}_i\|_2^2}{\|\mathbf{A}\|_F^2} + \frac{1}{n^2}\right)$ as in Algorithm 3 of [10]. Here $\|\mathbf{A}_i\|_2$ is the ℓ_2 norm of the i^{th} row of $\mathbf{A}$. Let $\mathbf{A}_S$ be the corresponding principal submatrix of $\mathbf{A}$, and let $\tilde{\lambda}_i(\mathbf{A})$ be the estimate of $\lambda_i(\mathbf{A})$ computed from $\mathbf{A}_S$ as in Algorithm 3 of [10]. If $s \geq \frac{c\log^{10} n}{\epsilon^8\delta^4}$, for large enough constant c, then with probability $\geq 1-\delta$, for all $i \in [n]$, $|\tilde{\lambda}_i(\mathbf{A}) - \lambda_i(\mathbf{A})| \leq \epsilon\|\mathbf{A}\|_F$.*

The above non-uniform sampling theorems immediately yield algorithms for testing the presence of a negative eigenvalue with magnitude at least $\epsilon\sqrt{\text{nnz}(\mathbf{A})}$ or $\epsilon\|\mathbf{A}\|_F$ respectively, strengthening the results of [5], which require eigenvalue magnitude at least ϵn. In the graph property testing literature, there is a rich line of work exploring the testing of bounded degree or sparse graphs [23, 7]. Theorem 3 can be thought of as first step in establishing a related theory of sublinear time approximation algorithms and property testers for sparse matrices. Due to lack of space, we defer the proofs of Theorems 3 and 4 to Section 4 and Appendix E of [10] respectively.

Surprisingly, in the non-uniform sampling case, the eigenvalue estimates derived from $\mathbf{A}_S$ cannot simply be its scaled eigenvalues, as in Theorem 1. E.g., when $\mathbf{A}$ is the identity, our row sampling probabilities are uniform in all cases. However, the scaled submatrix $\frac{n}{s} \cdot \mathbf{A}_S$ will be a scaled identity, and have eigenvalues equal to n/s – failing to give a $\pm\epsilon\sqrt{\text{nnz}(\mathbf{A})} = \pm\epsilon\|\mathbf{A}\|_F = \pm\epsilon\sqrt{n}$ approximation to the true eigenvalues (all of which are 1) unless $s \gtrsim \frac{\sqrt{n}}{\epsilon}$. To handle this, and related cases, we must argue that selectively zeroing out entries in sufficiently low probability rows/columns of $\mathbf{A}$ (see Algorithms 2 and 3 of [10]) does not significantly change the spectrum, and ensures concentration of the submatrix eigenvalues. It is not hard to see that simple random submatrix sampling fails even for the easier problem of singular value estimation. Theorems 3 and 4 give the first results of their kinds for this problem as well.

1.2 Related Work

Eigenspectrum estimation is a key primitive in numerical linear algebra, typically known as *spectral density estimation*. The eigenspectrum is viewed as a distribution with mass $1/n$ at each of the n eigenvalues, and the goal is to approximate this distribution [49, 35]. Applications include identifying motifs in social networks [15], studying Hessian and weight matrix spectra in deep learning [40, 51, 21], "spectrum splitting" in parallel eigensolvers [31], and the study of many systems in experimental physics and chemistry [48, 41, 28].

Recent work has studied sublinear time spectral density estimation for graph structured matrices – Braverman, Krishnan, and Musco [11] show that the spectral density of a normalized graph adjacency or Laplacian matrix can be estimated to ϵ error in the Wasserstein distance in $\tilde{O}(n/\operatorname{poly}(\epsilon))$ time. Cohen-Steiner, Kong, Sohler, and Valiant study a similar setting, giving runtime $2^{O(1/\epsilon)}$ [13]. We note that the additive error eigenvalue approximation result of Theorem 1 (analogously Theorems 3 and 4) directly gives an ϵn approximation to the spectral density in the Wasserstein distance – extending the above results to a much broader class of matrices. When $\|\mathbf{A}\|_\infty \leq 1$, $\mathbf{A}$ can have eigenvalues as large as n, while the normalized adjacency matrices studied in [13, 11] have eigenvalues in $[-1, 1]$. So, while the results are not directly comparable, our Wasserstein error can be thought as on order of their error of ϵ after scaling.

Our work is also closely related to a line of work on sublinear time property testing for bounded entry matrices, initiated by Balcan et al. [6]. In that work, they study testing of rank, Schatten-p norms, and several other global spectral properties. Sublinear time testing algorithms for the rank and other properties have also been studied under low-rank and bounded row norm assumptions on the input matrix [30, 33]. Recent work studies positive semidefiniteness testing and eigenvalue estimation in the matrix-vector query model, where each query computes $\mathbf{Ax}$ for some $\mathbf{x} \in \mathbb{R}^{n\times n}$. As in Theorem 4, $\pm\epsilon\|\mathbf{A}\|_F$ eigenvalue estimation can be achieved with $\operatorname{poly}(\log n, 1/\epsilon)$ queries in this model [37]. Finally, several works study streaming algorithms for eigenspectrum approximation [3, 32, 34]. These algorithms are not sublinear time – they require at least linear time to process the input matrix. However, they

use sublinear working memory. Note that Theorem 1 immediately gives a sublinear space streaming algorithm for eigenvalue estimation. We can simply store the sampled submatrix $\mathbf{A}_S$ as its entries are updated.

1.3 Technical Overview

In this section, we overview the main techniques used to prove Theorems 1, and then how these techniques are extended to prove Theorems 3 and 4. We start by defining a decomposition of any symmetric $\mathbf{A}$ into the sum of two matrices containing its large and small magnitude eigendirections.

▶ **Definition 5** (Eigenvalue Split). *Let $\mathbf{A} \in \mathbb{R}^{n\times n}$ be symmetric. For any $\epsilon, \delta \in (0,1)$, let $\mathbf{A}_o = \mathbf{V}_o\mathbf{\Lambda}_o\mathbf{V}_o^T$ where $\mathbf{\Lambda}_o$ is diagonal, with the eigenvalues of $\mathbf{A}$ with magnitude $\geq \epsilon\sqrt{\delta}n$ on its diagonal, and $\mathbf{V}_o$ has the corresponding eigenvectors as columns. Similarly, let $\mathbf{A}_m = \mathbf{V}_m\mathbf{\Lambda}_m\mathbf{V}_m^T$ where $\mathbf{\Lambda}_m$ has the eigenvalues of $\mathbf{A}$ with magnitude $< \epsilon\sqrt{\delta}n$ on its diagonal and $\mathbf{V}_m$ has the corresponding eigenvectors as columns. Then, $\mathbf{A}$ can be decomposed as*

$$\mathbf{A} = \mathbf{A}_o + \mathbf{A}_m = \mathbf{V}_o\mathbf{\Lambda}_o\mathbf{V}_o^T + \mathbf{V}_m\mathbf{\Lambda}_m\mathbf{V}_m^T.$$

Any principal submatrix of $\mathbf{A}$, $\mathbf{A}_S$, can be similarly written as

$$\mathbf{A}_S = \mathbf{A}_{o,S} + \mathbf{A}_{m,S} = \mathbf{V}_{o,S}\mathbf{\Lambda}_o\mathbf{V}_{o,S}^T + \mathbf{V}_{m,S}\mathbf{\Lambda}_m\mathbf{V}_{m,S}^T,$$

where $\mathbf{V}_{o,S}, \mathbf{V}_{m,S}$ are the corresponding submatrices obtained by sampling rows of $\mathbf{V}_o, \mathbf{V}_m$.

Since $\mathbf{A}_S$, $\mathbf{A}_{m,S}$ and $\mathbf{A}_{o,S}$ are all symmetric, we can use Weyl's eigenvalue perturbation theorem [50] to show that for all eigenvalues of $\mathbf{A}_S$,

$$|\lambda_i(\mathbf{A}_S) - \lambda_i(\mathbf{A}_{o,S})| \leq \|\mathbf{A}_{m,S}\|_2. \tag{1}$$

We will argue that the eigenvalues of $\mathbf{A}_{o,S}$ approximate those of $\mathbf{A}_o$ – i.e. all eigenvalues of $\mathbf{A}$ with magnitude $\geq \epsilon\sqrt{\delta}n$. Further, we will show that $\|\mathbf{A}_{m,S}\|_2$ is small with good probability. Thus, via (1), the eigenvalues of $\mathbf{A}_S$ approximate those of $\mathbf{A}_o$. In the estimation procedure of Theorem 1, all other small magnitude eigenvalues of $\mathbf{A}$ are estimated to be 0, which will immediately give our $\pm\epsilon n$ approximation bound when the original eigenvalue has magnitude $\leq \epsilon n$.

Bounding the eigenvalues of $\mathbf{A}_{o,S}$. The first step is to show that the eigenvalues of $\mathbf{A}_{o,S}$ well-approximate those of $\mathbf{A}_o$. As in [5], we critically use that the eigenvectors corresponding to large eigenvalues are *incoherent* – intuitively, since $\|\mathbf{A}\|_\infty$ is bounded, their mass must be spread out in order to witness a large eigenvalue. Specifically, [5] shows that for any eigenvector $\mathbf{v}$ of $\mathbf{A}$ with corresponding eigenvalue $\geq \epsilon\sqrt{\delta}n$, $\|\mathbf{v}\|_\infty \leq \frac{1}{\epsilon\sqrt{\delta}\cdot\sqrt{n}}$. We give related bounds on the Euclidean norms of the rows of $\mathbf{V}_o$ (the *leverage scores* of $\mathbf{A}_o$), and on these rows after weighting by $\mathbf{\Lambda}_o$.

Using these incoherence bounds, we argue that the eigenvalues of $\mathbf{A}_{o,S}$ approximate those of $\mathbf{A}_o$ up to $\pm\epsilon n$ error. A key idea is to bound the eigenvalues of $\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,S}^T\mathbf{V}_{o,S}\mathbf{\Lambda}_o^{1/2}$, which are identical to the non-zero eigenvalues of $\mathbf{A}_{o,S} = \mathbf{V}_{o,S}\mathbf{\Lambda}_o\mathbf{V}_{o,S}^T$. Via a matrix Bernstein bound and our incoherence bounds on $\mathbf{V}_o$, we show that this matrix is close to $\mathbf{\Lambda}_o$ with high probability. However, since $\mathbf{\Lambda}_o^{1/2}$ may be complex, the matrix is *not necessarily Hermitian* and standard perturbation bounds [42, 29] do not apply. Thus, to derive an eigenvalue

bound, we apply a perturbation bound of Bhatia [9], which generalizes Weyl's inequality to the non-Hermitian case, with a $\log n$ factor loss. To the best of our knowledge, this is the first time that perturbation theory bounds for non-Hermitian matrices have been used to prove improved algorithmic results in the theoretical computer science literature.

We note that in Appendix B of [10], we give an alternate bound, which instead analyzes the Hermitian matrix $(\mathbf{V}_{o,S}^T\mathbf{V}_{o,S})^{1/2}\mathbf{\Lambda}_o(\mathbf{V}_{o,S}^T\mathbf{V}_{o,S})^{1/2}$, whose eigenvalues are again identical to those of $\mathbf{A}_{o,S}$. This approach only requires Weyl's inequality, and yields an overall bound of $s = O\left(\frac{\log n}{\epsilon^4\delta}\right)$, improving the $\log n$ factors of Theorem 1 at the cost of worse ϵ dependence.

Bounding the spectral norm of $\mathbf{A}_{m,S}$. The next step is to show that all eigenvalues of $\mathbf{A}_{m,S}$ are small provided a sufficiently large submatrix is sampled. This means that the "middle" eigenvalues of $\mathbf{A}$, *i.e.* those with magnitude $\leq \epsilon\sqrt{\delta}n$ do not contribute much to any eigenvalue $\lambda_i(\mathbf{A}_S)$. To do so, we apply a theorem of [38, 44] which shows concentration of the spectral norm of a uniformly random submatrix of an entrywise bounded matrix. Observe that while $\|\mathbf{A}\|_\infty \leq 1$, such a bound will not in general hold for $\|\mathbf{A}_m\|_\infty$. Nevertheless, we can use the incoherence of $\mathbf{V}_o$ to show that $\|\mathbf{A}_o\|_\infty$ is bounded, which via triangle inequality, yields a bound on $\|\mathbf{A}_m\|_\infty \leq \|\mathbf{A}\|_\infty + \|\mathbf{A}_o\|_\infty$. In the end, we show that if $s \geq O(\frac{\log n}{\epsilon^2\delta})$, with probability at least $1-\delta$, $\|\mathbf{A}_{m,S}\|_2 \leq \epsilon s$. After the n/s scaling in the estimation procedure of Theorem 1, this spectral norm bound translates into an additive ϵn error in approximating the eigenvalues of $\mathbf{A}$.

Completing the argument. Once we establish the above bounds on $\mathbf{A}_{o,S}$ and $\mathbf{A}_{m,S}$, Theorem 1 is essentially complete. Any eigenvalue in $\mathbf{A}$ with magnitude $\geq \epsilon n$ will correspond to a nearby eigenvalue in $\frac{n}{s}\cdot\mathbf{A}_{o,S}$ and in turn, $\frac{n}{s}\cdot\mathbf{A}_S$ given our spectral norm bound on $\mathbf{A}_{m,S}$. An eigenvalue in $\mathbf{A}$ with magnitude $\leq \epsilon n$ may or may not correspond to a nearby by eigenvalue in $\mathbf{A}_{o,S}$ (it will only if it lies in the range $[\epsilon\sqrt{\delta}n, \epsilon n]$). In any case, in the estimation procedure of Theorem 1, such an eigenvalue will either be estimated using a small eigenvalue of $\mathbf{A}_S$, or be estimated as 0. In both instances, the estimate will give $\pm\epsilon n$ error.

Can we beat additive error? It is natural to ask if our approach can be improved to yield sublinear time algorithms with stronger relative error approximation guarantees for $\mathbf{A}$'s eigenvalues. Unfortunately, this is not possible – consider a matrix with just a single pair of entries $\mathbf{A}_{i,j}, \mathbf{A}_{j,i}$ set to 1. To obtain relative error approximations to the two non-zero eigenvalues, we must find the pair (i,j), as otherwise we cannot distinguish $\mathbf{A}$ from the all zeros matrix. This requires reading a $\Omega(n^2)$ of $\mathbf{A}$'s entries. More generally, consider $\mathbf{A}$ with a random $n/t \times n/t$ principal submatrix populated by all 1s, and with all other entries equal to 0. $\mathbf{A}$ has largest eigenvalue n/t. However, if we read $s \ll t^2$ entries of $\mathbf{A}$, with good probability, we will not see even a single one, and thus we will not be able to distinguish $\mathbf{A}$ from the all zeros matrix. This example establishes that any sublinear time algorithm with query complexity s must incur additive error at least $\Omega(n/\sqrt{s})$.

1.3.1 Improved Bounds via Non-Uniform Sampling

We now discuss how to give improved approximation bounds via non-uniform sampling. We focus on the $\pm\epsilon\sqrt{\text{nnz}(\mathbf{A})}$ bound of Theorem 3 using sparsity-based sampling. Theorem 4's proof (for row norm sampling) follows the same general ideas, but with some additional complications.

Theorem 3 requires sampling a submatrix $\mathbf{A}_S$, where each index i is included in S with probability $p_i = \min(1, \frac{s\,\mathrm{nnz}(\mathbf{A}_i)}{\mathrm{nnz}(\mathbf{A})})$. We reweight each sampled row by $\frac{1}{\sqrt{p_i}}$. Thus, if entry $\mathbf{A}_{ij}$ is sampled, it is scaled by $\frac{1}{\sqrt{p_i \cdot p_j}}$. When the rows have uniform sparsity (so all $p_i = s/n$), this ensures that the full submatrix is scaled by n/s, as in Theorem 1.

The proof of Theorem 3 follows the same outline as that of Theorem 1: we first argue that the outlying eigenvectors in $\mathbf{V}_o$ are incoherent, giving a bound on the norm of each row of $\mathbf{V}_o$ in terms of $\mathrm{nnz}(\mathbf{A}_i)$. We then apply a matrix Bernstein bound and Bhatia's non-Hermitian eigenvalue perturbation bound to show that the eigenvalues of $\mathbf{A}_{o,S}$ approximate those of $\mathbf{A}_o$ up to $\pm\epsilon\sqrt{\mathrm{nnz}(\mathbf{A})}$.

Bounding the spectral norm of $\mathbf{A}_{m,S}$. The major challenge is showing that the subsampled middle eigendirections do not significantly increase the approximation error by bounding the $\|\mathbf{A}_{m,S}\|_2$ by $\epsilon\sqrt{\mathrm{nnz}(\mathbf{A})}$. This is difficult since the indices in $\mathbf{A}_{m,S}$ are sampled nonuniformly, so existing bounds [44] on the spectral norm of uniformly random submatrices do not apply. We extend these bounds to the non-uniform sampling case, but still face an issue due to the rescaling of entries by $\frac{1}{\sqrt{p_i p_j}}$. In fact, without additional algorithmic modifications, $\|\mathbf{A}_{m,S}\|_2$ is simply not bounded by $\epsilon\sqrt{\mathrm{nnz}(\mathbf{A})}$! For example, as already discussed, if $\mathbf{A} = \mathbf{I}$ is the identity matrix, we get $\mathbf{A}_{m,S} = \frac{n}{s} \cdot \mathbf{I}$ and so $\|\mathbf{A}_{m,S}\|_2 = \frac{n}{s} > \epsilon\sqrt{\mathrm{nnz}(\mathbf{A})}$, assuming $s < \frac{\sqrt{n}}{\epsilon}$. Relatedly, suppose that $\mathbf{A}$ is tridiagonal, with zeros on the diagonal and ones on the first diagonals above and below the main diagonal. Then, if $s \geq \sqrt{n}$, with constant probability, one of the ones will be sampled and scaled by $\frac{n}{s}$. Thus, we will again have $\|\mathbf{A}_{m,S}\|_2 \geq \frac{n}{s} \geq \epsilon\sqrt{\mathrm{nnz}(\mathbf{A})}$, assuming $s < \frac{\sqrt{n}}{2\epsilon}$. Observe that this issue arrises even when trying to approximate just the singular values (the eigenvalue magnitudes). Thus, while an analogous bound to the uniform sampling result of Theorem 1 can easily be given for singular value estimation via matrix concentration inequalities (see Appendix G of [10]), to the best of our knowledge, Theorems 3 and 4 are the first of their kind even for singular value estimation.

Zeroing out entries in sparse rows/columns. To handle the above cases, we prove a novel perturbation bound, arguing that the eigenvalues of $\mathbf{A}$ are not perturbed by more than $\epsilon\sqrt{\mathrm{nnz}(\mathbf{A})}$ if we zero out any entry $\mathbf{A}_{ij}$ of $\mathbf{A}$ where $\sqrt{\mathrm{nnz}(\mathbf{A}_i) \cdot \mathrm{nnz}(\mathbf{A}_j)} \leq \frac{\epsilon\sqrt{\mathrm{nnz}(\mathbf{A})}}{c \log n}$. This can be thought of as a strengthening of Girshgorin's circle theorem, which would ensure that zeroing out entries in rows/columns with $\mathrm{nnz}(\mathbf{A}_i) \leq \epsilon\sqrt{\mathrm{nnz}(\mathbf{A})}$ does not perturb the eigenvalues by more than $\epsilon\sqrt{\mathrm{nnz}(\mathbf{A})}$. Armed with this perturbation bound, we argue that if we zero out the appropriate entries of $\mathbf{A}_S$ before computing its eigenvalues, then since we have removed entries in very sparse rows and columns which would be scaled by a large $\frac{1}{\sqrt{p_i p_j}}$ factor in $\mathbf{A}_S$, we can bound $\|\mathbf{A}_{m,S}\|_2$. This requires relating the magnitudes of the entries in $\mathbf{A}_{m,S}$ to those in $\mathbf{A}_S$ using the incoherence of the top eigenvectors, which gives bounds on the entries of $\mathbf{A}_{o,S} = \mathbf{A}_S - \mathbf{A}_{m,S}$.

Sampling model. We note that the sparsity-based sampling of Theorem 3 can be efficiently implemented in several natural settings. Given a matrix stored in sparse format, i.e., as a list of nonzero entries, we can easily sample a row with probability $\frac{\mathrm{nnz}(\mathbf{A}_i)}{\mathrm{nnz}(\mathbf{A})}$ by sampling a uniformly random non-zero entry and looking at its corresponding row. Via standard techniques, we can convert several such samples into a sampled set S close in distribution to having each $i \in [n]$ included independently with probability $\min\left(1, \frac{s\,\mathrm{nnz}(\mathbf{A}_i)}{\mathrm{nnz}(\mathbf{A})}\right)$. If we store the values of $\mathrm{nnz}(\mathbf{A}), \mathrm{nnz}(\mathbf{A}_1), \ldots, \mathrm{nnz}(\mathbf{A}_n)$, we can also efficiently access each p_i, which is

needed for rescaling and zeroing out entries. Also observe that if $\mathbf{A}$ is the adjacency matrix of a graph, in the standard graph query model [23], it is well known how to approximately count edges and sample them uniformly at random, i.e., compute $\text{nnz}(\mathbf{A})$ and sample its nonzero entries, in sublinear time [24, 17]. Further, it is typically assumed that one has access to the node degrees, i.e., $\text{nnz}(\mathbf{A}_1), \ldots, \text{nnz}(\mathbf{A}_n)$. Thus, our algorithm can naturally be used to estimate spectral graph properties in sublinear time.

The ℓ_2 norm-based sampling of Theorem 4 can also be performed efficiently using an augmented data structure for storing $\mathbf{A}$. Such data structures have been used extensively in the literature on quantum-inspired algorithms, and require just $O(\text{nnz}(\mathbf{A}))$ time to construct, $O(\text{nnz}(\mathbf{A}))$ space, and $O(\log n)$ time to update give an update to an entry of $\mathbf{A}$ [43, 12].

1.4 Towards Optimal Query Complexity

As discussed, Bakshi et al. [5] show that any algorithm which can test with good probability whether $\mathbf{A}$ has an eigenvalue $\leq -\epsilon n$ or else has all non-negative eigenvalues must read $\tilde{\Omega}\left(\frac{1}{\epsilon^2}\right)$ entries of $\mathbf{A}$. This testing problem is strictly easier than outputting $\pm\epsilon n$ error estimates of all eigenvalues, so gives a lower bound for our setting. If the queried entries are restricted to fall in a submatrix, [5] shows that this submatrix must have dimensions $\Omega\left(\frac{1}{\epsilon^2}\right) \times \Omega\left(\frac{1}{\epsilon^2}\right)$, giving total query complexity $\Omega\left(\frac{1}{\epsilon^4}\right)$. Closing the gap between our upper bound of $\tilde{O}\left(\frac{\log^3 n}{\epsilon^3}\right) \times \tilde{O}\left(\frac{\log^3 n}{\epsilon^3}\right)$ and the lower bound of $\Omega\left(\frac{1}{\epsilon^2}\right) \times \Omega\left(\frac{1}{\epsilon^2}\right)$ for submatrix queries is an intriguing open question.

Closing the gap. We show in Appendix A of [10] that this gap can be easily closed via a surprisingly simple argument if $\mathbf{A}$ is positive semidefinite (PSD). In that case, $\mathbf{A} = \mathbf{B}\mathbf{B}^T$ with $\mathbf{B} \in \mathbb{R}^{n \times n}$. Writing $\mathbf{A}_S = \mathbf{S}^T\mathbf{A}\mathbf{S}$ for a sampling matrix $\mathbf{S} \in \mathbb{R}^{n \times |S|}$, the non-zero eigenvalues of $\mathbf{A}_S$ are identical to those of $\mathbf{B}\mathbf{S}\mathbf{S}^T\mathbf{B}^T$. Via a standard approximate matrix multiplication analysis [16], one can then show that, for $s \geq \frac{1}{\epsilon^2\delta}$, with probability at least $1-\delta$, $\|\mathbf{B}\mathbf{B}^T - \mathbf{B}\mathbf{S}\mathbf{S}^T\mathbf{B}\|_F \leq \epsilon n$. Via Weyl's inequality, this shows that the eigenvalues of $\mathbf{B}\mathbf{S}\mathbf{S}^T\mathbf{B}$, and hence $\mathbf{A}_S$, approximate those of $\mathbf{A}$ up to $\pm\epsilon n$ error.[2]

Unfortunately, this approach breaks down when $\mathbf{A}$ has negative eigenvalues, and so cannot be factored as $\mathbf{B}\mathbf{B}^T$ for real $\mathbf{B} \in \mathbb{R}^{n \times n}$. This is more than a technical issue: observe that when $\mathbf{A}$ is PSD and has $\|\mathbf{A}\|_\infty \leq 1$, it can have at most $1/\epsilon$ eigenvalues larger than ϵn – since its trace, which is equal to the sum of its eigenvalues, is bounded by n, and since all eigenvalues are non-negative. When $\mathbf{A}$ is not PSD, it can have $\Omega(1/\epsilon^2)$ eigenvalues with magnitude larger than ϵn. In particular, if $\mathbf{A}$ is the tensor product of a $1/\epsilon^2 \times 1/\epsilon^2$ random ± 1 matrix and the $\epsilon^2 n \times \epsilon^2 n$ all ones matrix, the bulk of its eigenvalues (of which there are $1/\epsilon^2$) will concentrate around $1/\epsilon \cdot \epsilon^2 n = \epsilon n$. As a result it remains unclear whether we can match the $1/\epsilon^2$ dependence of the PSD case, or if a stronger lower bound can be shown for indefinite matrices.

Outside the ϵ dependence, it is unknown if full eigenspectrum approximation can be performed with sample complexity independent of the matrix size n. [5] achieve this for the easier positive semidefiniteness testing problem, giving sample complexity $\tilde{O}(1/\epsilon^2)$. However our bounds have additional $\log n$ factors. As discussed, in Appendix B of [10] we give an alternate analysis for Theorem 1, which shows that sampling a $O\left(\frac{\log n}{\epsilon^4\delta}\right) \times O\left(\frac{\log n}{\epsilon^4\delta}\right)$ submatrix suffices for $\pm\epsilon n$ eigenvalue approximation, saving a $\log^2 n$ factor at the cost of

[2] In fact, via more refined eigenvalue perturbation bounds [9] one can show an ℓ_2 norm bound on the eigenvalue approximation errors, which can be much stronger than the ℓ_∞ norm bound of Theorem 1.

worse ϵ dependence. However, removing the final $\log n$ seems difficult – it arises when bounding $\|\mathbf{A}_{m,S}\|_2$ via bounds on the spectral norms of random principal submatrices [38]. Removing it seems as though it would require either improving such bounds, or taking a different algorithmic approach, as simple modifications such as using bounds depending on the intrinsic dimension do not seem to help.

Also note that our $\log n$ and ϵ dependencies for non-uniform sampling (Theorems 3 and 4) are likely not tight. It is not hard to check that the lower bounds of [5] still hold in these settings. For example, in the sparsity-based sampling setting, by simply having the matrix entirely supported on a $\sqrt{\text{nnz}(\mathbf{A})} \times \sqrt{\text{nnz}(\mathbf{A})}$ submatrix, the lower bounds of [5] directly carry over. Giving tight query complexity bounds here would also be interesting. Finally, it would be interesting to go beyond principal submatrix based algorithms, to achieve improved query complexity, as in Corollary 2. Finding an algorithm matching the $\tilde{O}\left(\frac{1}{\epsilon^2}\right)$ overall query complexity lower bound of [5] is open even in the much simpler PSD setting.

2 Notation and Preliminaries

We now define notation and foundational results that we use throughout our work. For any integer n, let $[n]$ denote the set $\{1, 2, \ldots, n\}$. We write matrices and vectors in bold literals – e.g., $\mathbf{A}$ or $\mathbf{x}$. For a vector $\mathbf{x}$, we let $\|\mathbf{x}\|_2$ denote its Euclidean norm. We denote the eigenvalues of a symmetric matrix $\mathbf{A} \in \mathbb{R}^{n\times n}$ by $\lambda_1(\mathbf{A}) \geq \ldots \geq \lambda_n(\mathbf{A})$, in decreasing order. A symmetric matrix is positive semidefinite if all its eigenvalues are non-negative. For two matrices $\mathbf{A}, \mathbf{B}$, we let $\mathbf{A} \succeq \mathbf{B}$ denote that $\mathbf{A} - \mathbf{B}$ is positive semidefinite. For any matrix $\mathbf{A} \in \mathbb{R}^{n\times n}$ and $i \in [n]$, we let $\mathbf{A}_i$ denote the i^{th} row of $\mathbf{A}$. We let $\text{nnz}(\mathbf{A})$ denote the total number of non-zero elements in $\mathbf{A}$, $\|\mathbf{A}\|_\infty$ denote the largest magnitude of an entry, and $\|\mathbf{A}\|_2 = \max_{\mathbf{x}} \frac{\|\mathbf{A}\mathbf{x}\|_2}{\|\mathbf{x}\|_2}$ denote the spectral norm. We let $\|\mathbf{A}\|_F = (\sum_{i,j} \mathbf{A}_{ij}^2)^{1/2}$ denote the Frobenius norm, and $\|\mathbf{A}\|_{1\to 2}$ denote the maximum Euclidean norm of a column. For $\mathbf{A} \in \mathbb{R}^{n\times n}$ and $S \subseteq [n]$ we let $\mathbf{A}_S$ denote the principal submatrix corresponding to S. We let $\mathbb{E}_2$ denote the L_2 norm of a random variable, $\mathbb{E}_2[X] = (\mathbb{E}[X^2])^{1/2}$, where $\mathbb{E}[\cdot]$ denotes expectation.

We use the following basic facts and identities on eigenvalues throughout our proofs.

▶ **Fact 1** (Eigenvalue of Matrix Product). *For any two matrices $\mathbf{A} \in \mathbb{C}^{n\times m}, \mathbf{B} \in \mathbb{C}^{m\times n}$, the non-zero eigenvalues of $\mathbf{AB}$ are identical to those of $\mathbf{BA}$.*

▶ **Fact 2** (Gershgorin's circle theorem [20]). *Let $\mathbf{A} \in \mathbb{C}^{n\times n}$ with entries $\mathbf{A}_{ij}$. For $i \in [n]$, let $\mathbf{R}_i$ be the sum of absolute values of non-diagonal entries in the i^{th} row. Let $D(\mathbf{A}_{ii}, \mathbf{R}_i)$ be the closed disc centered at $\mathbf{A}_{ii}$ with radius $\mathbf{R}_i$. Then every eigenvalue of $\mathbf{A}$ lies within one of the discs $D(\mathbf{A}_{ii}, \mathbf{R}_i)$.*

▶ **Fact 3** (Weyl's Inequality [50]). *For any two Hermitian matrices $\mathbf{A}, \mathbf{B} \in \mathbb{C}^{n\times n}$ with $\mathbf{A} - \mathbf{B} = \mathbf{E}$, $\max_i |\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})| \leq \|\mathbf{E}\|_2$.*

Weyl's inequality ensures that a small Hermitian perturbation of a Hermitian matrix will not significantly change its eigenvalues. The bound can be extended to the case when the perturbation is not Hermitian, with a loss of an $O(\log n)$ factor; to the best of our knowledge this loss is necessary:

▶ **Fact 4** (Non-Hermitian perturbation bound [9]). *Let $\mathbf{A} \in \mathbb{C}^{n\times n}$ be Hermitian and $\mathbf{B} \in \mathbb{C}^{n\times n}$ be any matrix whose eigenvalues are $\lambda_1(\mathbf{B}), \ldots, \lambda_n(\mathbf{B})$ such that $Re(\lambda_1(\mathbf{B})) \geq \ldots \geq Re(\lambda_n(\mathbf{B}))$ (where $Re(\lambda_i(\mathbf{B}))$ denotes the real part of $\lambda_i(\mathbf{B})$). Let $\mathbf{A} - \mathbf{B} = \mathbf{E}$. For some universal constant C, $\max_i |\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})| \leq C \log n \|\mathbf{E}\|_2$*

Beyond the above facts, we use several theorems to obtain eigenvalue concentration bounds. We first state a theorem from [44], which bounds the spectral norm of a principal submatrix sampled uniformly at random from a bounded entry matrix. We build on this to prove the full eigenspectrum concentration result of Theorem 1.

▶ **Theorem 6** (Random principal submatrix spectral norm bound [38, 44]). *Let $\mathbf{A} \in \mathbb{C}^{n\times n}$ be Hermitian, decomposed into diagonal and off-diagonal parts: $\mathbf{A} = \mathbf{D} + \mathbf{H}$. Let $\mathbf{S} \in \mathbb{R}^{n\times n}$ be a diagonal sampling matrix with the j^{th} diagonal entry set to 1 independently with probability s/n and 0 otherwise. Then, for some universal constant C,*

$$\mathbb{E}_2\|\mathbf{SAS}\|_2 \leq C\left[\log n \cdot \mathbb{E}_2\|\mathbf{SHS}\|_\infty + \sqrt{\frac{s\log n}{n}} \cdot \mathbb{E}_2\|\mathbf{HS}\|_{1\to 2} + \frac{s}{n}\cdot\|\mathbf{H}\|_2\right] + \mathbb{E}_2\|\mathbf{SDS}\|_2.$$

For Theorems 3 and 4, we need an extension of Theorem 6 to the setting where rows are sampled non-uniformly. We will use two bounds here. The first is a decoupling and recoupling result for matrix norms. One can prove this lemma following an analogous result in [44] for sampling rows/columns uniformly. The proof is almost identical so we omit it.

▶ **Lemma 7** (Decoupling and recoupling). *Let $\mathbf{H}$ be a Hermitian matrix with zero diagonal. Let δ_j be a sequence of independent random variables such that $\delta_j = \frac{1}{\sqrt{p_j}}$ with probability p_j and 0 otherwise. Let $\mathbf{S}$ be a square diagonal sampling matrix with j^{th} diagonal entry set to δ_j. Then:*

$$\mathbb{E}_2\|\mathbf{SHS}\|_2 \leq 2\mathbb{E}_2\|\mathbf{SH\hat{S}}\|_2 \quad \textit{and} \quad \mathbb{E}_2\|\mathbf{SH\hat{S}}\|_\infty \leq 4\mathbb{E}_2\|\mathbf{SHS}\|_\infty,$$

where $\hat{\mathbf{S}}$ is an independent diagonal sampling matrix drawn from the same distribution as $\mathbf{S}$.

The second theorem bounds the spectral norm of a non-uniform random column sample of a matrix. We give a proof for uniform sampling in Appendix D of [10], following the results of [45].

▶ **Theorem 8** (Non-uniform column sampling – spectral norm bound). *Let $\mathbf{A}$ be an $m \times n$ matrix with rank r. Let δ_j be a sequence of independent random variables such that $\delta_j = \frac{1}{\sqrt{p_j}}$ with probability p_j and 0 otherwise. Let $\mathbf{S}$ be a square diagonal sampling matrix with j^{th} diagonal entry set to δ_j.*

$$\mathbb{E}_2\|\mathbf{AS}\|_2 \leq 5\sqrt{\log r}\cdot\mathbb{E}_2\|\mathbf{AS}\|_{1\to 2} + \|\mathbf{A}\|_2$$

We use a standard Matrix Bernstein inequality to bound the spectral norm of random submatrices.

▶ **Theorem 9** (Matrix Bernstein [46]). *Consider a finite sequence $\{\mathbf{S}_k\}$ of random matrices in $\mathbb{R}^{d\times d}$. Assume that for all k, $\mathbb{E}[\mathbf{S}_k] = \mathbf{0}$ and $\|\mathbf{S}_k\|_2 \leq L$. Let $\mathbf{Z} = \sum_k \mathbf{S}_k$ and let $\mathbf{V}_1, \mathbf{V}_2$ be semidefinite upper-bounds for the matrix valued variances $\mathbf{Var}_1(\mathbf{Z})$ and $\mathbf{Var}_2(\mathbf{Z})$:*

$$\mathbf{V}_1 \succeq \mathbf{Var}_1(\mathbf{Z}) \stackrel{\text{def}}{=} \mathbb{E}\left(\mathbf{ZZ}^T\right) = \sum_k \mathbb{E}\left(\mathbf{S}_k\mathbf{S}_k^T\right), \quad \textit{and}$$

$$\mathbf{V}_2 \succeq \mathbf{Var}_2(\mathbf{Z}) \stackrel{\text{def}}{=} \mathbb{E}\left(\mathbf{Z}^T\mathbf{Z}\right) = \sum_k \mathbb{E}\left(\mathbf{S}_k^T\mathbf{S}_k\right).$$

Then, letting $v = \max(\|\mathbf{V}_1\|_2, \|\mathbf{V}_2\|_2)$, for any $t \geq 0$,

$$\mathbb{P}(\|\mathbf{Z}\|_2 \geq t) \leq 2d\cdot\exp\left(\frac{-t^2/2}{v + Lt/3}\right).$$

For real valued random variables, we use the standard Bernstein inequality.

▶ **Theorem 10** (Bernstein inequality [8]). *Let $\{z_j\}$ for $j \in [n]$ be independent random variables with zero mean such that $|z_j| \leq M$ for all j. Then for all positive t,*

$$\mathbb{P}\left(\left|\sum_{j=1}^{n} z_j\right| \geq t\right) \leq \exp\left(\frac{-t^2/2}{\sum_{i=1}^{n} \mathbb{E}[z_i^2] + Mt/3}\right).$$

3 Sublinear Time Eigenvalue Estimation using Uniform Sampling

We now prove our main eigenvalue estimation result – Theorem 1. We give the pseudocode for our principal submatrix based estimation procedure in Algorithm 1. We will show that any positive or negative eigenvalue of $\mathbf{A}$ with magnitude $\geq \epsilon n$ will appear as an approximate eigenvalue in $\mathbf{A}_S$ with good probability. Thus, in step 5 of Algorithm 1, the positive and negative eigenvvalues of $\mathbf{A}_S$ are used to estimate the outlying largest and smallest eigenvalues of $\mathbf{A}$. All other interior eigenvalues of $\mathbf{A}$ are estimated to be 0, which will immediately give our $\pm\epsilon n$ approximation bound when the original eigenvalue has magnitude $\leq \epsilon n$.

Algorithm 1 Eigenvalue estimator using uniform sampling.

1: **Input:** Symmetric $\mathbf{A} \in \mathbb{R}^{n\times n}$ with $\|\mathbf{A}\|_\infty \leq 1$, Accuracy $\epsilon \in (0,1)$, failure prob. $\delta \in (0,1)$.
2: Fix $s = \frac{c\log(1/(\epsilon\delta))\cdot\log^3 n}{\epsilon^3\delta}$ where c is a sufficiently large constant.
3: Add each index $i \in [n]$ to the sample set S independently with probability $\frac{s}{n}$. Let the principal submatrix of $\mathbf{A}$ corresponding S be $\mathbf{A}_S$.
4: Compute the eigenvalues of $\mathbf{A}_S$: $\lambda_1(\mathbf{A}_S) \geq \ldots \geq \lambda_{|S|}(\mathbf{A}_S)$.
5: For all $i \in [|S|]$ with $\lambda_i(\mathbf{A}_S) \geq 0$, let $\tilde{\lambda}_i(\mathbf{A}) = \frac{n}{s}\cdot\lambda_i(\mathbf{A}_S)$. For all $i \in [|S|]$ with $\lambda_i(\mathbf{A}_S) < 0$, let $\tilde{\lambda}_{n-(|S|-i)}(\mathbf{A}) = \frac{n}{s}\cdot\lambda_i(\mathbf{A}_S)$. For all remaining $i \in [n]$, let $\tilde{\lambda}_i(\mathbf{A}) = 0$.
6: **Return:** Eigenvalue estimates $\tilde{\lambda}_1(\mathbf{A}) \geq \ldots \geq \tilde{\lambda}_n(\mathbf{A})$.

Running time. Observe that the expected number of indices chosen by Algorithm 1 is $s = \frac{c\log(1/(\epsilon\delta))\cdot\log^3 n}{\epsilon^3\delta}$. A standard concentration bound can be used to show that with high probability $(1 - 1/\operatorname{poly}(n))$, the number of sampled entries is $O(s)$. Thus, the algorithm reads a total of $O(s^2)$ entries of $\mathbf{A}$ and runs in $O(s^\omega)$ time – the time to compute a full eigendecomposition of $\mathbf{A}_S$.

3.1 Outer and Middle Eigenvalue Bounds

Recall that we will split $\mathbf{A}$ into two symmetric matrices (Definition 5): $\mathbf{A}_o = \mathbf{V}_o\mathbf{\Lambda}_o\mathbf{V}_o^T$ which contains its large magnitude (outlying) eigendirections with eigenvalue magnitudes $\geq \epsilon\sqrt{\delta}n$ and $\mathbf{A}_m = \mathbf{V}_m\mathbf{\Lambda}_m\mathbf{V}_m^T$ which contains its small magnitude (middle) eigendirections.

We first show that the eigenvectors in $\mathbf{V}_o$ are *incoherent*. I.e., that their (eigenvalue weighted) squared row norms are bounded. This ensures that the outlying eigenspace of $\mathbf{A}$ is well-approximated via uniform sampling.

▶ **Lemma 11** (Incoherence of outlying eigenvectors). *Let $\mathbf{A} \in \mathbb{R}^{n\times n}$ be symmetric with $\|\mathbf{A}\|_\infty \leq 1$. Let $\mathbf{V}_o$ be as in Definition 5. Let $\mathbf{V}_{o,i}$ denote the i^{th} row of $\mathbf{V}_o$. Then,*

$$\|\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,i}\|_2^2 \leq \frac{1}{\epsilon\sqrt{\delta}} \qquad \text{and} \qquad \|\mathbf{V}_{o,i}\|_2^2 \leq \frac{1}{\epsilon^2\delta n}.$$

Proof. Observe that $\mathbf{AV}_o = \mathbf{V}_o\mathbf{\Lambda}_o$. Let $[\mathbf{AV}_o]_i$ denote the i^{th} row of the $\mathbf{AV}_o$. Then we have

$$\|[\mathbf{AV}_o]_i\|_2^2 = \|[\mathbf{V}_o\mathbf{\Lambda}_o]_i\|_2^2 = \sum_{j=1}^{r} \lambda_j^2 \cdot \mathbf{V}_{o,i,j}^2, \tag{2}$$

where $r = \text{rank}(\mathbf{A}_o)$, $\mathbf{V}_{o,i,j}$ is the $(i,j)^{\text{th}}$ element of $\mathbf{V}_o$ and $\lambda_j = \mathbf{\Lambda}_o(j,j)$. $\|\mathbf{A}\|_\infty \leq 1$ by assumption and since $\mathbf{V}_o$ has orthonormal columns, its spectral norm is bounded by 1, thus we have $\|[\mathbf{AV}_o]_i\|_2^2 = \|[\mathbf{A}]_i\mathbf{V}_o\|_2^2 \leq \|[\mathbf{A}]_i\|_2^2 \cdot \|\mathbf{V}_o\|_2^2 \leq n$. Therefore, by (2), we have:

$$\sum_{j=1}^{r} \lambda_j^2 \cdot \mathbf{V}_{o,i,j}^2 \leq n. \tag{3}$$

Since by definition of $\mathbf{\Lambda}_o$, $|\lambda_j| \geq \epsilon\sqrt{\delta}n$ for all j, we finally have $\|\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,i}\|_2^2 = \sum_{j=1}^{r} \lambda_j \cdot \mathbf{V}_{o,i,j}^2 \leq \frac{n}{\epsilon\sqrt{\delta}n} = \frac{1}{\epsilon\sqrt{\delta}}$ and $\|\mathbf{V}_{o,i}\|_2^2 = \sum_{j=1}^{r} \mathbf{V}_{o,i,j}^2 \leq \frac{n}{\epsilon^2\delta n^2} = \frac{1}{\epsilon^2\delta n}$. ◀

Let $\bar{\mathbf{S}} \in \mathbb{R}^{n\times|S|}$ be the scaled sampling matrix satisfying $\bar{\mathbf{S}}^T\mathbf{A}\bar{\mathbf{S}} = \frac{n}{s} \cdot \mathbf{A}_S$. We next apply Lemma 11 in conjunction with a matrix Bernstein bound to show that $\mathbf{\Lambda}_o^{1/2}\mathbf{V}_o^T\bar{\mathbf{S}}\bar{\mathbf{S}}^T\mathbf{V}_o\mathbf{\Lambda}_o^{1/2}$ concentrates around its expectation, $\mathbf{\Lambda}_o$. Since by Fact 1, this matrix has identical eigenvalues to $\frac{n}{s}\cdot\mathbf{A}_{o,S} = \bar{\mathbf{S}}^T\mathbf{V}_o\mathbf{\Lambda}_o\mathbf{V}_o^T\bar{\mathbf{S}}$, this allows us to argue that the eigenvalues of $\frac{n}{s}\cdot\mathbf{A}_{o,S}$ approximate those of $\mathbf{\Lambda}_o$.

▶ **Lemma 12** (Concentration of outlying eigenvalues). *Let $S \subseteq [n]$ be sampled as in Algorithm 1 for $s \geq \frac{c\log(1/(\epsilon\delta))}{\epsilon^3\sqrt{\delta}}$ where c is a sufficiently large constant. Let $\bar{\mathbf{S}} \in \mathbb{R}^{n\times|S|}$ be the scaled sampling matrix satisfying $\bar{\mathbf{S}}^T\mathbf{A}\bar{\mathbf{S}} = \frac{n}{s} \cdot \mathbf{A}_S$. Letting $\mathbf{\Lambda}_o, \mathbf{V}_o$ be as in Definition 5, with probability at least $1-\delta$,*

$$\|\mathbf{\Lambda}_o^{1/2}\mathbf{V}_o^T\bar{\mathbf{S}}\bar{\mathbf{S}}^T\mathbf{V}_o\mathbf{\Lambda}_o^{1/2} - \mathbf{\Lambda}_o\|_2 \leq \epsilon n.$$

Proof. Define $\mathbf{E} = \mathbf{\Lambda}_o^{1/2}\mathbf{V}_o^T\bar{\mathbf{S}}\bar{\mathbf{S}}^T\mathbf{V}_o\mathbf{\Lambda}_o^{1/2} - \mathbf{\Lambda}_o$. For all $i \in [n]$, let $\mathbf{V}_{o,i}$ be the i^{th} row of $\mathbf{V}_o$ and define the matrix valued random variable

$$\mathbf{Y}_i = \begin{cases} \frac{n}{s}\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,i}\mathbf{V}_{o,i}^T\mathbf{\Lambda}_o^{1/2}, & \text{with probability } s/n \\ 0 & \text{otherwise.} \end{cases} \tag{4}$$

Define $\mathbf{Q}_i = \mathbf{Y}_i - \mathbb{E}[\mathbf{Y}_i]$. Observe that $\mathbf{Q}_1, \ldots, \mathbf{Q}_n$ are independent random variables and that $\sum_{i=1}^{n}\mathbf{Q}_i = \mathbf{\Lambda}_o^{1/2}\mathbf{V}_o^T\bar{\mathbf{S}}\bar{\mathbf{S}}^T\mathbf{V}_o\mathbf{\Lambda}_o^{1/2} - \mathbf{\Lambda}_o = \mathbf{E}$. Further, observe that $\|\mathbf{Q}_i\|_2 \leq \max\left(1, \frac{n}{s}-1\right)\cdot\|\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,i}\mathbf{V}_{o,i}^T\mathbf{\Lambda}_o^{1/2}\|_2 \leq \max\left(1, \frac{n}{s}-1\right)\cdot\|\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,i}\|_2^2$. Now, $\|\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,i}\|_2^2 \leq \frac{1}{\epsilon\sqrt{\delta}}$ by Lemma 11. Thus, $\|\mathbf{Q}_i\|_2 \leq \frac{n}{\epsilon\sqrt{\delta}s}$. The variance $\mathbf{Var}(\mathbf{E}) \overset{\text{def}}{=} \mathbb{E}(\mathbf{E}\mathbf{E}^T) = \mathbb{E}(\mathbf{E}^T\mathbf{E}) = \sum_{i=1}^{n}\mathbb{E}[\mathbf{Q}_i^2]$ can be bounded as:

$$\begin{aligned}\sum_{i=1}^{n}\mathbb{E}[\mathbf{Q}_i^2] &= \sum_{i=1}^{n}\left[\frac{s}{n}\cdot\left(\frac{n}{s}-1\right)^2 + \left(1-\frac{s}{n}\right)\right]\cdot(\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,i}\mathbf{V}_{o,i}^T\mathbf{\Lambda}_o\mathbf{V}_{o,i}\mathbf{V}_{o,i}^T\mathbf{\Lambda}_o^{1/2}) \\ &\preceq \sum_{i=1}^{n}\frac{n}{s}\cdot\|\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,i}\|_2^2\cdot(\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,i}\mathbf{V}_{o,i}^T\mathbf{\Lambda}_o^{1/2}).\end{aligned} \tag{5}$$

Again by Lemma 11, $\|\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,i}\|_2^2 \leq \frac{1}{\epsilon\sqrt{\delta}}$. Plugging back into (5) we can bound,

$$\sum_{i=1}^{n}\mathbb{E}[\mathbf{Q}_i^2] \preceq \sum_{i=1}^{n}\frac{n}{s}\cdot\frac{1}{\epsilon\sqrt{\delta}}\cdot(\mathbf{\Lambda}_o^{1/2}\mathbf{V}_{o,i}\mathbf{V}_{o,i}^T\mathbf{\Lambda}_o^{1/2}) = \frac{n}{s\epsilon\sqrt{\delta}}\mathbf{\Lambda}_o \preceq \frac{n^2}{s\epsilon\sqrt{\delta}}\cdot\mathbf{I}.$$

Since $\mathbf{Q}_i^2$ is PSD, this establishes that $\|\mathbf{Var}(\mathbf{E})\|_2 \leq \frac{n^2}{s\epsilon\sqrt{\delta}}$. We then apply Theorem 9 (the matrix Bernstein inequality) with $L = \frac{n}{s\epsilon\sqrt{\delta}}$, $v = \frac{n^2}{s\epsilon\sqrt{\delta}}$, and $d \leq \frac{1}{\epsilon^2\delta}$ since there are at most $\frac{\|\mathbf{A}\|_F^2}{\delta\epsilon^2 n^2} \leq \frac{1}{\epsilon^2\delta}$ outlying eigenvalues with magnitude $\geq \sqrt{\delta}\epsilon n$ in $\mathbf{\Lambda}_o$. This gives:

$$\mathbb{P}\left(\|\mathbf{E}\|_2 \geq \epsilon n\right) \leq \frac{2}{\epsilon^2\delta} \cdot \exp\left(\frac{-\epsilon^2 n^2/2}{v + L\epsilon n/3}\right) \leq \frac{2}{\epsilon^2\delta} \cdot \exp\left(\frac{-\epsilon^2 n^2/2}{\frac{n^2}{s\epsilon\sqrt{\delta}} + \frac{\epsilon n^2}{3s\epsilon\sqrt{\delta}}}\right)$$
$$\leq \frac{2}{\epsilon^2\delta} \cdot \exp\left(\frac{-s\epsilon^3\sqrt{\delta}}{4}\right).$$

Thus, if we set $s \geq \frac{c\log(1/(\epsilon\delta))}{\epsilon^3\sqrt{\delta}}$ for large enough c, then the probability is bounded above by δ, completing the proof. ◀

We cannot prove an analogous leverage score bound to Lemma 11 for the interior eigenvectors of $\mathbf{A}$ appearing in $\mathbf{V}_m$. Thus we cannot apply a matrix Bernstein bound as in Lemma 12. However, we can use Theorem 6 to show that the spectral norm of the random principal submatrix $\mathbf{A}_{m,S}$ is not too large, and thus that the eigenvalues of $\mathbf{A}_S = \mathbf{A}_{o,S} + \mathbf{A}_{m,S}$ are close to those of $\mathbf{A}_{o,S}$.

▶ **Lemma 13** (Spectral norm bound – sampled middle eigenvalues)**.** *Let $\mathbf{A} \in \mathbb{R}^{n\times n}$ be symmetric with $\|\mathbf{A}\|_\infty \leq 1$. Let $\mathbf{A}_m$ be as in Definition 5. Let S be sampled as in Algorithm 1. If $s \geq \frac{c\log n}{\epsilon^2\delta}$ for some sufficiently large constant c, then with probability at least $1-\delta$, $\|\mathbf{A}_{m,S}\|_2 \leq \epsilon s$.*

Proof. Let $\mathbf{A}_m = \mathbf{D}_m + \mathbf{H}_m$ where $\mathbf{D}_m$ is the matrix of diagonal elements and $\mathbf{H}_m$ the matrix of off-diagonal elements. Let $\mathbf{S} \in \mathbb{R}^{n\times|S|}$ be the binary sampling matrix with $\mathbf{A}_{m,S} = \mathbf{S}^T\mathbf{A}_m\mathbf{S}$. From Theorem 6, we have for some constant C,

$$\mathbb{E}_2[\|\mathbf{A}_{m,S}\|_2] \leq C\left[\log n \cdot \mathbb{E}_2[\|\mathbf{S}^T\mathbf{H}_m\mathbf{S}\|_\infty] + \sqrt{\frac{s\log n}{n}}\mathbb{E}_2[\|\mathbf{H}_m\mathbf{S}\|_{1\to2}] + \frac{s}{n}\|\mathbf{H}_m\|_2\right] + \mathbb{E}_2[\|\mathbf{S}^T\mathbf{D}_m\mathbf{S}\|]. \tag{6}$$

Considering the various terms in (6), we have $\|\mathbf{S}^T\mathbf{H}_m\mathbf{S}\|_\infty \leq \|\mathbf{A}_m\|_\infty$ and $\|\mathbf{S}^T\mathbf{D}_m\mathbf{S}\|_2 = \|\mathbf{S}^T\mathbf{D}_m\mathbf{S}\|_\infty \leq \|\mathbf{A}_m\|_\infty$. We also have

$$\|\mathbf{H}_m\|_2 \leq \|\mathbf{A}_m\|_2 + \|\mathbf{D}_m\|_2 \leq \|\mathbf{A}_m\|_2 + \|\mathbf{A}_m\|_\infty \leq \epsilon\delta^{1/2}n + \|\mathbf{A}_m\|_\infty$$

and

$$\|\mathbf{H}_m\mathbf{S}\|_{1\to2} \leq \|\mathbf{A}_m\mathbf{S}\|_{1\to2} \leq \|\mathbf{A}_m\|_{1\to2} \leq \sqrt{n}.$$

The final bound follows since $\mathbf{A}_m = \mathbf{V}_m\mathbf{V}_m^T\mathbf{A}$, where $\mathbf{V}_m\mathbf{V}_m^T$ is an orthogonal projection matrix. Thus, $\|\mathbf{A}_m\|_{1\to2} \leq \|\mathbf{A}\|_{1\to2} \leq \sqrt{n}$ by our assumption that $\|\mathbf{A}\|_\infty \leq 1$. Plugging all these bounds into (6) we have, for some constant C,

$$\mathbb{E}_2[\|\mathbf{A}_{m,S}\|_2] \leq C\left[\log n \cdot \|\mathbf{A}_m\|_\infty + \sqrt{\log n \cdot s} + s \cdot \epsilon\delta^{1/2}\right]. \tag{7}$$

It remains to bound $\|\mathbf{A}_m\|_\infty$. We have $\mathbf{A} = \mathbf{A}_m + \mathbf{A}_o$ and thus by triangle inequality,

$$\|\mathbf{A}_m\|_\infty \leq \|\mathbf{A}\|_\infty + \|\mathbf{A}_o\|_\infty = 1 + \|\mathbf{A}_o\|_\infty. \tag{8}$$

Writing $\mathbf{A}_o = \mathbf{V}_o \mathbf{\Lambda}_o \mathbf{V}_o^T$ (see Definition 5), and letting $\mathbf{V}_{o,i}$ denote the i^{th} row of $\mathbf{V}_o$, the $(i,j)^{\text{th}}$ element of $\mathbf{A}_o$ has magnitude

$$|\mathbf{A}_{o,i,j}| = |\mathbf{V}_{o,i} \mathbf{\Lambda}_o \mathbf{V}_{o,j}^T| \leq \|\mathbf{V}_{o,i}\|_2 \cdot \|\mathbf{\Lambda}_o \mathbf{V}_{o,j}^T\|_2,$$

by Cauchy-Schwarz. From Lemma 11, we have $\|\mathbf{V}_{o,i}\|_2 \leq \frac{1}{\epsilon \delta^{1/2} \sqrt{n}}$. Also, from (2), $\|\mathbf{\Lambda}_o \mathbf{V}_{o,j}^T\|_2 = \|[\mathbf{A}\mathbf{V}_o]_j\|_2 \leq \sqrt{n}$. Overall, for all i,j we have $\mathbf{A}_{o,i,j} \leq \frac{1}{\epsilon \delta^{1/2} \sqrt{n}} \cdot \sqrt{n} = \frac{1}{\epsilon \delta^{1/2}}$, giving $\|\mathbf{A}_o\|_\infty \leq \frac{1}{\epsilon \delta^{1/2}}$. Plugging back into (8) and in turn (7), we have for some constant C,

$$\mathbb{E}_2[\|\mathbf{A}_{m,S}\|_2] \leq C \left[\frac{\log n}{\epsilon \delta^{1/2}} + \sqrt{s \log n} + s \epsilon \delta^{1/2} \right].$$

Setting $s \geq \frac{c \log n}{\epsilon^2 \delta}$ for sufficiently large c, all terms in the right hand side of the above equation are bounded by $\epsilon \sqrt{\delta} s$ and so

$$\mathbb{E}_2[\|\mathbf{A}_{m,S}\|_2] \leq 3 \epsilon \sqrt{\delta} s$$

Thus, by Markov's inequality, with probability at least $1 - \delta$, we have $\|\mathbf{A}_{m,S}\|_2 \leq 3\epsilon s$. We can adjust ϵ by a constant to obtain the required bound. ◀

3.2 Main Accuracy Bounds

We now restate our main result, and give its proof via Lemmas 12 and 13.

▶ **Theorem 1** (Sublinear Time Eigenvalue Approximation). *Let $\mathbf{A} \in \mathbb{R}^{n \times n}$ be symmetric with $\|\mathbf{A}\|_\infty \leq 1$ and eigenvalues $\lambda_1(\mathbf{A}) \geq \ldots \geq \lambda_n(\mathbf{A})$. Let $S \subseteq [n]$ be formed by including each index independently with probability s/n as in Algorithm 1. Let $\mathbf{A}_S$ be the corresponding principal submatrix of $\mathbf{A}$, with eigenvalues $\lambda_1(\mathbf{A}_S) \geq \ldots \geq \lambda_{|S|}(\mathbf{A}_S)$.*

For all $i \in [|S|]$ with $\lambda_i(\mathbf{A}_S) \geq 0$, let $\tilde{\lambda}_i(\mathbf{A}) = \frac{n}{s} \cdot \lambda_i(\mathbf{A}_S)$. For all $i \in [|S|]$ with $\lambda_i(\mathbf{A}_S) < 0$, let $\tilde{\lambda}_{n-(|S|-i)}(\mathbf{A}) = \frac{n}{s} \cdot \lambda_i(\mathbf{A}_S)$. For all other $i \in [n]$, let $\tilde{\lambda}_i(\mathbf{A}) = 0$. If $s \geq \frac{c \log(1/(\epsilon\delta)) \cdot \log^3 n}{\epsilon^3 \delta}$, for large enough constant c, then with probability $\geq 1 - \delta$, for all $i \in [n]$, $\lambda_i(\mathbf{A}) - \epsilon n \leq \tilde{\lambda}_i(\mathbf{A}) \leq \lambda_i(\mathbf{A}) + \epsilon n$.

Proof. Let $\mathbf{S} \in \mathbb{R}^{n \times |S|}$ be the binary sampling matrix with a single one in each column such that $\mathbf{S}^T \mathbf{A} \mathbf{S} = \mathbf{A}_S$. Let $\bar{\mathbf{S}} = \sqrt{n/s} \cdot \mathbf{S}$. Following Definition 5, we write $\mathbf{A} = \mathbf{A}_o + \mathbf{A}_m$. By Fact 1 we have that the nonzero eigenvalues of $\frac{n}{s} \cdot \mathbf{A}_{o,S} = \bar{\mathbf{S}}^T \mathbf{V}_o \mathbf{\Lambda}_o \mathbf{V}_o^T \bar{\mathbf{S}}$ are identical to those of $\mathbf{\Lambda}_o^{1/2} \mathbf{V}_o^T \bar{\mathbf{S}} \bar{\mathbf{S}}^T \mathbf{V}_o \mathbf{\Lambda}_o^{1/2}$ where $\mathbf{\Lambda}_o^{1/2}$ is the square root matrix of $\mathbf{\Lambda}_o$ such that $\mathbf{\Lambda}_o^{1/2} \mathbf{\Lambda}_o^{1/2} = \mathbf{\Lambda}_o$.

Note that $\mathbf{\Lambda}_o$ is Hermitian. However $\mathbf{\Lambda}_o^{1/2}$ may be complex, and hence $\mathbf{\Lambda}_o^{1/2} \mathbf{V}_o^T \bar{\mathbf{S}} \bar{\mathbf{S}}^T \mathbf{V}_o \mathbf{\Lambda}_o^{1/2}$ is *not necessarily Hermitian*, although it does have real eigenvalues. Thus, we can apply the perturbation bound of Fact 4 to $\mathbf{\Lambda}_o$ and $\mathbf{\Lambda}_o^{1/2} \mathbf{V}_o^T \bar{\mathbf{S}} \bar{\mathbf{S}}^T \mathbf{V}_o \mathbf{\Lambda}_o^{1/2}$ to claim for all $i \in [n]$, and some constant C,

$$|\lambda_i(\mathbf{\Lambda}_o^{1/2} \mathbf{V}_o^T \bar{\mathbf{S}} \bar{\mathbf{S}}^T \mathbf{V}_o \mathbf{\Lambda}_o^{1/2}) - \lambda_i(\mathbf{\Lambda}_o)| \leq C \log n \|\mathbf{\Lambda}_o^{1/2} \mathbf{V}_o^T \bar{\mathbf{S}} \bar{\mathbf{S}}^T \mathbf{V}_o \mathbf{\Lambda}_o^{1/2} - \mathbf{\Lambda}_o\|_2.$$

By Lemma 12 applied with error $\frac{\epsilon}{2C \log n}$, with probability at least $1 - \delta$, for any $s \geq \frac{c \log(1/(\epsilon\delta)) \cdot \log^3 n}{\epsilon^3 \sqrt{\delta}}$ (for a large enough constant c) we have $\|\mathbf{\Lambda}_o^{1/2} \mathbf{V}_o^T \bar{\mathbf{S}} \bar{\mathbf{S}}^T \mathbf{V}_o \mathbf{\Lambda}_o^{1/2} - \mathbf{\Lambda}_o\|_2 \leq \frac{\epsilon n}{2C \log n}$. Thus, for all i,

$$\left| \lambda_i(\mathbf{\Lambda}_o^{1/2} \mathbf{V}_o^T \bar{\mathbf{S}} \bar{\mathbf{S}}^T \mathbf{V}_o \mathbf{\Lambda}_o^{1/2}) - \lambda_i(\mathbf{\Lambda}_o) \right| < \frac{\epsilon n}{2}. \tag{9}$$

We note that the conceptual part of the proof is essentially complete: the nonzero eigenvalues of $\frac{n}{s} \cdot \mathbf{A}_{o,S}$ are identical to those of $\mathbf{\Lambda}_o^{1/2} \mathbf{V}_o^T \bar{\mathbf{S}} \bar{\mathbf{S}}^T \mathbf{V}_o \mathbf{\Lambda}_o^{1/2}$, which we have shown well approximate those of $\mathbf{\Lambda}_o$ and in turn $\mathbf{A}_o$. i.e., the non-zero eigenvalues of $\frac{n}{s} \cdot \mathbf{A}_{o,S}$ approximate all outlying

eigenvalues of $\mathbf{A}$. It remains to carefully argue how these approximations should be "lined up" given the presence of zero eigenvalues in the spectrum of these matrices. We also must account for the impact of the interior eigenvalues in $\mathbf{A}_{m,S}$, which is limited by the spectral norm bound of Lemma 13. The rest of the argument is completed in Theorem 1 of [10]. ◀

▶ Remark. The proof of Lemma 12 and consequently, Theorem 1 can be modified to give better bounds for the case when the eigenvalues of $\mathbf{A}_o$ lie in a bounded range – between $\epsilon^a\sqrt{\delta}n$ and $\epsilon^b n$ where $0 \leq b \leq a \leq 1$. See Theorem 9 in Appendix C of [10] for details. For example, if all the top eigenvalues are equal, one can show that $s = \tilde{O}\left(\frac{\log^2 n}{\epsilon^2}\right)$ suffices to give $\pm\epsilon n$ error, nearly matching the lower bound of [5]. This indicates that improving Theorem 1 in general requires tackling the case when the outlying eigenvalues in $\mathbf{\Lambda}_o$ have a wide range.

4 Conclusion

We present efficient algorithms for estimating all eigenvalues of a symmetric matrix with bounded entries up to additive error ϵn, by reading just a $\text{poly}(\log n, 1/\epsilon) \times \text{poly}(\log n, 1/\epsilon)$ random principal submatrix. We give improved error bounds of $\epsilon\sqrt{\text{nnz}(\mathbf{A})}$ and $\epsilon\|\mathbf{A}\|_F$ when the rows/columns are sampled with probabilities proportional to their sparsities or squared ℓ_2 norms, respectively (see Section 4 and Appendix E of [10]). We also perform numerical simulations which demonstrate the effectiveness of our algorithms in practice (see Section 5 of [10]).

Our work leaves several open questions. In particular, it is open if our query complexity for $\pm\epsilon n$ approximation can be improved, possibly to $\tilde{O}(\log^c n/\epsilon^4)$ total entries using principal submatrix queries or $\tilde{O}(\log^c /\epsilon^2)$ entries using general queries. The later bound is open even when $\mathbf{A}$ is PSD, a setting where we know that sampling a $O(1/\epsilon^2) \times O(1/\epsilon^2)$ principal submatrix (with $O(1/\epsilon^4)$ total entries) does suffice. Additionally, it is open if we can achieve sample complexity independent of n, by removing all $\log n$ factors, as have been done for the easier problem of testing positive semidefiniteness [5]. See Section 1.4 for more details. Finally, it would be interesting to identify additional assumptions on $\mathbf{A}$ or on the sampling model where stronger approximation guarantees (e.g., relative error) can be achieved in sublinear time.

Streaming k-Edit Approximate Pattern Matching via String Decomposition

Sudatta Bhattacharya
Computer Science Institute of Charles University, Prague, Czech Republic

Michal Koucký
Computer Science Institute of Charles University, Prague, Czech Republic

Abstract

In this paper we give an algorithm for streaming k-edit approximate pattern matching which uses space $\widetilde{O}(k^2)$ and time $\widetilde{O}(k^2)$ per arriving symbol. This improves substantially on the recent algorithm of Kociumaka, Porat and Starikovskaya [22] which uses space $\widetilde{O}(k^5)$ and time $\widetilde{O}(k^8)$ per arriving symbol. In the k-edit approximate pattern matching problem we get a pattern P and text T and we want to identify all substrings of the text T that are at edit distance at most k from P. In the streaming version of this problem both the pattern and the text arrive in a streaming fashion symbol by symbol and after each symbol of the text we need to report whether there is a current suffix of the text with edit distance at most k from P. We measure the total space needed by the algorithm and time needed per arriving symbol.

1 Introduction

Pattern matching is a classical problem of finding occurrences of a given pattern P in text T. It can be solved in time linear in the size of the pattern and text [21, 4, 20]. The classical algorithms use space that is proportional to the pattern size. In a surprising work [25], Porat and Porat were the first to design a pattern matching algorithm that uses less space. They designed an *on-line* algorithm that pre-processes the pattern P into a small data structure, and then it receives the text symbol by symbol. After receiving each symbol of the text, the algorithm is able to report whether the pattern matches the current suffix of the text. The algorithm uses poly-logarithmic amount of memory for storing the data structure and processing the text. This represents a considerable achievement in the design of pattern matching algorithms.

Porat and Porat also gave a small-space online algorithm that solves approximate pattern matching up-to Hamming distance k, *k-mismatch approximate pattern matching*. In this problem we are given the pattern P and a parameter k, and we should find all substrings of the

text T that are at Hamming distance at most k from P. Their algorithm uses $\widetilde{O}(k^3)$ space, and requires $\widetilde{O}(k^2)$ time per arriving symbol of the text. Subsequently this was improved to space $\widetilde{O}(k)$ and time $\widetilde{O}(\sqrt{k})$ [10]. There has been a series of works [5, 9, 10, 19, 18, 15, 27, 26, 17] on online and streaming pattern matching, and the line of work culminated in the work of Clifford, Kociumaka and Porat [11] who gave a fully *streaming* algorithm with similar parameters as [10].

In the streaming setting, also the pattern arrives symbol by symbol and we do not have the space to store all of it at once. An important feature of the algorithm of Clifford, Kociumaka and Porat is that their algorithm not only reports the k-mismatch occurrences of the pattern but for each k-mismatch occurrence of P it can also output the full information about the difference between P and the current suffix of the text, so called *mismatch information*.

Beside approximate pattern matching with respect to Hamming distance, researchers also consider approximate pattern matching with respect to other similarity measures such as edit distance. Edit distance $\mathrm{ED}(x, y)$ of two strings x and y is the minimum number of insertions, deletions and substitutions needed to transform x into y. The *k-edit approximate pattern matching problem* is a variant of the approximate pattern matching where we should find all substrings of T that are at edit distance at most k from P. Since there could be quadratically many such substrings, we usually only require to report for each position in T whether there is a substring of T ending at that position that has edit distance at most k from P. In the streaming version of the problem we want to output the minimal distance of P to a current suffix of the text after receiving each symbol of T. Again we assume that the text as well as the pattern arrive symbol by symbol, and we are interested in how much space the algorithm uses, and how much time it takes to process each symbol.

Starikovskaya [27] proposed a streaming algorithm for the k-edit pattern matching problem, which uses $\widetilde{O}(k^8\sqrt{m})$ space and takes $\widetilde{O}(k^2\sqrt{m} + k^{13})$ time per arriving symbol. Here, we denote $m = |P|$ and $n = |T|$. Recently, using a very different technique Kociumaka, Porat and Starikovskaya [22] constructed a streaming algorithm, which uses $\widetilde{O}(k^5)$ space and $\widetilde{O}(k^8)$ amortized time per arriving symbol of the text.

In this work we substantially improve on the result of Kociumaka, Porat and Starikovskaya. We give a streaming algorithm for k-edit approximate pattern matching that uses $\widetilde{O}(k^2)$ space and $\widetilde{O}(k^2)$ time per arriving symbol.

▶ **Theorem 1.** *Given integer $k \geq 0$, there exists a randomized streaming algorithm for the k-edit approximate pattern matching problem that uses $\widetilde{O}(k^2)$ bits of space and takes $\widetilde{O}(k^2)$ time per arriving symbol of the text.*

We speculate that some amortization techniques could bring the time complexity of our k-edit approximate pattern matching algorithm further down. However, it seems unlikely to achieve complexity below $\widetilde{O}(k)$ per arriving symbol as one could then solve the plain edit distance problem in sub-quadratic time contradicting the Strong Exponential Time Hypothesis (SETH) [2]. It is an interesting open question to achieve smaller space complexity than $\widetilde{O}(k^2)$. Currently, all known sketching techniques for edit distance that people use for k-edit approximate pattern matching give sketches of size $\Omega(k^2)$.

The technique of Kociumaka, Porat and Starikovskaya [22] for edit distance pattern matching to large extent emulates the inner working of Hamming approximate pattern matching algorithms. To that effect Kociumaka, Porat and Starikovskaya had to design a *rolling* sketch for edit distance where multiple sketches can be "homomorphically" combined into one. This requires sophisticated machinery. Here we use a somewhat different approach. We use a recent locally consistent decomposition of strings which preserves edit distance of Bhattacharya and Koucký [3]. The decomposition in essence translates edit distance

to Hamming distance. Hence, we apply the k-mismatch approximate pattern matching algorithm of Clifford, Kociumaka and Porat [11] on the stream of symbols coming from the decomposition as a black box. Bhattacharya and Koucký [3] also constructed a rolling sketch with limited update abilities, namely adding and deleting a symbol. We do not use that sketch here.

1.1 Related work

Landau and Vishkin [23] gave the first algorithm for the *k-mismatch approximate pattern matching* problem which runs in time $O(k(m \log m + n))$ and takes $O(k(m+n))$ amount of space. This was then improved to $O(m \log m + kn)$ time and $O(m)$ space by Galil and Giancarlo [13]. Later, Amir, Lewenstein and Porat [1] proposed two algorithms running in time $O(n\sqrt{k \log k})$ and $\widetilde{O}(n+k^3(n/m))$. The latter was improved by Clifford, Fontaine, Porat, Sach and Starikovskaya [10] who gave an $\widetilde{O}(n+k^2(n/m))$ time algorithm. Charalampopoulos, Kociumaka and Wellnitz, in their FOCS'20 paper [7], also proposed an $\widetilde{O}(n + k^2(n/m))$ time algorithm with slightly better *polylog* factors. An $\widetilde{O}(n + kn/\sqrt{m})$ time algorithm was given by Gawrychowski and Uznański [16], which showed a nice tradeoff between the $O(n\sqrt{k \log k})$ and $\widetilde{O}(n + k^2(n/m))$ running times. Not only that, they also showed that their algorithm is essentially optimal upto *polylog* factors, by proving a matching conditional lower bound. The *polylog* factors in the running time were then improved further by a randomized algorithm by Chan, Golan, Kociumaka, Kopelowitz and Porat [6], with running time $O(n + kn(\sqrt{\log m/m}))$. This problem is thus quite well studied.

For the edit distance counterpart of the problem however, there is still a significant gap between the best upper bound and the known conditional lower bound. Landau and Vishkin [24] proposed an $O(nk)$ time algorithm for the problem. This algorithm is still the state of the art for larger values of k. Cole and Hariharan [12] gave an algorithm running in time $O(n + m + k^4(n/m))$(this runs faster if $m \geq k^3$). In their unified approach paper [7], Charalampopoulos, Kociumaka and Wellnitz also proposed an algorithm running in time $O(n + m + k^4(n/m))$. The same authors in their FOCS'22 paper [8] gave an algorithm running in time $O(n + k^{3.5}\sqrt{\log m \log kn/m})$, finally improving the bound after 20 years. For the lower bound, Backurs and Indyk [2] proved that a truly subquadratic time algorithm for computing edit distance would falsify SETH. This would imply that an algorithm for the k-edit approximate pattern matching which is significantly faster than $O(n + k^2(n/m))$ is highly unlikely.

Online *k-mismatch approximate pattern matching* problem was first solved by Benny Porat and Ely Porat in 2009 [25]. They gave an online algorithm with running time $\widetilde{O}(k^2)$ and space $\widetilde{O}(k^3)$ per arriving symbol of the text. Clifford, Fontaine, Porat, Sach and Starikovskaya in their SODA'16 paper [10], improved it to $\widetilde{O}(k^2)$ space and $O(\sqrt{k} \log k + poly(\log(n)))$ time per arriving symbol of the text. Clifford, Kociumaka and Porat [11] proposed a randomized streaming algorithm which uses $O(k \log (m/k))$ space and $O(\log (m/k)(\sqrt{k \log k} + \log^3 m))$ time per arriving symbol. The space upper bound is optimal up-to logarithmic factors, matching the communication complexity lower bound. All these algorithms use some form of rolling sketch.

In the streaming model, Starikovskaya proposed a randomized algorithm [27] for the k-edit approximate pattern matching problem, which takes $O(k^8\sqrt{m} \log^6 m)$ space and $O((k^2\sqrt{m} + k^{13}) \log^4 m)$ time per arriving symbol. Kociumaka, Porat and Starikovskaya [22] proposed an improved randomized streaming algorithm, which takes $\widetilde{O}(k^5)$ space and $\widetilde{O}(k^8)$ amortized time per arriving symbol of the text.

2 Notations and preliminaries

We use a standard notation. For any string $x = x_1x_2x_2 \dots x_n$ and integers p, q, $x[p]$ denotes x_p, $x[p, q]$ represents substring $x' = x_p \dots x_q$ of x, and $x[p, q) = x[p, q - 1]$. If $q < p$, then $x[p, q]$ is the empty string ε. $x[p, \dots]$ represents $x[p, |x|]$, where $|x|$ is the length of x. "$\cdot$"-operator is used to denote concatenation, e.g $x \cdot y$ is the concatenation of two strings x and y. For strings x and y, $\mathrm{ED}(x, y)$ is the minimum number of modifications (*edit operations*) required to change x into y, where a single modification can be adding a character, deleting a character or substituting a character in x. All logarithms are based-2 unless stated otherwise. For integers $p > q$, $\sum_{i=p}^{q} a_i = 0$ by definition regardless of a_i's.

2.1 Grammars

We will use the following definitions from [3]. They are taken essentially verbatim. Let $\Sigma \subseteq \Gamma$ be two alphabets and $\# \notin \Gamma$. A *grammar* G is a set of *rules* of the type $c \to ab$ or $c \to a^r$, where $c \in (\Gamma \cup \{\#\}) \setminus \Sigma$, $a, b \in \Gamma$ and $r \in \mathbb{N}$. c is the *left hand side* of the rule, and ab or a^r is the *right hand side* of the rule. $\#$ is the starting symbol. The size $|G|$ of the grammar is the number of rules in G. We only consider grammars where each $a \in \Gamma \cup \{\#\}$ appears on the left hand side of at most one rule of G, we call such grammars *deterministic*. The $\mathrm{eval}(G)$ is the string from Σ^* obtained from $\#$ by iterative rewriting of the intermediate results by the rules from G. If the rewriting process never stops or stops with a string not from Σ^*, $\mathrm{eval}(G)$ is undefined. We use $\mathrm{eval}(G_1, G_2, \dots, G_t)$ to denote the concatenation $\mathrm{eval}(G_1) \cdot \mathrm{eval}(G_2) \cdots \mathrm{eval}(G_t)$. Using a depth-first traversal of a deterministic grammar G we can calculate its *evaluation size* $|\mathrm{eval}(G)|$ in time $O(|G|)$. Given a deterministic grammar G and an integer m less or equal to its evaluation size, we can construct in time $O(|G|)$ another grammar G' of size $O(|G|)$ such that $\mathrm{eval}(G') = \mathrm{eval}(G)[m, \dots]$. G' will use some new auxiliary symbols.

We will use the following observation of Ganesh, Kociumaka, Lincoln and Saha [14]:

▶ **Proposition 2** ([14]). *There is an algorithm that on input of two grammars G_x and G_y of size at most m computes the edit distance k of $\mathrm{eval}(G_x)$ and $\mathrm{eval}(G_y)$ in time $O((m + k^2) \cdot \mathrm{poly}(\log(m + n)))$, where $n = |\mathrm{eval}(G_x)| + |\mathrm{eval}(G_y)|$.*

We remark that the above algorithm can be made to output also full information about edit operations that transform $\mathrm{eval}(G_x)$ to $\mathrm{eval}(G_y)$. We will also use the following proposition which can be obtained from Landau-Vishkin algorithm [23] see e.g. a combination of Lemma 6.2 and Theorem 7.13 in [7]:

▶ **Corollary 3.** *For every pair of grammars G_x and G_y representing strings x and y, respectively, and given a parameter k we can find in time $O((m + k^2) \cdot \mathrm{poly}(\log(m + n)))$, where $n = |x| + |y|$ and $m = |G_x| + |G_y|$, the length of a suffix of x with the minimum edit distance to y among all the suffixes of x, provided that the edit distance of the suffix and y is at most k. If the edit distance of all the suffixes of x to y is more than k then the algorithm stops in the given time and reports that no suffix was found.*

3 Decomposition algorithm

Bhattacharya and Koucký [3] give a string decomposition algorithm (*BK-decomposition algorithm*) that splits its input string into blocks, each block represented by a small grammar. With high probability over the choice of randomness of the algorithm, two strings of length

at most n and edit distance at most k are decomposed so that the number of blocks is the same and at most k corresponding pairs of blocks differ. The edit distance between the two strings corresponds to the sum of edit distances of differing pairs of blocks.

More specifically, the BK-decomposition algorithm gets two parameters n and k, $k \leq n$, and an input x. It selects at random pair-wise independent functions $C_1, \ldots, C_L$ and S-wise independent functions $H_0, \ldots, H_L$ from certain hash families, and using those hash functions it decomposes x into blocks, and outputs a grammar for each of the block. We call the sequence of the produced grammars the *BK-decomposition of* x. Here, parameters $L = \lceil \log_{3/2} n \rceil + 3$ and $S = O(k \log^3 n \log^* n)$. As shown in [3], the algorithm satisfies the following property.

▶ **Proposition 4** (Theorem 3.1 [3]). *Let x be a string of length at most n. The BK-decomposition algorithm outputs a sequence of grammars $G_1, \ldots, G_s$ such that for n large enough:*

1. *With probability at least $1 - 2/n$, $x = \mathrm{eval}(G_1, \ldots, G_s)$.*
2. *With probability at least $1 - 2/\sqrt{n}$, for all $i \in \{1, \ldots, s\}$, $|G_i| \leq S$.*

The randomness of the algorithm is over the random choice of functions $C_1, \ldots, C_L$ and $H_0, \ldots, H_L$.

The functions $C_1, \ldots, C_L$ can be described using $O(\log^2 n)$ bits in total and the S-wise independent functions $H_0, \ldots, H_L$ can be described using $O(S \log^2 n)$ bits in total. We also need the following special case of Theorem 3.12 [3].

▶ **Proposition 5** (Theorem 3.12 [3]). *Let $u, x, y \in \Gamma^*$ be strings such that $|ux|, |y| \leq n$ and $\mathrm{ED}(x, y) \leq k$. Let $G_1^x, \ldots, G_s^x$ and $G_1^y, \ldots, G_{s'}^y$ be the sequence of grammars output by the BK-decomposition algorithm on input ux and y respectively, using the same choice of random functions $C_1, \ldots, C_L$ and $H_0, \ldots, H_L$. With probability at least $1 - 1/5$ the following is true: There exist an integer $r \geq 1$, such that*

$$x = \mathrm{eval}(G^x_{s-s'+1})[r, \ldots] \cdot \mathrm{eval}(G^x_{s-s'+2}, \ldots, G^x_s) \quad \& \quad y = \mathrm{eval}(G^y_1, \ldots, G^y_{s'}),$$

and

$$\mathrm{ED}(x, y) = \mathrm{ED}(\mathrm{eval}(G^x_{s-s'+1})[r, \ldots], \mathrm{eval}(G^y_1)) + \sum_{i=2}^{s'} \mathrm{ED}(\mathrm{eval}(G^x_{s-s'+i}), \mathrm{eval}(G^y_i)).$$

The grammars for x can be built incrementally. For a fixed choice of functions C_i, H_i, and a string x we say that grammars $G_1^x, \ldots, G_t^x$ are *definite* in its BK-decomposition $G_1^x, \ldots, G_s^x$ if for any string z and the BK-decomposition $G_1^{xz}, \ldots, G_{s'}^{xz}$ of xz obtained using the same functions C_i, H_i, $G_1^x = G_1^{xz}$, $\ldots$, $G_t^x = G_t^{xz}$. It turns out that all, but $\widetilde{O}(1)$ last grammars in the BK-decomposition of x are always definite. The following claim appears in [3]:

▶ **Proposition 6** (Lemma 4.2 [3]). *Let n and k be given and $R = O(\log n \log^* n)$ be a suitably chosen parameter. Let $x, z \in \Gamma^*$, $|xz| \leq n$. Let $H_0, \ldots, H_L, C_1, \ldots, C_L$ be given. Let $G_1^x, G_2^x, \ldots, G_s^x$ be the output of the BK-decomposition algorithm on input x, and $G_1^{xz}, G_2^{xz}, \ldots, G_{s'}^{xz}$ be the output of the decomposition algorithm on input xz using the given hash functions.*

1. *$G_i^x = G_i^{xz}$ for all $i = 1 \ldots, s - R$.*
2. *$|x| \leq \sum_{i=1}^{\min(s+R, s')} |\mathrm{eval}(G_i^{xz})|$.*

The following claim bounds the resources needed to update BK-decomposition of x when we append a symbol a to it.

▶ **Proposition 7** (Theorem 5.1 [3]). *Let $k \leq n$ be given and $R = O(\log n \log^* n)$ be a suitably chosen parameter. Let functions $C_1, \ldots, C_L$ and $H_0, \ldots, H_L$ be given. Let $a \in \Sigma$ and $x \in \Sigma^*$ be of length at most n, and let $G_1^x, \ldots, G_s^x$ be the grammars output by the BK-decomposition algorithm on input x using functions $C_1, \ldots, C_L, H_0, \ldots, H_L$.* UpdateActiveGrammars($G^x_{s-\min(s,R+1)+1}, \ldots, G^x_s, a$) *outputs a sequence of grammars $G'_1, \ldots, G'_{t'}$ such that $G^x_1, \ldots, G^x_{s-\min(s,R+1)}, G'_1, \ldots, G'_{t'}$ is the sequence that would be output by the BK-decomposition algorithm on $x \cdot a$ using the same functions $C_1, \ldots, C_L, H_0, \ldots, H_L$. The update algorithm runs in time $\widetilde{O}(k)$ and outputs $t' \leq 4RL$ grammars.*

3.1 Encoding a grammar

Let S and $M = O(S \log n) = O(k \log^4 n \log^* n)$ be parameters determined by the BK-decomposition algorithm. [3] shows that each grammar of size at most S can be encoded as a string of size M over some polynomial-size alphabet $\{1, \ldots, 2\alpha\}$, where the integer α can be chosen so that $2M/\alpha \leq 1/n$. The encoding Enc satisfies that if two grammars differ, their encodings differ in every coordinate. The encoding is randomized, and one needs $O(\log n)$ random bits to select the encoding function. The encoding can be calculated in time linear in M, and given $\mathrm{Enc}(G)$ we can decode G in time $O(M)$. The encoding satisfies:

▶ **Proposition 8.** *Let G, G' be two grammars of size at most S output by BK-decomposition algorithm. Let encoding* Enc *be chosen at random.*

1. $\mathrm{Enc}(G) \in \{1, \ldots, 2\alpha\}^M$.
2. *If $G = G'$ then* $\mathrm{Enc}(G) = \mathrm{Enc}(G')$.
3. *If $G \neq G'$ then with probability at least $1 - (2M/\alpha)$,* $\mathrm{Ham}(\mathrm{Enc}(G), \mathrm{Enc}(G')) = M$, *that is they differ in every symbol.*

3.2 k-mismatch approximate pattern matching

Clifford, Kociumaka and Porat [11] design a streaming algorithm for *k-mismatch approximate pattern matching* with the following properties. The algorithm first reads a pattern P symbol by symbol, and then it reads a text T symbol by symbol. Upon reading each symbol of the text it reports whether the word formed by the last received $|P|$ symbols of the text are within Hamming distance at most k from the pattern. If they are within Hamming distance at most k we can request the algorithm to report the mismatch information between the current suffix of the text and the pattern. The parameters k and n are given to the algorithm at the beginning, where n is an upper bound on the total length of the pattern and the text. By *mismatch information* between two strings x and y of the same length we understand $\mathrm{MIS}(x, y) = \{(i, x[i], y[i]);\ i \in \{1, \ldots, |x|\}$ *and* $x[i] \neq y[i]\}$. So the Hamming distance of x and y is $\mathrm{Ham}(x, y) = |\mathrm{MIS}(x, y)|$. Clifford, Kociumaka and Porat [11] give the following main theorem.

▶ **Proposition 9** ([11]). *There exists a streaming k-*mismatch approximate pattern matching *algorithm which uses $O(k \log n \log(n/k))$ bits of space and takes $O((\sqrt{k \log k} + \log^3 n) \log(n/k))$ time per arriving symbol. The algorithm is randomised and its answers are correct with high probability, that is it errs with probability inverse polynomial in n. For each reported occurrence, the mismatch information can be reported on demand in $O(k)$ time.*

4 Algorithm overview

Now we provide the high-level view of how we proceed. We will take the pattern P and apply on it the BK-decomposition algorithm. That will give us grammars $G_1^P, G_2^P, \ldots, G_r^P$ encoding the pattern. This has to be done incrementally as the symbols of P arrive. Then we will incrementally apply the BK-decomposition algorithm on the text T.

We will not store all the grammars in memory, instead we will use the *K-mismatch approximate pattern matching algorithm* of Clifford, Kociumaka and Porat [11] (*CKP-match algorithm*) on the grammars. Here $K = k \cdot M$, where M is the encoding size of each grammar. For a suitable parameter $R = \widetilde{O}(1)$, we will feed the grammars $G_1^P, \ldots, G_{r-R}^P$ to the CKP-match algorithm as a pattern. In particular, we will encode each grammar by the encoding function Enc from Section 3.1, and we will feed the encoding into the CKP-match algorithm symbol by symbol.

Then as the symbols of the text T will arrive, we will incrementally build the grammars for T while maintaining only a small set of *active* grammars. Grammars that become *definite* will be fed into the CKP-match algorithm as its input text. (Again each one of the grammars encoded by Enc.) The CKP-match algorithm will report *K-mismatch* occurrences of our pattern in the text. Each *K-mismatch* occurrence corresponds to a match of the pattern grammars to the text grammars, with up-to k differing pairs of grammars. We will recover the differing pairs of grammars and calculate their overall edit distance. We will combine this edit distance with the edit distance of the last R grammars of the pattern from the last R grammars of the text. (The last R grammars of the text contain the active grammars which were not fed into the CKP-match algorithm, yet.) If the total edit distance of the match does not exceed the threshold k, we report it as an k-edit occurrence of P in T. If required we can also output the edit operations that transform the pattern into a suffix of T. (Among the current suffixes of T we pick the one which gives the smallest edit distance from P.)

The success probability of our scheme in reporting a particular occurrence of P in T is some constant $\geq 1/2$. Thus, we run the processes in parallel $O(\log n)$ times with independently chosen randomness to achieve small error-probability.

We describe our algorithm in more details next.

5 Description of the algorithm

Now we describe one run of our algorithm. The algorithm receives parameters n and k, based on them it sets parameters $L = O(\log n)$, $R = O(\log n \log^* n)$, $S = O(k \log^3 n \log^* n)$, $M = O(k \log^4 n \log^* n)$, $K = k \cdot M = O(k^2 \log^4 n \log^* n)$. Then it chooses at random pairwise independent functions $C_1, \ldots, C_L$ and S-wise independent functions $H_0, \ldots, H_L$ needed by the BK-decomposition algorithm. It also selects the required randomness for the encoding function Enc. It initializes the CKP-match algorithm for *K-mismatch* approximate pattern matching on strings of length at most $n \cdot M$.

There are two phases of the algorithm. In the first phase the algorithm receives a pattern P symbol by symbol and incrementally builds a sequence of grammars $G_1^P, \ldots, G_r^P$ representing the pattern P. All but the last R grammars are encoded using Enc and sent to our instance of CKP-match algorithm as its pattern (symbol by symbol of each encoding). In the second phase our algorithm receives an input text T symbol by symbol. It will incrementally build a sequences of grammars $G_1^T, G_2^T, \ldots$ representing the received text. Whenever one of the grammars becomes *definite* it is encoded by Enc and sent to our instance of CKP-match algorithm as the next part of its input text (symbol by symbol).

In the first phase, our algorithm uses the procedure given by Proposition 7 to construct the grammars $G_1^P, \ldots, G_r^P$ incrementally by adding symbols of P. The algorithm maintains a buffer of $2R$ *active* grammars which are updated by the addition of each symbol. Whenever the number of active grammars exceeds $2R$ we encode the *oldest* (left-most) grammars that are definite and pass them to our instance of CKP-match algorithm as the continuation of its pattern. The precise details of updating the grammars of the pattern are similar to that of updating them for text which we will elaborate on more. After the input pattern ends, we keep only R grammars $G_{r-R+1}^P, \ldots, G_r^P$, and we send all the other grammars to the CKP-match algorithm. Then we announce to the CKP-match algorithm the end of its input pattern. So the CKP-match algorithm received as its pattern encoding of grammars $G_1^P, \ldots, G_{r-R}^P$ in this order. (In the case we end up with fewer than $R+1$ grammars representing P ($r \leq R$), we apply a *naïve* pattern matching algorithm without need for the CKP-match algorithm. We leave this simple case as an exercise to the reader.) For the rest of this description we assume that $r > R$.

In the second phase, the algorithm will receive the input text T symbol by symbol. It will incrementally build a sequence of grammars representing the text using the algorithm from Proposition 7. We will keep at most R *active* grammars $G_1^a, \ldots, G_t^a$ on which the algorithm from Proposition 7 will be applied. The active grammars represent a current suffix of T. The prefix of T up-to that suffix is represented by grammars $G_1^T, \ldots, G_s^T$ which are definite. Out of those definite grammars we will explicitly store only the last R in a buffer, the other grammars will not be stored explicitly. (They will be used to calculate the current edit distance and to run the update algorithm from Proposition 7.) The encoding of all the definite grammars will be fed into the CKP-match algorithm as its input text whenever we detect that a grammar is definite.

As the algorithm proceeds over the text it calculates a sequence of integers $m_1, m_2, \ldots, m_s$, where the algorithm stores only the last R of them in a buffer. Each value m_i is the minimal edit distance of $\mathrm{eval}(G_1^P, \ldots, G_{r-R}^P)$ (a prefix of the pattern) to any suffix of $\mathrm{eval}(G_1^T, \ldots, G_i^T)$ (a suffix of a prefix of the text) if the edit distance is less than k. m_i is considered infinite otherwise. (Values $m_1, \ldots, m_{r-R-1}$ are all considered to be infinite.) The value m_i will be calculated after G_i^T becomes definite and we send the grammar to our CKP-match algorithm. (The CKP-match algorithm will facilitate its calculation.) Values m_i will be used to calculate the edit distance of the current suffix of the input text received by the algorithm. See Fig. 1 for an illustration.

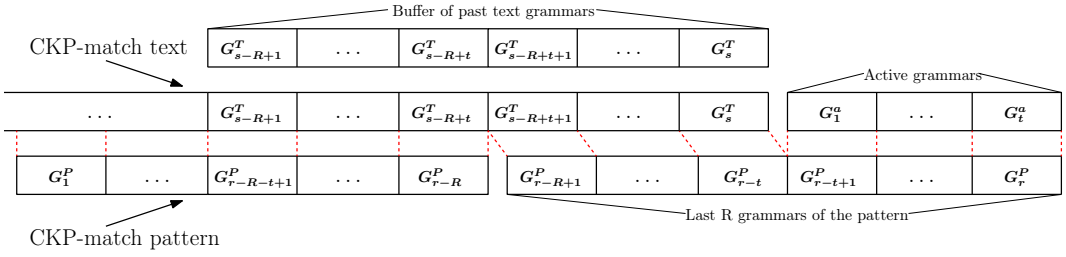

Figure 1 The alignment of text and pattern grammars after arrival of some text symbol. The pattern P is represented by grammars $G_1^P, \ldots, G_r^P$. Grammars $G_1^P, \ldots, G_{r-R}^P$ are encoded by Enc and sent to the CKP-match algorithm as its pattern. The current text T is represented by the sequence of grammars $G_1^T, \ldots, G_s^T, G_1^a, \ldots, G_t^a$. Grammars $G_1^T, \ldots, G_s^T$ are encoded and committed to the CKP-match algorithm as its text. Grammars $G_1^a, \ldots, G_t^a$ are active grammars of the text, and might change as more symbols are added to the text.

We are ready to describe the basic procedures performed by the algorithm.

Symbol arrival. Upon receiving the next symbol a of the input text, our algorithm invokes the algorithm from Proposition 7 on the $R+1$ grammars $G^T_{s-R+t}, \ldots, G^T_s, G^a_1, \ldots, G^a_t$ to append the symbol a. From the algorithm we receive back grammars $G^T_{s-R+t}, \ldots, G^T_s, G'^a_1, \ldots, G'^a_{t'}$, where $t' < 4RL$. (Here, $\mathrm{eval}(G'^a_1, \ldots, G'^a_{t'}) = \mathrm{eval}(G^a_1, \ldots, G^a_t) \cdot a$. The grammars $G^T_{s-R+t}, \ldots, G^T_s$ received from the algorithm are discarded as they are definite and should not change. The update algorithm needs them to have the proper context for compression.) If $t' > R$ then grammars $G'^a_1, \ldots, G'^a_{t'-R}$ become definite and we will *commit* each of them to the CKP-match algorithm as explained further. We will commit them in order $G'^a_1, \ldots, G'^a_{t'-R}$. The remaining grammars $G'^a_{t'-R+1}, \ldots, G'^a_{t'}$ are relabelled as $G^a_1, \ldots, G^a_t$ and become the active grammars for the addition of the next symbol.

At this point our algorithm can output the minimal possible edit distance of the pattern to any suffix of the text received up-to this point. We explain below how such query is calculated.

Committing a grammar. When a grammar G becomes definite the algorithm commits the grammar as follows. Thus far, grammars $G_1, \ldots, G_s$ were committed and the sequence of values $m_1, \ldots, m_s$ was calculated. We set $G_{s+1} = G$, calculate encoding $\mathrm{Enc}(G_{s+1})$ and send the encoding symbol by symbol to our CKP-match algorithm. At this point we can calculate m_{s+1} using the mismatch information provided by our CKP-match algorithm. If $s + 1 < r - R$ then we set m_{s+1} to ∞ otherwise we continue as follows to calculate m_{s+1}.

We query our CKP-match algorithm for the Hamming distance between encoding of $G^P_1, \ldots, G^P_{r-R}$ (the pattern to the CKP-match algorithm) and the encoding of $G^T_{s-r+R+2}$, $G^T_{s-r+R+3}, \ldots, G^T_{s+1}$ (the current suffix of the text of the CKP-match algorithm). If the Hamming distance is less than $K = k \cdot M$, then we let the CKP-match algorithm to recover the mismatch information. By the design of the encoding function, if two grammars differ then their encodings differ in all M positions (unless the encoding function Enc fails which happens only with negligible probability.) Hence, the mismatch information consists of encoding of up-to k pairs of grammars, with their indexes relative to the pattern. Thus, from the mismatch information we recover pairs of grammars $(G_1, G'_1), \ldots, (G_{k'}, G'_{k'})$, for some $k' \leq k$ where G_i come from the text and G'_i come from the pattern.

If (G_1, G'_1) is not the very first grammar pair $(G^T_{s-r+R+2}, G^P_1)$ (which we recognize by their index in the mismatch information) then we compute the edit distance for each pair of strings $\mathrm{eval}(G_i)$ and $\mathrm{eval}(G'_i)$, $i = 1, \ldots, k'$. We set m_{s+1} to be the sum of those distances.

If (G_1, G'_1) is the pair (G^T_{s-R+2}, G^P_1) then we apply the algorithm from Corollary 3 to calculate the minimal edit distance between any suffix of $\mathrm{eval}(G_1)$ and the string $\mathrm{eval}(G'_1)$. For $i = 2, \ldots, k'$, we compute the edit distance of $\mathrm{eval}(G_i)$ and $\mathrm{eval}(G'_i)$. We set m_{s+1} to be the sum of the k' calculated values.

However, if the CKP-match algorithm declares that the Hamming distance of its pattern to its current suffix is more than K, we set $m_{s+1} = \infty$.

Finally, we discard G_{s-r+R} from the buffer of the last R committed grammars, and we discard m_{s-R+2} from the buffer of values m_i. We set s to be $s + 1$. This finishes the process of committing a single grammar G, and a next grammar might be committed.

Pattern edit distance query. After we process the arrival of a new symbol, update the active grammars as described above and commit grammars as necessary, the algorithm is ready to answer the edit distance query on the current suffix of the text T and the pattern P. At this point grammars $G^T_1, \ldots, G^T_s$ were already committed to the CKP-match algorithm. There are current active grammars $G^a_1, \ldots, G^a_t$ which were not committed to the CKP-match

algorithm, and there are R grammars $G^P_{r-R+1}, \ldots, G^P_r$ of the input pattern that were not committed to the CKP-match algorithm as part of its pattern. To answer the edit distance query we will compare the edit distance of those last R grammars of pattern P with the last grammars of the text, and we will combine this with a certain value m_i, namely m_{s-R+t}.

Let $d = R-t$. If $d > 0$, for $i = 1, \ldots, d$ compute the edit distance of each pair $\mathrm{eval}(G^T_{s-d+i})$ and $\mathrm{eval}(G^P_{r-R+i})$. (Each grammar G^T_{s-d+i} is available in the buffer of the last R committed grammars.) For $i = d+1, \ldots, R$, compute the edit distance of each pair $\mathrm{eval}(G^a_{i-d})$ and $\mathrm{eval}(G^P_{r-R+i})$. Sum those R values together with m_{s-d}. If the sum is less than k output it, otherwise output ∞.

Since we are running $O(\log n)$ independent copies of our algorithm, each of the copies produces an estimate on the edit distance and we output the smallest estimate. That is the correct value with high probability.

6 Correctness of the algorithm

In this section we argue that the algorithm produces a correct output. First we analyze the probability of certain bad events happening when the algorithm fails and then we argue the correctness of the output assuming none of the bad events happens. There are several sources of failure in our algorithm.

1. The BK-decomposition algorithm might produce a decomposition of either the pattern or some suffix of the text with a grammar that is too big or with grammars that do not represent expected strings. (A failure of Proposition 4.)
2. The BK-decomposition algorithm produces a correct decomposition of the pattern and all suffixes of the text but grammars of some suffix of the text T and the pattern P do not align well. (A failure of Proposition 5.)
3. The encoding function Enc fails for some pair of grammars produced by the BK-decomposition algorithm that the CKP-match algorithm is supposed to compare. (A failure of Proposition 8.)
4. BK-decomposition algorithm does not fail but the CKP-match algorithm fails to identify a *K-mismatch* occurrence of its pattern or fails to produce correct mismatch information. (A failure of Proposition 9.)

The failure probability of events 1), 3) and 4) will be each bounded by inverse polynomial in n, where n is the parameter sent to those algorithms as an upper bound on the length of the processed strings. Thus, if we expect our algorithm to process a text and a pattern of size at most N, we can set the parameter n for the BK-decomposition algorithm to be N^4 and for the CKP-algorithm to be $N^4 \cdot M = \widetilde{O}(N^5)$, where M is calculated from $n = N^4$ and k of the BK-decomposition algorithm. (Parameter k for the BK-decomposition algorithm is set to k, and for the CKP-algorithm to $K = k \cdot M = \widetilde{O}(k^2)$.) We will run $2 \log N$ independent copies of our algorithm on the same text and pattern. Next we calculate the probability of failure in case 1), 3) and 4) in a particular copy of the algorithm.

Event 1. There is one pattern P of length at most N, the probability of either of the two conditions in Proposition 4 failing on P is at most $4/\sqrt{n} = 4/N^2$. The probability of failure of Proposition 4 on any the at most N prefixes of the text T is at most $N \cdot 4/\sqrt{n} = 4/N$. Thus the probability of the bad event 1) happening is at most $4/N + 4/N^2$.

Event 3. There are at most N grammars of the pattern encoded by Enc and there are at most N grammars of the text encoded by Enc and committed. Thus there are at most N^2 pairs of grammars on which Proposition 8 could fail by encoding two distinct grammars

by strings of Hamming distance less than M (failure in the third part of Proposition 8). Given our setting of parameters, the probability of the bad event 3) happening is at most $N^2/n = 1/N^2$.

Event 4. The probability that the CKP-match algorithm fails during its execution is at most $1/n = 1/N^4$.

Thus, the probability of a failure of 1), 3) or 4) is at most $5/N$, for N large enough. We run $2\log N$ copies of the algorithm so the probability that any of the copies fails because of events 1), 3), or 4) is at most $10\log N/N$.

If none of the events 1), 3) and 4) occurs during the execution of the algorithm then the pattern and the text are correctly decomposed into grammars by the BK-decomposition, the grammars are properly encoded by Enc, and the CKP-match algorithm correctly identifies all the occurrences of the pattern grammars in the committed text grammars, and for each of the occurrences we correctly recover the differing pairs of pattern and text grammars. Assuming this happens, we want to argue that with a high probability our algorithm will correctly identify k-edit occurrences of the pattern P in the text T.

After receiving a prefix of the text $T[1,\ell]$, $\ell \le N$, we want to determine whether some suffix of $T[1,\ell]$ has edit distance at most k from the pattern P. Let a be such that $T[a,\ell]$ has the minimal distance from P. Clearly, if the edit distance between $T[a,\ell]$ and P is at most k then $a \in \{\ell - |P| - k + 1, \dots, \ell - |P| + k + 1\}$. By Proposition 5 applied on $u = T[1, a-1]$, $x = T[a,\ell]$ and $y = P$, each of the $2\log N$ copies of our algorithm has probability at least $4/5$ that the grammars of T are well aligned with grammars of P. Being well aligned means that $T[a,\ell]$ is a suffix of $\mathrm{eval}(G^T_{s-r+t+1}, \dots, G^T_s, G^a_1, \dots, G^a_t)$ and

$$\begin{aligned}\mathrm{ED}(T[a,\ell], P) &= \mathrm{ED}(\mathrm{eval}(G^T_{s-r+t+1})[b,\dots], \mathrm{eval}(G^P_1)) \\ &+ \sum_{i=2}^{r-t} \mathrm{ED}(\mathrm{eval}(G^T_{s-r+t+i}), \mathrm{eval}(G^P_i)) \\ &+ \sum_{i=r-t+1}^{r} \mathrm{ED}(\mathrm{eval}(G^a_{i-r+t}), \mathrm{eval}(G^P_i)),\end{aligned}$$

for appropriate b. Moreover, the minimality of a implies that

$$\begin{aligned}\mathrm{ED}(T[a,\ell], P) &= \min_b \mathrm{ED}(\mathrm{eval}(G^T_{s-r+t+1})[b,\dots], \mathrm{eval}(G^P_1)) \\ &+ \sum_{i=2}^{r-t} \mathrm{ED}(\mathrm{eval}(G^T_{s-r+t+i}), \mathrm{eval}(G^P_i)) \\ &+ \sum_{i=r-t+1}^{r} \mathrm{ED}(\mathrm{eval}(G^a_{i-r+t}), \mathrm{eval}(G^P_i)).\end{aligned}$$

Notice, regardless of whether Proposition 5 fails or not, the right-hand-side of the last equation is always at least $\mathrm{ED}(T[a,\ell], P)$ since it is an upper-bound on the true edit distance of P to some suffix of T. We will argue that each copy of the algorithm outputs the right-hand-side value of that equation if it has value at most k, and ∞ otherwise. Moreover, if at least one of the copies of our algorithm has $T[a,\ell]$ and P well aligned, then the minimum among the values output by the different copies of our algorithm is $\mathrm{ED}(T[a,\ell], P)$.

Since we have $2\log N$ copies of the algorithm, the probability that none of the decompositions aligns $T[a,\ell]$ and P well is at most $(1/5)^{2\log N} < 1/N^4$. This upper-bounds the probability of error of outputting a wrong value of $\min_b \mathrm{ED}(T[b,\ell], P)$ after receiving ℓ symbols of the text. As there will be at most N distinct values of ℓ, the probability of outputting

a wrong estimate of the edit distance of P to some suffix of T is at most $N \cdot 1/N^4 = 1/N^3$, conditioned on none of the bad events 1), 3) or 4) happening. Overall, the probability of a failure of our algorithm is at most $O(\log N/N) \leq 1/\sqrt{N}$, for N large enough, and it could be made an arbitrary small polynomial in N by choosing the parameters differently (n vs N).

It remains to argue that the copy of our algorithm which aligns $T[a,\ell]$ and P well, outputs their edit distance. Consider the copy of the algorithm that aligns grammars of $T[a,\ell]$ and P well. After arrival of the symbol $T[\ell]$ and updating the grammars, there are active grammars $G_1^a,\ldots,G_t^a$, committed grammars $G_1^T,\ldots,G_s^T$ and the pattern grammars $G_1^P,\ldots,G_r^P$. If $\mathrm{ED}(T[a,\ell],P)$ is at most k then the number of grammars in which P differs from the last r grammars of T is at most k. Thus the CKP-match algorithm can identify the differing grammars when computing the value m_{s-R+t} which is set to

$$\begin{aligned} m_{s-R+t} &= \min_b \mathrm{ED}(\mathrm{eval}(G^T_{s-r+t+1})[b,\ldots],\mathrm{eval}(G_1^P)) \\ &+ \sum_{i=2}^{r-R} \mathrm{ED}(\mathrm{eval}(G^T_{s-r+t+i}),\mathrm{eval}(G_i^P)). \end{aligned}$$

Since, $m_{s-R+t} \leq \mathrm{ED}(T[a,\ell],P) \leq k$, we have the true value of m_{s-R+t}. Thus,

$$\begin{aligned} \mathrm{ED}(T[a,\ell],P) &= m_{s-R+t} \\ &+ \sum_{i=r-R+1}^{r-t} \mathrm{ED}(\mathrm{eval}(G^T_{s-r+t+i}),\mathrm{eval}(G_i^P)) \\ &+ \sum_{i=r-t+1}^{r} \mathrm{ED}(\mathrm{eval}(G^a_{i-r+t}),\mathrm{eval}(G_i^P)). \end{aligned}$$

That is precisely how we evaluate the edit distance query of our algorithm.

If $\mathrm{ED}(T[a,\ell],P) > k$ then we will output a value $> k$ as we output some upper bound on the edit distance. Any value $> k$ is treated as the infinity.

7 Time complexity of the algorithm

In the first phase, we incrementally construct the grammars for the pattern P, using the BK-decomposition algorithm from Proposition 7 on each symbol of P at a time. Updating the active grammars for each new symbol takes $\widetilde{O}(k)$ time, committing each of the possible $\widetilde{O}(1)$ definite grammars to the CKP-match algorithm takes $\widetilde{O}(M \cdot \sqrt{K}) = \widetilde{O}(k^2)$. Thus the time needed per arriving symbol of the pattern is $\widetilde{O}(k^2)$.

For each symbol of the text that arrives during the second phase of the algorithm we need to update the active grammars of the text, update m_s, and evaluate the edit distance of the pattern from the current suffix of text. This includes parts *Symbol arrival, Committing a grammar* and *Pattern edit distance query* of the algorithm.

Symbol arrival. Appending a symbol using the BK-decomposition algorithm from Proposition 7 takes $\widetilde{O}(k)$ time.

Committing a grammar. Encoding the grammar takes $O(M)$ time using the algorithm from Proposition 8, and committing it to the CKP-match algorithm takes time $\widetilde{O}(k^2)$, as in the pattern case.

Querying the CKP-match algorithm for Hamming distance K takes $O(K) = \widetilde{O}(k^2)$ time. This recovers at most k pairs of distinct grammars $(G_i, G_i^{'})$, $1 \leq i \leq k$. Computing edit distance k_i of each pair of strings $\mathrm{eval}(G_i)$ and $\mathrm{eval}(G_i^{'})$, takes $\widetilde{O}(S + k_i^2) = \widetilde{O}(k + k_i^2)$ time using Proposition 2. If $\sum_i k_i \leq k$, the total time for the edit distance computation is bounded

by $\widetilde{O}(k^2)$. If the computation runs for longer we can stop it as we know m_s is larger than k. Running the algorithm from Corollary 3 on the first pair of distinct grammars to compute the minimum edit distance between any suffix of eval(G_1) and the string eval(G_1') takes $\widetilde{O}(S + k^2)$ time. Thus committing a grammar takes time at most $\widetilde{O}(k^2)$ where the longest time takes the minimization algorithm on the first pair of grammars.

Pattern edit distance query. This step requires the alignment of the last R grammars of the pattern with the appropriate grammars of the text and computing their edit distances. Using Proposition 2, computing edit distances of R pairs of grammars takes $R \times \widetilde{O}(k^2) = \widetilde{O}(k^2)$ time.

As there are at most $\widetilde{O}(1)$ committed grammars after processing each new symbol, the total time of this step is $\widetilde{O}(k^2)$ per arriving symbol.

8 Space complexity of the algorithm

During either phase of the algorithm, we store $O(RL) = \widetilde{O}(1)$ active and updated grammars and buffer last $O(R)$ committed grammars. This requires space $\widetilde{O}(k)$. Furthermore, the CKP-match algorithm requires $\widetilde{O}(K) = \widetilde{O}(k^2)$ space. The edit distance algorithm of Proposition 2 cannot use more space than its running time so each invocation uses at most $\widetilde{O}(k^2)$ space. Similarly, Corollary 3 uses space $\widetilde{O}(k^2)$. Thus our algorithm uses space at most $\widetilde{O}(k^2)$ at any point during its computation.

On Computing the Vertex Connectivity of 1-Plane Graphs

Abstract

A graph is called *1-plane* if it has an embedding in the plane where each edge is crossed at most once by another edge. A crossing of a 1-plane graph is called an $\times$*-crossing* if there are no other edges connecting the endpoints of the crossing (apart from the crossing pair of edges). In this paper, we show how to compute the vertex connectivity of a 1-plane graph G without $\times$-crossings in linear time.

To do so, we show that for any two vertices u, v in a minimum separating set S, the distance between u and v in an auxiliary graph $\Lambda(G)$ (obtained by planarizing G and then inserting into each face a new vertex adjacent to all vertices of the face) is small. It hence suffices to search for a minimum separating set in various subgraphs Λ_i of $\Lambda(G)$ with small diameter. Since $\Lambda(G)$ is planar, the subgraphs Λ_i have small treewidth. Each minimum separating set S then gives rise to a partition of Λ_i into three vertex sets with special properties; such a partition can be found via Courcelle's theorem in linear time.

1 Introduction

The class of *planar graphs*, which are graphs that can be drawn on the plane without crossings, is fundamental to both graph theory and graph algorithms. Many problems can be more efficiently solved in planar graphs than in general graphs. However, real-world graphs, such as social networks and biological networks, are typically non-planar. But they are often *near-planar*, i.e., close to planar in some sense. One such graph class is the *1-planar graphs*, i.e., graphs that can be drawn on the plane such that each edge is crossed at most once. Introduced in 1965 [28], both structural and algorithmic properties of 1-planar graphs have been studied extensively, see [17, 21] for overviews.

In this paper, we look at the problem of vertex connectivity for 1-planar graphs. The problem of *vertex connectivity* is fundamental in graph theory: given a connected graph G, what is the size (denoted by $\kappa(G)$) of the smallest *separating set*, i.e., set of vertices whose removal makes G disconnected? Vertex connectivity has many applications, e.g. in network reliability and for measuring social cohesion.

Known Results. For an n-vertex m-edge graph G, one can test in linear (i.e. $O(m+n)$) time whether $\kappa(G) \geq 1$ with a graph traversal algorithm. In 1969, Kleitman [20] showed how to test $\kappa(G) \leq k$ in time $O(k^2nm)$. Subsequently, [29] and [18] presented linear-time algorithms to decide k-connectivity for $k = 2$ and $k = 3$ respectively. (Some errors in [18] were corrected in [15].) For $\kappa(G) = 4$, the first $O(n^2)$ algorithm was by Kanevsky and Ramachandran [19]. For $\kappa(G) \in O(1)$, the first $O(n^2)$ algorithm was by Nagamochi and Ibaraki [27]. For general k and m, the fastest running times are $\tilde{O}(n^\omega + nk^\omega)$ [25] and $\tilde{O}(kn^2)$ [16]. (Here, $\tilde{O}(g(n)) = O(g(n)\log^c n)$ for some constant c, and $\omega < 2.372$ is the matrix multiplication exponent.) Both algorithms are randomized and are correct with high probability. The fastest deterministic algorithm takes time $O(m \cdot (n + \min\{k^{5/2}, kn^{3/4}\}))$ [12].

Recent breakthroughs brought the run-time to test k-connectivity down to $\widehat{O}(m + \min\{n^{1.75}k^{1+k/2}, n^{1.9}k^{2.5}\})$ when $k < n^{1/8}$ [13], and to $\tilde{O}(m + nk^3)$ for randomized algorithms [11]. (Here $\widehat{O}(g(n)) = O(g(n)^{1+o(1)})$.) Very recently, Li et al. [24] showed that in fact $\widehat{O}(m)$ run-time can be achieved for randomized algorithms, independent of k. On the other hand, the problem of obtaining a deterministic linear time algorithm for deciding vertex connectivity is still open.

Vertex Connectivity in Planar Graphs. Any simple planar graph G has at most $3n - 6$ edges, hence has a vertex with at most five distinct neighbours, so $\kappa(G) \leq 5$. Since $\kappa(G) \leq 3$ can be tested in linear time, it only remains to test whether $\kappa(G) = 4$ or $\kappa(G) = 5$. In 1990, Laumond [23] gave a linear time algorithm to compute $\kappa(G)$ for maximal planar graphs. In 1999, Eppstein gave an algorithm to test vertex connectivity of all planar graphs in linear time [8]. His algorithm inspired the current work, and so we review it briefly here. Given a planar graph G with a fixed planar embedding (a *plane* graph), let the *radialization* be the plane graph obtained by adding a new vertex inside each face of G and connecting this *face vertex* to all vertices on the boundary of the face. The subgraph formed by the newly added edges is called the *radial graph* $R(G)$ [10]. The following is known.

▶ **Theorem 1** (attributed to Nishizeki in [8]). *Let S be a minimal separating set of a plane graph G. Then there is a cycle C in $R(G)$ with $V(C) \cap V(G) = S$ such that there are vertices of G inside and outside C.*

It hence suffices to find a shortest cycle C in $R(G)$ for which $V(C) \cap V(G)$ is a separating set of G. Since $\kappa(G) \leq 5$, this reduces to the problem of testing the existence of a bounded-length cycle (with some separation properties) in a planar graph. Eppstein solves this in linear time by modifying his planar subgraph isomorphism algorithm suitably [8].

Our Results. In this paper, we consider testing vertex connectivity of near-planar graphs, a topic that to our knowledge has not been studied before. We focus on 1-planar graphs that come with a fixed 1-planar embedding (*1-plane graphs*), since testing 1-planarity is NP-hard [14]. Since a simple 1-planar graph G has at most $4n-8$ edges [3], we have $\kappa(G) \leq 7$. For technical reasons we assume that G has no $\times$-*crossing*, i.e., a crossing without other edges among the endpoints of the crossing edges.

Let G be a 1-plane graph without $\times$-crossings. Inspired by Eppstein's approach, we define a planar auxiliary graph $\Lambda(G)$, and show that G has a separating set of size k if and only if $\Lambda(G)$ has a *co-separating triple* with size- and diameter-restrictions. (Roughly speaking, "co-separating triple" means that the vertices of $\Lambda(G)$ can be partitioned into three sets (A, X, B), such that X separates A, B in $\Lambda(G)$ while simultaneously $X \cap V(G)$ separates $A \cap V(G)$ and $B \cap V(G)$ in G. Detailed definitions are in Section 2.)

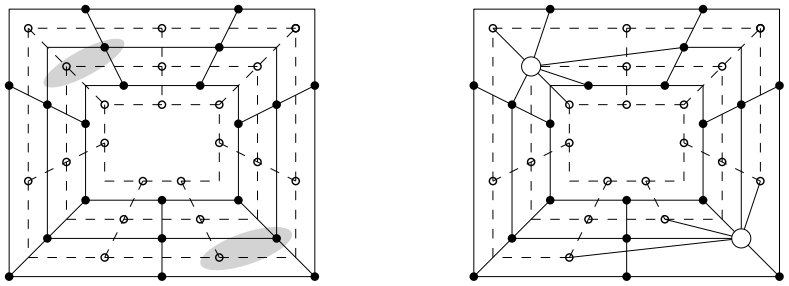

Figure 1 Theorem 2 does not hold for 1-plane graphs with ×-crossings.

▶ **Theorem 2.** *Let G be a 1-plane graph without ×-crossings. Then G has a separating set of size at most k if and only if $\Lambda(G)$ has a co-separating triple (A, X, B) where $|X \cap V(G)| \leq k$ and the subgraph of $\Lambda(G)$ induced by X has diameter at most $4k$.*

Let S be a minimum separating set of G and let (A, X, B) be the co-separating triple derived from S with this theorem. Since vertices of X are close to each other in $\Lambda(G)$, we can project (A, X, B) onto a subgraph $\Lambda_i \subseteq \Lambda(G)$ of diameter $O(|S|)$ to obtain a co-separating triple (A_i, X, B_i) of Λ_i. Conversely, we will show that with a suitable definition of subgraph Λ_i every co-separating triple (A_i, X, B_i) of Λ_i can be extended into a co-separating triple (A, X, B) of $\Lambda(G)$ from which we can obtain $X \cap V(G)$ as a separating set of G. Since Λ_i is planar and has diameter $O(|S|)$, it has treewidth $O(|S|)$. Using standard approaches for graphs of small treewidth, and by $\kappa(G) \leq 7$, we can search for (A_i, X, B_i) in linear time. Therefore we will obtain:

▶ **Theorem 3.** *The vertex connectivity of a 1-plane graph without ×-crossings can be computed in linear time.*

Limitations. We briefly discuss here the difficulty with ×-crossings. Figure 1(a) shows two copies of a graph that are interleaved to produce a 1-planar embedding such that each crossing is an ×-crossing. When these two graphs are fused together by identifying two pairs of vertices that are diametrically opposite to each other (shown by grey blobs in Figure 1(a)), we get the graph G in Figure 1(b). The two fused vertices form a separating set of G. Moreover, this is the only minimum separating set since both graphs in Figure 1(a) are 3-connected. This example can be extended (by adding more concentric layers and more vertices within each layer) to show that the distance between the two fused vertices can be made arbitrarily large even in $\Lambda(G)$. Thus Theorem 2 fails to hold for graphs with ×-crossings, and in consequence our techniques to test vertex connectivity cannot be extended to them.

Organization of the Paper. In Section 2, we lay out the preliminaries, defining co-separating triples and $\Lambda(G)$ for 1-plane graphs. In Section 3, we generalize Theorem 1 to the class of *full 1-plane graphs*, which are 1-plane graphs where the endpoints of each crossing induce the complete graph K_4. Using this result we prove Theorem 2 in Section 4, and turn it into a linear-time algorithm in Section 5. We summarize in Section 6.

2 Preliminaries

We assume familiarity with graphs, see e.g. [7]. All graphs in this paper are assumed to be connected and have no loops. A *separating set* of a graph G is a set S of vertices such that $G \setminus S$ is disconnected; we use the term *flap* for a connected component of $G \setminus S$. Set S *separates* two sets A, B if there is no path connecting A and B in $G \setminus S$. The *vertex connectivity* of G, denoted $\kappa(G)$, is the cardinality of a minimum separating set. For any vertex set A, an *A-vertex* is a vertex that belongs to A; we also write *G-vertex* for a vertex of $V(G)$.

A drawing of a graph in the plane is called *good* if edges are simple curves that intersect only if they properly cross or have a common endpoint, any two edges intersect at most once, and no three edges cross in a point. A *1-planar graph* is a graph that has a good drawing in the plane where each edge is crossed at most once; such a drawing is called a *1-planar drawing* and a graph with a given 1-planar drawing is called a *1-plane graph*. Throughout the paper, we assume that we are given a 1-plane graph G.

Let $\{(u, v), (w, x)\}$ be a crossing in G, i.e., edges (u, v) and (w, x) cross each other. The vertices $\{u, v, w, x\}$ are called *endpoints of the crossing*; these are four distinct vertices since the drawing is good. Two endpoints are called *consecutive* if they are not the two ends of (u, v) or (w, x). We distinguish six types of crossings by whether consecutive endpoints are adjacent (see Figure 2). As in [9], we call a crossing *full* if $\{u, v, w, x\}$ induces K_4, and *almost-full* if $\{u, v, w, x\}$ induces K_4 minus one edge.[1] We call it *bowtie* if $\{u, v, w, x\}$ induces a cycle, *arrow* if $\{u, v, w, x\}$ induces $K_{1,3}$ plus one edge, *chair* if $\{u, v, w, x\}$ induces a path of length three (the *length* of a path is its number of edges), and the crossing is an $\times$-crossing otherwise (no edges connecting consecutive endpoints of the crossing). For an almost-full crossing, there are exactly two consecutive non-adjacent endpoints; we call these the *wing tips* and the other two endpoints the *spine-vertices*. For an arrow crossing, depending on whether an endpoint is adjacent to zero or two of its consecutive endpoints, we call it the *tail* or *tip*; the other two endpoints are the *base vertices*.

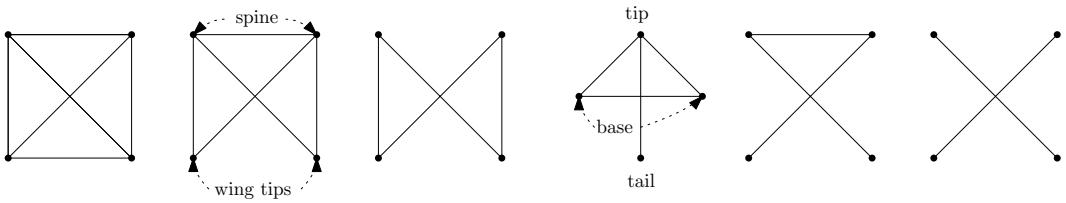

Figure 2 Types of crossings. From left to right: Full, almost-full, bowtie, arrow, chair and $\times$.

The *planarization* of G, denoted $G^\times$, is obtained by replacing any crossing $\{(u, v), (w, x)\}$ with a *dummy vertex*, i.e., remove the crossing edges and insert (at the point where the crossing used to be) a new vertex adjacent to all of u, v, w, x. The resulting drawing is *planar*, i.e., has no crossings. In a planar drawing Γ, a *face* is a maximal region of $\mathbb{R}^2 \setminus \Gamma$. Drawing Γ defines at each vertex v the *rotation* $\rho(v)$, which is the circular list of incident edges and faces, ordered clockwise.

[1] If G has parallel edges, then "$\{u, v, w, x\}$ induces graph H" is intended to mean "the underlying simple graph of the graph induced by $\{u, v, w, x\}$ is H".

Pre-processing. In Figure 2, we assumed that any edge (u, x) between consecutive endpoints of a crossing is actually drawn near that crossing, i.e., $G^\times$ contains a face incident to (u, x) and the dummy vertex of the crossing. (We call such a face a *kite face* and the edge a *kite edge*.) In general this may not be true. But if (u, x) exists elsewhere in the drawing, then we can duplicate it and insert it as a kite edge. This affects neither 1-planarity nor vertex connectivity nor crossing type, so assume from now on that at any crossing all edges among consecutive endpoints exist as kite edges. Since we never create a face of $G^\times$ that is bounded by two edges, graph G continues to have at most $4n - 8$ edges.

Radial Planarization. Recall that Eppstein [8] used the radialization to compute the vertex connectivity of a planar graph. We now generalize this concept to our 1-plane graph G as follows. The *radial planarization*, denoted $\Lambda(G)$, is obtained by first planarizing G to obtain $G^\times$, and then radializing $G^\times$ (see Figure 3). In other words, we add a *face vertex* f inside each face F of $G^\times$, and for every incidence of F with a vertex v we add an edge (v, f), drawn inside F and inserted in the drawing of $\Lambda(G)$ such that it bisects the occurrence of F in the rotation $\rho(v)$. (Repeated incidences of F with v give rise to parallel edges (f, v).) As in [10], we use the term *radial graph* for the subgraph $R(G)$ of $\Lambda(G)$ formed by the edges incident with face vertices. Note that $\Lambda(G)$ has three types of vertices: G-vertices, dummy vertices that replace crossings of G, and face vertices. For a cycle C in $\Lambda(G)$, we define the shortcut $\mathbf{V}_G(C) := V(G) \cap V(C)$ for the G-vertices of C.

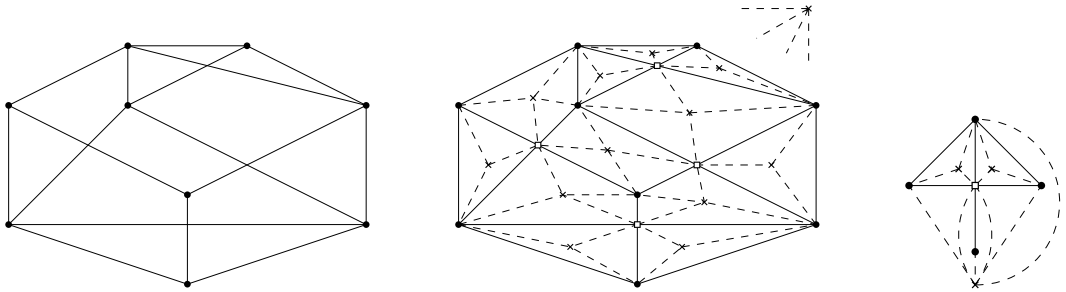

Figure 3 (a) A 1-plane graph G. (b) Its radial planarization $\Lambda(G)$. (c) $\Lambda(G)$ if G is an arrow crossing. Face vertices are crosses, dummy vertices are white squares, edges of $R(G)$ are dashed.

Co-separating Triple. We now clarify what it means to be separating in G and $\Lambda(G)$ simultaneously. We will actually give this definition for an arbitrary graph Λ that shares some vertices with G (since it will later be needed for graphs derived from $\Lambda(G)$).

▶ **Definition 4** (Co-separating triple). *Let Λ be a graph that shares some vertices with G. A partition of the vertices of Λ into three sets (A, X, B) is called a* co-separating triple of Λ *if it satisfies the following properties:*

1. *Each of A, X and B contains at least one G-vertex.*
2. *For any two vertices $a \in A$ and $b \in B$, there is no edge (a, b) in either $E(\Lambda)$ or $E(G)$.*

We say that a co-separating triple of Λ has *diameter* d if any two vertices of X have distance at most d in Λ. When $\Lambda = \Lambda(G)$, then all G-vertices belong to Λ, and since A and B both contain G-vertices the following is immediate:

▶ **Observation 5.** *If (A, X, B) is a co-separating triple of $\Lambda(G)$, then X is a separating set of $\Lambda(G)$ and $X \cap V(G)$ is a separating set of G.*

3 Full 1-Plane Graphs

In this section, we study *full 1-plane graphs*, i.e., 1-plane graphs where all crossings are full. In this case, we will find a co-separating triple (A, X, B) that has a special form (this will be needed in Section 4): Vertex set X contains no dummy vertices, forms a cycle C in $R(G)$, and A and B are exactly the vertices inside and outside this cycle in the planar drawing of $\Lambda(G)$. (In other words, we generalize Theorem 1.)

▶ **Theorem 6.** *Let G be a full 1-plane graph and S be a minimal separating set of G. Then there is a cycle C in $R(G)$ such that C does not visit dummy vertices, $\mathbf{V}_G(C) = S$, and there are vertices of G inside and outside C.*

Proof. The broad idea is to take a maximal path in $R(G)$ that alternates between S-vertices and face vertices with suitable properties, and then close it up into a cycle C of $R(G)$ that separates two vertices of G. Hence C automatically does not visit dummy vertices and $\mathbf{V}_G(C) = S$ since S is minimal. We explain the details now.

Call a face F of $G^\times$ a *transition face* if F is either incident to an edge between two S-vertices, or F is incident to vertices from different flaps of $G \setminus S$. The corresponding face vertex in $\Lambda(G)$ is called a *transition-face vertex*. By walking along the boundary of a transition face, one can easily show the following (see the full version [2]):

▷ Claim 7. Every transition face F contains at least two vertices of S or two incidences with the same vertex of S.

In consequence, any transition-face vertex has (in $R(G)$) two edges to vertices of S. Vice versa, any S-vertex v has (in $R(G)$) two transition-face neighbours, because in the planarization $G^\times$ we transition at v from edges leading to one flap of $G \setminus S$ to edges leading to another flap and back; this can happen only at transition faces. See the full version [2] for a proof of the following claim (and for the formal definition of "clockwise between").

▷ Claim 8. Let (v, t_1) and (v, t_2) be two edges of G such that $v \in S$ and t_1 and t_2 are in different flaps of $G \setminus S$. Then there exists a transition face incident to v that is clockwise between (v, t_1) and (v, t_2).

With this, it is obvious that we can find a simple cycle C that alternates between transition-face vertices and S-vertices, but we need to ensure that C has vertices of G inside and outside, and for this, we choose C more carefully. Formally, let v_1 be an arbitrary S-vertex. Let $P = v_1 \dots v_k$ be a simple path that alternates between transition-face vertices and S-vertices and that is maximal in the following sense: $v_k \in S$, and for any transition-face vertex v_{k+1} adjacent to v_k and any S-vertex v_{k+2} adjacent to v_{k+1}, at least one of v_{k+1}, v_{k+2} already belongs to P. Since $v_k \in S$ and S is minimal, v_k has neighbours t_1, t_2 in different flaps of $G \setminus S$. Applying Claim 8 twice gives a transition face F clockwise between (v_k, t_1) and (v_k, t_2), and a transition face F' clockwise between (v_k, t_2) and (v_k, t_1). If $k > 1$, then (up to renaming of t_1, t_2, F') we may assume that v_{k-1} is the face vertex of F'. Hence for $k > 1$, edge (v_k, f) (where f is the face vertex of F) is not on P, and the same holds vacuously also if $k = 1$. We have cases:

- In the first case, $f \in P$, say $f = v_i$ for some $1 \le i \le k-1$ (Figure 4(a)). Then $C := v_i v_{i+1} \dots v_k v_i$ is a cycle with t_1 and t_2 on opposite sides.
- In the second case $f \notin P$. By Claim 7, $R(G)$ contains at least two edges e, e' that connect f to S-vertices. Up to renaming we may assume that $e = (v_k, f)$. Consider extending P via e and e'. By maximality of P the result is non-simple, and by $f \notin P$ therefore $e' = (f, v_i)$ for some $1 \le i \le k$.

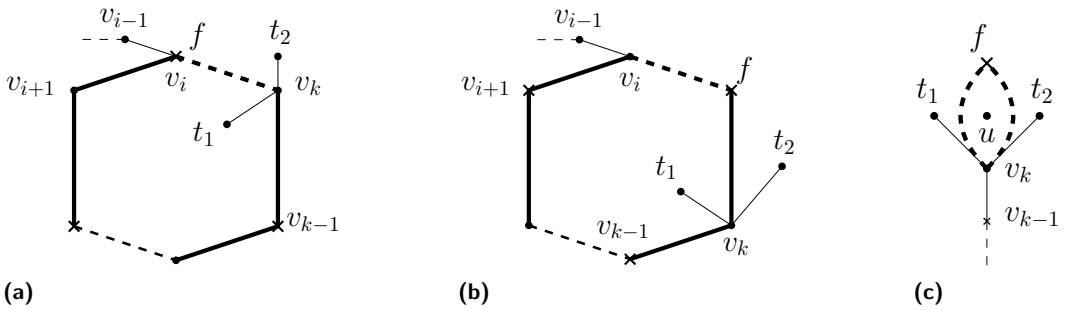

Figure 4 Constructing the cycle C (bold) in $R(G)$.

If $1 \leq i \leq k-1$ (Figure 4(b)), then define simple cycle $C := v_i v_{i+1} \dots v_k f v_i$ and observe that it has t_1 and t_2 on opposite sides. Otherwise ($i = k$) both edges e, e' connect v_k to f (Figure 4(c)), and we let C be the cycle consisting of e and e'. There can be parallel edges incident to f only because face F of $G^\times$ was incident to v_k repeatedly. Edges e, e' were then added to $\Lambda(G)$ in such a way that at least one other G-vertex on the boundary of F lies between those incidences on either side of cycle C.

So in either case we have constructed a cycle C in $R(G)$ with $\mathbf{V}_G(C) \subseteq S$ that does not visit dummy vertices and with two G-vertices (say a and b) inside and outside C. To show that $\mathbf{V}_G(C) = S$, it is sufficient (by minimality of S) to show that $\mathbf{V}_G(C)$ is separating in G. To see this, fix any path π from a to b in G and let π_Λ be the corresponding path in $\Lambda(G)$ obtained by replacing crossings by dummy vertices. Path π_Λ must intersect C, but it uses only G-vertices and dummy vertices while C uses only G-vertices and face vertices, so π_Λ intersects C in a vertex of G and $\mathbf{V}_G(C)$ hence separates a from b in G. ◀

4 1-Plane Graphs Without $\times$-Crossings

In this section, we prove Theorem 2: Minimal separating sets correspond to co-separating triples with small diameter. One direction is easy: If $\Lambda(G)$ has a co-separating triple (A, X, B) with $|V(G) \cap X| \leq k$, then from Observation 5, G has a separating set of size at most k.

Proving the other direction is harder, and we first give an outline. For the rest of this section, fix a minimal separating set S, and two arbitrary flaps ϕ_1, ϕ_2 of $G \setminus S$. We first augment graph G to G_{aug} by adding more edges; this is done to reduce the types of crossings that can exist and thereby the number of cases. (Augmenting the graph is *only* used as a tool to prove Theorem 2; the vertex connectivity algorithm does not use it.) We then find a cycle C for $\Lambda(G_{\text{aug}})$ with vertices of G inside and outside C such that all vertices of S are in the neighbourhood of C. To do so we temporarily modify G_{aug} further to make it a full 1-plane graph G^+_{aug}, appeal to Theorem 6, and show that the resulting cycle can be used for C. By setting $X_{\text{aug}} = V(C) \cup S$, this cycle gives a co-separating triple $(A_{\text{aug}}, X_{\text{aug}}, B_{\text{aug}})$ of $\Lambda(G_{\text{aug}})$, and using C we can argue that the diameter of the graph induced by X_{aug} is small. Finally we undo the edge-additions to transfer the co-separating triple from $\Lambda(G_{\text{aug}})$ to $\Lambda(G)$.

Augmentation. We define the *augmentation* of G with respect to S, ϕ_1, ϕ_2 to be the graph $G_{\text{aug}} := G_{\text{aug}}(S, \phi_1, \phi_2)$ obtained as the result of the following iterative process:

For any two consecutive endpoints u, x of a crossing, if there is no kite edge (u, x) and it could be added without connecting flaps ϕ_1, ϕ_2, then add the kite edge, update the flaps ϕ_1 and ϕ_2 (because they may have grown by merging with other flaps), and repeat.

By construction S remains a separating set with flaps ϕ_1, ϕ_2 in G_{aug}, and it is minimal since adding edges cannot decrease connectivity. Also, one can easily show the following properties of crossings in G_{aug} (here not having $\times$-crossings is crucial), see Figure 5 for an illustration, and the full version [2] for details.

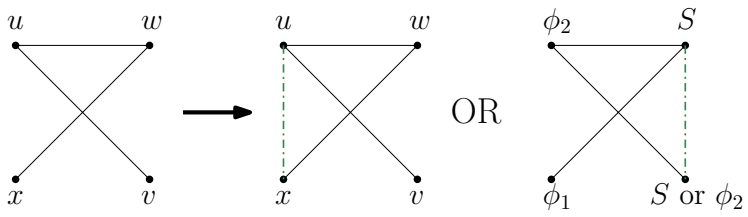

Figure 5 At a chair crossing, we can always add an edge to create an arrow-crossing.

▶ **Observation 9.** *The crossings of $G_{\text{aug}} = G_{\text{aug}}(S, \phi_1, \phi_2)$ have the following properties:*

1. *Any crossing is full, almost-full or an arrow crossing.*
2. *At any almost-full crossing, the spine vertices belong to S and the wing tips belong to ϕ_1 and ϕ_2.*
3. *At any arrow crossing, the tip belongs to S, the tail belongs to one of ϕ_1, ϕ_2, and the base vertices belong to the other of ϕ_1, ϕ_2.*

Extending Theorem 1? Note that we expanded Theorem 1 (for plane graphs) to Theorem 6 (for full 1-plane graphs), but as we illustrate now, it cannot be expanded to 1-plane graphs without $\times$-crossings. One example for this is the graph that exists of exactly one arrow crossing (see Figure 3(c)), because the tip is a separating set, but there is no 2-cycle in $R(G)$ that contains the tip. For an example with higher connectivity, consider Figure 6. The figure shows a 1-plane graph where each crossing is an arrow crossing or a chair crossing. The graph is 4-connected and a minimum separating set S is shown by vertices marked with white disks. One can verify that in the radial planarization of the graph, there is no 8-cycle in $R(G)$ that contains all vertices in S. (This example will also be used later as running example for our approach.)

Cycle C in $\Lambda(G_{\text{aug}})$. So we cannot hope to find a cycle C in $\Lambda(G_{\text{aug}})$ with G-vertices on both sides that goes *exactly* through S. But we can find a cycle C that is "adjacent" to all of S. To make this formal, define for a cycle C in $\Lambda(G_{\text{aug}})$ the set $\mathbf{V}_\times(C)$ to be the set of all vertices of C that are vertices of $G^\times_{\text{aug}}$, i.e., they are G-vertices or dummy vertices of $\Lambda(G_{\text{aug}})$.

▶ **Lemma 10.** *There is a cycle C in $\Lambda(G_{\text{aug}})$ that uses only edges of $R(G_{\text{aug}})$ and such that*
(1) *every vertex in $\mathbf{V}_\times(C)$ is either in S or is a dummy vertex adjacent to an S-vertex,*
(2) *every S-vertex is either in $\mathbf{V}_\times(C)$ or adjacent to a dummy vertex in $\mathbf{V}_\times(C)$,*
(3) *there are G-vertices that are not in S both inside and outside C, and*
(4) *S separates G-vertices inside C from G-vertices outside C in G_{aug}.*

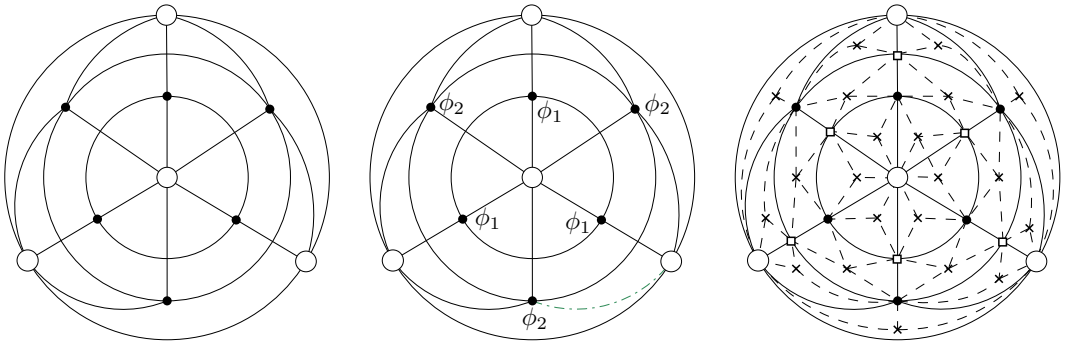

Figure 6 A 4-connected 1-plane graph G, its augmentation G_{aug} with respect to the minimum separating set S (white disks, the added edge is green/dot-dashed), and its radial planarization $\Lambda(G_{\text{aug}})$. Note that the unique chair crossing in G becomes an arrow crossing in G_{aug}. The radial graph does not have an 8-cycle passing through S.

Proof. As outlined, we first convert G_{aug} to a full 1-plane graph G^+_{aug} as follows (see Figure 7 for the abstract construction and Figure 8(a) for the running example): At every almost-full crossing and every arrow crossing, replace the crossing with a dummy vertex. At every arrow crossing, furthermore add a *base edge*, which connects the base vertices and is inserted so that it forms a full crossing. Since every crossing of G_{aug} is full, almost-full or arrow, all crossings of G^+_{aug} are full. We use $D := V(G^+_{\text{aug}}) \setminus V(G)$ for the new vertices and note that every vertex in D is adjacent to an S-vertex and corresponds to a dummy vertex in $\Lambda(G_{\text{aug}})$.

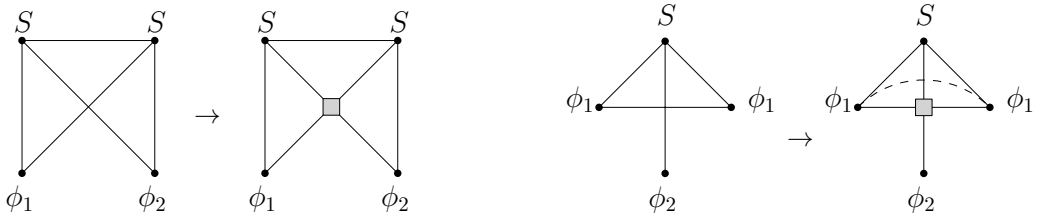

Figure 7 From G_{aug} to G^+_{aug}. Vertices in D are grey squares, the base edge is dashed.

Define $S^+ := S \cup D$ and observe that this is a separating set of G^+_{aug} since no edge of G^+_{aug} connects ϕ_1 with ϕ_2. Apply Theorem 6 to G^+_{aug} and a subset of S^+ that is minimally separating. This gives a cycle C in $R(G^+_{\text{aug}})$ such that $\mathbf{V}_{G^+_{\text{aug}}}(C) \subseteq S^+$, C does not visit dummy vertices of G^+_{aug}, and there are G^+_{aug}-vertices inside and outside C. See Figure 8(b). We claim that C satisfies all conditions, for which we first need to show that it actually is a cycle in $\Lambda(G_{\text{aug}})$. The only difference between $\Lambda(G_{\text{aug}})$ and $\Lambda(G^+_{\text{aug}})$ is at each base edge: Here $\Lambda(G^+_{\text{aug}})$ has an extra vertex c (the dummy vertex for the crossing created by the base edge) and the four incident face vertices, while $\Lambda(G_{\text{aug}})$ has only the two face vertices of the kite faces at the arrow crossing. But by Theorem 6 cycle C does not visit c, so C also is a cycle of $\Lambda(G_{\text{aug}})$.

To see that C satisfies (1), observe that $\mathbf{V}_\times(C) = \mathbf{V}_{G^+_{\text{aug}}}(C) \subseteq S^+ = S \cup D$, and every vertex of D is a dummy vertex of $\Lambda(G_{\text{aug}})$ that is adjacent to an S-vertex. Next we show (3). We know that there exist two vertices $a, b \in V(G^+_{\text{aug}})$ inside and outside C. If $a \in S \cup D$, then inspection of Figure 7 shows that a has a neighbour a' in $\phi_1 \cup \phi_2$ (hence $a' \in V(G)$ but $a' \notin S \cup D$). By $\mathbf{V}_\times(C) \subseteq S \cup D$ therefore a' is on the same side of C as a. Up to renaming hence $a \notin S \cup D$, and likewise $b \notin S \cup D$. This proves (3).

Before proving (2) and (4), we first show that the same vertices a and b are separated (in G_{aug}) by the set S' consisting of all S-vertices that are in $\mathbf{V}_\times(C)$ or adjacent to $\mathbf{V}_\times(C) \cap D$. To do so, pick an arbitrary path π from a to b in G_{aug}. We define a path π^+ in G^+_{aug} that corresponds to π as follows: use the same set of edges of π, except if π used an edge (r, s) that is part of an almost-full or an arrow crossing. At an almost-full crossing, we replace (r, s) by a path r-d-s where $d \in D$ is the dummy vertex. At an arrow crossing we have two cases. If r, s were the base vertices, then we replace (r, s) by the base edge. If r, s were tip and tail, then we replace (r, s) by r-d-s where $d \in D$ is the dummy vertex.

Since π^+ is a path from inside C to outside C in G_{aug}, it contains a vertex $w \in \mathbf{V}_\times(C) \subseteq S \cup D$. If $w \in S$, then define $t := w$. If $w \in D$, then near w path π^+ must have had the form r-w-s for some $(r, s) \in \pi$, due to our construction of π^+. Furthermore, (r, s) either belongs to an almost-full crossing, or to an arrow crossing with (r, s) connecting the tip and tail. For both types of crossings, one of r, s belongs to S, and we define t to be this vertex. So we have found a vertex $t \in S$ on π that is either on $\mathbf{V}_\times(C)$ or adjacent to a dummy vertex $d \in D \cap \mathbf{V}_\times(C)$. Therefore $t \in S'$ and so any path from a to b intersects S'. So $S' \subseteq S$ is a separating set of G_{aug}, hence by minimality $S' = S$, which proves (2). Also the G-vertices a and b are inside and outside C and separated by S, which proves (4). ◀

Notice that this lemma immediately implies a co-separating triple $(A_{\text{aug}}, X_{\text{aug}}, B_{\text{aug}})$ of G_{aug}: Fix such a cycle C, let $X_{\text{aug}} = V(C) \cup S$ and let A_{aug} and B_{aug} be the sets of vertices of $\Lambda(G_{\text{aug}}) \setminus X_{\text{aug}}$ inside and outside C respectively. See Figure 8(c). Clearly this is a partition, and by Lemma 10(3), both A_{aug} and B_{aug} have a G-vertex. As A_{aug} and B_{aug} are on opposite sides of cycle C, $V(C) \subseteq X_{\text{aug}}$ separates A_{aug} and B_{aug} in $\Lambda(G_{\text{aug}})$, and by Lemma 10(4), $S \subseteq X_{\text{aug}}$ separates $A_{\text{aug}} \cap V(G)$ and $B_{\text{aug}} \cap V(G)$ in G_{aug}. Therefore there can be no edge (a, b) with $a \in A_{\text{aug}}$ and $b \in B_{\text{aug}}$ in either $\Lambda(G_{\text{aug}})$ or G_{aug}.

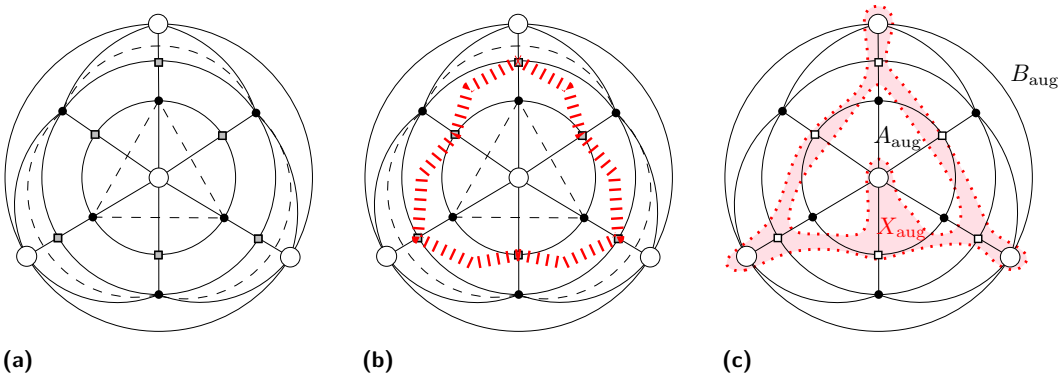

Figure 8 Finding a co-separating triple for the graph G from Figure 6. (a) Graph G^+_{aug}; vertices in D are grey squares and base edges are dashed. (b) Cycle C for the minimal cutting set D; we do not show the face-vertices. Note that every vertex of S is adjacent (in G_{aug}) to a dummy-vertex on C. (c) The resulting co-separating triples $(A_{\text{aug}}, X_{\text{aug}}, B_{\text{aug}})$.

Small Diameter. In order to prove Theorem 2, we first argue that the subgraph of $\Lambda(G_{\text{aug}})$ induced by X_{aug} has small diameter. Clearly the diameter of this graph is in $O(|C|)$ since all vertices of X_{aug} are on C or adjacent to it by Lemma 10(2). However, $|C|$ may not be in $O(|S|)$, which is why we need a more careful analysis to bound the length of a walk connecting two vertices of X_{aug}. Furthermore, to transfer the diameter-bound to $\Lambda(G)$ later, we need to exclude the edges that were added in G_{aug} from such walks. Write $E_{\text{aug}} := E(G_{\text{aug}}) \setminus E(G)$

(in Figure 6 the unique edge in E_{aug} is green/dash-dotted). Recall that edges in E_{aug} are kite edges, hence connect two vertices of G and have no crossing, therefore these edges also exist in $\Lambda(G_{\text{aug}})$.

▶ **Lemma 11.** *For any two vertices $u, v \in X_{aug}$, there is a walk W from u to v in $\Lambda(G_{\text{aug}})$ that has length at most $4|S|$ and does not use edges of E_{aug}.*

Proof. Since $u, v \in X_{\text{aug}}$, they are either in $\mathbf{V}_\times(C)$ (recall that this includes dummy vertices of $\Lambda(G_{\text{aug}})$ on C), or face vertices on C, or in S. In the latter two cases they are within distance one of some vertex in $\mathbf{V}_\times(C)$. So there exist vertices $u', v' \in \mathbf{V}_\times(C)$ that are within distance at most one of u and v, respectively. Enumerate one of the paths between u', v' along cycle C as $x_0, \ldots, x_{2t}$ with $x_0 = u'$ and $x_{2t} = v'$. (Observe that the vertices in $\mathbf{V}_\times(C)$ are exactly the even-indexed ones since C uses edges of $R(G_{\text{aug}})$.) Each vertex x_{2i} for $i = 0, \ldots, t$ is either in S (then set $s_{2i} := x_{2i}$), or by Lemma 10(1) it is a dummy vertex that has a neighbour $s_{2i} \in S$. Define π to be the walk

$$u, u'{=}x_0, s_0, x_0, x_1, x_2, s_2, x_2, x_3, \ldots, x_{2i-1}, x_{2i}, s_{2i}, x_{2i}, x_{2i+1}, \ldots, s_{2t}, x_{2t}{=}v', v,$$

i.e., it is the walk from u to v via C with detours at even-indexed vertices to reach an S-vertex. Observe that π has two properties: (1) At most three consecutive vertices in π do not belong to S, and at the ends there are at most two consecutive vertices not in S; (2) if y, z are two consecutive vertices of π that are different, then at least one of them is a face vertex or a dummy vertex, hence $(y, z) \notin E_{\text{aug}}$. We call a walk that satisfies (1) and (2) an *S-hopping walk*.

Let W be the shortest S-hopping walk from u to v. Observe that W can visit any S-vertex at most once, for otherwise we could find a shorter S-hopping walk by omitting the part between a repeated S-vertex. Since W contains at most three vertices between any two S-vertices, and at most two vertices not in S at the beginning and end, it has length at most $4|S|$. ◀

From G_{aug} to G. We now show how to transform $(A_{\text{aug}}, X_{\text{aug}}, B_{\text{aug}})$ into a co-separating triple (A, X, B) of $\Lambda(G)$ of small diameter. Recall that $G_{\text{aug}} = G \cup E_{\text{aug}}$, so $\Lambda(G_{\text{aug}})$ is obtained from $\Lambda(G)$ by inserting the edges E_{aug} and splitting any face vertex of a face that was divided by an edge in E_{aug}. We undo this in two parts. First, remove the edges of E_{aug} from $\Lambda(G_{\text{aug}})$. This does not affect the separation properties of $(A_{\text{aug}}, X_{\text{aug}}, B_{\text{aug}})$ since we only remove edges, and it maintains the diameter since the walks of Lemma 11 do not use E_{aug}. The second step is to identify face vertices that belong to the same face of G. Define sets A, B, X to be the same as $A_{\text{aug}}, B_{\text{aug}}, X_{\text{aug}}$ except that face vertices that were identified need to be replaced. To do so, observe that A_{aug} and B_{aug} are on opposite sides of C, and so no face vertex of A_{aug} can get identified with a face vertex of B_{aug} unless they both get identified with a face vertex of C. Thus the resulting face vertices come in three kinds: entirely composed of face vertices of A_{aug} (add these to A), entirely composed of face vertices of B_{aug} (add these to B), and containing a face vertex of C (add these to X).

Clearly A, B, X contain vertices of G since $A_{\text{aug}}, B_{\text{aug}}, X_{\text{aug}}$ did and we only identified face vertices. Assume for contradiction that (a, b) is an edge of G or $\Lambda(G)$ for some $a \in A$ and $b \in B$. Then (a, b) is not an edge in G_{aug} or $\Lambda(G_{\text{aug}})$. Thus at least one of a, b must be a face vertex that resulted from identifications. But with our choice of A and B then there was some edge (a', b') in $\Lambda(G_{\text{aug}})$ connecting vertices in A_{aug} and B_{aug}, a contradiction. Thus (A, X, B) is the desired co-separating triple and Theorem 2 holds.

5 Computing Vertex Connectivity in Linear Time

In this section, we show how to use Theorem 2 to obtain a linear time algorithm for finding the vertex connectivity of 1-plane graphs without $\times$-crossings. The crucial insight is that we only need to find the smallest k for which there is a co-separating triple (A, X, B) with $|X \cap V(G)| = k$. Moreover, the subgraph of $\Lambda(G)$ induced by X has small diameter. Therefore we can create some subgraphs $\Lambda_1, \Lambda_2, \ldots$ of $\Lambda(G)$ that have small treewidth and X belongs to at least one subgraph. (We assume that the reader is familiar with treewidth and its implications for algorithms; see for example [4] or the full version [2].) We can search for a co-separating triple within these subgraphs using standard approaches for graphs of bounded treewidth, quite similar to the planar subgraph isomorphism algorithm by Eppstein [8].

The Graphs Λ_i. As a first step, we perform a breadth-first search in $\Lambda(G)$ starting at an arbitrary vertex (the *root*); let T be the resulting BFS-tree. For $j = 1, 2, \ldots$ let V_j (the *jth layer*) be the vertices at distance $j-1$ from the root, and let d be the largest index where V_j is non-empty. Define $V_j := \emptyset$ for any index $j < 1$ or $j > d$. For any $a \leq b$, the notation $\Lambda[V_a \cup \cdots \cup V_b]$ will be a shortcut for the subgraph of $\Lambda(G)$ induced by $V_a \cup \cdots \cup V_b$.

Assume that we know the size $k \leq 7$ of the separating set that we seek (we will simply try all possibilities for k later). Define $w = 4k + 2 \leq 30$, so we know that any two vertices in X (of some putative co-separating triple (A, X, B) that satisfies the conclusion of Theorem 2) have distance at most $w - 2$ in $\Lambda(G)$. Hence X belongs to $V_{i+1} \cup \ldots \cup V_{i+w-2}$ for some $i \in \{0, \ldots, d-w+2\}$. Thus we will search for X within $\Lambda[V_{i+1} \cup \ldots \cup V_{i+w-2}]$, but to guarantee that there are vertices representing A and B we also keep two extra layers above and below (i.e., layers $V_{i-1}, V_i, V_{i+w-1}, V_{i+w}$). Furthermore, we add an edge set U_{i-1} ('upper edges') within V_{i-1} and an edge set L_{i+w} ('lower edges') within V_{i+w} that have some special properties.

▷ Claim 12. For $i \in \{0, \ldots, d-w+2\}$, there exist sets of edges U_{i-1} (connecting vertices of V_{i-1}) and L_{i+w} (connecting vertices of V_{i+w}) such that the following holds:

1. Two vertices $u, v \in V_{i-1}$ can be connected via edges of U_{i-1} if and only if there exists a path in $\Lambda[V_1 \cup \cdots \cup V_{i-1}]$ that connects u and v.
2. Two vertices $u, v \in V_{i+w}$ can be connected via edges of L_{i+w} if and only if there exists a path in $\Lambda[V_{i+w} \cup \cdots \cup V_d]$ that connects u and v.
3. The graph $\Lambda_i := \Lambda[V_{i-1} \cup \ldots \cup V_{i+w}] \cup U_{i-1} \cup L_{i+w}$ is planar and has radius at most $w+2$.

Furthermore, $\sum_{j=0}^{d-w+2} |U_j| + |L_j| \in O(n)$ and we can compute these sets in time $O(n)$.

Proof. For U_{i-1}, this is easy. If $i = 0, 1$ then V_{i-1} is empty and $U_{-1} = \emptyset$ works. Otherwise, pick an arbitrary vertex r_{i-1} in V_{i-1}, and let U_{i-1} be the edges that connect r_{i-1} to all other vertices of V_{i-1}. In consequence, all vertices of V_{i-1} can be connected within U_{i-1}, but this is appropriate since they can all be connected within the BFS-tree T, using only layers $1, \ldots, i-1$ of T. Graph $\Lambda[V_{i-1} \cup \cdots \cup V_{i+w}] \cup U_{i-1}$ is planar, because it can be obtained from the planar graph $\Lambda[V_1 \cup \cdots \cup V_{i+w}]$ by first contracting every vertex in layers $2, \ldots, i-2$ into its parent in T (yielding one super-node at the root), and then contracting this super-node into r_{i-1}.

For L_{i+w}, existence likewise is easy (and was argued by Eppstein [8]): Simply contract any edge of $\Lambda[V_{i+w} \cup \cdots \cup V_d]$ that has at least one endpoint not in V_{i+w}, and let L_{i+w} be the edges within V_{i+w} that remain at the end. However, it is not obvious how one could implement contraction in overall linear time; we give an alternate approach for this in the full version [2].

Since both U_{i-1} and L_{i+w} can be seen as obtained via contractions, graph Λ_i is planar. To prove the radius-bound, define r to be r_{i-1} if $i \geq 2$ and to be the root of T otherwise. Any vertex $v \in \Lambda_i$ has distance at most $w+2$ from r, because we can go upward from v in T at most $w+1$ times until we either reach a vertex v in V_{i-1} (which is $r=r_{i-1}$ or adjacent to it due to U_{i-1}), or $i \in \{0,1\}$ and we reach the root of T (which is r). ◁

An example of graph Λ_i is given in the full version [2].

Co-separating Triples in Λ_i. We continue to assume that we know $k \leq 7$ (and hence $w = 4k+2 \leq 30$). Crucial for the correctness of our search for a co-separating triple in $\Lambda(G)$ is that it suffices to search in Λ_i for all i.

▶ **Lemma 13.** *There exists a co-separating triple (A, X, B) of $\Lambda(G)$ with diameter k if and only if there exists an index $i \in \{0, \ldots, w-d+2\}$ and a co-separating triple (A_i, X, B_i) of Λ_i with diameter k for which $X \subseteq \Lambda[V_{i+1} \cup \cdots \cup V_{i+w-2}]$.*

Proof. Let (A, X, B) be a co-separating triple of $\Lambda(G)$. Since X has diameter at most $w-2$, all vertices of X lie in the layers $i+1, \ldots, i+w-2$ for some index i. Let A_i and B_i be subsets of A and B restricted to the vertices of Λ_i. We now show that (A_i, X, B_i) is a co-separating triple of Λ_i. Clearly these sets partition Λ_i. Condition 1 ('each set contains a G-vertex') clearly holds for X. To see that it holds for A_i, consider graph G in which $X \cap V(G)$ separates non-empty sets $A \cap V(G)$ and $B \cap V(G)$. Since G is connected, there exists an edge (a, x) with $a \in A \cap V(G)$ and $x \in X \cap V(G)$. This edge may or may not exist in $\Lambda(G)$, but if it does not then it got replaced by a-c-x with a dummy vertex c. So a has distance at most two from a vertex in $V_{i+1} \cup \cdots \cup V_{i+w-2}$ and hence belongs to $V_{i-1} \cup \cdots \cup V_{i+w}$, and so to Λ_i and to A_i. The argument is symmetric for B_i.

Now we argue Condition 2 ('no edges between A_i and B_i in Λ_i or G'). Fix two vertices $a \in A_i$ and $b \in B_i$. Since $A_i \subseteq A$ and $B_i \subseteq B$, there is no edge (a, b) in either $\Lambda(G)$ or G. So we are done unless (a, b) is an edge of U_{i-1} or L_{i+w}. Assume $(a, b) \in L_{i+w}$, the other case is similar. By Claim 12(2), there exists a path π in $\Lambda[V_{i+w} \cup \cdots \cup V_d]$ connecting a and b. No vertex of π belongs to X, and so the vertices of π either all belong to A or all belong to B since (A, X, B) is co-separating. This contradicts $a \in A$ and $b \in B$.

We now prove the other direction. Let (A_i, X, B_i) be a co-separating triple of some Λ_i with $X \subseteq \Lambda[V_{i+1} \cup \cdots \cup V_{i+w-2}]$. We define A and B as follows. Begin with all vertices in A_i and B_i, respectively; with this all vertices in Λ_i belong to one of A, X, B. Now consider any vertex v that does not belong to Λ_i, so either $v \in V_1 \cup \cdots \cup V_{i-2}$ or $v \in V_{i+w+1} \cup \cdots \cup V_d$. Assume the latter (the other case is similar), and let K be the component of $\Lambda[V_{i+w} \cup \cdots \cup V_d]$ that contains v. By Claim 12(2), there exists a component K' of graph (V_{i+w}, L_{i+w}) that contains exactly the vertices of $K \cap V_{i+w}$. The vertices of K' must either all be in A_i, or they must all be in B_i, because they are in layer V_{i+w} (so not in X) and they are connected via L_{i+w}. Assign v (and actually all vertices of K) to A if $V(K') \subseteq A_i$, and to B otherwise.

We now show that partition (A, X, B) is a co-separating triple of $\Lambda(G)$. Clearly Condition 1 holds since already A_i and B_i contain G-vertices. To show Condition 2, consider two vertices $a \in A$ and $b \in B$ and assume for contradiction that there is an edge (a, b) in either G or $\Lambda(G)$. This means that at least one of a, b is not in $V_{i-1} \cup \cdots \cup V_{i+w}$, else edge (a, b) would contradict that (A_i, X, B_i) was co-separating in Λ_i. Say $a \in V_{i+w+1} \cup \cdots \cup V_d$, all other cases are similar. With this it is impossible that (a, b) is an edge of $\Lambda(G)$: Such an edge would put a, b into the same component of $\Lambda[V_{i+w} \cup \cdots \cup V_d]$, but by construction of A and B we know that all vertices of such a component are put into the same set of A and B.

So (a, b) must be an edge of $G \setminus \Lambda(G)$, which means that it is crossed. Let c be the dummy vertex on (a, b). If $c \in A$ then (c, b) is an edge of $\Lambda(G)$ with endpoints in A and B, which we proved impossible already. Likewise $c \in B$ is impossible, so we must have $c \in X$. But then $c \in V_{i+1} \cup \cdots \cup V_{i+w-2}$, which puts its neighbour a into $V_i \cup \cdots \cup V_{i+w-1}$, a contradiction. ◀

Subroutine (To Find a Separating Set of Size k). We continue to assume that we know $k \leq 7$ (and hence $w = 4k + 2 \leq 30$). We also assume that edge-sets U_j and L_j have been computed already for all possible indices j, and that the edges of $\Lambda(G)$ have been split into $2d + 1$ sets $E_0, E_{0,1}, \ldots, E_{d-1,d}, E_d$ where E_j (for $j = 0, \ldots, d$) are all edges within layer V_j while $E_{j-1,j}$ (for $j = 1, \ldots, d$) are all edges connecting V_j to V_{j+1}. Perform the following for $i = 0, \ldots, d-w+2$:

1. Compute Λ_i. This takes time $O(|E(\Lambda_i)|)$ time: The vertices are $V_{i-1} \cup \cdots \cup V_{i+w}$, the edges are $U_{i-1} \cup E_{i-1,i} \cup E_i \cup \cdots \cup E_{i+w-1,i+w} \cup L_{i+w}$, and all these sets are pre-computed.
2. Since Λ_i is a planar graph with radius at most $w + 2$, it has treewidth $O(w)$ [8] and a corresponding tree decomposition $\mathcal{T}$ can be found in $O(|E(\Lambda_i)|)$ time. We may also assume that $\mathcal{T}$ has $O(|\Lambda_i|)$ bags.
3. We want to express Condition 2 of a co-separating triple as a condition in a single graph, and so define Λ_i^+ as follows: Begin with graph Λ_i, and add to it any edge (v, w) of G that is crossed (so is replaced in $\Lambda(G)$ by a path v-c-w via dummy vertex c) and for which v, w, c all belong to Λ_i.
4. Create a tree decomposition $\mathcal{T}^+$ of Λ_i^+ as follows. Begin with $\mathcal{T}$. For any bag Y and any dummy vertex $c \in Y$, add to Y all neighbours of c that belong to Λ_i. One can argue that this is a tree decomposition of Λ_i^+ of width $O(5w) = O(1)$, and can be computed in $O(|\mathcal{T}|) = O(|\Lambda_i|)$ time, see the full version [2].
5. Test whether Λ_i has a co-separating triple (A, X, B) for which X contains exactly k vertices of G and lies within $V_{i+1} \cup \cdots \cup V_{i+w-2}$. One can show (see the full version [2]) that this can be expressed in *monadic second-order logic*, using graph Λ_i^+ for defining adjacencies. By Courcelle's famous theorem [6], since Λ_i^+ has a tree decomposition of constant width, therefore the test can be done in $O(|\mathcal{T}^+|) = O(|\Lambda_i|)$ time.
6. If we find such a co-separating triple, then break (and output $X \cap V(G)$ as a separating set of size k), else try the next i.

The run-time for one index i is hence $O(|E(\Lambda_i)|)$. To bound the total run-time, we must bound $\sum_{i=0}^{d} |E(\Lambda_i)|$. Since each Λ_i uses $w+2$ consecutive layers, any edge of $\Lambda(G)$ belong to at most $w + 2$ sets in $E(\Lambda_0), \ldots, E(\Lambda_{d-w+1})$. Any edge in $U_0, \ldots, U_d, L_0, \ldots, L_d$ belongs to exactly one set in $E(\Lambda_0), \ldots, E(\Lambda_{d-w+1})$. Therefore $\sum_{i=0}^{d-w+1} |E(\Lambda_i)| \leq (w + 2)|E(\Lambda(G)| + \sum_{i=0}^{d-w+1}(|U_i| + |L_i|) \in O(w|E(\Lambda(G))|) + O(n)$, which by $w \in O(1)$ and $|E(\Lambda(G)| \in O(n)$ shows that the total run-time is linear.

The Final Algorithm. The algorithm for testing vertex-connectivity hence proceeds as follows. First pre-process G and duplicate edges to become kite edges where required. Then compute $\Lambda(G)$, the BFS-tree and the layers, and the edge-sets $E_j, E_{j,j+1}$, U_j and L_j for $j = 0, \ldots, d+2$. All this takes $O(n)$ time since $\Lambda(G)$ has $O(n)$ edges. For $k = 1, \ldots, 7$, run the sub-routine to test whether there exists a separating set of size k; this will necessarily find the minimum such set. Each such run takes time $O(n)$, and since there is a constant number of them the overall time is linear and Theorem 3 holds.

6 Outlook

In this paper, we showed that the vertex connectivity of a 1-plane graph G without $\times$-crossings can be computed in linear time. The main insight is that the distance (in an auxiliary graph) between any two vertices of a minimum separating set of G must be bounded. We close with some open questions. First, can we deal with $\times$-crossings?

▶ **Open problem 1.** *Can the vertex connectivity of an arbitrary 1-plane graph be computed in linear time?*

In our 'bad example' (Figure 1), *all* crossings were $\times$-crossings. As a first step towards Problem 1, could we at least compute the vertex connectivity in linear time if the number of $\times$-crossings is bounded by a constant?

Throughout the paper, we assumed that the input came with a fixed 1-planar embedding. We did this since testing 1-planarity is NP-hard [14]. However, it might be easier to test whether there exists a 1-planar embedding without $\times$-crossing; all the existing NP-hardness proofs of 1-planarity that we are aware of [14, 22, 1, 5] have $\times$-crossings in the 1-planar drawings.

▶ **Open problem 2.** *Is it NP-hard to test whether a given graph has a 1-planar drawing without $\times$-crossing?*

The crucial ingredient for our result was the structural property that vertices of a separating set are close in some sense. Are there similar structural properties for edge connectivity or bisections? Are there similar results for other classes of near-planar graphs?

Abstract

We study the problem of estimating the ST-diameter of a graph that is subject to a bounded number of edge failures. An *f-edge fault-tolerant ST-diameter oracle* (f-FDO-ST) is a data structure that preprocesses a given graph G, two sets of vertices S, T, and positive integer f. When queried with a set F of at most f edges, the oracle returns an estimate $\widehat{D}$ of the ST-diameter $\operatorname{diam}(G-F, S, T)$, the maximum distance between vertices in S and T in $G-F$. The oracle has stretch $\sigma \geqslant 1$ if $\operatorname{diam}(G-F, S, T) \leqslant \widehat{D} \leqslant \sigma \operatorname{diam}(G-F, S, T)$. If S and T both contain all vertices, the data structure is called an *f-edge fault-tolerant diameter oracle* (f-FDO). An *f-edge fault-tolerant distance sensitivity oracles* (f-DSO) estimates the pairwise graph distances under up to f failures.

We design new f-FDOs and f-FDO-STs by reducing their construction to that of *all-pairs* and *single-source* f-DSOs. We obtain several new tradeoffs between the size of the data structure, stretch guarantee, query and preprocessing times for diameter oracles by combining our black-box reductions with known results from the literature.

We also provide an information-theoretic lower bound on the space requirement of approximate f-FDOs. We show that there exists a family of graphs for which any f-FDO with sensitivity $f \geqslant 2$ and stretch less than $5/3$ requires $\Omega(n^{3/2})$ bits of space, regardless of the query time.

1 Introduction

The diameter, i.e., the largest distance between any two vertices, is one of the most fundamental graph parameters for it measures how fast information can spread in a network. The problem of approximating the diameter of a given graph in a time-efficient manner has been extensively studied [1, 3, 4, 25, 26, 27, 43, 44, 45]. Here, we investigate the diameter computation problem in the fault-tolerant model. The interest in this setting stems from the

fact that most real-world networks are prone to errors. These failures, though unpredictable, are transient due to some simultaneous repair process that is undertaken in these applications. This has motivated the research on designing fault-tolerant oracles for various graph problems in the past decade. An *f-edge/vertex fault-tolerant oracle* is a compact data structure that can quickly report the desired solution or graph property of the network on occurrence of up to f edge/vertex failures. The parameter f that describes the degree of robustness against errors is known as the *sensitivity* of the oracle. A lot of work has been done in designing fault-tolerant structures for various problems like connectivity [20, 32, 33], finding shortest paths [2, 12, 36], and distance sensitivity oracles [5, 7, 14, 24, 30, 31, 34, 47].

While the fault-tolerant model has been studied a lot for distances, the landscape of fault-tolerant diameter oracles is far less explored. For a given graph $G = (V, E)$ and two sets $S, T \subseteq V$ of vertices, an *f-edge fault-tolerant diameter oracle* (f-FDO-ST) is a data structure that stores information about G after a preprocessing step. When queried with a set F of at most f edges, the oracle returns an upper bound of the ST-diameter $\operatorname{diam}(G - F, S, T) = \max_{s \in S, t \in T} d_{G-F}(s, t)$ of $G - F$. This is the maximum among all s-t-distances for $s \in S$ and $t \in T$ under the condition that none of the shortest paths can use an edge in the query set F. We say that the oracle has a stretch of $\sigma \geqslant 1$ if the value $\widehat{D}$ returned upon query F satisfies $\operatorname{diam}(G - F, S, T) \leqslant \widehat{D} \leqslant \sigma \operatorname{diam}(G - F, S, T)$. When $S = T = V$, the data structure is called an *f-edge fault-tolerant diameter oracle* (f-FDO).

The problem of designing f-FDOs was originally raised by Henzinger, Lincoln, Neumann, and Vassilevska Williams [40] and has recently been studied by Bilò, Cohen, Friedrich, and Schirneck [17] and the same authors together with Choudhary [15], see also Section 1.1.

The problem of designing f-FDO-ST can be seen as a generalisation of the Bichromatic Diameter, a problem in which the two sets S and T form a partition of V. The latter problem is motivated by several related, well-studied problems in computational geometry, e.g., Bichromatic Diameter on point sets (commonly known as Bichromatic Farthest Pair), where one seeks to determine the farthest pair of points in a given set of points in space. The problem of Bichromatic Diameter was studied by Dalirrooyfard, Vassilevska Williams, Vyas, and Wein [28].

Given the plethora of work on distance oracles and the close connection between the distance and the diameter problem, a natural question is if we can convert the results on distance computation under failures into analogous oracles for the diameter without sacrificing much on our performance parameters.

▶ **Question.** *Are there black-box reductions from fault-tolerant diameter oracles to fault-tolerant distance oracles without considerable overhead in stretch, query time, and space?*

In this work, we present several such reductions and, from them, conclude trade-offs between the space, stretch, preprocessing, and query time for diameter oracles. In more detail, our techniques for obtaining upper bounds is by presenting reductions to the problem of constructing *f-edge fault-tolerant distance sensitivity oracles* (f-DSOs) in two widely studied categories. The *all-pairs* variant can be queried with any pair of vertices $s, t \in V$ and set $F \subseteq E$ of f failures and reports (an estimate) of the distance $d_{G-F}(s, t)$ between s and t in $G - F$. In the *single-source* variant, the source s is fixed and the set of allowed queries consists of the target vertices t together with a set F of failures.

For the regular diameter ($S = T = V$), we provide two theorems showing that both all-pairs and single-source f-DSOs can be used to construct f-FDOs.

Table 1 Properties of the f-FDOs obtained via Theorem 1 using all-pairs f-DSOs from the literature. The applicable graph class (un-/directed, un-/weighted) is determined by the f-DSO. W denotes the maximum edge weight for graphs with arbitrary positive weights, M is the maximum edge weight for integer weighted graphs. The parameter $k \geqslant 1$ is a positive integer, $\varepsilon > 0$ a positive real, $\alpha \in [0, 1]$ is a real number in the unit interval, and $\omega < 2.37286$ denotes the matrix multiplication exponent.

▶ **Theorem 1.** *Let G be a (undirected or directed) graph with n vertices, m edges, and possibly positive edge weights. Given access to an f-DSO $\mathcal{D}$ for G with stretch $\sigma \geqslant 1$, preprocessing time $\mathtt{P}$, space $\mathtt{S}$, and query time $\mathtt{Q}$, one can construct an f-FDO for G with stretch $1+\sigma$, preprocessing time $O(\mathtt{P} + mn\log n)$, space $O(\mathtt{S})$, and query time $O(f^2\mathtt{Q})$.*

In Section 1.2, we review existing all-pairs f-DSOs. By applying the reduction stated in Theorem 1 we obtain new f-FDOs as listed in Table 1.

The following theorem shows how we can use the single-source variant of distance sensitivity oracles to construct f-FDOs.

▶ **Theorem 2.** *Let G be a (undirected or directed) graph with n vertices, m edges, and possibly positive edge weights. Given access to a single-source f-DSO $\mathcal{D}$ for G with stretch $\sigma \geqslant 1$, preprocessing time $\mathtt{P}$, space $\mathtt{S}$, and query time $\mathtt{Q}$, one can construct an f-FDO for G with stretch $2(1+\sigma)$, preprocessing time $O(\mathtt{P})$, space $O(\mathtt{S})$, and query time $O(f\mathtt{Q})$.*

Section 1.3 discusses single-source f-DSOs from the literature. Together with Theorem 2 they give new f-FDOs, summarized in Table 2.

The main technical contribution of this work, however, is a novel fault-tolerant data structure for the more general ST-diameter problem that was introduced and studied in recent years. For example, Backurs, Roditty, Segal, Vassilevska Williams, and Wein [4] proved that for any undirected graph one can compute a 3-approximation of the ST-diameter in $O(mn)$ time. They also provided a randomized algorithm that computes a 2-approximation of the ST-diameter in $\widetilde{O}(m\sqrt{n})$ time.[1] Dalirrooyfard, Vassilevska Williams, Vyas, and Wein [28] studied the problem of computing the bi-chromatic ST-diameter, the special case of ST-diameter problem where the sets S and T form a partition of V. Similar to f-FDOs, we explore the problem of designing compact oracles that report the ST-diameter of a graph after occurrences of up to f failures. We present reductions between f-DSOs and f-FDO-STs, as stated in the following theorem. To the best of our knowledge, our paper is the first work that provides some results on f-FDO-STs, for general values of f.

[1] For a non-negative function $g(n, m, f)$, we write $\widetilde{O}(g)$ for $O(g \cdot \mathsf{polylog}(n))$.

Table 2 Properties of the f-FDOs obtained via Theorem 2 using single-source f-DSOs from the literature. The applicable graph class (un-/directed, un-/weighted) is determined by the single-source f-DSO. W denotes the maximum edge weight for graphs with arbitrary positive weights, M is the maximum edge weight for integer weighted graphs. The parameter $\varepsilon > 0$ is a positive real and $\omega < 2.37286$ denotes the matrix multiplication exponent.

Sensitivity	Stretch	Space	Query time	Preprocessing Time	Ref.
1	4	$\widetilde{O}(n^{3/2})$	$\widetilde{O}(1)$	$\widetilde{O}(mn^{1/2}+n^2)$	[16, 38]
1	4	$\widetilde{O}(n^{3/2}M^{1/2})$	$\widetilde{O}(1)$	$\widetilde{O}(n^{\omega}M)$	[16]
1	$4+\varepsilon$	$\widetilde{O}(n(\log W)\varepsilon^{-1})$	$O(\log\log_{1+\varepsilon}(nW))$	$\mathsf{poly}(n)$	[5, 8, 13]
1	6	$O(n)$	$O(1)$	$\widetilde{O}(mn)$	[13]
$f \geqslant 1$	$4f+4$	$\widetilde{O}(fn)$	$\widetilde{O}(f^3)$	$\widetilde{O}(fm)$	[14]

▶ **Theorem 3.** *Let $G=(V,E)$ be an undirected graph with n vertices, m edges, and possibly positive edge weights. Let $S,T \subseteq V$ be two non-empty sets. Given access to an f-DSO for G with stretch $\sigma \geqslant 1$, preprocessing time $\mathtt{P}$, space $\mathtt{S}$, and query time $\mathtt{Q}$, one can compute an f-FDO-ST for G with preprocessing time $\mathtt{P}+\widetilde{O}(mn+n|S||T|)$ and stretch $1+3\sigma$. Additionally, the f-FDO-ST has the following properties.*

- *If the sensitivity is $f=o(\log n)$, the oracle requires $\mathtt{S}+O(n^{3/2}(2^f+\log n))$ space and has a query time of $O(f^2(2^f+\mathtt{Q}))$.*
- *If $f=\Omega(\log n)$, the oracle requires $\mathtt{S}+O(n^2)$ space and has a query time of $O(f^2(f+\mathtt{Q}))$.*

Some more remarks on the preprocessing time stated in Theorem 3 may be in order. The reduction itself takes time $\mathtt{P}+O(mn+n^2\log n+n|S||T|)$ to compute but requires that the shortest paths in G are unique. The total preprocessing time depends on how this condition is achieved. It is always possible to guarantee unique shortest paths either by randomly perturbing the edge weights with sufficiently small values, see [41], or by using a more complex deterministic method, also known as *lexicographic perturbation* [19, 21, 39]. While the first method increases the preprocessing only by a constant factor, it makes the preprocessing procedure randomized. Lexicographic perturbation, in turn, increases the time by an additive $O(mn+n^2\log^2 n)$ term [19]. By applying the reduction stated in Theorem 3 to existing all-pairs f-DSOs we obtain the f-FDOs listed in Table 3.

In addition, we present improved constructions of f-FDO-STs for the important case of a single source or target, i.e., when $|S|=1$ or $|T|=1$, or when one is only given access to single-source f-DSOs. In the following, for the sake of readability, when $S=\{s\}$, we will use "sT-diameter" instead of "ST-diameter" or "$\{s\}T$-diameter", same for the oracles.

▶ **Theorem 4.** *Let $G=(V,E)$ be an undirected graph with n vertices, m edges, and possibly positive edge weights. Let $s \in V$ be a vertex and $T \subseteq V$ a non-empty set. Given a single-source f-DSO for G with preprocessing time $\mathtt{P}$, space $\mathtt{S}$, query time $\mathtt{Q}$, and stretch σ, one can compute an f-FDO-sT for G with preprocessing time $\mathtt{P}+O(m+n\log n)$, space $\mathtt{S}+O(n)$, query time $O(f^2+f\mathtt{Q})$, and stretch $1+2\sigma$. For unweighted graphs, the preprocessing time can be improved to $\mathtt{P}+O(m)$.*

Table 4 shows the f-fault-tolerant sT-diameter-oracle obtained from Theorem 4.

Table 3 Properties of the f-FDO-ST for undirected graphs obtained via Theorem 3 using all-pairs f-DSOs from the literature. The preprocessing time is omitted due to space reasons. W denotes the maximum edge weight for graphs with arbitrary positive weights, M is the maximum edge weight for integer weighted graphs. The parameter $k \geqslant 1$ is a positive integer, $\varepsilon > 0$ a positive real, $\alpha \in [0, 1]$ is a real number in the unit interval, and $\omega < 2.37286$ denotes the matrix multiplication exponent.

▶ **Theorem 5.** *Let $G=(V,E)$ be an undirected graph with n vertices, m edges, and possibly positive edge weights. Let S, T be two non-empty subsets of V. Given a single-source f-DSO for G with preprocessing time $\mathtt{P}$, space $\mathtt{S}$, query time $\mathtt{Q}$, and stretch σ, one can compute an f-FDO-ST for G with preprocessing time $O(\mathtt{P}+m+n\log n)$, space $O(\mathtt{S}+n)$, query time $O(f^2+f\mathtt{Q})$, and stretch $2+5\sigma$. For unweighted graphs, the preprocessing time can be improved to $O(\mathtt{P}+m)$*

Table 5 corresponds to the oracles obtained via Theorem 5.

We also prove an information-theoretic lower bound on the space requirement of approximate f-FDOs that support $f \geqslant 2$ edge failures. Note that the lower bound in Theorem 6 holds independently of the query time. It is known from work of Bilò, Cohen, Friedrich, and Schirneck [17] that f-FDOs with stretch $\sigma < 1.5$ require $\Omega(n^2)$ bits of space, and in our work we complement this result by proving that f-FDOs with stretch $\sigma < 5/3$ require $\Omega(n^{1.5})$ bits of space. Obtaining $\Omega(n^2)$ lower bound for f-FDOs with stretch $\sigma < 2$ for undirected unweighted graphs is an interesting open problem.

▶ **Theorem 6.** *Let n be a positive integer. Any f-FDO or f-FDO-ST for n-vertex graphs with sensitivity $f \geqslant 2$ and stretch $\frac{5}{3}-\varepsilon$ for any $\varepsilon > 0$ requires $\Omega(n^{3/2})$ bits of space.*

Outline. This work is structured as follows. In the remainder of this section, we review the literature focusing on diameter oracles and distance sensitivity oracles. We then fix our notations and some preliminaries in Section 2. Section 3 presents our constructions of f-FDO-ST, for the general case of $S, T \subseteq V$. In Section 4 we consider the special case of a single source, that is, of f-FDO-sT. In Section 5 we prove the space lower bound. The proofs of Theorems 1 and 2 follow from similar ideas as discussed in Section 3 and are deferred to the full version of the paper.

1.1 Related Work on Fault-Tolerant Diameter Oracles

Fault-tolerant diameter oracles were introduced by Henzinger, Lincoln, Neumann, and Vassilevska Williams [40]. They showed that for a single failure in unweighted directed graphs, one can compute in time $\widetilde{O}(mn + n^{1.5}\sqrt{Dm/\varepsilon})$, where $\varepsilon \in (0,1]$ and D is the diameter of the graph, a 1-FDO with $1+\varepsilon$ stretch that has $O(m)$ space, constant query time. Bilò, Cohen, Friedrich, and Schirneck [17] showed that one can improve the preprocessing time to $\widetilde{O}(mn + n^2/\varepsilon)$, which is nearly optimal under certain conditional hardness assumptions for combinatorial algorithms (see [40]). They also showed that fast matrix multiplication reduces the preprocessing time for dense graphs to $\widetilde{O}(n^{2.5794} + n^2/\varepsilon)$.

Bilò, Choudhary, Cohen, Friedrich, and Schirneck [15] addressed the problem of computing 1-FDOs with $o(m)$ space. They showed that for unweighted directed graphs with diameter $D = \omega(n^{5/6})$, there is a 1-FDO with $\widetilde{O}(n)$ space, $1 + \frac{n^{5/6}}{D} = 1 + o(1)$ stretch, and $O(1)$ query time. It has a preprocessing time of $O(mn)$. In the same work it was also shown that for graphs with diameter $D = \omega((n^{4/3}\log n)/(\varepsilon\sqrt{m}))$ and any $\varepsilon > 0$, there is a $(1+\varepsilon)$-stretch 1-FDO, with preprocessing time $O(mn)$, space $o(m)$, and constant query time.

For *undirected* graphs the space requirement can be reduced. There is a folklore construction that combines the DSO by Bernstein and Karger [11] with the observation that in undirected graphs the eccentricity of an arbitrary vertex is a 2-approximation of the diameter. This results in an 1-FDO with stretch 2 and constant query time that takes only $O(n)$ space, details can be found in [17, 40].

For $f > 1$ edge failures in undirected graphs with non-negative edge weights, Bilò et al. [17] presented an f-FDO with $(f+2)$ stretch, $O(f^2\log^2 n)$ query time, $\widetilde{O}(fn)$ space, and $\widetilde{O}(fm)$ preprocessing time. A lower bound in that work showed that f-FDO with finite stretch must have $\Omega(fn)$ space, nearly matching their construction.

Table 6 Existing f-sensitive all-pairs distance oracles for undirected graphs. The parameter $k \geqslant 1$ is a positive integer, $\varepsilon > 0$ a positive real, $\alpha \in [0,1]$ is a real number in the unit interval, and $\omega < 2.37286$ denotes the matrix multiplication exponent.

We are not aware of any $O(n)$-sized, constant-stretch FDOs for *directed* graphs with arbitrary diameter in the literature prior to this work, not even for sensitivity ($f = 1$). Also, no non-trivial f-FDOs with $o(f)$-stretch were known. To the best of our knowledge, we are the first to study the problem of general f-FDO-STs with $S, T \neq V$.

We now discuss the known information-theoretic lower bounds for FDOs. Bilò, Cohen, Friedrich, Schirneck [17] showed that any FDO with stretch $\sigma < 3/2$ for undirected unweighted graphs requires $\Omega(m)$ bits of space, even for $f = 1$. They also extended the same lower bound of $\Omega(m)$ bits to edge-weighted graphs and $\sigma < 2$. Bilò, Choudhary, Cohen, Friedrich, and Schirneck [15] extended this result to directed graphs. In particular, they showed that for directed unweighted graphs with diameter $D = O(\sqrt{n}/m)$, any FDO with stretch better than $\left(\frac{3}{2} - \frac{1}{D}\right)$ requires $\Omega(m)$ bits of space. They further proved that for directed graphs any f-FDO requires $\Omega(2^{f/2}n)$ bits of space, as long as $2^{f/2} = O(n)$.

1.2 All-Pairs Distance Sensitivity Oracles

The first distance-sensitive oracle was in the context of directed graphs [29]. It maintained exact distances and was capable of handling a single edge failure. The space requirement of this oracle is $O(n^2 \log n)$ and its query time is $O(\log n)$. This was later generalized to handle a single vertex or edge failure in [30]. Demetrescu, Thorup, Chowdhury, and Ramachandran [30] presented an exact 1-sensitive distance oracle of size $O(n^2 \log n)$, $O(1)$ query time and $\widetilde{O}(mn^2)$ preprocessing time. Later, in two consecutive papers, Bernstein and Karger improved the preprocessing time (while keeping the space and query time unchanged), first to $O(n^2\sqrt{m})$ in [10] and then to $\widetilde{O}(mn)$ in [11]. Baswana and Khanna [8] considered approximate 1-DSOs for unweighted graphs. More precisely, they presented a data structure of size $O(k^5 n^{1+1/k}\frac{\log^3 n}{\varepsilon^4})$, $(2k-1)(1+\varepsilon)$ stretch and $O(k)$ query time. Duan and Pettie [32] considered the case of two failures (vertices or edges) with exact distances. The size of their oracle is $O(n^2 \log^3 n)$, the query time is $O(\log n)$ and the construction time is polynomial.

Using fast matrix multiplication, Weimann and Yuster [47] presented, for any parameter $\alpha \in [0,1]$, a DSO that can handle up to $O(\log n/\log\log n)$ edges or vertices failures with $\widetilde{O}(n^{2-(1-\alpha)/f})$ query time and $O(Mn^{\omega+1-\alpha})$ preprocessing time for directed graphs with integer weights in the range $[-M, M]$, where $\omega < 2.373$ is the matrix multiplication exponent. In [35], Grandoni and Vassilevska Williams presented a distance sensitivity oracle with

Table 7 Existing f-sensitive single-source distance oracles for undirected graphs W denotes the maximum edge weight for graphs with arbitrary positive weights, M is the maximum edge weight for integer weighted graphs. The parameter $\varepsilon > 0$ is a positive real and $\omega < 2.37286$ denotes the matrix multiplication exponent.

$f \geqslant 1$	$2f+1$	$\widetilde{O}(fn)$	$\widetilde{O}(f^2)$	$\widetilde{O}(fm)$	[14]

subcubic $\widetilde{O}(Mn^{\omega+1/2}+Mn^{\omega+\alpha(4-\omega)})$ preprocessing time and sublinear $\widetilde{O}(n^{1-\alpha})$ query time. Van den Brand and Saranurak [18] presented a distance-sensitive oracle that can handle $f \geqslant \log n$ updates (where an update is an edge insertion or deletion), with $\widetilde{O}(Mn^{\omega+(3-\omega)\mu})$ preprocessing time, $\widetilde{O}(Mn^{2-\mu}f^2+Mnf^{\omega})$ update time, and $\widetilde{O}(Mn^{2-\mu}f+Mnf^2)$ query time, where the parameter $\mu \in [0,1]$ can be chosen. Chechik and Cohen [22] presented a 1-DSO with with subcubic $\widetilde{O}(Mn^{2.873})$ preprocessing time and $\widetilde{O}(1)$ query time. This was improved by Ren [42] and later by Gu and Ren [37], who obtained a 1-DSO with $\widetilde{O}(Mn^{2.5794})$ preprocessing time and constant query time. Recently Duan and Ren [34] presented an exact f-DSO with $O(fn^4)$ space, $f^{O(f)}$ query time, and $n^{O(f)}$ preprocessing time.

In Table 6 we summarize several of the above f-DSOs for undirected graphs.

1.3 Related Work on Single-Source Distance Sensitivity Oracles

First, we discuss undirected graphs. Baswana and Khanna [8] showed that unweighted undirected graphs can be preprocessed in $O(m\sqrt{n/\varepsilon})$ time to compute a $(1+\varepsilon)$-stretch single-source edge/vertex fault-tolerant distance-oracle of size $O(n\log n+n/\varepsilon^3)$ and constant query time. For weighted graphs, they showed the construction of an $O(n\log n)$ size oracle which can report 3-approximate distances on single failure in $O(1)$ time. Bilò, Gualà, Leucci, and Proietti [13] showed that for a single edge failure in weighted graphs we can compute an $O(n)$-size oracle with stretch 2 and constant query time. Also, a construction is provided that has $1+\varepsilon$ stretch, with $O\big(\varepsilon^{-1}n\log(1/\varepsilon)\big)$ size and $O\big(\varepsilon^{-1}\log n\log(1/\varepsilon)\big)$ query time. All the results stated till now are for a single edge or vertex failure only. For multiple failures, Bilò, Gualà, Leucci, and Proietti [14] gave a construction of size $O(fn\log^2 n)$, computable in $\widetilde{O}(mf)$ time that reports $(2f+1)$-stretched distances in $O(f^2\log^2 n)$ time.

Bilò, Cohen, Friedrich, and Schirneck [16] presented several additional single-source DSOs. For undirected unweighted graphs, they presented a single-source DSO that has size $O(n^{3/2})$, query time $\widetilde{O}(1)$ and $\widetilde{O}(m\sqrt{n}+n^2)$ preprocessing time. For graphs with integer edge weights in the range $[1,M]$ and using fast matrix multiplication, they presented a single-source DSO with $O(M^{1/2}n^{3/2})$ space, $\widetilde{O}(1)$ query time and $\widetilde{O}(Mn^{\omega})$ preprocessing time. For sparse graphs with $m=O(M^{3/7}n^{7/4})$ they presented a single-source DSO with the same size, $\widetilde{O}(1)$ query time, and subquadratic $\widetilde{O}(M^{7/8}m^{1/2}n^{11/8})$ preprocessing time.

For directed graphs, Baswana, Choudhary, Hussain, and Roditty [5] showed that we can preprocess directed weighted graphs with edge weights in range $[1,W]$ to compute an oracle of $\widetilde{O}(\varepsilon^{-1}n\log W)$ size that reports $(1+\varepsilon)$-approximate distances on single edge/vertex

failure in $\widetilde{O}(\log \log_{1+\varepsilon}(nW))$ time. Gupta and Singh [38] designed exact distance oracles of $\widetilde{O}(n^{3/2})$ size that on single edge/vertex failure in directed/undirected unweighted graphs reports distances in $\widetilde{O}(1)$ time. In Table 7 we summarize several of the above f-DSOs for undirected graphs.

2 Preliminaries

For a given graph $G = (V, E)$, possibly with positive edge weights, we denote by $d_G(u, v)$ the distance in G from vertex $u \in V$ to vertex $v \in V$. Given two non-empty subsets $S, T \subseteq V$, the *ST-diameter* of G is defined as $\mathrm{diam}(G, S, T) = \max_{s \in S, t \in T} d_G(s, t)$. With a little abuse of notation, when $S = \{s\}$ (resp., $T = \{t\}$), we also use $\mathrm{diam}(G, s, T)$ (resp., $\mathrm{diam}(G, S, t)$) as a shorthand of $\mathrm{diam}(G, \{s\}, T)$ (resp., $\mathrm{diam}(G, S, \{t\})$) for the sT-diameter (resp., St-diameter). Moreover, if $S = T = V$, we use $\mathrm{diam}(G)$ instead of $\mathrm{diam}(G, V, V)$.

For a given set $F \subseteq E$, we denote by $G - F$ the graph obtained from G by removing all the edges of F. If H is a subgraph of G, we use $V(H)$ and $E(H)$ for the vertices and edges of H, respectively. An *f-edge fault-tolerant distance sensitivity oracle* (f-DSO) with *stretch* $\sigma \geqslant 1$ is a data structure that answers queries (u, v, F) with $u, v \in V$ and $F \subseteq E$ with $|F| \leqslant f$. It returns an estimate $\widehat{d}_{G-F}(u, v)$ of the distance from u to v in $G - F$ such that $d_{G-F}(u, v) \leqslant \widehat{d}_{G-F}(u, v) \leqslant \sigma \cdot d_{G-F}(u, v)$. An *$f$-edge fault-tolerant ST-diameter oracle* (f-FDO-ST) with stretch σ returns, upon query $F \subseteq E$ with $|F| \leqslant f$, an estimate $\widehat{D} = \widehat{D}(F, S, T)$ of the ST-diameter of $G - F$ such that $\mathrm{diam}(G-F, S, T) \leqslant \widehat{D} \leqslant \sigma \cdot \mathrm{diam}(G-F, S, T)$. If $S = \{s\}$ is a singleton or $S = T = V$ are both the whole vertex set, we abbreviate such oracles for as f-FDO-sT and f-FDO, respectively.

3 ST-Diameter Oracles

We start by showing how to use distance sensitivity oracles to design data structures for the fault-tolerant ST-diameter, i.e., the ST-diameter of $G - F$ after a set of edges $F \subseteq E$ failed. The maximum number f of supported failures is called the sensitivity of the data structure. The result is formally stated in Theorem 3.

In the following, we assume that the shortest paths in G are made unique. This way, we can identify a shortest path with its endpoints, which enabled saving both in the time-efficiency of the preprocessing and the space-efficiency of the resulting data structure. In particular, it allows for a subquadratic (in n) space overhead over the underlying f-DSO. However, the precise way how to make the paths unique influences the nature of the preprocessing. As discussed in Section 1, one can ensure a unique shortest path in a random fashion by slightly perturbing the edge weights. Alternatively, lexicographic perturbation [19, 21, 39] provides a deterministic procedure but adds an $O(mn + n^2 \log^2 n)$ term to the running time.

Let $\pi_{u,v}$ denote the (unique) shortest path in G from u to v. Fix a set $F \subseteq E$ of at most f edges and recall that we use $V(F)$ to denote the set of endpoints of edges in F. Our f-DSO-ST uses a data structure to map S and T into two suitable subsets S' and T' of $V(F)$, respectively. A vertex $v \in V(F)$ belongs to S' (resp., T') if there exists a shortest path $\pi_{s,t}$ from some $s \in S$ to some $t \in T$ such that v is a vertex on $\pi_{s,t}$ and the subpath $\pi_{s,v}$ (resp., $\pi_{v,t}$) of $\pi_{s,t}$ from s to v (resp., from t to v) contains no vertex of $V(F)$ other than v. Note that $\pi_{s,v}$ (resp., $\pi_{v,t}$) is completely contained in $G - F$, whence $d_{G-F}(s, v) = d_G(s, v)$ (analogously for $d_{G-F}(v, t)$). The sizes of $S', T' \subseteq V(F)$ are in $O(f)$.

3.1 Query Algorithm

Before describing the data structure, we present the query algorithm. Let $\mathcal{D}$ denote the f-DSO with stretch $\sigma \geqslant 1$ that is assumed in Theorem 3. Given the query F, our diameter oracle computes the two sets S' and T'. Next, for every two vertices u and v such that $u \in S'$ and $v \in T'$, it queries $\mathcal{D}$ with the triple (u, v, F) to obtain a σ-approximation of $d_{G-F}(u, v)$. The f-FDO-ST returns the value $\widehat{D} = \operatorname{diam}(G, S, T) + \max_{(u,v)\in S'\times T'} \mathcal{D}(u, v, F)$.

Given S' and T', the time needed to compute $\widehat{D}$ is $O(f^2\mathtt{Q})$, where $\mathtt{Q}$ is the query time of the f-DSO $\mathcal{D}$. The value $\operatorname{diam}(G, S, T)$ can be precomputed.

▶ **Lemma 7.** *The f-FDO-ST has a stretch of $1 + 3\sigma$.*

Proof. Let $s \in S$ and $t \in T$ be two arbitrary vertices. We first show that $d_{G-F}(s, t) \leqslant \widehat{D}$, that is, the returned value never underestimates the ST-diameter of $G - F$. We only need to prove the case in which some of the failing edges in F belong to $\pi_{s,t}$ as otherwise $d_{G-F}(s, t) = d_G(s, t) \leqslant \operatorname{diam}(G, S, T) \leqslant \widehat{D}$. Thus, let x_s (resp., x_t) be the vertex of $V(F)$ that is closest to s (resp., t) in $\pi_{s,t}$. By definition of S', T', we have $x_s \in S'$ and $x_t \in T'$ and thus $d_{G-F}(s, x_s) = d_G(s, x_s)$ and $d_{G-F}(x_t, t) = d_G(x_t, t)$. Moreover, it holds that $d_{G-F}(s, x_s) + d_{G-F}(x_t, t) = d_G(s, x_s) + d_G(x_t, t) \leqslant \operatorname{diam}(G, S, T)$ as π_{s,x_s} and $\pi_{x_t,t}$ are vertex-disjoint. Using the triangle inequality twice and the fact that $\max_{(u,v)\in S'\times T'} \mathcal{D}(u, v, F)$ never underestimates $\operatorname{diam}(G-F, S', T')$, we get

$$\begin{aligned} d_{G-F}(s, t) &\leqslant d_{G-F}(s, x_s) + d_{G-F}(x_s, x_t) + d_{G-F}(x_t, t) \\ &\leqslant \operatorname{diam}(G, S, T) + \operatorname{diam}(G-F, S', T') \leqslant \widehat{D}. \end{aligned}$$

We now prove that $\widehat{D} \leqslant (1 + 3\sigma) \cdot \operatorname{diam}(G-F, S, T)$. Let $u \in S'$ and $v \in T'$ be arbitrary. There are $s \in S$ and $t \in T$ such that $d_{G-F}(s, u), d_{G-F}(v, t) \leqslant \operatorname{diam}(G, S, T)$. We arrive at

$$\begin{aligned} \mathcal{D}(u, v, F) &\leqslant \sigma\, d_{G-F}(u, v) \leqslant \sigma\big(d_{G-F}(u, s) + d_{G-F}(s, t) + d_{G-F}(t, v)\big) \\ &\leqslant \sigma\big(\operatorname{diam}(G, S, T) + \operatorname{diam}(G-F, S, T) + \operatorname{diam}(G, S, T)\big) \\ &\leqslant 3\sigma \operatorname{diam}(G-F, S, T), \end{aligned}$$

thus $\widehat{D} = \operatorname{diam}(G, S, T) + \max_{u\in S', v\in T'} \mathcal{D}(u, v, F) \leqslant (1 + 3\sigma) \operatorname{diam}(G - F, S, T)$. ◀

3.2 Data Structure for the Sets S' and T' for Large Sensitivity

Recall that, given the failure set F, the set S' contains all $v \in V(F)$ such that there are $s \in T$ and $t \in T$ for which v is the closest vertex to s on $V(F) \cap E(\pi_{s,t})$, analogously for T'. We now describe the data structure that computes the sets S' and T', focusing on S' since the case of T' follows in the same fashion.

The construction algorithm depends on the sensitivity f. Suppose first that $f = \Omega(\log n)$. For each vertex $v \in V$, the data structure stores the shortest-path tree T_v of G rooted at v and mark some of its vertices. Namely, all $s \in S$ are marked for which there is a $t \in T$ such that v lies on the path $\pi_{s,t}$. For every two vertices $s \in S$ and $t \in T$, $\pi_{s,t}$ contains v if and only if $d_G(s, t) = d_G(s, v) + d_G(v, t)$. We used here that the paths are unique. It suffices to compute the all-pairs distances in G in time $O(mn + n^2 \log n)$ time[2] and use them to mark the vertices of T_v for *all* v with the obvious $O(n|S||T|)$-time algorithm.

[2] The time needed for this step reduces to $O(mn)$ in case G is unweighted or has only small integer or even floating point weights (in exponent-mantissa representation) using Thorup's algorithm [46].

Additionally, each vertex u of T_v is annotated with the value $count_v(u)$, the number of marked vertices in the subtree $(T_v)_u$ rooted at u. For a fixed tree T_v, all values $count_v(u)$ are computable in $O(n)$ time in a bottom-up fashion. Finally, we store, for each T_v, a data structure that supports least common ancestor (LCA) queries in constant time. Such structures can be built in time and space that is linear in the size of the tree [9]. The time needed to construct the data structure is $O(mn + n^2 \log n + n|S||T|)$ and the space is $O(n^2)$.

To answer a query F, the algorithm scans all the vertices $v \in V(F)$ and decides which of them to include in S'. The graph $T_v - F$ is a collection of rooted trees. (Possibly some of the trees degenerated to isolated vertices.) We observe that $v \in S'$ if and only if $T_v - F$ contains a marked vertex that is still reachable from v. To check this condition, the algorithm computes the set F_0 of all the edges $\{u, w\} \in F$ that are contained in T_v. This is the case if and only if the LCA of u and w in T_v is either u or w.

Next, we define a notion of domination for edges in F_0. We say that an edge $\{u, w\} \in F_0$, where u is the parent of w in T_v, is *dominated* by another edge $\{a, b\} \in F_0$, where a is the parent of b in T_v, if $\{u, w\}$ is in the subtree of T_v rooted at b. This is equivalent to b being the LCA of b and u. The query algorithm removes all dominated edges from F_0, which can be done in $O(|F_0|^2) = O(f^2)$ time.

Recall that $count_v(v)$ is the overall number of marked vertices in T_v. Evidently, some vertex in $T_v - F$ is reachable from v iff they are in the same connected component. Thus, there is a marked vertex reachable from v if and only if $count_v(v)$ is strictly larger than the number of marked vertices contained in those components of $T_v - F$ that do *not* contain v. Indeed, the difference between those two values is exactly the *number* of marked vertices reachable from v. Each connected component of $T_v - F$ that does not contain v is a tree T' rooted at some vertex $w \in V(F_0)\backslash\{v\}$. Let u be the parent of w in T_v. Compared to the full subtree $(T_v)_u$ rooted at u, T' is missing those subtrees "further down" that are rooted at some other vertex b whose parent a is a vertex of T'. Those are exactly the edges $\{a, b\} \in F_0$ that are dominated by $\{u, w\}$. Accordingly, the value $count_v(u)$ counts the marked vertices in T' and additionally those in the subtrees rooted at the vertices b. By removing all dominated edges from F_0, we avoid any double counting and ensure that $count_v(v) - \sum_{u \in V(F_0)} count_v(u)$ is indeed the quantity we are interested in. It can be computed in time $O(f)$ for each v.

3.3 Small Sensitivity

We now modify the data structure in the case where the sensitivity $f = o(\log n)$ is sublogarithmic. If so, the information of all the trees T_v can be stored in a more compact way. For every vertex $v \in V$, we define a new representation $\mathcal{T}_v$ of the tree T_v by first removing unnecessary parts and then replacing long paths with single edges. This corresponds to the two steps of the compression described below. For the first one, we need the following definition. We say a subtree $\mathcal{T}_v$ of T_v preserves the *source-to-leaf reachability* if, for every set $F \subseteq E$ of up to f failing edges, there is a marked vertex of T_v that is reachable from the source v in $T_v - F$ if and only if there is a leaf of $\mathcal{T}_v$ that is reachable from v in $\mathcal{T}_v - F$.

The first compression step. We first describe how to preserve the source-to-leaf reachability. We select a set $\mathcal{L}_v \subseteq S$ of at most 2^f marked vertices and set $\mathcal{T}_v$ as the smallest subtree of T_v that contains v and $\mathcal{L}_v$. We say that a marked vertex s of T_v is *relevant* if there is no marked vertex $s' \neq s$ that is contained in the path from v to s in T_v.

We compute $\mathcal{L}_v$ as follows. We construct a DAG G_v that is obtained from a copy of T_v in which each edge (u, u'), with u being the parent of u' in T_v, is directed from u to u'. The DAG is augmented with a dummy sink vertex x that contains an incoming directed edge

from each relevant vertex s of T_v. We then run the algorithm of Baswana, Choudhary, and Roditty [6] to compute a subgraph H_v of G_v such that (i) the in-degree of each vertex of H_v is at most 2^f and (ii) for every possible set F of at most f edge failures, each vertex u is reachable from v in the graph $G_v - F$ iff u is reachable from v in $H_v - F$.

The set $\mathcal{L}_v$ of marked vertices corresponds to the tails of the edges in H_v that enter the sink x. As x has in-degree of at most 2^f in H_v, the size of $\mathcal{L}_v$ is $O(2^f)$. Moreover, $\mathcal{L}_v$ is the set of leaves of $\mathcal{T}_v$. The following lemma proves the correctness of our selection algorithm.

▶ **Lemma 8.** *For every $F \subseteq E(G)$, with $|F| \leqslant f$, there is a marked vertex of T_v that is reachable from v in $T_v - F$ iff there is a vertex of $\mathcal{L}_v$ that is reachable from v in $\mathcal{T}_v - F$.*

Proof. Fix a set F of at most f failing edges of G. As $\mathcal{T}_v$ is a subtree of T_v, if there is a vertex in $\mathcal{L}_v$ that is reachable from v in $\mathcal{T}_v - F$, then the same marked vertex is reachable from v in $T_v - F$. To prove the other direction, let X be the set of all marked vertices that are reachable from v in $T_v - F$. We prove that $X \cap \mathcal{L}_v \neq \emptyset$. Let $s \in X$ be a marked vertex that is reachable from v in $T_v - F$. Let $s^* \in S$ be the vertex closest to v in the path from v to s in T_v (possibly, $s^* = s$). We have that s^* is relevant and is reachable from v in $T_v - F$. This implies that the sink x is reachable from v in $G_v - F$ via the path that goes through s^*. As a consequence, x is also reachable in $H_v - F$. Hence, there is a vertex in $\mathcal{L}_v$ that is also reachable from v in $\mathcal{T}_v - F$. Therefore, $X \cap \mathcal{L}_v \neq \emptyset$. ◀

The second compression step. After the first compression step, the tree $\mathcal{T}_v$ contains at most 2^f leaves. However, it might still be the case that the number of vertices of $\mathcal{T}_v$ is large due to the presence of very long paths connecting two consecutive *branch vertices*, i.e., vertices of $\mathcal{T}_v$ with two or more children. The second step of compressing $\mathcal{T}_v$ allows us to represent long paths between consecutive branch vertices in a more compact way.

Let x and y be two consecutive branch vertices in $\mathcal{T}_v$, i.e., x is an ancestor of y in $\mathcal{T}_v$ and the internal vertices of the path P from x to y are not branch vertices. We say that P is *long* if it contains at least $\sqrt{n}$ edges. If the path P is long, we substitute the path P in $\mathcal{T}_v$ with a *representative* edge between x and y (so we also remove all the internal vertices of P from the tree) and we add the path P to the set $\mathcal{P}$ of long paths. So, in every tree $\mathcal{T}_v$, we replace every long path between two consecutive branch vertices with a representative edge. We observe that $\mathcal{P}$ can be computed in $O(n^2)$ time. Moreover, we observe that $\mathcal{P}$ contains $O(n^{3/2})$ paths as each tree T_v contributes with at most $\sqrt{n}$ long paths.

Next, we use the algorithm given in [2] to hit all the long paths in $\mathcal{P}$ with a set Z of $O(\sqrt{n}\log n)$ *pivot* vertices in $O(|\mathcal{P}|\sqrt{n}) = O(n^2)$ time, where a path is *hit* if we select a pivot vertex that belongs to the path. For each pivot $z \in Z$, we store the shortest-path tree T_z of G rooted at z. By construction, each long path $P \in \mathcal{P}$ between two consecutive branch vertices x and y of a tree $\mathcal{T}_v$ is contained in T_z, for some $z \in Z$ that hits P; moreover, a vertex $z \in Z$ that hits P is also the least-common-ancestor of x and y in T_z.

The representative edge (x, y) in $\mathcal{T}_v$ stores a pointer to the tree T_z of any pivot z that hits P (ties can be arbitrarily broken). Clearly, after the second compression step, each tree $\mathcal{T}_v$ contains $O(2^f\sqrt{n})$ vertices. Therefore, the overall size needed to store all the trees $\mathcal{T}_v$ is $O(2^f n^{3/2})$. Moreover, storing the trees T_z for all the pivots in Z requires $O(n)$ space per tree, for a total of $O(n^{3/2}\log n)$ space. Hence, the overall size of our data structure is $O(n^{3/2}(2^f + \log n))$.

Now, given a set F of at most f failing edges, we describe how the query algorithm computes the set S' in $O(f^2 2^f)$ time. As before, for every $v \in V(F)$, we need to understand whether v must be added to S' or not. In the following, we fix $v \in V(F)$ and explain how to

check whether $v \in S'$ or not in $O(f2^f)$ time. We recall that v must be added to S' iff there is a marked vertex in $T_v - F$ that is still reachable from v. By Lemma 8, this is equivalent to having a leaf of $\mathcal{L}_v$ that is reachable from v in $\mathcal{T}_v - F$.

We visit the tree $\mathcal{T}_v$ and we remove from $\mathcal{T}_v$ all edges that correspond to edges in F. This can be easily done in $O(f)$ time for each non-representative edge using least-common-ancestor queries. For the representative edges we proceed as follows. We consider all the representative edges in $\mathcal{T}_v$. Let (x, y) be a representative edge of $\mathcal{T}_v$ and let z be the pivot of the tree T_z that is associated with the edge (x, y) in $\mathcal{T}_v$. We remove (x, y) from $\mathcal{T}_v$ iff there is a failing edge in F that is contained in the path P in T_z from x to y. We check whether P contains some edges of F in $O(f)$ time as follows. We look at all the failing edges in F and, for each failing edge $(u, u') \in F$, we check whether (u, u') is an edge of P using a constant number of *least-common-ancestor* queries in the tree T_z.[3] As each tree $\mathcal{T}_v$ contains $O(2^f)$ representative edges and we need $O(f)$ time to understand if a representative edge can be removed or not from the tree, we need $O(f2^f)$ to understand which are the representative edges that need to be removed from $\mathcal{T}_v$, for a fixed $v \in V(F)$.

Once all edges that represent F have been removed from $\mathcal{T}_v$, it is enough to check whether there is a vertex of $\mathcal{L}_v$ that is still reachable from v. This can be clearly done in $O(f^2)$ time per tree $\mathcal{T}_v$ using the values k_u, as already discussed for the case in which $f = \Omega(\log n)$. In particular, for every vertex u in $\mathcal{T}_v$, the value k_u is equal to the number of vertices of $\mathcal{L}_v$ that are contained in the subtree of $\mathcal{T}_v$ rooted at u.

4 Single-Source sT-Diameter Oracles

In the following theorem, we address the question of computing an sT-diameter oracle using a single-source DSO with source s. We restate the relevant theorem below. Its proof uses similar ideas as those shown in Section 3, but the single-source setting allows for a better preprocessing time, space, and stretch.

▶ **Theorem 4.** *Let $G = (V, E)$ be an undirected graph with n vertices, m edges, and possibly positive edge weights. Let $s \in V$ be a vertex and $T \subseteq V$ a non-empty set. Given a single-source f-DSO for G with preprocessing time $\mathtt{P}$, space $\mathtt{S}$, query time $\mathtt{Q}$, and stretch σ, one can compute an f-FDO-sT for G with preprocessing time $\mathtt{P} + O(m + n \log n)$, space $\mathtt{S} + O(n)$, query time $O(f^2 + f\mathtt{Q})$, and stretch $1 + 2\sigma$. For unweighted graphs, the preprocessing time can be improved to $\mathtt{P} + O(m)$.*

Proof. Let $\mathcal{D}$ denote the single-source f-DSO. The preprocessing algorithm for the f-FDO-sT first constructs $\mathcal{D}$ with source s. It also computes a shortest path tree T_s of G rooted at s. Each node $v \in V(T_s) = V$ is annotated with a pointer to its parent node and its respective number in the pre-order and post-order traversal of T_s. Similarly as above, the algorithm also computes the value $count(v)$ for every v, which is the number of descendants of v (including v itself) that are in T. Finally, it stores the maximum distance $C = \max_{t \in T} d_G(s, t)$ from the root among the vertices in the set T. The preprocessing takes total time $\mathtt{P} + O(m + n \log n)$ in general weighted graphs and, again, can be reduced to $\mathtt{P} + O(m)$ for certain classes of weights [46]. Storing the oracle and the tree takes $\mathtt{S} + O(n)$ space.

[3] We observe that (u, u') is on the path P iff one of the following two conditions hold: (i) the least-common-ancestor of u and x in T_z is u and the least-common-ancestor of u' and x in T_z is u'; (ii) the least-common-ancestor of u and y in T_z is u and the least-common-ancestor of u' and y in T_z is u'.

For the query, consider a set $F \subseteq E$ of up to f failing edges and let $F_0 = F \cap E(T_s)$ be those failures that are in the tree. Consider the collection of rooted (sub-)trees $T_s - F_0$. Define X_F to be the set of roots of those trees that contain some vertex from T. For some $v \in V$, let $\mathcal{D}(v, F)$ be the σ-approximation of the replacement distance $d_{G-F}(s, v)$ computed by the DSO $\mathcal{D}$. Our sT-diameter oracle answers the query F by reporting the value

$$\widehat{D} = C + \max_{x \in X_F} \mathcal{D}(x, F).$$

Regarding the correctness of that answer, consider a vertex $t \in T$. Let $x \in X_F$ be the root of the subtree of T_s that contains t. There is a path from s to t in $G - F$ of length at most $d_{G-F}(s, x) + d_G(x, t) \leqslant d_{G-F}(s, x) + d_G(s, t) \leqslant \mathcal{D}(x, F) + C$. Hence, we have $d_{G-F}(s, t) \leqslant C + \max_{x \in X_F} \mathcal{D}(x, F)$, that is, $\operatorname{diam}(G-F, s, T) \leqslant \widehat{D}$. We next prove $\widehat{D} \leqslant (1 + 2\sigma) \cdot \operatorname{diam}(G-F, s, T)$. Let $x_0 \in X_F$ be the maximizer of $\mathcal{D}(x, F)$, and $t \in T$ be in the tree in $T_s - F_0$ that is rooted in x_0. Then, we have $d_{G-F}(s, x_0) \leqslant d_{G-F}(s, t) + d_G(t, x_0) \leqslant d_{G-F}(s, t) + d_G(t, s) \leqslant 2 \cdot d_{G-F}(s, t)$. We used here that G is undirected so that we can go "up" the tree from t to x_0. From this, we get

$$\widehat{D} = C + \mathcal{D}(x_0, F) \leqslant C + \sigma \cdot d_{G-F}(s, x_0) \leqslant C + 2\sigma \cdot d_{G-F}(s, t) \leqslant (1 + 2\sigma) \cdot \operatorname{diam}(G - F, s, T).$$

Given X_F, computing $\widehat{D}$ takes time $O(f\mathtt{Q})$. It remains to show how to compute X_F from F in $O(f^2)$ time. Recall that we know the parent of every non-root node in T_s. We use it to first obtain F_0 from F in time $O(f)$ as an edge $\{a, b\}$ is in T_s iff a is parent of b or vice versa.

For each edge $e \in F_0$, let $b(e)$ be the endpoint of e that is farther from the source s. Next, define $B_0 = \{b(e) \mid e \in F_0\} \cup \{s\}$. Every root in X_F is either the source s or the "lower" endpoint of a failing edge, i.e., $X_F \subseteq B_0$. For each $b \in B_0$, let $B_0(b)$ be the closest proper descendants of b in B_0, if any. That is, on the paths in T_s between b and any $b' \in B_0(b)$ there is no other vertex from B_0. We can compute the sets $B_0(b)$ for all $b \in B_0$ simultaneously in total time $O(|B_0|^2) = O(f^2)$ as follows. A vertex is a proper ancestor of b' iff its pre-order number is strictly smaller than that of b' and its post-order number is strictly larger. So finding those takes time $O(|B_0|)$ for each $b' \in B_0$. Then, b' is in the set $B_0(b)$ for the proper ancestor b with the highest pre-order number.

Finally, observe that a vertex $b \in B_0$ lies in X_F if and only if there is at least one vertex of T that falls into the subtree of T_s rooted at v but not in any of the subtrees rooted at (proper) descendants of b in B_0. To check this condition via the counts, we only need to consider the immediate descendants in $B_0(b)$. If the element of T is in some lower subtree, then it is also accounted for by an immediate descendant. In summary, some $b \in B_0$ is in X_F iff $\mathit{count}(b) - \sum_{b' \in B_0(b)} \mathit{count}(b') > 0$. This proves that X_F is computable in time $O(f^2)$. ◀

We now handle multiple sources, that is, we build an f-FDO-ST for a general set S. The next result is a straightforward reduction to the sT-case. As it turns out, it is enough to construct the sT-diameter oracle for two arbitrary vertices $s \in S$ and $t \in T$. Due to lack of space, the proof of Lemma 9 is deferred to the full version of the paper.

▶ **Lemma 9.** *Let $G = (V, E)$ be an undirected graph with n vertices, m edges, and possibly positive edge weights. Let $S, T \subseteq V$ be non-empty sets of vertices, and $s \in S$ and $t \in T$ be two vertices. Suppose one is given access to an f-FDO-sT and an f-FDO-tS for G with respective preprocessing times $\mathtt{P}_{sT}$ and $\mathtt{P}_{tS}$, space requirements $\mathtt{S}_{sT}$ and $\mathtt{S}_{tT}$, query times $\mathtt{Q}_{sT}$ and $\mathtt{Q}_{sT}$, and stretches σ_{sT} and σ_{tS}. Then, one can compute an f-FDO-ST for G with preprocessing time $\mathtt{P}_{sT} + \mathtt{P}_{tS}$, space $\mathtt{S}_{sT} + \mathtt{S}_{tS}$, query time $\mathtt{Q}_{sT} + \mathtt{Q}_{tT}$, and stretch $\sigma_{sT} + \sigma_{tS} + \min(\sigma_{sT}, \sigma_{tS})$.*

Table 8 Conditions for the presence of edges between the vertex sets of graph G in Section 5. The symbol $\oplus$ stands for the exclusive or. All conditions are symmetric with respect to the index pairs (i,x), (j,y), and (k,z), whence H is undirected.

Set Pair	Vertex Pair	Edge Condition
$A \times A$		independent set
$B \times B$	$b[i,j,k],\ b[x,y,z]$	$(i=x) \oplus (j=y)$
$C \times C$	$c[i,j,k],\ c[x,y,z]$	$(i=x) \oplus (j=y)$
$D \times D$		independent set
$A \times B$	$a[i,j],\ b[x,y,z]$	$(i=x) \wedge (z=0)$
$B \times C$	$b[i,j,k],\ c[x,y,z]$	$(i=x) \wedge (j=y)$
$C \times D$	$c[i,j,k],\ d[x,y]$	$(j=y) \wedge (k=0)$

Combining Theorem 4 and Lemma 9 gives a reduction from f-FDO-ST to single-source f-DSOs. However, it results in a data structure with a stretch of $3+6\sigma$, where σ is the original stretch of the f-DSO We can improve this by not treating Lemma 9 as a black box.

▶ **Theorem 5.** *Let $G=(V,E)$ be an undirected graph with n vertices, m edges, and possibly positive edge weights. Let S,T be two non-empty subsets of V. Given a single-source f-DSO for G with preprocessing time $\mathtt{P}$, space $\mathtt{S}$, query time $\mathtt{Q}$, and stretch σ, one can compute an f-FDO-ST for G with preprocessing time $O(\mathtt{P}+m+n\log n)$, space $O(\mathtt{S}+n)$, query time $O(f^2+f\mathtt{Q})$, and stretch $2+5\sigma$. For unweighted graphs, the preprocessing time can be improved to $O(\mathtt{P}+m)$*

Proof. Let $s \in S$ and $t \in T$ be arbitrary. The preprocessing algorithm of the f-FDO-ST uses the single-source f-DSO twice, once for source s and once for t, to construct an f-FDO-sT $\mathcal{D}_{sT}$ and an f-FDO-tS $\mathcal{D}_{tS}$ both with stretch $1+2\sigma$, as described in Theorem 4.

For a set $F \subseteq E$ of at most f edge failures, let $\mathcal{D}_{sT}(F)$ and $\mathcal{D}_{tS}(F)$ be the respective $(1+2\sigma)$-approximations of $\operatorname{diam}(G-F,s,T)$ and $\operatorname{diam}(G-F,t,S)$. Further, let $\mathcal{D}_{st}(F)$ be a σ-approximation of $d_{G-F}(s,t)$, obtained from the DSO with source s. The query algorithm outputs $\widehat{D} = \mathcal{D}_{tS}(F) + \mathcal{D}_{st}(F) + \mathcal{D}_{sT}(F)$. Let $(s_0,t_0) \in S \times T$. We have

$$\begin{aligned} d_{G-F}(s_0,t_0) &\leqslant d_{G-F}(s_0,t) + d_{G-F}(t,s) + d_{G-F}(s,t_0) \\ &\leqslant \mathcal{D}_{tS}(F) + \mathcal{D}_{st}(F) + \mathcal{D}_{sT}(F) \leqslant (2+5\sigma)\cdot \operatorname{diam}(G-F,S,T). \end{aligned}$$ ◀

5 Space Lower Bound

Recall that Theorem 6 states a space lower bound for f-FDOs and f-FDO-STs with sensitivity $f \geqslant 2$ in that if they have stretch better than $5/3$, they must take $\Omega(n^{3/2})$ space. The theorem is implied by the following lemma, which we prove in this section.

▶ **Lemma 10.** *For infinitely many n, there is a graph $G=(V,E)$ with n vertices (and two sets $S,T \subseteq V$) such that any data structure that decides for any pair of edges $e,e' \in E$, whether $G-\{e,e'\}$ has diameter (resp., ST-diameter) 3 or 5 requires $\Omega(n^{3/2})$ bits of space.*

We first construct an auxiliary graph H. Let $n=6N$ for some N which is a perfect square. In the following, indices i,j range over the set $[\sqrt{N}]$ and k ranges over $\{0,1\}$ Define four pairwise disjoint sets of vertices $A=\{a[i,j]\}_{i,j}$, $B=\{b[i,j,k]\}_{i,j,k}$, $C=\{c[i,j,k]\}_{i,j,k}, D=\{d[i,j]\}_{i,j}$ with respective cardinalities $N, 2N, 2N$, and N. The vertex set of H is $V(H)=A\cup B\cup C\cup D$. The edges in H are shown in Table 8 and are defined

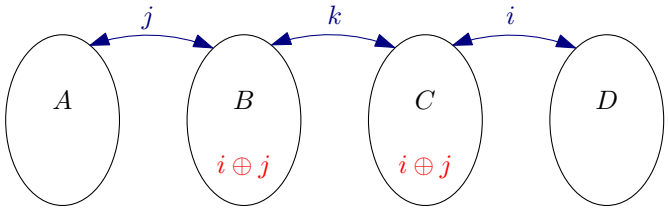

Figure 1 Visual representation of the graph H. Each vertex corresponds to a tuple $[i, j]$ or $[i, j, k]$ and belongs to one of the sets A, B, C, or D. To move from vertex $a[i, j]$ to $b[i', j', k']$ it must be the case that $i = i'$ and $k' = 0$, but one can jump from any j to any j'. This is marked by the blue edge labeled j between sets A and B, analogously for the other pairs of sets. When moving inside the sets B or C *either* the first index $i \neq i'$ *or* the second one $j \neq j'$ changes, marked by the red labels. Sets A and D have no internal edges.

depending on the relations among the indices of the participating vertices. For example, some edge $\{b[i, j, k],\ b[x, y, z]\}$ between elements of B and C exists if and only if *either* i and x are equal *or* j and y are equal, while $k, z \in \{0, 1\}$ can be arbitrary. Note that the number of edges in E is $\Theta(N^{3/2}) = \Theta(n^{3/2})$.

▶ **Lemma 11.** *The diameter of H is at most* 3.

Proof. To verify that the diameter of H is at most 3, we give explicit paths of length at most 3 between all possible vertex pairs from the sets A, B, C, and D. Note that all paths below are reversible as the edges are undirected. The symbol $\overline{x}$ stands for any index from $[\sqrt{N}]$ except x, analogously for $\overline{y}$.

- For vertices $a[i, j], a[x, y] \in A$, we distinguish two cases depending on whether the first indices $i \neq x$ are different or not. In the first case, the vertices are joined by the path $(a[i, j], b[i, y, 0], b[x, y, 0], a[x, y])$. In the second case, the middle two vertices are the same, thus the path shortens to $(a[i, j], b[x, y, 0], a[x, y])$.
- Symmetrically, for vertices $d[i, j], d[x, y] \in D$, the cases are defined with respect two the second indices, i.e., whether $j \neq y$. The paths are $(d[i, j], c[x, j, 0], c[x, y, 0], d[x, y])$ and $(d[i, j], c[x, y, 0], d[x, y])$, respectively.
- For vertices $b[i, j, k], b[x, y, z] \in B$, the generic path is $(b[i, j, k], b[x, j, k], b[x, y, z])$. If $i = x$, then the first two vertices are the same; if $j = y$, the last two are. The argument for vertices $c[i, j, k], c[x, y, z] \in C$ is the same.
- For the vertex pair $(a[i, j], b[x, y, z]) \in A \times B$, the ley point is that any edge inside of B changes exactly one of the first two indices. If $i \neq x$, the path is $(a[i, j], b[i, y, 0], b[x, y, z])$, otherwise it is $(a[i, j], b[x, \overline{y}, 0], b[x, y, z])$.
- The pair $(d[i, j], c[x, y, z]) \in D \times C$ is handled symmetrically. If $j \neq y$, the path is $(d[i, j], c[x, j, 0], c[x, y, z])$, otherwise it is $(d[i, j], b[\overline{x}, y, 0], b[x, y, z])$.
- Vertex pair $(a[i, j], c[x, y, z]) \in A \times C$: path $(a[i, j], b[i, y, 0], c[i, y, z], c[x, y, z])$. Note that if $i = x$ the last two vertices are the same. Vertex pair $(d[i, j], b[x, y, z]) \in D \times B$: path $(d[i, j], c[x, j, 0], b[x, j, z], b[x, y, z])$.
- Vertex pair $(a[i, j], d[x, y]) \in A \times D$: path $(a[i, j], b[i, y, 0], c[i, y, 0], d[x, y])$.
- Vertex pair $(b[i, j, k], c[x, y, z]) \in B \times C$: the path $(b[i, j, k], b[x, j, k], c[x, j, k], c[x, y, z])$ possibly shortens if consecutive vertices are the same. ◀

Consider an arbitrary binary $\sqrt{N} \times \sqrt{N} \times \sqrt{N}$ matrix (tensor) M. We build a supergraph $G \supseteq H$ embedding the information about the entries of M in the fault-tolerant diameter of G under dual failures, i.e., $\mathrm{diam}(G-F)$ with $|F| = 2$. The number of possible matrices M will then imply the space lower bounds for diameter oracles for G.

The graph G contains all vertices and edges of H and the following additional edges.

- For all $i, j, y \in [\sqrt{N}]$, if $M[i, j, y] = 1$, then add $\{a[i, j], b[i, y, 1]\}$ as an edge of G.
- For all $i, x, y \in [\sqrt{N}]$, if $M[i, x, y] = 1$, then add $\{c[i, y, 1], d[x, y]\}$.

Note that the diameter of G remains at most 3.

Consider any four indices $i, j, x, y \in [\sqrt{N}]$ such that $i \neq x$ and $j \neq y$. We define two sets F, F' both containing pairs of vertices in $V = V(H)$. First, let $F \subseteq E(H) \subseteq E$ contain $e_1 = \{a[i, j], b[i, y, 0]\}$ and $e_2 = \{c[i, y, 0], d[x, y]\}$. Secondly, let F' be the set comprising the two pairs $e'_1 = \{a[i, j], b[i, y, 1]\}$ and $e'_2 = \{c[i, y, 1], d[x, y]\}$. Note that the elements of F' are only edges of G if the entries $M[i, j, y]$ and $M[i, x, y]$ are 1.

▶ **Lemma 12.** *For any four indices $i, j, x, y \in [\sqrt{N}]$ such that $i \neq x$ and $j \neq y$, the diameter of $G - (F \cup F')$ is at least 5.*

Proof. We show that the distance between $a[i, j]$ and $d[x, y]$ in $G - (F \cup F')$ is at least 5. Contrarily, assume that $P = (a[i, j], w_1, w_2, w_3, d[x, y])$ is a path of length at most 4. P must pass across sets $A \to B$, $B \to C$, and $C \to D$ and change the indices from (i, j) to (x, y).

The neighborhood of $a[i, j]$ in $G - (F \cup F')$ is the set

$$\Big\{b[i, \overline{y}, 0] \mid \overline{y} \in [\sqrt{N}] \setminus \{y\}\Big\} \cup \Big\{b[i, \overline{y}, 1] \mid \overline{y} \in [\sqrt{N}] \setminus \{y\} \wedge M[i, j, \overline{y}]\} = 1\Big\}.$$

The index i cannot change on the first edge $\{a[i, j], w_1\}$ of P and, since the edges $e_1 = \{a[i, j], b[i, y, 0]\} \in F$ and $e'_1 = \{a[i, j], b[i, y, 1]\} \in F'$ are missing, the second index of w_1 must differ from y. Symmetrically, the change of j cannot take place on the last edge $\{w_3, d[x, y]\}$ and the first index of w_3 must differ from x. At least one of the edges $\{w_1, w_2\}$ or $\{w_2, w_3\}$ passes from B to C, w.l.o.g. let this be $\{w_1, w_2\}$. This edge (already present in H) cannot change any of the indices. We are left with $\{w_2, w_3\}$. If P has strictly less than 4 edges, then $w_2 = w_3$. Otherwise, either both endpoints w_2 and w_3 are in B, both are in C or there is exactly one in either. None of those cases allows one to make the *two* necessary changes to the indices simultaneously. ◀

▶ **Lemma 13.** *The diameter of $(G - F) \cup F'$ is 3.*

Proof. The proof is very similar to that of Lemma 11, only that every time the edge $e_1 = \{a[i, j], b[i, y, 0]\} \in F$ (respectively, $e_2 = \{c[i, y, 0], d[x, y]\}$) has been used, it is replaced by $e'_1 = \{a[i, j], b[i, y, 1]\} \in F'$ (respectively, by $e'_2 = \{c[i, y, 1], d[x, y]\}$). ◀

▶ **Lemma 14.** *The diameter of $G - F$ is at most 3 if $M[i, j, y] = M[i, x, y] = 1$, and at least 5 if $M[i, j, y] = M[i, x, y] = 0$.*

Proof. The diameter of graph $G - F$ is at least 5 if neither vertex pair in F' is an edge of G by Lemma 12. This is only true if $M[i, j, y] = M[i, x, y] = 0$. Conversely, by Lemma 13, the diameter is at most 3 if both edges in F' lie in G, i.e., if $M[i, j, y] = M[i, x, y] = 1$. ◀

We now finish the proof of Lemma 10. Suppose there exists a data structure that distinguishes whether after any two edges fail the diameter of the resulting graph is bounded by 3 or at least 5. We can use it to infer the entry $M[i, j, y]$ for any triple $(i, j, y) \in [\sqrt{N}]^3$

of indices such that i and j differ from each other, and j and y differ. We compute the edges in F with respect to the indices $i \neq x = j \neq y$ and apply Lemma 14 to check whether $M[i,j,y] = M[i,x,y] = 1$ or $M[i,j,y] = M[i,x,y] = 0$. For the assertion in Lemma 10 about the ST-diameter, we choose $S = A$ and $T = D$. Since there are $2^{\sqrt{N}(\sqrt{N}-1)^2} = 2^{\Omega(n^{3/2})}$ collections of possible answers, the oracle must take $\Omega(n^{3/2})$ bits of space.

Abstract

We generalize the celebrated isoperimetric inequality of Khot, Minzer, and Safra (SICOMP 2018) for Boolean functions to the case of real-valued functions $f : \{0,1\}^d \to \mathbb{R}$. Our main tool in the proof of the generalized inequality is a new Boolean decomposition that represents every real-valued function f over an arbitrary partially ordered domain as a collection of Boolean functions over the same domain, roughly capturing the distance of f to monotonicity and the structure of violations of f to monotonicity.

We apply our generalized isoperimetric inequality to improve algorithms for testing monotonicity and approximating the distance to monotonicity for real-valued functions. Our tester for monotonicity has query complexity $\widetilde{O}(\min(r\sqrt{d}, d))$, where r is the size of the image of the input function. (The best previously known tester makes $O(d)$ queries, as shown by Chakrabarty and Seshadhri (STOC 2013).) Our tester is nonadaptive and has 1-sided error. We prove a matching lower bound for nonadaptive, 1-sided error testers for monotonicity. We also show that the distance to monotonicity of real-valued functions that are α-far from monotone can be approximated nonadaptively within a factor of $O(\sqrt{d \log d})$ with query complexity polynomial in $1/\alpha$ and the dimension d. This query complexity is known to be nearly optimal for nonadaptive algorithms even for the special case of Boolean functions. (The best previously known distance approximation algorithm for real-valued functions, by Fattal and Ron (TALG 2010) achieves $O(d \log r)$-approximation.)

1 Introduction

We investigate the structure of real-valued functions over the domain $\{0,1\}^d$, the d-dimensional hypercube. Our main contribution is a generalization of a powerful tool from the analysis of Boolean functions, specifically, isoperimetric inequalities[1], to the case of real-valued functions. Isoperimetric inequalities for the undirected hypercube were studied by Margulis [34] and Talagrand [40]. Chakrabarty and Seshadhri [19] had a remarkable insight to develop a directed analogue of the Margulis inequality. This beautiful line of work culminated in the directed analogue of the Talagrand inequality proved by Khot, Minzer, and Safra [32]. We refer to this as the KMS inequality. As Khot, Minzer, and Safra explain in their celebrated work, the Margulis inequality follows from the Talagrand inequality and, more generally, the directed analogue of the Talagrand inequality implies all the other inequalities we mentioned. We generalize all these inequalities to the case of real-valued functions[2].

For the directed case, we prove a generalization of the KMS inequality for functions $f\colon \{0,1\}^d \to \mathbb{R}$. To generalize the *undirected* isoperimetric inequalities, we give a property testing interpretation of the Talagrand inequality. With this interpretation, it is easy to show a generalization of the undirected Talagrand inequality to the case of real-valued functions.

Our proofs of the new isoperimetric inequalities reduce the general case to the Boolean case. Our main tool for generalizing the KMS inequality is a new Boolean decomposition theorem that represents every real-valued function f over an arbitrary partially ordered domain as a collection of Boolean functions over the same domain, roughly capturing the distance of f to monotonicity and the structure of violations of f to monotonicity.

We apply our generalized isoperimetric inequality to improve algorithms for testing monotonicity and approximating the distance to monotonicity for real-valued functions. Our algorithm for testing monotonicity is nonadaptive and has 1-sided error. An algorithm is *nonadaptive* if its input queries do not depend on answers to previous queries. A property testing algorithm has *1-sided error* if it always accepts all inputs with the property it is testing. We show that our algorithm for testing monotonicity is optimal among nonadaptive, 1-sided error testers. Our distance approximation algorithm is nonadaptive. Its query complexity is nearly optimal for nonadaptive algorithms, even for the special case of Boolean functions.

1.1 Isoperimetric Inequalities for Real-Valued Functions

We view the domain of functions $f\colon \{0,1\}^d \to \mathbb{R}$ as the vertices of a d-dimensional hypercube. For the directed isoperimetric inequalities, the edges of the hypercube are ordered pairs (x,y), where $x,y \in \{0,1\}^d$ and there is a unique[3] $i \in [d]$ such that $x_i = 0, y_i = 1$, and $x_j = y_j$ for all coordinates $j \in [d] \setminus \{i\}$. This defines a natural partial order on the domain: $x \preceq y$ if $x_i \leq y_i$ for all coordinates $i \in [d]$ or, equivalently, if there is a directed path from x to y in the hypercube. A function $f\colon \{0,1\}^d \to \mathbb{R}$ is *monotone* if $f(x) \leq f(y)$ whenever $x \preceq y$. The distance to monotonicity of a function $f\colon \{0,1\}^d \to \mathbb{R}$, denoted $\varepsilon(f)$, is the minimum of

[1] We discuss isoperimetric inequalities that study the size of the "boundary" between the points on which the function takes value 0 and the points on which it takes value 1. The boundary size is defined in terms of the edges of the d-dimensional hypercube with vertices labeled by the values of the function. The edges of the hypercube might be directed or undirected, depending on the type of the inequality.

[2] Following our initial manuscript, [10] and [14] proved generalizations of the KMS inequality to Boolean functions over hypergrids. We remark that our techniques also extend these inequalities to real-valued functions, $f\colon [n]^d \to \mathbb{R}$. See Section 1.3 for more discussion.

[3] Given a positive integer $\ell \in \mathbb{Z}^+$, we let $[\ell]$ denote the set $\{1, 2, \ldots, \ell\}$.

$|\{x \in \{0,1\}^d \colon f(x) \neq g(x)\}|/2^d$ over all monotone functions $g \colon \{0,1\}^d \to \mathbb{R}$. An edge (x, y) is *violated* by f if $f(x) > f(y)$. Let $\mathcal{S}_f^-$ be the set of violated edges. For $x \in \{0,1\}^d$, let $I_f^-(x)$ be the number of *outgoing* violated edges incident on x, specifically,

$$I_f^-(x) = \left|\left\{y \colon (x,y) \in \mathcal{S}_f^-\right\}\right|.$$

Our main result is the following isoperimetric inequality.

▶ **Theorem 1.1** (Isoperimetric Inequality). *There exists a constant $C > 0$, such that for all functions $f \colon \{0,1\}^d \to \mathbb{R}$,*

$$\mathop{\mathbb{E}}_{\boldsymbol{x} \sim \{0,1\}^d}\left[\sqrt{I_f^-(\boldsymbol{x})}\right] \geq C \cdot \varepsilon(f). \tag{1}$$

Theorem 1.1 is a generalization of the celebrated inequality of Khot, Minzer, and Safra [32] that was strengthened by Pallavoor et al. [36], who proved (1) for the special case of Boolean functions $f \colon \{0,1\}^d \to \{0,1\}$. We show that the same inequality holds for real-valued functions without any dependence on the size of the image of the function. In addition, the constant C is only a factor of 2 smaller than the constant in the inequality of Pallavoor et al.

Applications to monotonicity testing and distance approximation rely on a stronger, "robust" version of Theorem 1.1. The robust version considers an arbitrary 2-coloring $\texttt{col} \colon \mathcal{S}_f^- \to \{\text{red}, \text{blue}\}$ of the violated edges. The color of an edge is used to specify whether the edge is counted towards the lower or the upper endpoint. Let $I^-_{f,\text{red}}(x)$ be the number of *outgoing* red violated edges incident on x, and $I^-_{f,\text{blue}}(x)$ be the number of *incoming* blue violated edges incident on x, specifically,

$$I^-_{f,\text{red}}(x) = \left|\left\{y \colon (x,y) \in \mathcal{S}_f^-,\, \texttt{col}(x,y) = \text{red}\right\}\right|;$$
$$I^-_{f,\text{blue}}(y) = \left|\left\{x \colon (x,y) \in \mathcal{S}_f^-,\, \texttt{col}(x,y) = \text{blue}\right\}\right|.$$

Our next theorem is a generalization of the robust isoperimetric inequality for Boolean functions established by Khot, Minzer, and Safra and strengthened by Pallavoor et al. As before, the constant C is only a factor of 2 smaller for the real-valued case than for the Boolean case.

▶ **Theorem 1.2** (Robust Isoperimetric Inequality). *There exists a constant $C > 0$, such that for all functions $f \colon \{0,1\}^d \to \mathbb{R}$ and colorings $\texttt{col} \colon \mathcal{S}_f^- \to \{\text{red}, \text{blue}\}$,*

$$\mathop{\mathbb{E}}_{\boldsymbol{x} \sim \{0,1\}^d}\left[\sqrt{I^-_{f,\text{red}}(\boldsymbol{x})}\right] + \mathop{\mathbb{E}}_{\boldsymbol{y} \sim \{0,1\}^d}\left[\sqrt{I^-_{f,\text{blue}}(\boldsymbol{y})}\right] \geq C \cdot \varepsilon(f).$$

Note that Theorem 1.2 implies Theorem 1.1 by considering the coloring where all violated edges are red. Therefore, we only present a proof of Theorem 1.2.

1.1.1 Boolean Decomposition

Our main technical contribution is the Boolean decomposition (Theorem 1.3). It allows us to prove Theorem 1.2 by reducing the general case of real-valued functions to the special case of Boolean functions. Theorem 1.3 states that every non-monotone function f can be decomposed into Boolean functions $f_1, f_2, \ldots, f_k$ that collectively preserve the distance to monotonicity of f and violate a subset of the edges violated by f. Crucially, they violate edges in vertex-disjoint subgraphs of the hypercube.

Our Boolean decomposition works for functions over any partially ordered domain. We represent such a domain by a directed acyclic graph (DAG). For a DAG $\mathcal{G}$, we denote its vertex set by $V(\mathcal{G})$ and its edge set by $E(\mathcal{G})$. A DAG $\mathcal{G}$ determines a natural partial order on its vertex set: for all $x, y \in V(\mathcal{G})$, we have $x \preceq y$ if and only if $\mathcal{G}$ contains a path from x to y. A function $f\colon V(\mathcal{G}) \to \mathbb{R}$ is *monotone* if $f(x) \leq f(y)$ whenever $x \preceq y$. An edge (x, y) of $\mathcal{G}$ is *violated* by f if $f(x) > f(y)$. The definitions of $\varepsilon(f)$, the distance of f to monotone, and $\mathcal{S}_f^-$, the set of violated edges, are the same as for the special case of the hypercube.

▶ **Theorem 1.3** (Boolean Decomposition). *Suppose $\mathcal{G}$ is a DAG and $f\colon V(\mathcal{G}) \to \mathbb{R}$ is a function over the vertices of $\mathcal{G}$ that is not monotone. Then, for some $k \geq 1$, there exist Boolean functions $f_1, \ldots, f_k\colon V(\mathcal{G}) \to \{0,1\}$ and vertex-disjoint (induced) subgraphs $\mathcal{H}_1, \ldots, \mathcal{H}_k$ of $\mathcal{G}$ for which the following hold:*

1. $2\sum_{i=1}^{k} \varepsilon(f_i) \geq \varepsilon(f)$.
2. $\mathcal{S}_{f_i}^- \subseteq \mathcal{S}_f^- \cap E(\mathcal{H}_i)$ *for all* $i \in [k]$.

We derive Theorem 1.2 from Theorem 1.3 in Section 2 and prove Theorem 1.3 in Section 3.

A natural first attempt to proving Theorem 1.1 is to try reducing to the special case of Boolean functions (the KMS inequality) via a thresholding argument. Given $f\colon \{0,1\}^d \to \mathbb{R}$ and $t \in \mathbb{R}$, define $h_t\colon \{0,1\}^d \to \{0,1\}$ to be $h_t(x) = 1$ iff $f(x) > t$. Clearly, this can only reduce the left-hand side of (1) since the influential edges of h_t are a subset of the influential edges of f. Thus, if there exists some $t \in \mathbb{R}$ such that $\varepsilon(h_t) = \Omega(\varepsilon(f))$, then applying the KMS inequality to h_t would show that the inequality also holds for f. In fact, this technique easily allows us to reduce the *undirected* inequality for the real-valued case to the Boolean case, without any significant additional ideas (see Section 7 of the full version [11] for details). However, in the directed setting, a simple argument shows that there exists f for which $\varepsilon(h_t) \leq \varepsilon(f)/r$ for all $t \in \mathbb{R}$, where r is the size of the image of f. Thus, we use additional ideas to prove Theorem 1.1 by a reduction to the KMS inequality. The highly structured decomposition of Theorem 1.3 gives a collection of vertex-disjoint subgraphs $\mathcal{H}_1, \ldots, \mathcal{H}_k$ of the directed hypercube where, in each $\mathcal{H}_i$, an independent "variable thresholding rule" can be applied, yielding the Boolean function f_i. The "threshold" for each vertex x in $\mathcal{H}_i$ depends on the values of the function at a particular set of vertices reachable from x.

The Boolean decomposition is quite powerful: in addition to enabling us to prove the new isoperimetric inequality, it can be used to easily derive a lower bound on the number of edges violated by a real-valued function directly from the bound for the Boolean case, without relying on Theorem 1.2. This bound is used to analyze the edge tester for monotonicity whose significance is described in Section 1.2. The early works on monotonicity testing [30, 25, 39] have shown that $|\mathcal{S}_f^-| \geq \varepsilon(f) \cdot 2^d$ for every Boolean function f on the domain $\{0,1\}^d$. In other words, the number of edges violated by f is at least the number of points on which the value of the function has to change to make it monotone. This bound was generalized to the case of real-valued functions by [25, 39] who showed that $|\mathcal{S}_f^-| \geq (\varepsilon(f)/\lceil \log r \rceil) \cdot 2^d$ for every real-valued function f on the domain $\{0,1\}^d$ and with image size r. (The size of the image of f is the number of distinct values it takes.) Chakrabarty and Seshadhri [17] improved this bound by a factor of $\Theta(\log r)$, thus removing the dependence on the size of the image of the function. Our Boolean decomposition of a real-valued function f in terms of Boolean functions $f_1, \ldots, f_k$, given by Theorem 1.3, yields this result of [17] as an immediate corollary of the special case for Boolean functions:

$$|\mathcal{S}_f^-| \geq \sum_{i=1}^{k} |\mathcal{S}_{f_i}^-| \geq \sum_{i=1}^{k} \varepsilon(f_i) \cdot 2^d \geq \varepsilon(f) \cdot 2^{d-1},$$

where the inequalities follow by first applying Item 2 of Theorem 1.3, then applying the bound for the Boolean case, and, finally, applying Item 1 of Theorem 1.3.

1.1.2 Undirected Isoperimetric Inequality for Real-Valued Functions

The original isoperimetric inequality of Talagrand [40] treats the domain $\{0,1\}^d$ as an undirected hypercube. An undirected edge $\{x,y\}$ is *influential* if $f(x) \neq f(y)$. Let $I_f(x)$ be the number of influential edges $\{x,y\}$ incident on $x \in \{0,1\}^d$ for which $f(x) > f(y)$. This definition ensures that each influential edge is counted towards $I_f(x)$ for exactly one vertex x. The variance $\mathrm{var}(f)$ of a Boolean function is defined as $p_0(1-p_0)$, where p_0 is the probability that $f(x) = 0$ for a uniformly random point x in the domain. Talagrand [40] proved the following.

▶ **Theorem 1.4** (Talagrand Inequality [40]). *For all functions* $f\colon \{0,1\}^d \to \{0,1\}$,

$$\mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^d}\left[\sqrt{I_f(\boldsymbol{x})}\right] \geq \sqrt{2}\ \mathrm{var}(f). \tag{2}$$

Before generalizing Theorem 1.4 to real-valued functions, we reinterpret it using a property testing notion. Observe that the natural definition of the variance of a real-valued function results in a quantity that depends on specific values of the function, whereas whether an edge is influential depends only on whether the values on its endpoints are different and not on the specific values themselves. So, variance is not a suitable notion for generalizing this inequality. We replace the variance of f with the distance of f to constant, denoted $\mathtt{dist}(f, \mathbf{const})$, i.e., the minimum of $\Pr_{\boldsymbol{x}\sim\{0,1\}^d}[f(\boldsymbol{x}) \neq g(\boldsymbol{x})]$ over all constant functions $g\colon \{0,1\}^d \to \mathbb{R}$. For a Boolean function f, the distance to constant is $\min\{p_0, (1-p_0)\}$ and, therefore, the left-hand side of (2) is at least $\mathtt{dist}(f, \mathbf{const})/\sqrt{2}$. Next, we state our generalization of Talagrand's inequality. See Section 7 of the full version [11] for the proof.

▶ **Theorem 1.5** (Undirected Isoperimetric Inequality). *For all functions* $f\colon \{0,1\}^d \to \mathbb{R}$,

$$\mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^d}\left[\sqrt{I_f(\boldsymbol{x})}\right] \geq \frac{\mathtt{dist}(f, \mathbf{const})}{2\sqrt{2}}.$$

Note that natural generalizations of the Margulis inequality and the inequality of Chakrabarty and Seshadhri to the real range follow from Theorem 1.2 (for the the special case of Boolean functions, the implication is discussed in [32], and it holds for the real range for the same reasons).

1.2 Applications of Our Isoperimetric Inequality for Real-Valued Functions

We apply our generalized isoperimetric inequality (Theorem 1.2) to improve algorithms for testing monotonicity and approximating the distance to monotonicity for real-valued functions.

1.2.1 Monotonicity Testing

Monotonicity of functions, first studied in the context of property testing by Goldreich et al. [30], is one of the most widely investigated properties in this model [26, 25, 39, 33, 29, 1, 28, 31, 3, 38, 2, 7, 15, 12, 17, 18, 19, 13, 16, 21, 5, 23, 35, 8, 32, 20, 9]. A function is ε-far from monotone if its distance to monotonicity is at least ε; otherwise, it is ε-close to monotone. An ε-tester for monotonicity is a randomized algorithm that, given a parameter $\varepsilon \in (0,1)$ and oracle access to a function f, accepts with probability at least $2/3$ if f is monotone and rejects with probability at least $2/3$ if f is ε-far from monotone. Prior to

our work, the best monotonicity tester for real-valued functions was the *edge tester*. The edge tester, introduced by [30], queries the values of f on the endpoints of uniformly random edges of the hypercube and rejects if it finds a violated edge. As we discussed in Section 1.1, a series of works [30, 25, 39, 17] proved lower bounds on $|\mathcal{S}_f^-|$, the number of violated edges, resulting in the tight analysis of the edge tester for both Boolean and real-valued functions: $O(d/\varepsilon)$ queries are sufficient (and also necessary, e.g., for $f(x) = 1 - x_1$, the anti-dictator function). For many years, it remained open whether an $o(d)$-query tester for monotonicity existed, until a sequence of breakthroughs [19, 22, 32] designed testers for Boolean functions with query complexity $\widetilde{O}(d^{7/8}), \widetilde{O}(d^{5/6})$, and finally $\widetilde{O}(\sqrt{d})$. Prior to our work, the same question remained open for functions with image size, r, greater than 2.

We show that when r is small compared to d, monotonicity can be tested with $o(d)$ queries. (Note that $r \leq 2^d$.)

▶ **Theorem 1.6.** *There exists a nonadaptive, 1-sided error ε-tester for monotonicity of functions $f\colon \{0,1\}^d \to \mathbb{R}$ that makes $\widetilde{O}\Big(\min\big(\frac{r\sqrt{d}}{\varepsilon^2}, \frac{d}{\varepsilon}\big)\Big)$ queries and works for all functions f with image size r.*

The proof of Theorem 1.6 (in Section 4) heavily relies on the generalized isoperimetric inequality of Theorem 1.2. We extend several other combinatorial properties of Boolean functions to real-valued functions. In particular, the persistence of a vertex $x \in \{0,1\}^d$ is a key combinatorial concept in the analysis. A vertex $x \in \{0,1\}^d$ is τ-persistent if, with high probability, a random walk that starts at x and takes τ steps in the d-dimensional directed hypercube ends at a vertex y for which $f(y) \leq f(x)$. As we show, the upper bound on the number of vertices which are not τ-persistent grows linearly with the distance τ *and* the image size r. For the tester analysis, one needs to carefully choose the distance parameter τ for which many vertices are τ-persistent. In particular, this value of τ also depends on the image size r, resulting in the linear dependence on r in the query complexity of the tester.

1.2.2 Our Lower Bound for Testing Monotonicity

We show that our monotonicity tester is optimal among nonadaptive, 1-sided error testers.

▶ **Theorem 1.7.** *There exists a constant $\varepsilon > 0$, such that for all $d, r \in \mathbb{N}$, every nonadaptive, 1-sided error ε-tester for monotonicity of functions $f\colon \{0,1\}^d \to [r]$ requires $\Omega(\min(r\sqrt{d}, d))$ queries.*

We prove Theorem 1.7 by generalizing a construction of Fischer et al. [29] that showed that nonadaptive, 1-sided error monotonicity testers of Boolean functions must make $\Omega(\sqrt{d})$ queries. We refer the reader to Section 6 of the full version [11] for the proof. Blais et al. [12] demonstrated that every tester for monotonicity over the d-dimensional hypercube domain requires $\Omega(\min(d, r^2))$ queries. Our lower bound is stronger when $r \in [2, \sqrt{d}]$, although it applies only to nonadaptive, 1-sided error algorithms.

1.2.3 Approximating the Distance to Monotonicity

Motivated by the desire to handle noisy inputs, Parnas et al. [38] generalized the property testing model to tolerant testing. There is a direct connection between tolerant testing of a property and approximating the distance to the property with additive and multiplicative error in the sense that these problems can be reduced to each other with the right setting of parameters and have the same query complexity up to logarithmic factors (see, e.g., [38, Claim 2] and [36, Theorem A.1]). One clean way to state distance approximation guarantees

is to replace the additive error α with the promise that the input function is α-far from the property, as specified in the following definition. A randomized *c-approximation algorithm for the distance to monotonicity,* where $c > 1$, is given a parameter $\alpha \in (0, 1)$ and oracle access to a function $f\colon \{0,1\}^d \to \mathbb{R}$ that is α-far from monotone. It outputs an estimate $\hat{\varepsilon}$ that, with probability at least $2/3$, satisfies $\varepsilon(f) \leq \hat{\varepsilon} \leq c \cdot \varepsilon(f)$.

Fattal and Ron [27] studied the problem of approximating the distance to monotonicity for real-valued functions over the hypergrid domain $[n]^d$. For the special case of the hypercube domain, they give an $O(d \log r)$-approximation algorithm for functions with image size r that makes $\text{poly}(d, 1/\alpha)$ queries. Theorem 1.2 allows us to improve on their result, by showing that the algorithm of Pallavoor et al. [36] for approximating the distance to monotonicity of Boolean functions also works for real-valued functions, without any loss in the approximation guarantee.

▶ **Theorem 1.8.** *There exists a nonadaptive $O(\sqrt{d \log d})$-approximation algorithm for the distance to monotonicity that, given a parameter $\alpha \in (0, 1)$ and oracle access to a function $f\colon \{0,1\}^d \to \mathbb{R}$ that is α-far from monotone, makes $\text{poly}(d, 1/\alpha)$ queries.*

Pallavoor et al. prove that this approximation ratio is nearly optimal for nonadaptive algorithms, even for the special case of Boolean functions. We also note that, by the connection between tolerant testing and erasure-resilient testing observed by Dixit et al. [24], our Theorem 1.8 implies the existence of an erasure-resilient ε-tester for monotonicity of functions $f : \{0,1\}^d \to \mathbb{R}$ that can handle up to $\Theta(\varepsilon/\sqrt{d \log d})$ erasures with query complexity $\text{poly}(d, 1/\varepsilon)$. The tester of Dixit et al. could handle only $O(\varepsilon/d)$ erasures. For the proof of Theorem 1.8, we refer the reader to Section 5 of the full version [11].

1.3 Other Prior Work on Monotonicity Testing and Open Questions

The query complexity of monotonicity testing of Boolean functions over the hypercube has been resolved for nonadaptive testers by Chen et al. [21, 23] who proved a lower bound of $\widetilde{\Omega}(\sqrt{d})$. For adaptive testers, the best lower bound known to date is $\widetilde{\Omega}(d^{1/3})$, also shown by [23]. It is an open question whether adaptive algorithms can do better than nonadaptive ones for functions over the hypercube domain, both in the case of Boolean functions and, more generally, for functions with small image size. As we mentioned before, there is a lower bound of $\Omega(d)$ for functions with image size $\Omega(\sqrt{d})$ [12].

Monotonicity testing has also been studied for functions on other types of domains, including general partially ordered domains [29], with particular attention to the hypergrid domain $[n]^d$. (It has also been investigated in the context where the distance to monotonicity is the normalized L_p distance instead of the Hamming distance [6], but we focus our attention here on the Hamming distance.) When $d = 1$, monotonicity testing on the hypergrid $[n]$ is equivalent to testing sortedness of n-element arrays. This problem was introduced by Ergun et al. [26]. Its query complexity has been completely pinned down in terms of n and ε by [26, 28, 18, 4]: it is $\Theta(\frac{\log(\varepsilon n)}{\varepsilon})$. Pallavoor et al. [35, 37] considered the setting when the tester is given an additional parameter r, the number of distinct elements in the array, and obtained an $O((\log r)/\varepsilon)$-query algorithm. There are also lower bounds for this setting: $\Omega(\log r)$ for nonadaptive algorithms by [13] and $\Omega(\frac{\log r}{\log \log r})$ for all testers for the case when $r = n^{1/3}$ by [4].

For general d, Black et al. [8, 9] gave an $\widetilde{O}(d^{5/6})$-query tester for Boolean functions $f\colon [n]^d \to \{0,1\}$. For real-valued functions, Chakrabarty and Seshadhri [17, 18] proved basically matching upper and lower bounds of $O((d \log n)/\varepsilon)$ and $\Omega((d \log n - \log \varepsilon^{-1})/\varepsilon)$. However, their lower bound only applies for functions with a large image. Pallavoor et al. [35]

gave an $O(\frac{d}{\varepsilon} \cdot \log \frac{d}{\varepsilon} \cdot \log r)$-query tester, where r, the size of the image, is given to the tester as a parameter. It remains open whether there is an $\widetilde{O}(\sqrt{d})$-query tester for Boolean functions on the hypergrid domain.

1.3.1 Discussion of Results Published After our Initial Manuscript

Recently, in independent works, [10] and [14] showed generalizations of the isoperimetric inequality of [32] to Boolean functions on general hypergrids (see [10, Theorem 1.4] and [14, Theorem 1.3]). These works obtain $\widetilde{O}(n\sqrt{d}/\varepsilon^2)$-query and $\widetilde{O}(n^3\sqrt{d}/\varepsilon^2)$-query nonadaptive, 1-sided error monotonicity testers, respectively, for such functions. Our Boolean decomposition (Theorem 1.3) implies that these isoperimetric inequalities also hold for functions $f\colon [n]^d \to \mathbb{R}$ by the approach described in Section 2. We also believe that this should imply the existence of an $\widetilde{O}(rn\sqrt{d}/\varepsilon^2)$-query tester for functions $f\colon [n]^d \to [r]$. A possible approach to proving this could be to generalize the analysis given in Section 7 of [10] to the case of range $[r]$. Presumably, this would follow the same approach as in our Section 4 in which we prove Theorem 1.6, but adapted to hypergrids. Since [10, 14] were published well after our initial manuscript, we will refrain from going into further details on their relationship with our results.

2 Directed Talagrand Inequality for Real-Valued Functions

In this section, we use our Boolean decomposition (Theorem 1.3) to prove Theorem 1.2, which easily implies the non-robust version (Theorem 1.1) as we point out in the introduction. Let $f\colon \{0,1\}^d \to \mathbb{R}$ be a non-monotone function over the d-dimensional hypercube and let $\texttt{col}\colon \mathcal{S}_f^- \to \{\text{red}, \text{blue}\}$ be an arbitrary 2-coloring of $\mathcal{S}_f^-$. Given $x \in \{0,1\}^d$ and a subgraph $\mathcal{H}$ of the d-dimensional hypercube, we define the quantities

$$I^-_{f,\text{red},\mathcal{H}}(x) = \left|\left\{y\colon (x,y) \in \mathcal{S}_f^- \cap E(\mathcal{H}),\, \texttt{col}(x,y) = \text{red}\right\}\right|;$$
$$I^-_{f,\text{blue},\mathcal{H}}(y) = \left|\left\{x\colon (x,y) \in \mathcal{S}_f^- \cap E(\mathcal{H}),\, \texttt{col}(x,y) = \text{blue}\right\}\right|.$$

Let $f_1, \ldots, f_k\colon \{0,1\}^d \to \{0,1\}$ be the Boolean functions and $\mathcal{H}_1, \ldots, \mathcal{H}_k$ be the vertex-disjoint subgraphs of the d-dimensional hypercube that are guaranteed by Theorem 1.3. Let C' denote the constant from the robust Boolean isoperimetric inequality (Theorem 2.7 of [36]) that is hidden by Ω. We have

$$\begin{aligned}
&\mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^d}\left[\sqrt{I^-_{f,\text{red}}(\boldsymbol{x})}\right] + \mathop{\mathbb{E}}_{\boldsymbol{y}\sim\{0,1\}^d}\left[\sqrt{I^-_{f,\text{blue}}(\boldsymbol{y})}\right] \\
&\geq \mathop{\mathbb{E}}_{\boldsymbol{x}}\left[\sqrt{I^-_{f,\text{red},\bigcup_{i=1}^k \mathcal{H}_i}(\boldsymbol{x})}\right] + \mathop{\mathbb{E}}_{\boldsymbol{y}}\left[\sqrt{I^-_{f,\text{blue},\bigcup_{i=1}^k \mathcal{H}_i}(\boldsymbol{y})}\right] && (3)\\
&= \sum_{i=1}^k \left(\mathop{\mathbb{E}}_{\boldsymbol{x}}\left[\sqrt{I^-_{f,\text{red},\mathcal{H}_i}(\boldsymbol{x})}\right] + \mathop{\mathbb{E}}_{\boldsymbol{y}}\left[\sqrt{I^-_{f,\text{blue},\mathcal{H}_i}(\boldsymbol{y})}\right]\right) && (4)\\
&\geq \sum_{i=1}^k \left(\mathop{\mathbb{E}}_{\boldsymbol{x}}\left[\sqrt{I^-_{f_i,\text{red},\mathcal{H}_i}(\boldsymbol{x})}\right] + \mathop{\mathbb{E}}_{\boldsymbol{y}}\left[\sqrt{I^-_{f_i,\text{blue},\mathcal{H}_i}(\boldsymbol{y})}\right]\right) && (5)\\
&= \sum_{i=1}^k \left(\mathop{\mathbb{E}}_{\boldsymbol{x}}\left[\sqrt{I^-_{f_i,\text{red}}(\boldsymbol{x})}\right] + \mathop{\mathbb{E}}_{\boldsymbol{y}}\left[\sqrt{I^-_{f_i,\text{blue}}(\boldsymbol{y})}\right]\right) && (6)
\end{aligned}$$

$$\geq \sum_{i=1}^{k} C' \cdot \varepsilon(f_i) \tag{7}$$

$$\geq \frac{C' \cdot \varepsilon(f)}{2}. \tag{8}$$

The inequality (3) holds because $\bigcup_{i=1}^{k} \mathcal{H}_i$ is a subgraph of the d-dimensional hypercube. The equality (4) holds because the $\mathcal{H}_i$'s are vertex-disjoint. The inequality (5) holds since $\mathcal{S}^-_{f_i} \subseteq \mathcal{S}^-_f$ and the equality (6) holds since $\mathcal{S}^-_{f_i} \subseteq E(\mathcal{H}_i)$ (these are both by item 2 of Theorem 1.3). Finally, (7) is due to [36, Theorem 2.7] and (8) is due to item 1 of Theorem 1.3.

3 Boolean Decomposition: Proof of Theorem 1.3

In this section, we prove Boolean Decomposition (Theorem 1.3). Our results consider any partially ordered domain, which we represent by a DAG $\mathcal{G}$. The *transitive closure* of $\mathcal{G}$, denoted $\mathrm{TC}(\mathcal{G})$, is the graph with vertex set $V(\mathcal{G})$ and edge set $\{(x, y) \colon x \prec y\}$. The *violation graph* of f is the graph $(V(\mathcal{G}), E')$, where E' is the set of edges of $\mathrm{TC}(\mathcal{G})$ violated by f.

In Section 3.1, we define the key notion of sweeping graphs and identify some of their important properties. In Section 3.2, we prove a general lemma that shows how to use a matching M in $\mathrm{TC}(\mathcal{G})$ to find vertex-disjoint sweeping graphs in $\mathcal{G}$ satisfying a "matching rearrangement" property. The techniques in Section 3.1 and Section 3.2 are inspired by the techniques of [8] used to analyze Boolean functions on the hypergrid domain, $[n]^d$. In Section 3.3, we apply our matching decomposition lemma to a carefully chosen matching to obtain the subgraphs $\mathcal{H}_1, \ldots, \mathcal{H}_k$. Finally, in Section 3.4, we define the Boolean functions $f_1, \ldots, f_k$ and complete the proof of Theorem 1.3.

3.1 Sweeping Graphs and Their Properties

Given a graph $\mathcal{G}$ and two subgraphs $\mathcal{H}_1$ and $\mathcal{H}_2$, we define the union $\mathcal{H}_1 \cup \mathcal{H}_2$ to be the graph with vertex set $V(\mathcal{H}_1) \cup V(\mathcal{H}_2)$ and edge set $E(\mathcal{H}_1) \cup E(\mathcal{H}_2)$.

▶ **Definition 3.1** ((S,T)-Sweeping Graphs). *Given a DAG $\mathcal{G}$ and $s, t \in V(\mathcal{G})$, define $\mathcal{H}(s,t)$ to be the subgraph of $\mathcal{G}$ formed by the union of all directed paths in $\mathcal{G}$ from s to t. Given two disjoint subsets $S, T \subseteq V(\mathcal{G})$, define the* (S,T)-sweeping graph*, denoted $\mathcal{H}(S,T)$, to be the union of directed paths in $\mathcal{G}$ that start from some $s \in S$ and end at some $t \in T$. That is,*

$$\mathcal{H}(S,T) = \bigcup_{(s,t) \in S \times T} \mathcal{H}(s,t).$$

Note that if $s \not\preceq t$ then $\mathcal{H}(s,t) = \emptyset$.

We now prove three properties of sweeping graphs which we use in Section 3.4 to analyze our functions $f_1, \ldots, f_k$. Given disjoint sets $S, T \subseteq V(\mathcal{G})$ and $z \in V(\mathcal{H}(S,T))$, define the sets

$$S(z) = \{s \in S \colon s \preceq z\} \text{ and } T(z) = \{t \in T \colon z \preceq t\}.$$

▷ Claim 3.2 (Properties of Sweeping Graphs). Let $\mathcal{G}$ be a DAG and $S, T \subseteq V(\mathcal{G})$ be disjoint sets.

1. *(Property of Nodes in a Sweeping Graph):* If $z \in V(\mathcal{H}(S,T))$ then $S(z) \neq \emptyset$ and $T(z) \neq \emptyset$.
2. *(Property of Nodes Outside of a Sweeping Graph):* If $z \in V(\mathcal{G}) \setminus V(\mathcal{H}(S,T))$ then at most one of the following is true: (a) $\exists y \in V(\mathcal{H}(S,T))$ such that $z \prec y$, (b) $\exists x \in V(\mathcal{H}(S,T))$ such that $x \prec z$.
3. *(Sweeping Graphs are Induced):* If $x, y \in V(\mathcal{H}(S,T))$ and $(x,y) \in E(\mathcal{G})$ then $(x,y) \in E(\mathcal{H}(S,T))$.

Proof. Property 1 holds by definition of the sweeping graph $\mathcal{H}(S,T)$. If $z \in V(\mathcal{H}(S,T))$, then, by definition of $\mathcal{H}(S,T)$, there exist $s \in S$ and $t \in T$ for which z belongs to some directed path from s to t. That is, $z \in V(\mathcal{H}(s,t))$. Thus, $s \in S(z)$ and $t \in T(z)$, and property 1 holds.

We now prove property 2. Suppose, for the sake of contradiction, that there exist $x, y, z \in V(\mathcal{G})$ for which $x, y \in V(\mathcal{H}(S,T))$, $z \notin V(\mathcal{H}(S,T))$, and $x \prec z \prec y$. By property 1, there exist some $s \in S(x)$ and some $t \in T(y)$. Then $s \preceq x \prec z \prec y \preceq t$ and, consequently, z belongs to some directed path from s to t. Thus, $z \in V(\mathcal{H}(s,t))$, and so $z \in V(\mathcal{H}(S,T))$. This is a contradiction.

We now prove property 3. Suppose $x, y \in V(\mathcal{H}(S,T))$ and $(x,y) \in E(\mathcal{G})$. By property 1, there exist $s \in S$ and $t \in T$ for which $s \preceq x$ and $y \preceq t$. Since $(x,y) \in E(\mathcal{G})$, we have $x \prec y$ and so $s \preceq x \prec y \preceq t$. Thus, the edge (x,y) belongs to a directed path from s to t. That is, $(x,y) \in E(\mathcal{H}(s,t))$ and so $(x,y) \in E(\mathcal{H}(S,T))$. ◁

3.2 Matching Decomposition Lemma for DAGs

In this section, we prove the following matching decomposition lemma. Recall that $\mathrm{TC}(\mathcal{G})$ denotes the transitive closure of $\mathcal{G}$, which is the graph with vertex set $V(\mathcal{G})$ and edge set $\{(x,y) \colon x \prec y\}$. Consider a matching M in $\mathrm{TC}(\mathcal{G})$. We represent $M \colon S \to T$ as a bijection between two disjoint sets $S, T \subseteq V(\mathcal{G})$ of the same size for which $s \prec M(s)$ for all $s \in S$. For a set $S' \subseteq S$, define $M(S') = \{M(s) \colon s \in S'\}$. Note that for convenience we will sometimes abuse notation and represent M as the set of pairs, $\{(s, M(s)) \colon s \in S\}$, instead of as a bijection.

▶ **Lemma 3.3** (Matching Decomposition Lemma for DAGs). *For every DAG $\mathcal{G}$ and every matching $M \colon S \to T$ in $\mathrm{TC}(\mathcal{G})$, there exist partitions $(S_i \colon i \in [k])$ of S and $(T_i \colon i \in [k])$ of T, where $M(S_i) = T_i$ for all $i \in [k]$, and the following hold.*

1. (Sweeping Graph Disjointness): *$V(\mathcal{H}(S_i, T_i)) \cap V(\mathcal{H}(S_j, T_j)) = \emptyset$ for all $i \neq j \in [k]$.*
2. (Matching Rearrangement Property): *For all $i \in [k]$ and $(x,y) \in S_i \times T_i$, if $x \prec y$ then there exists a matching $\widehat{M} \colon S_i \to T_i$ in $\mathrm{TC}(\mathcal{G})$ for which $(x,y) \in \widehat{M}$.*

Proof. In Algorithm 1, we show how to construct partitions $(S_i \colon i \in [k])$ for S and $(T_i \colon i \in [k])$ for T from a matching M in $\mathrm{TC}(\mathcal{G})$. We use the following notion of conflicting pairs.

▶ **Definition 3.4** (Conflicting Pairs). *Given a DAG $\mathcal{G}$ and four disjoint sets $X, Y, X', Y' \subset V(\mathcal{G})$, we say the two pairs (X,Y) and (X',Y') conflict if $V(\mathcal{H}(X,Y)) \cap V(\mathcal{H}(X',Y')) \neq \emptyset$.*

Algorithm 1 Algorithm for constructing conflict-free pairs from a matching M.

Require: A DAG $\mathcal{G}$ and a matching $M \colon S \to T$ in $\mathrm{TC}(\mathcal{G})$.

$\mathcal{Q}_0 \leftarrow \{(\{x\}, \{y\}) \colon (x,y) \in M\}$ ▷ Initialize pairs using M
for $s \geq 0$ **do**
  if two pairs $(X,Y) \neq (X',Y') \in \mathcal{Q}_s$ *conflict* **then**
    $\mathcal{Q}_{s+1} \leftarrow (\mathcal{Q}_s \setminus \{(X,Y),(X',Y')\}) \cup \{(X \cup X', Y \cup Y')\}$ ▷ Merge conflicting pairs
  else
    $s^* \leftarrow s$ and **return** $\mathcal{Q}_{s^*}$ ▷ Terminate when there are no conflicts

The following observation is apparent and by design of Algorithm 1.

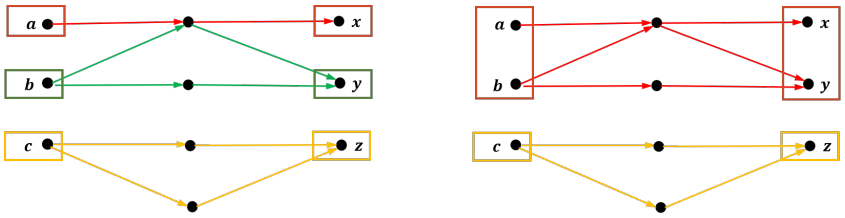

Figure 1 An illustration for Algorithm 1 with input matching $M = \{(a,x),(b,y),(c,z)\}$. We initialize $\mathcal{Q}_0 = \{(\{a\},\{x\}),(\{b\},\{y\}),(\{c\},\{z\})\}$. The pairs $(\{a\},\{x\})$ and $(\{b\},\{y\})$ conflict, so we merge them to obtain a new and final collection $Q_1 = \{(\{a,b\},\{x,y\}),(\{c\},\{z\})\}$.

▶ **Observation 3.5** (Loop Invariants of Algorithm 1). *For all $s \in \{0,1,\ldots,s^*\}$, (a) $M(X) = Y$ for all $(X,Y) \in \mathcal{Q}_s$, (b) $(X : (X,\cdot) \in \mathcal{Q}_s)$ is a partition of S, and (c) $(Y : (\cdot,Y) \in \mathcal{Q}_s)$ is a partition of T.*

Given a matching $M : S \to T$ in $\mathrm{TC}(\mathcal{G})$, we run Algorithm 1 to obtain the set $\mathcal{Q}_{s^*}$. See Fig. 1 for an illustration. Define $k = |\mathcal{Q}_{s^*}|$ and let $\{(S_i,T_i) : i \in [k]\}$ be the set of pairs in $\mathcal{Q}_{s^*}$. By Observation 3.5, $(S_i : i \in [k])$ is a partition of S, $(T_i : i \in [k])$ is a partition of T, and $M(S_i) = T_i$ for all $i \in [k]$. Item 1 of Lemma 3.3 holds since Algorithm 1 terminates at step s only when all pairs in $\mathcal{Q}_s$ are non-conflicting (recall Definition 3.4). Thus, to prove Lemma 3.3 it only remains to prove item 2. To do so, we prove the following Claim 3.6, that easily implies item 2. Note that while we only require Claim 3.6 to hold for the special case of $s = s^*$, using an inductive argument on s allows us to give a proof for all $s \in \{0,1,\ldots,s^*\}$.

▷ Claim 3.6 (Rematching Claim). For all $s \in \{0,1,\ldots,s^*\}$, pairs $(X,Y) \in \mathcal{Q}_s$, and $(x,y) \in X \times Y$, there exists a matching $\widehat{M} : X \setminus \{x\} \to Y \setminus \{y\}$ in $TC(\mathcal{G})$.

Proof. The proof is by induction on s. For the base case, if $s = 0$, then, by inspection of Algorithm 1, for $(X,Y) \in \mathcal{Q}_0$, we must have $X = \{x\}$ and $Y = \{y\}$. Thus, setting $\widehat{M} = \emptyset$ trivially proves the claim.

Now let $s > 0$. Fix some $(X,Y) \in \mathcal{Q}_s$ and $(x,y) \in X \times Y$. Let $(X_1,Y_1),(X_2,Y_2) \in \mathcal{Q}_{s-1}$ be the pairs of sets in $\mathcal{Q}_{s-1}$ for which $x \in X_1$ and $y \in Y_2$. First, if $(X_1,Y_1) = (X_2,Y_2)$, then by induction there exists a matching $\widehat{M}' : X_1 \setminus \{x\} \to Y_1 \setminus \{y\}$ in $\mathrm{TC}(\mathcal{G})$. Note that by definition of Algorithm 1, we must have $X_1 \subseteq X$ and $Y_1 \subseteq Y$. Then the required matching is $\widehat{M} = \widehat{M}' \cup M|_{X \setminus X_1}$ where $M|_{(\cdot)}$ denotes the restriction of the original matching M to the set $(\cdot)$. Suppose $(X_1,Y_1) \neq (X_2,Y_2)$. This is the interesting case, and we give an accompanying illustration in Fig. 2. By definition of Algorithm 1, it must be that (X_1,Y_1) and (X_2,Y_2) *conflict* (recall Definition 3.4) and were merged to form $X = X_1 \cup X_2$ and $Y = Y_1 \cup Y_2$. Thus, there exists some vertex $z \in V(\mathcal{H}(X_1,Y_1)) \cap V(\mathcal{H}(X_2,Y_2))$ and $x_1 \in X_1, y_1 \in Y_1, x_2 \in X_2, y_2 \in Y_2$ for which $x_1 \preceq z \preceq y_1$ and $x_2 \preceq z \preceq y_2$.

We now invoke the inductive hypothesis to get matchings $\widehat{M}_1 : X_1 \setminus \{x\} \to Y_1 \setminus \{y_1\}$ and $\widehat{M}_2 : X_2 \setminus \{x_2\} \to Y_2 \setminus \{y\}$ in $\mathrm{TC}(\mathcal{G})$. Observe that $x_2 \preceq z \preceq y_1$ and thus we can match x_2 and y_1. The required matching in $\mathrm{TC}(\mathcal{G})$ is $\widehat{M} = \widehat{M}_1 \cup \widehat{M}_2 \cup \{(x_2,y_1)\}$. ◁

We conclude the proof of Lemma 3.3 by showing that Claim 3.6 implies item 2. We are given $(S_i,T_i) \in \mathcal{Q}_{s^*}$ for some $i \in [k]$ and $(x,y) \in S_i \times T_i$ where $x \prec y$. By Claim 3.6, there exists a matching $\widehat{M}' : S_i \setminus \{x\} \to T_i \setminus \{y\}$ in $\mathrm{TC}(\mathcal{G})$. We set $\widehat{M} = \widehat{M}' \cup \{(x,y)\}$. Since $x \prec y$, the final matching $\widehat{M} : S_i \to T_i$ is a matching in $\mathrm{TC}(\mathcal{G})$ which contains the pair (x,y). ◀

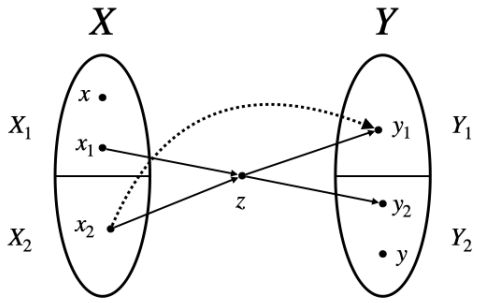

Figure 2 An illustration for the case of $(X_1, Y_1) \neq (X_2, Y_2)$ in the proof of Claim 3.6. The solid lines represent directed paths. The dotted line represents the pair (x_2, y_1) added to obtain the final matching $\widehat{M}$. The only vertices of $X \cup Y$ not participating in $\widehat{M}$ are x and y.

3.3 Specifying a Matching to Construct the Subgraphs $\mathcal{H}_1, \ldots, \mathcal{H}_k$

In this section, we apply Lemma 3.3 to a carefully chosen matching M in order to construct our vertex-disjoint subgraphs $\mathcal{H}_1, \ldots, \mathcal{H}_k$.

▶ **Definition 3.7** (Max-weight, Min-cardinality Matching). *A matching M in $\mathrm{TC}(\mathcal{G})$ is a max-weight, min-cardinality matching for f if M maximizes $\sum_{(x,y)\in M}(f(x) - f(y))$ and among such matchings minimizes $|M|$.*

Henceforth, let M denote a max-weight, min-cardinality matching. Let S and T denote the set of lower and upper endpoints, respectively, of M. We use the following well-known fact on matchings in the violation graph.

▶ **Fact 3.8** (Corollary 2 [29]). *For a DAG $\mathcal{G}$ and function $f\colon V(\mathcal{G}) \to \mathbb{R}$, the distance to monotonicity $\varepsilon(f)$ is equal to the size of the minimum vertex cover of the violation graph of f divided by $|V(\mathcal{G})|$.*

▶ **Fact 3.9.** *M is a matching in the violation graph of f that is also maximal. That is, (a) $f(x) > f(y)$ for all $(x, y) \in M$ and (b) $|M| \geq (\varepsilon(f) \cdot |V(\mathcal{G})|)/2$.*

Proof. First, for the sake of contradiction, suppose $f(x) \leq f(y)$ for some pair $(x, y) \in M$. Then we can set $M = M \setminus \{(x, y)\}$, which can only increase $\sum_{(x,y)\in M}(f(x) - f(y))$ and will decrease $|M|$ by 1. This contradicts the definition of M. Thus, $f(x) > f(y)$ for all $(x, y) \in M$ and so M is a matching in the *violation graph of f*. Second, since M maximizes $\sum_{(x,y)\in M}(f(x) - f(y))$, it must also be a *maximal* matching in the violation graph of f. Thus, (b) follows from Fact 3.8 and the fact that the size of any maximal matching is at least half the size of the minimum vertex cover. ◀

We now apply Lemma 3.3 to M, obtaining the partitions $(S_i\colon i \in [k])$ and $(T_i\colon i \in [k])$ for S and T, respectively, for which $M(S_i) = T_i$ for all $i \in [k]$. For each $i \in [k]$, let $\mathcal{H}_i = \mathcal{H}(S_i, T_i)$. We use the collection of sweeping graphs $\mathcal{H}_1, \ldots, \mathcal{H}_k$ to prove Theorem 1.3. Note that these subgraphs are all vertex-disjoint by item 1 of Lemma 3.3. We use item 2 of Lemma 3.3 to prove the following lemma regarding the (S_i, T_i) pairs. The proof crucially relies on the fact that M is a max-weight, min-cardinality matching.

▶ **Lemma 3.10** (Property of the Pairs (S_i, T_i)). *For all $i \in [k]$ and $(x, y) \in S_i \times T_i$, if $x \prec y$ then $f(x) > f(y)$.*

Proof. Suppose there exists $i \in [k]$, $x \in S_i$, and $y \in T_i$ for which $x \prec y$ and $f(x) \leq f(y)$. By item 2 of Lemma 3.3 there exists a matching $\widehat{M}\colon S \to T$ in $\mathrm{TC}(\mathcal{G})$ for which $(x, y) \in \widehat{M}$. In particular, since M and $\widehat{M}$ have identical sets of lower and upper endpoints,

$$\sum_{(s,t)\in\widehat{M}} (f(s) - f(t)) = \sum_{(s,t)\in M} (f(s) - f(t)) \text{ and } |\widehat{M}| = |M|.$$

Now set $\widehat{M}' = \widehat{M} \setminus \{(x, y)\}$ and observe that since $f(x) \leq f(y)$,

$$\sum_{(s,t)\in\widehat{M}'} (f(s) - f(t)) \geq \sum_{(s,t)\in M} (f(s) - f(t)) \text{ and } |\widehat{M}'| < |M|.$$

Therefore, M is not a max-weight, min-cardinality matching and this is a contradiction. ◀

3.4 Tying it Together: Defining the Boolean Functions $f_1, \ldots, f_k$

We are now equipped to define the functions $f_1, \ldots, f_k\colon V(\mathcal{G}) \to \{0, 1\}$ and complete the proof of Theorem 1.3. First, given $i \in [k]$ and $z \in V(\mathcal{G}) \setminus V(\mathcal{H}_i)$, we say that z is *below* $\mathcal{H}_i$ if there exists $y \in V(\mathcal{H}_i)$ for which $z \prec y$, and z is *above* $\mathcal{H}_i$ if there exists $x \in V(\mathcal{H}_i)$ for which $x \prec z$. Since $\mathcal{H}_i$ is the (S_i, T_i)-sweeping graph, by item 2 of Claim 3.2, vertex z cannot be both below and above $\mathcal{H}_i$, simultaneously. Second, given $z \in V(\mathcal{H}_i)$, we define the set $T_i(z) = \{t \in T_i\colon z \preceq t\}$. Note that by item 1 of Claim 3.2, $T_i(z) \neq \emptyset$ for all $z \in V(\mathcal{H}_i)$, and so the quantity $\max_{t\in T_i(z)} f(t)$ is always well-defined.

▶ **Definition 3.11.** *For each $i \in [k]$, define the function $f_i\colon V(\mathcal{G}) \to \{0, 1\}$ as follows. For every $z \in V(\mathcal{G})$,*

$$f_i(z) = \begin{cases} 1, & \text{if } z \in V(\mathcal{H}_i) \text{ and } f(z) > \max_{t\in T_i(z)} f(t), \\ 0, & \text{if } z \in V(\mathcal{H}_i) \text{ and } f(z) \leq \max_{t\in T_i(z)} f(t), \\ 1, & \text{if } z \notin V(\mathcal{H}_i) \text{ and } z \text{ is above } \mathcal{H}_i, \\ 0, & \text{if } z \notin V(\mathcal{H}_i) \text{ and } z \text{ is not above } \mathcal{H}_i. \end{cases}$$

See Fig. 3 for an illustration of the values of f_i. We first prove item 1 of Theorem 1.3. Recall that $M(S_i) = T_i$ for all $i \in [k]$. Let $M_i = M|_{S_i}$ denote the matching M restricted to S_i. Consider $x \in S_i$. By Lemma 3.10, $f(x) > f(y)$ for all $y \in T_i$ such that $x \prec y$. Thus, $f(x) > \max_{t\in T_i(x)} f(t)$ and so $f_i(x) = 1$. Now consider $y \in T_i$. Observe that $y \in T_i(y)$. Thus, clearly, $f(y) \leq \max_{t\in T_i(y)} f(t)$, and so $f_i(y) = 0$. Therefore, $f_i(x) = 1$ for all $x \in S_i$ and $f_i(y) = 0$ for all $y \in T_i$. In particular, $f_i(x) = 1 > 0 = f_i(M(x))$ for all $x \in S_i$ and so M_i is a matching in the violation graph of f_i. Thus, $\varepsilon(f_i) \geq \frac{|M_i|}{|V(\mathcal{G})|}$ for all $i \in [k]$. Then

$$\sum_{i=1}^{k} \varepsilon(f_i) \geq |V(\mathcal{G})|^{-1} \sum_{i=1}^{k} |M_i| = |V(\mathcal{G})|^{-1} \cdot |M| \geq |V(\mathcal{G})|^{-1} \cdot \frac{\varepsilon(f) \cdot |V(\mathcal{G})|}{2} = \frac{\varepsilon(f)}{2}$$

by the above argument and Fact 3.9. Thus, item 1 of Theorem 1.3 holds.

To prove item 2 of Theorem 1.3, we need to show that, for all $i \in [k]$, the following hold:

$$\mathcal{S}^-_{f_i} \subseteq E(\mathcal{H}_i) \text{ and } \mathcal{S}^-_{f_i} \subseteq \mathcal{S}^-_f.$$

We first prove that $\mathcal{S}^-_{f_i} \subseteq E(\mathcal{H}_i)$. Consider an edge $(x, y) \in E(\mathcal{G}) \setminus E(\mathcal{H}_i)$. We need to show that $f_i(x) \leq f_i(y)$. First, observe that if both $x, y \in V(\mathcal{H}_i)$, then by item 3 of Claim 3.2, we have $(x, y) \in E(\mathcal{H}_i)$. Thus, we only need to consider the following three cases. Recall that $f_i(x), f_i(y) \in \{0, 1\}$.

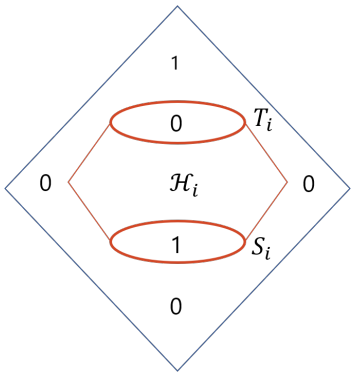

Figure 3 An illustration for the Boolean function f_i of Definition 3.11. The diamond represents the DAG $\mathcal{G}$ whose paths are directed from bottom to top. The hexagon represents the sweeping graph $\mathcal{H}_i = \mathcal{H}(S_i, T_i)$. The value of f_i is 1 for the vertices in S_i and 0 for the vertices in T_i. For vertices outside of $\mathcal{H}_i$, its value is 1 for the vertices that are above $\mathcal{H}_i$ and 0 for all other vertices.

1. $x \in V(\mathcal{H}_i)$, $y \notin V(\mathcal{H}_i)$: In this case, y is above $\mathcal{H}_i$, and so $f_i(y) = 1$. Thus, $f_i(x) \leq f_i(y)$.
2. $x \notin V(\mathcal{H}_i)$, $y \in V(\mathcal{H}_i)$: In this case, x is below $\mathcal{H}_i$, and so x is *not* above $\mathcal{H}_i$ by item 2 of Claim 3.2. Thus, $f_i(x) = 0$, and so $f_i(x) \leq f_i(y)$.
3. $x \notin V(\mathcal{H}_i)$, $y \notin V(\mathcal{H}_i)$: If x is above $\mathcal{H}_i$, then y is above $\mathcal{H}_i$ as well, and so $f_i(x) = f_i(y) = 1$. Otherwise, x is *not* above $\mathcal{H}_i$ and so $f_i(x) = 0$. Thus, $f_i(x) \leq f_i(y)$.

Therefore, $S^-_{f_i} \subseteq E(\mathcal{H}_i)$.

We now prove that $\mathcal{S}^-_{f_i} \subseteq \mathcal{S}^-_f$. Consider an edge $(x, y) \in \mathcal{S}^-_{f_i}$. Then $f_i(x) = 1$ and $f_i(y) = 0$. Since $S^-_{f_i} \subseteq E(\mathcal{H}_i)$, we get $(x, y) \in E(\mathcal{H}_i)$ and so $x, y \in V(\mathcal{H}_i)$. By definition of the functions f_i, it holds that $f(x) > \max_{t \in T_i(x)} f(t)$ and $f(y) \leq \max_{t \in T_i(y)} f(t)$. Since $x \prec y$, then $T_i(y) \subseteq T_i(x)$, because all vertices reachable from y are also reachable from x. Therefore,

$$f(x) > \max_{t \in T_i(x)} f(t) \geq \max_{t \in T_i(y)} f(t) \geq f(y).$$

Thus, $f(x) > f(y)$, and so $(x, y) \in \mathcal{S}^-_f$. As a result, $S^-_{f_i} \subseteq \mathcal{S}^-_f$ and item 2 of Theorem 1.3 holds. This concludes the proof of Theorem 1.3.

4 Testing Monotonicity of Real-Valued Functions

In this section, we prove Theorem 1.6. Some details have been omitted from this version. The omitted portion can be found in Section 4.3 of the full version [11]. We show that the tester of [32] for Boolean functions can be employed to test monotonicity of real-valued functions. The tester is simple: it queries two comparable vertices x and y and rejects if the pair exhibits a violation to monotonicity for f. The tester tries different values τ for the distance between x and y, that is, the number of coordinates on which they differ. The key step in the analysis of [32] (and in our analysis) is to show that for some choice of τ, the tester will detect a violation to monotonicity with high enough probability. The extra factor of r in the query complexity of our tester arises because we are forced to choose τ which is a factor of $(r-1)$ smaller than for the Boolean case. Intuitively, the reason for this is that as the walk length τ increases, the probability that the function value stays below a certain threshold decreases. We make this precise in Section 4.2.

We first define the distribution from which the tester samples x and y. Following this, we present the tester as Algorithm 2. Let p denote the largest integer for which $2^p \leq \sqrt{d/\log d}$. In Algorithm 2, we sample pairs of vertices at distance τ, where τ ranges over the powers of two up to 2^p.

▶ **Definition 4.1** (Pair Test Distribution). *Given parameters $b \in \{0,1\}$ and a positive integer τ, define the following distribution $\mathcal{D}_{\texttt{pair}}(b,\tau)$ over pairs $(x,y) \in (\{0,1\}^d)^2$. Sample $\boldsymbol{x}$ uniformly from $\{0,1\}^d$. Let $\boldsymbol{S} = \{i \in [d] \colon \boldsymbol{x}_i = b\}$. If $\tau > |\boldsymbol{S}|$, then set $\boldsymbol{y} = \boldsymbol{x}$. Otherwise, sample a uniformly random set $\boldsymbol{T} \subseteq \boldsymbol{S}$ of size $|\boldsymbol{T}| = \tau$. Obtain $\boldsymbol{y}$ by setting $\boldsymbol{y}_i = 1 - \boldsymbol{x}_i$ if $i \in \boldsymbol{T}$ and $\boldsymbol{y}_i = \boldsymbol{x}_i$ otherwise.*

Algorithm 2 Monotonicity Tester for $f \colon \{0,1\}^d \to \mathbb{R}$.

Require: Parameters $\varepsilon \in (0,1)$, dimension d, and image size r; oracle access to function $f \colon \{0,1\}^d \to \mathbb{R}$.

for all $b \in \{0,1\}$ and $\tau \in \{1,2,4,\ldots,2^p\}$ **do**
  repeat $\widetilde{O}\left(\min\left(\frac{r\sqrt{d}}{\varepsilon^2}, \frac{d}{\varepsilon}\right)\right)$ times:
    Sample $(\boldsymbol{x},\boldsymbol{y}) \sim \mathcal{D}_{\texttt{pair}}(b,\tau)$.
    if $b = 0$ and $f(\boldsymbol{x}) > f(\boldsymbol{y})$ **then reject**. ▷ if $b = 0$ then $\boldsymbol{x} \preceq \boldsymbol{y}$
    if $b = 1$ and $f(\boldsymbol{x}) < f(\boldsymbol{y})$ **then reject**. ▷ if $b = 1$ then $\boldsymbol{x} \succeq \boldsymbol{y}$
accept.

Our tester only uses comparisons between function values, not the values themselves. Thus, for the purposes of our analysis we can consider functions with the range $[r]$ w.l.o.g.

When $\tau = 1$, the algorithm is simply sampling edges from the d-dimensional hypercube. The distribution from which we sample is not the uniform distribution on edges, but following an argument from [32], we can assume that for $\tau = 1$, our tester has the same guarantees as the edge tester.

The choice of the distance parameter τ for which the rejection probability of the tester is high depends on the existence of a certain "good" bipartite subgraph of violated edges. Our analysis differs from the analysis of [32] both in how we obtain the "good" subgraph of violated edges and in the choice of the optimal distance parameter τ.

We extend the following definitions from [32]. Let $G(A,B,E_{AB})$ denote a directed bipartite graph with vertex sets A and B and all edges in E_{AB} *directed* from A to B.

▶ **Definition 4.2** ((K,Δ)-Good Graphs). *A directed bipartite graph $G(A,B,E_{AB})$ is (K,Δ)-good if for X,Y such that either $X = A$, $Y = B$ or $X = B$, $Y = A$, we have: (a) $|X| = K$. (b) Vertices in X have degree exactly Δ. (c) Vertices in Y have degree at most 2Δ. The graph G is (K,Δ)-left-good if $X = A$ and (K,Δ)-right-good if $X = B$.*

The *weight* of $x \in \{0,1\}^d$, denoted by $|x|$, is the number of coordinates of x with value 1.

▶ **Definition 4.3** (Persistence). *Given $f \colon \{0,1\}^d \to [r]$ and an integer $\tau \in \left[1, \sqrt{\frac{d}{\log d}}\right]$, a vertex $x \in \{0,1\}^d$ of weight in the range $\frac{d}{2} \pm O(\sqrt{d \log d})$ is* τ-right-persistent *for f if*

$$\Pr_{\boldsymbol{y}}[f(\boldsymbol{y}) \leq f(x)] > \frac{9}{10},$$

where $\boldsymbol{y}$ is obtained by choosing a uniformly random set $\boldsymbol{T} \subset \{i \in [d] \colon x_i = 0\}$ of size τ and setting $\boldsymbol{y}_i = 1$ if $i \in \boldsymbol{T}$ and $\boldsymbol{y}_i = x_i$ otherwise[4]. We define τ-left-persistence symmetrically.

We use the following technical claim implicitly shown in the analysis of the tester of [32].

[4] Note that $\tau \geq |\{i \in [d] \colon x_i = 0\}|$ by our assumption on x and τ.

▷ Claim 4.4 ([32]). Suppose there exists a (K, Δ)-right-good subgraph $G(A, B, E_{AB})$ of the directed d-dimensional hypercube, such that (a) $E_{AB} \subseteq \mathcal{S}_f^-$, (b) $K\sqrt{\Delta} = \Theta(\frac{\varepsilon(f)\cdot 2^d}{\log d})$, and (c) at least $\frac{99}{100}|B|$ of the vertices in B are $(\tau'-1)$-right-persistent for some τ' such that $\tau' \cdot \Delta \ll d$. Then there exists a constant $C' > 0$, such that for $(\boldsymbol{x}, \boldsymbol{y}) \sim \mathcal{D}_{\texttt{pair}}(0, \tau')$,

$$\Pr_{\boldsymbol{x},\boldsymbol{y}}[f(\boldsymbol{x}) > f(\boldsymbol{y})] \geq \frac{C' \cdot \tau'}{d} \cdot \frac{K}{2^d} \cdot \Delta.$$

The analogous claim holds given a (K, Δ)-left-good subgraph with many $(\tau'-1)$-left-persistent vertices in A and $(\boldsymbol{x}, \boldsymbol{y})$ drawn from $\mathcal{D}_{\texttt{pair}}(1, \tau')$.

In Section 4.1, we prove Lemma 4.6 which obtains a good subgraph for f satisfying conditions (a) and (b) of Claim 4.4. In Section 4.2, we prove Lemma 4.8 which gives an upper bound on the fraction of non-persistent vertices, enabling us to satisfy condition (c). The remainder of the proof of Theorem 1.6 is deferred to the full version [11]. In particular, in Section 4.3 of the full version, we use Lemma 4.6 and Lemma 4.8 to show that the conditions of Claim 4.4 are satisfied and then use this to prove Theorem 1.6.

4.1 Existence of a Good Bipartite Subgraph

In this section, we prove Lemma 4.6 on the existence of good bipartite subgraphs for real-valued functions, which was proved in [32] for the special case of Boolean functions. This lemma crucially relies on our isoperimetric inequality for real-valued functions (Theorem 1.2). We first state (without proof) a combinatorial result of [32], which we need for our lemma.

▶ **Lemma 4.5** (Lemma 6.5 of [32]). *Let $G(A, B, E_{AB})$ be a directed bipartite graph whose vertices have degree at most 2^s. Suppose in addition, that for any 2-coloring of its edges $\texttt{col} : E_{AB} \to \{\text{red}, \text{blue}\}$ we have*

$$\sum_{x \in A} \sqrt{\deg_{\text{red}}(x)} + \sum_{y \in B} \sqrt{\deg_{\text{blue}}(y)} \geq L, \tag{9}$$

where $\deg_{\text{red}}(x)$ denotes the number of red edges incident on x and $\deg_{\text{blue}}(y)$ denotes the number of blue edges incident on y. Then $G(A, B, E_{AB})$ contains a subgraph that is (K, Δ)-good with $K\sqrt{\Delta} \geq \frac{L}{8s}$.

We can now generalize Lemma 7.1 of [32].

▶ **Lemma 4.6.** *For all functions $f : \{0,1\}^d \to \mathbb{R}$, there exists a subgraph $G(A, B, E_{AB})$ of the directed, d-dimensional hypercube which is (K, Δ)-good, where $K\sqrt{\Delta} = \Theta(\frac{\varepsilon(f)\cdot 2^d}{\log d})$ and $E_{AB} \subseteq \mathcal{S}_f^-$.*

Proof. Our proof relies on Lemma 4.5. Condition (9) is clearly reminiscent of the isoperimetric inequality in Theorem 1.2. We want to partition the vertices in $\{0,1\}^d$ into sets A and B such that all the violated edges are directed from A to B and apply Theorem 1.2 to the resulting graph. In addition, we want (9) to hold for a big enough value of L. In the Boolean case, we can simply partition the vertices by function values. In contrast, for real-valued functions, a vertex $x \in \{0,1\}^d$ can be incident on both incoming and outgoing violated edges. To overcome this challenge we resort to the bipartiteness of the directed hypercube, where each edge is between a vertex with an odd weight and a vertex with an even weight. Partition $\mathcal{S}_f^-$ into two sets:

$$E_0 = \{(x, y) \in \mathcal{S}_f^- : |x| \text{ is even}\};$$

$E_1 = \{(x, y) \in \mathcal{S}_f^- : |x| \text{ is odd}\}$.

For $j \in \{0, 1\}$, let V_j and W_j denote the set of lower and upper endpoints, respectively, of the edges in E_j. We consider the two subgraphs $G_j(V_j, W_j, E_j)$ for $j \in \{0, 1\}$. Notice that the vertices in $V_0 \cup W_1$ have even weight and the vertices in $V_1 \cup W_0$ have odd weight. Obviously, V_0 and W_1 may not be disjoint, and similarly V_1 and W_0 may not be disjoint, and thus G_0 and G_1 may not be vertex-disjoint.

We quickly explain why we cannot simply use Lemma 4.5 with either G_0 or G_1. Fix a 2-coloring of the edges $E_0 \cup E_1$. By averaging, one of the graphs will have a high enough contribution to left-hand side of the isoperimetric inequality of Theorem 1.2. Assume this graph is G_0. As a result, condition (9) will hold for G_0 with $L = \Omega(\varepsilon \cdot 2^d)$. However, one cannot guarantee that condition (9) holds for *all* possible colorings of the edges of G_0. Our construction below describes how to combine G_0 and G_1 so that we can jointly "feed" them into Lemma 4.5.

We construct copies $\widehat{G}_0$ and $\widehat{G}_1$ of G_0 and G_1, so that $\widehat{G}_0$ contains a vertex labelled $(x, 0)$ for each vertex x of G_0, and $\widehat{G}_1$ contains a vertex $(x, 1)$ for each vertex x of G_1. For each edge (x, y) in G_0 we add an edge from $(x, 0)$ to $(y, 0)$ in $\widehat{G}_0$. We do the same for the edges of G_1. Note that each edge of $\mathcal{S}_f^-$ has exactly one copy, either in $\widehat{G}_0$ or $\widehat{G}_1$.

Let $\widehat{G}(\widehat{V}, \widehat{W}, \mathcal{S}_f^-)$ denote the union of the two vertex-disjoint graphs $\widehat{G}_0$ and $\widehat{G}_1$. That is,

$$\widehat{V} = \{(x, 0) \mid x \in V_0\} \cup \{(x, 1) \mid x \in V_1\},$$
$$\widehat{W} = \{(y, 0) \mid y \in W_0\} \cup \{(y, 1) \mid y \in W_1\}.$$

All the edges of $\widehat{G}$ are directed from $\widehat{V}$ to $\widehat{W}$. Although imprecise, we think of the edges of $\widehat{G}$ as $\mathcal{S}_f^-$, since each edge in $\mathcal{S}_f^-$ has exactly one copy in $\widehat{G}$.

Consider a 2-coloring $\texttt{col}\colon \mathcal{S}_f^- \to \{\text{red}, \text{blue}\}$. Observe that

$$\begin{aligned}
\sum_{(x,\cdot)\in\widehat{V}} \sqrt{I^-_{f,\text{red}}(x)} + \sum_{(y,\cdot)\in\widehat{W}} \sqrt{I^-_{f,\text{blue}}(x)} &= \sum_{x\in V_0\cup V_1} \sqrt{I^-_{f,\text{red}}(x)} + \sum_{y\in W_0\cup W_1} \sqrt{I^-_{f,\text{blue}}(y)} \\
&= \sum_{\substack{x\in\{0,1\}^d \\ |x| \text{ is even}}} \sqrt{I^-_{f,\text{red}}(x)} + \sqrt{I^-_{f,\text{blue}}(x)} + \sum_{\substack{x\in\{0,1\}^d \\ |x| \text{ is odd}}} \sqrt{I^-_{f,\text{red}}(x)} + \sqrt{I^-_{f,\text{blue}}(x)} \\
&= \sum_{x\in\{0,1\}^d} \sqrt{I^-_{f,\text{red}}(x)} + \sum_{y\in\{0,1\}^d} \sqrt{I^-_{f,\text{blue}}(y)} \geq C \cdot \varepsilon(f) \cdot 2^d,
\end{aligned}$$

where the inequality holds by Theorem 1.2.

By construction, $I^-_{f,\text{red}}(x) = \deg_{\text{red}}((x, \cdot))$ for all $(x, \cdot) \in \widehat{V}$ and $I^-_{f,\text{blue}}(y) = \deg_{\text{blue}}((y, \cdot))$ for all $(y, \cdot) \in \widehat{W}$. We have that condition (9) of Lemma 4.5 holds with $L = C \cdot \varepsilon(f) \cdot 2^d$. Thus, $\widehat{G}$ contains a subgraph $G_{\text{good}}(A, B, E_{AB})$ that is (K, Δ)-good with $K\sqrt{\Delta} \geq \frac{L}{8 \log d}$. Without loss of generality, assume $G_{\text{good}}(A, B, E_{AB})$ is (K, Δ)-right-good.

Let $G_{\text{good},0} = (A_0, B_0, E_{A_0B_0})$ denote the subgraph of G_{good} lying in $\widehat{G}_0$ and let $G_{\text{good},1} = (A_1, B_1, E_{A_1B_1})$ denote the subgraph of G_{good} lying in $\widehat{G}_1$. Since $B_0 \cap B_1 = \emptyset$, we know that either $|B_0| \geq K/2$ or $|B_1| \geq K/2$. Suppose $|B_0| \geq K/2$. Moreover, since $\widehat{G}_0$ and $\widehat{G}_1$ are vertex-disjoint subgraphs, the degree of a vertex of $A_0 \cup B_0$ in $G_{\text{good},0}$ is the same its degree in G_{good}. Thus, $G_{\text{good},0}$ is a $(K/2, \Delta)$-right-good subgraph of the d-dimensional directed hypercube for which $\frac{K}{2}\sqrt{\Delta} \geq \frac{L}{16 \log d}$.

By removing some vertices from B_0, and redefining K if necessary, we may assume that $K\sqrt{\Delta} = \Theta\left(\frac{\varepsilon(f)\cdot 2^d}{\log d}\right)$. This completes the proof of Lemma 4.6. ◀

4.2 Bounding the Number of Non-Persistent Vertices

We prove Lemma 4.8 that bounds the number of non-persistent vertices for a function f and a given distance parameter τ. All results in this section also hold for τ-left-persistence.

For a function $f\colon \{0,1\}^d \to \mathbb{R}$, we define I_f^- as $\frac{|\mathcal{S}_f^-|}{2^d}$.

▶ **Corollary 4.7** (Corollary of Theorem 6.6, Lemma 6.8 of [32]). *Consider a function $h\colon \{0,1\}^d \to \{0,1\}$ and an integer $\tau \in \left[1, \sqrt{\frac{d}{\log d}}\right]$. If $I_h^- \leq \sqrt{d}$ then*

$$\Pr_{\boldsymbol{x}\sim\{0,1\}^d}\left[\boldsymbol{x} \text{ is not } \tau\text{-right-persistent for } h\right] = O\left(\frac{\tau}{\sqrt{d}}\right). \tag{10}$$

We generalize the above result to functions with image size $r \geq 2$.

▶ **Lemma 4.8.** *Consider a function $f\colon \{0,1\}^d \to [r]$ and an integer $\tau \in \left[1, \sqrt{\frac{d}{\log d}}\right]$. If $I_f^- \leq \sqrt{d}$, then*

$$\Pr_{\boldsymbol{x}\sim\{0,1\}^d}\left[\boldsymbol{x} \text{ is not } \tau\text{-right-persistent for } f\right] = (r-1)\cdot O\left(\frac{\tau}{\sqrt{d}}\right).$$

Proof. For all $t \in [r]$, define the threshold function $h_t\colon \{0,1\}^d \to \{0,1\}$ as:

$$h_t(x) = \begin{cases} 1 & \text{if } f(x) > t, \\ 0 & \text{otherwise.} \end{cases}$$

Observe that for all $t \in [r]$, we have $\mathcal{S}_{h_t}^- \subseteq \mathcal{S}_f^-$, and thus $I_{h_t}^- \leq I_f^- \leq \sqrt{d}$. By Corollary 4.7, we have that (10) holds for $h = h_t$ for all $t \in [r]$. Next, we point out that a vertex $x \in \{0,1\}^d$ is τ-right-persistent for f if and only if x is τ-right-persistent for the Boolean function $h_{f(x)}$. Too see this, consider a vertex z such that $x \prec z$. First, note that $h_{f(x)}(x) = 0$. Second, note that $h_{f(x)}(z) = 1$ if and only if $f(z) > f(x)$ by definition of $h_{f(x)}$. Therefore, $f(z) \leq f(x)$ if and only if $h_{f(x)}(z) \leq h_{f(x)}(x)$. Finally, note that all vertices are persistent for h_r since $h_r(x) = 0$ for all $x \in \{0,1\}^d$. Using these observations, we have

$$\begin{aligned}
&\Pr_{\boldsymbol{x}\sim\{0,1\}^d}[\boldsymbol{x} \text{ is not } \tau\text{-right-persistent for } f] \\
&= \Pr_{\boldsymbol{x}\sim\{0,1\}^d}\left[\boldsymbol{x} \text{ is not } \tau\text{-right-persistent for } h_{f(\boldsymbol{x})}\right] \\
&\leq \Pr_{\boldsymbol{x}\sim\{0,1\}^d}[\exists t \in [r-1]\colon \boldsymbol{x} \text{ is not } \tau\text{-right-persistent for } h_t] \\
&\leq \sum_{t=1}^{r-1} \Pr_{\boldsymbol{x}\sim\{0,1\}^d}[\boldsymbol{x} \text{ is not } \tau\text{-right-persistent for } h_t] \\
&= \sum_{t=1}^{r-1} O\left(\frac{\tau}{\sqrt{d}}\right) = (r-1)\cdot O\left(\frac{\tau}{\sqrt{d}}\right),
\end{aligned}$$

where the second inequality is by the union bound and the last equality is due to the fact that (10) holds for all h_t, $t \in [r]$. ◀

The Geometry of Tree-Based Sorting

Abstract

We study the connections between sorting and the binary search tree (BST) model, with an aim towards showing that the fields are connected more deeply than is currently appreciated. While any BST can be used to sort by inserting the keys one-by-one, this is a very limited relationship and importantly says nothing about parallel sorting. We show what we believe to be the first formal relationship between the BST model and sorting. Namely, we show that a large class of sorting algorithms, which includes mergesort, quicksort, insertion sort, and almost every instance-optimal sorting algorithm, are equivalent in cost to offline BST algorithms. Our main theoretical tool is the geometric interpretation of the BST model introduced by Demaine et al. [18], which finds an equivalence between searches on a BST and point sets in the plane satisfying a certain property. To give an example of the utility of our approach, we introduce the log-interleave bound, a measure of the information-theoretic complexity of a permutation π, which is within a $\lg \lg n$ multiplicative factor of a known lower bound in the BST model; we also devise a parallel sorting algorithm with polylogarithmic span that sorts a permutation π using comparisons proportional to its log-interleave bound. Our aforementioned result on sorting and offline BST algorithms can be used to show existence of an offline BST algorithm whose cost is within a constant factor of the log-interleave bound of any permutation π.

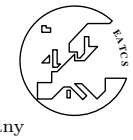
1 Introduction

Comparison-based sorting and searching on a BST are among the most elementary, important, and well-studied algorithmic topics in all of theoretical computer science. It has long been observed that they are closely related: both enjoy better performance on sequences that are information-theoretically simpler, such as reversals of sorted lists, sequences with long runs of consecutive keys, or sequences composed from simple shuffles of sorted lists. Indeed, their respective searches for instance optimality have yielded the independent discovery of almost identical results [34]. Despite the extensive number of similar results throughout the literature, there is comparatively very little known about the *formal* relationship between sorting and the binary search tree (BST) model. In this paper, we present what we believe to be the first formal relation between the sorting cost model and the BST model. Our result shows that a large class of sorting algorithms, which includes mergesort, quicksort, insertion

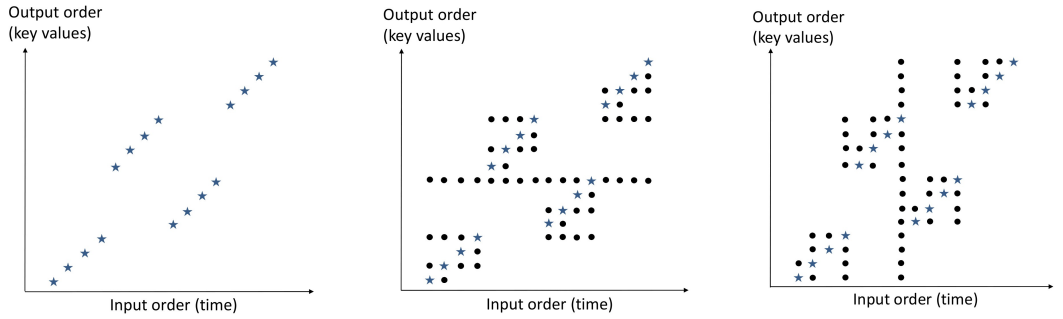


sort, and most adaptive sorting algorithms, are equivalent in cost to offline algorithms in the BST model. As this class is large and contains many well-studied algorithms, we find it interesting that we are able to show any kind of new and nontrivial theoretical result based on this characterization.

Binary Search Trees. The binary search tree is a fundamental data structure that stores an ordered universe of keys in a dynamic tree. A search for a key begins with a pointer to the root of the tree and at each step performs one of two unit-cost actions: move the pointer to a parent or child node, or perform a rotation. Rotations are key to understanding the power of the model, because they allow frequently queried elements to be kept close to the root of the tree as well as exploiting other kinds of order in the sequence of queried keys. The power of rotations is related to the concept of *instance optimality*, a general term which refers to the fact that an algorithm can enjoy improvements on its worst-case complexity on well-defined sets of "easy" inputs. Many BST algorithms perform better than their worst-case complexity (i.e. $\log n$ per operation) on various kinds of input [37, 19, 18, 3]. Beyond these specific improvements, the hope for a more general kind of instance optimality is crisply expressed by the *dynamic optimality conjecture* of Sleator and Tarjan [35], which states that there exists a binary search tree whose performance on any online sequence of searches is constant factor competitive with the best offline algorithm for that sequence. The dynamic optimality conjecture remains open. Another equally important open question is whether there is an offline efficient algorithm for calculating even an approximately optimal number of rotations for a given input sequence. These problems have been the subject of extensive work both in the past [38, 16, 15, 19, 21, 8] and at the present moment [26, 13, 7, 25, 23].

Sorting. Similarly to the BST model, where rotations are used to achieve instance optimality for particular classes of inputs, in comparison-based sorting an *adaptive sorting algorithm* performs fewer comparisons when the input is "closer" to sorted by some measure. In this field a *measure of disorder* for a list L is paired with an algorithm which is *optimal* for this measure. Here, optimal roughly means that sorting L only requires the number of comparisons needed to distinguish it from all other lists which are more presorted than L [34]. An accompanying notion is that a measure of disorder may be *superior* (inferior) to another measure – that is, always requires fewer comparisons for any given permutation. Mannila first formalized these ideas [31]. After this, many researchers devised new measures of disorder and corresponding optimal algorithms [17, 22, 24, 28, 29, 27, 33, 34]; furthermore, there was also interest in work-optimal parallel versions of optimal sorting algorithms [11, 30, 14]. It remains an open problem whether there exists a measure which is provably superior to any possible measure of disorder.

Arborally Satisfied Point Sets and Sorting. One of our most important tools in connecting BSTs and sorting is the geometric interpretation of BSTs [18, 20]. In this interpretation, an access sequence of n keys is represented as an $n \times n$ grid with time order (input order) on one axis (here the x axis) and key order (output order) on the other axis. Points are added to the grid to account for all keys that must be visited when searching or inserting the keys one at a time from left to right. Demaine et al. [18], and Derryberry, Sleator, and Wang [20] show that for any BST algorithm, the accesses plotted in the plane must satisfy the property that for every pair of points p, q (both original and added points), there is a monotonic path (e.g. up and right) from p to q consisting of horizontal and vertical segments with a point at



(a) The input sequence.

(b) Sequence arborally satisfied using quicksort.

(c) Sequence arborally satisfied using mergesort.

Figure 1 On the left, the input sequence plotted in the plane. In the middle, the input sequence arborally satisfied using accesses corresponding to quicksort. On the right, the input sequence arborally satisfied using accesses corresponding to mergesort.

each corner[1]. Demaine et al. refer to such a set of points as being *arborally satisfied*, and show that any such set of size m implies the sequence of n keys can be searched or inserted in cost $O(m)$ in the BST model.

We observe that the geometric approach is also useful for sorting, since unlike the BST model, it does not directly enforce an order of insertion. As some evidence of the utility of the geometric approach, consider the following two algorithms that can be used to arborally satisfy a set of accesses. The first algorithm starts by choosing a random point, then adding accesses to that point across its entire row of the point set. Then, it recurses above and below the row, and in each partition it picks a random point and adds new points to all locations in its row for which there is a key in the partition. It is not hard to verify the points added in this way are arborally satisfied: any point p can get to a point q by going up (or down) to the row that separated them, then across to column of q and up (down) to q. Second, consider another algorithm that adds points across the middle column, and then for the left and right, add points along their middle columns for all points in those halves. Recursing to the base case again gives an arborally satisfied set. See Figure 1 for an example of both of these algorithms. The attentive reader may have noticed that the accesses added in the first algorithm correspond to the comparisons made by the quicksort algorithm, and the accesses added in the second algorithm correspond to comparisons made by the mergesort algorithm. We will extend these ideas to more interesting algorithms in this paper.

We note that in addition to being of significant theoretical interest, taking advantage of locality in key sequences is widely practical for both search trees and sorting. Sleator and Tarjan won the ACM Kannelakis Theory and Practice award for their work on splay trees and its applications for reducing key search time in several widely used applications. Adaptive sorting algorithms are widely adopted in practice, including *timsort*, which is implemented as built-in libraries for Python, Java, Swift, and Rust, among other languages [2].

1.1 Our Results

In this paper we present specific results relating sorting and BSTs using arborally satisfied sets. Our first result is an explicit relation between the cost models of a broad set of sorting algorithms and BST algorithms. The specific set of algorithms, which we refer to as *tree-based*

[1] The papers have their own preferred definition, but the definitions are all equivalent.

sorting algorithms and which are formally defined in Section 3, are divided into two classes: *BST mergesorts* are sorting algorithms based on recursive merges of the input, where the keys being merged are stored in binary search trees; *BT partition sorts* are sorting algorithms based on recursive partitions of the input based on key ordering, where the keys are stored in a binary tree. In Section 3, we show that these two types of algorithms are "dual" to each other in the following way: a BST mergesort $\mathcal{A}$ sorting permutation π with cost $\mathcal{A}(\pi)$ implies the existence of binary tree (BT) partition sort $\mathcal{B}$ sorting π^{-1} with cost $\mathcal{A}(\pi)$, and vice versa.

The category of tree-based sorting algorithms is large. Both quicksort and mergesort on lists fall into the category of tree-based sorting algorithms, as lists are simply a special case of trees. Sorting by insertion into a BST is also a BST mergesort, since the merges can be carried out in any order. McIlroy's adaptive sorting algorithms – namely, insertion sort with exponential search and mergesort with exponential search – are BST mergesorts [32]. These algorithms were influential in the development of timsort [2], a mergesort algorithm that breaks the input into runs of increasing or decreasing keys and merges them based on certain ordering criteria; since it is also a mergesort on lists, timsort is a BST merge. In their capstone paper on adaptive sorting, Petersson and Moffat cover the three most powerful known adaptive sorting algorithms – local insertion sort, historical insertion sort, and regional insertion sort. Local insertion sort is a BST mergesort as it inserts into a BST with a single additional pointer, which can be converted to the BST model with constant overhead [13]. Historical and regional insertion sort are not BST mergesorts as presented by the authors, but independently discovered data structures would yield BST mergesorts with the same bounds [35, 21].

Theorem 1 shows that for any tree-based sorting algorithm that sorts access sequence π using $\mathcal{A}(\pi)$ accesses, there exists an offline algorithm in the BST model which searches for each key in π using $O(\mathcal{A}(\pi))$ accesses. The proof of Theorem 1 is subtle and nontrivial and requires several new insights relating to the geometric interpretation of the BST model. In the following statement, $\mathrm{OPT}_{\mathrm{BST}}(\pi)$ refers to the cost of the best offline algorithm.

▶ **Theorem 1.** *Let $\mathcal{A}$ be a tree-based sorting algorithm which sorts permutation π using $\mathcal{A}(\pi)$ accesses. Then $OPT_{BST}(\pi) \in O(\mathcal{A}(\pi))$.*

As some evidence for the utility of our approach, we introduce the log-interleave bound, a measure of the information-theoretic complexity of a permutation π. The log-interleave bound is an upper bound on the number of bits needed to encode π; it can also be understood from an algorithmic perspective as a mergesort with a more efficient merge step. Our main results on the log-interleave bound illustrate the connections between sorting and the BST model. In the statements of the following results, we use the notation $\mathrm{LIB}(\pi)$ to refer to the log-interleave bound of a permutation π. This will be defined formally in Section 4.

The first result is a proof that the log-interleave bound is within a $\lg \lg n$ multiplicative factor of the optimal offline BST algorithm on any permutation. Somewhat similarly to Demaine et al.'s proof of the closeness to optimality of tango trees [19], our proof shows closeness to optimality by comparing the log-interleave bound with Wilber's interleave bound [38], a lower bound in the BST model.

▶ **Theorem 17.** *For any permutation π, $IB(\pi) \leq LIB(\pi) \in O(\lg \lg n\ IB(\pi))$.*

Next, we show that there is a work optimal *parallel* sorting algorithm related to the log-interleave bound. The next result is a parallel mergesort featuring a merge step which combines recent work on parallel split and join of BSTs [4] with a BST from [9] and an analysis which shows that with this new merge step, the mergesort sorts a sequence π in

$O(\text{LIB}(\pi))$ work. While the span of this algorithm is greater than the span of a typical parallel sort and indeed may be open to improvement, all existing parallel sorting algorithms present guarantees only for very weak measures of disorder [14, 30].

▶ **Theorem 21.** *There exists a parallel mergesort which for any permutation π performs $O(LIB(\pi))$ work with polylogarithmic span.*

Finally, a corollary of Theorem 6 shows that there is an offline BST algorithm that incurs cost $O(\text{LIB}(\pi))$, and thus that the log-interleave bound is an upper bound in the BST model.

▶ **Corollary 22.** *There exists an offline BST algorithm $\mathcal{A}$ such that $\mathcal{A}(\pi) = O(LIB(\pi))$.*

Model of Computation. Our results for the parallel algorithms are given for the binary-fork-join model [5]. In this model a process can fork two child processes, which work in parallel and when both complete, the parent process continues. Costs are measured in terms of the work (total number of instructions across all processes) and span (longest dependence path among processes). Any algorithm in the binary forking model with W work and S span can be implemented on a CRCW PRAM with P processors in $O(W/P + S)$ time with high probability [1, 6], so the results here are also valid on the PRAM, maintaining work efficiency.

1.2 Related Work

Upper and Lower Bounds in the BST Model. The pursuit of dynamic optimality led to a string of work in both upper and lower bounds on the cost of a sequence of searches on a BST. Three important upper bounds in the literature are the *dynamic finger bound* [35, 16, 15, 13, 8, 23], the *working set bound* [35], and the *unified bound* [3, 21], which respectively state that accessing an element is fast if its key is close to the key of the previous search, if its key has been searched recently, and a combination of the two. There has also been significant work in lower bounding the cost of an access sequence in the BST model. Two such lower bounds, the *interleave bound* and the *funnel bound*, were introduced by Wilber in [38]; a recent work by Lecomte and Weinstein [26] affirmatively settled the 30-year open question of whether the funnel bound was tighter than the interleave bound, proving a $\lg \lg n$ multiplicative separation in some cases. Another lower bound, the *rectangle bound*, was introduced by Demaine et al. in [18].

Progress on Dynamic Optimality. The BST which comes closest to dynamic optimality is the *tango tree* of Demaine et al. [19], which has a competitive ratio of $O(\lg \lg n)$ with respect to the best offline algorithm. Wilber's interleave bound was vital in the analysis of the competitive ratio, since the authors showed that on any access sequence x, the tango tree uses $O(\lg \lg n \ \text{IB}(x))$ accesses, where $\text{IB}(x)$ represents the interleave bound of the sequence. In [37], Wang et al. introduce the multi-splay tree, a BST which achieves $O(\lg \lg n)$ optimality with better worst-case guarantees than the tango tree. Prominent candidates for a dynamically optimal algorithm include the splay tree, which was presented by Sleator and Tarjan at the same time as the dynamic optimality conjecture [35], and the Greedy algorithm presented in Demaine et al.'s geometric interpretation of the BST model [18].

Other Data Structures and the BST model. The *min-heap*, which stores a set of keys and supports inserting arbitrary elements and extracting and deleting the minimum element. Recently, Kozma and Saranurak show an explicit relation between the BST model and the

heap cost model [25], as well as proposing an analogue of the dynamic optimality conjecture for heaps. Specifically, they show that for every heapsort algorithm (that is, an algorithm which sorts a permutation π with cost $\mathcal{A}(\pi)$ by inserting its keys into a heap and repeatedly extracting the minimum element) corresponds to an insertion sort into a BST algorithm which incurs cost $\mathcal{A}(\pi)$ on the inverse permutation π^{-1}. Their insight came from relating the rotation operation in a BST to the link operation in a heap, which allowed them to relate the corresponding cost models.

Adaptive Sorting in Parallel. During the period of interest in the adaptive sorting model, researchers were also interested in work-optimal parallel sorting algorithms with polylogarithmic span. Unsurprisingly, such algorithms exist for practical measures Runs and Inv [11, 14]; one also exists for Osc, a generalization of Inv [30] that is still theoretically weak. To our knowledge there are no results on parallel sorting algorithms which are optimal with respect to any stronger measures.

2 Preliminaries

Terminology. Throughout this paper, we will use the terms **list**, **permutation**, and **access sequence** interchangeably to refer to some ordering of the keys $1, 2, \ldots, n$. The term access sequence is used in the literature on BSTs to denote a sequence of queries to a BST; unless otherwise stated, an access sequence is presumed not to contain repeated keys.

The Binary Search Tree Model. A binary tree (BT) is either a *leaf* or a *node* consisting of a left binary tree, a key and a right binary tree. A binary seach tree (BST) is a binary tree where the keys have a total order, and for each node in the tree all keys in its left subtree are less than its key, and all keys in its right tree are greater.

The following definition of the BST model is drawn from [35, 38, 19]. The model assumes an initial BST with keys $[1, 2, \ldots, n]$ and an access sequence $[x_1, x_2, \ldots, x_m]$ of searches, where $x_i \in \{1, 2, \ldots, n\}$. Each search starts at the root and at each node it visits, it may perform one of the following actions: (a) move to the right child, left child, or parent, or (b) perform a rotation of the node and its parent. Each of these actions has unit cost and the search must visit its specified key. We refer to an algorithm that decides on what actions to perform for each search as a **BST algorithm**. A BST algorithm may be offline – meaning it can see the entire sequence of queries ahead of time – or online, meaning that queries are revealed one at a time.

Wilber's Interleave Bound. Wilber's interleave bound is a lower bound on the cost of accessing any sequence in the BST model. Given an access sequence π consisting of the keys $x_1, x_2, \ldots, x_n$, fix a static binary tree P (meaning it will never be rotated) with the keys of π at the leaves in the order they appear in π. Calculate the interleave bound of π as follows: query the keys in π in sorted order. For each vertex v_j, label each element i of the sequence with R or L, depending on whether accessing i in P goes through the right or the left subtree of v_j, respectively (if i is in neither subtree, give it no label). The interleave bound of v_j, denoted $\mathrm{IB}(v_j)$, is the number of switches between R and L in the labels if the keys are queried in sorted order. The interleave bound of the entire access sequence π is calculated by summing over the interleave bounds of each vertex, so $\mathrm{IB}(\pi) = \sum_{v \in P} \mathrm{IB}(v_i)$. As the lower bound holds for an arbitrary tree P, the interleave bound of the sequence is usually understood to refer to the maximum over all static trees. See Figure 3 for an example calculation.

Arborally Satisfied Sets. In [21], Derryberry et al. formalize a connection between binary search trees and points in the plane satisfying a certain property. An access sequence can be plotted in the plane where one axis represents key values and the other axis represents the ordering of the search sequence (that is, time). In the context of sorting, these axes can also be referred to as input order and output order. In this work, we use the horizontal axis for time and the vertical access for keyspace. See Figure 1 for an example of an arborally satisfied set.

In addition to plotting the search sequence on the plane, one can also plot the key values of the nodes which a BST algorithm accesses (for search or rotations) while searching for a node. When searching for an element x_i which is inserted at time i, the values of the nodes in the search path are plotted on the same vertical. Demaine et al. [18] proved that such a plot satisfies the following property:

▶ **Definition 2.** *Given a set P of points in the plane, P is **arborally satisfied** if for every two points $x, y \in P$ that are not on the same vertical or horizontal, the rectangle defined by x and y contains at least one point in addition to x and y.*

As mentioned in Section 1, a useful equivalent definition of arboral satisfaction is that there must be a monotonic path (e.g. consisting only of moves up and to the right) between x and y with a point at every corner. Note that any valid search on a BST will only touch nodes in a subtree τ_i of tree T, where τ_i includes the root of T. We sometimes refer to such a subtree as a **top tree** of T.

Demaine et al. show that a BST can be used to arborally satisfy an access sequence plotted in the plane. However, one can also use an algorithm that directly places points in the plane rather than using a BST.

▶ **Definition 3.** *Given a set of points in the plane corresponding to an access sequence π, an **offline arboral satisfaction algorithm** adds points to the plane to make an arborally satisfied set. An **online arboral satisfaction algorithm** also adds points in the plane to form an arborally satisfied set, but accesses are revealed one by one in input order and the algorithm must produce an arborally satisfied set at each time.*

Demaine et al. show that a BST algorithm is equivalent to an arboral satisfaction algorithm, but they also show a more surprising result: an arboral satisfaction algorithm is equivalent to a BST algorithm. Specifically, they show that an offline (online) arboral satisfaction algorithm requiring $f(\pi)$ accesses to arborally satisfy a search sequence π can be transformed to an offline (online) BST algorithm requiring $O(f(\pi))$ accesses to search for the elements of a sequence π.

3 Tree-based Sorting

Towards the goal of unifying the BST model and sorting, we ask the following question: when can the costs of a sorting algorithm be related to the costs of a BST algorithm? Clearly not every comparison-based sorting algorithm should be relatable to the BST model: as mentioned in Section 1, for example, an algorithm that guesses and checks could take $O(n)$ steps for an arbitrary permutation. Our investigation is therefore limited to sorting over binary trees, and in particular it considers a class of mergesort and partition sort (related to quicksort) algorithms on binary trees.

3.1 Mergesort

We first consider mergesorts in which the sequences to be merged are represented as BSTs. "Mergesort" is interpreted here as merging based on any split of the input sequence, not just splits into equally-sized parts; thus insertion sort using a sequence of insertions into a BST is a special case of mergesort. The cost of these algorithms is measured in terms of the number of accesses to the tree required during the mergesort, which will always be at least as great as the number of comparisons. We capture the idea of a BST mergesort more formally before giving the theorem statement.

A merge will interleave contiguous subsequences from its two inputs. We refer to each of these subsequences as *blocks* and we refer to the ends of each block as *block boundaries*. The block boundaries need to be accessed to even verify that the merge is correct. The following defines a merge that examines some top part of two trees to generate its output.

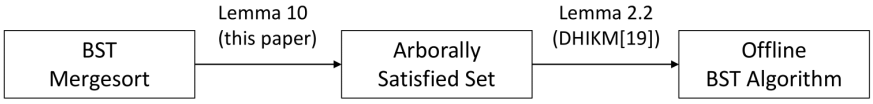
▶ **Definition 4.** *A* ***BST merge*** *takes two BSTs T_A and T_B, and for some top trees τ_a of T_A and τ_b of T_B, returns a BST T such that for some top tree τ of T, $\tau = \tau_a \cup \tau_b$, the subtrees of τ correspond to unchanged subtrees of τ_a and τ_b, and τ contains the block boundaries. The* number of accesses *used by the merge is $|\tau|$.*

▶ **Definition 5.** *A* ***BST mergesort*** *recursively splits the input sequence into two parts each of size at least 1, sorts each part with a BST mergesort, and executes a BST merge on the results. A mergesort on an input of size 1 returns its input. The* number of accesses *used by the mergesort is the sum of accesses across all merges.*

This leads to the main theorem.

▶ **Theorem 6.** *Let $\mathcal{A}$ be a BST mergesort algorithm which sorts permutation π using $\mathcal{A}(\pi)$ accesses. Then $OPT_{BST}(\pi) \in O(\mathcal{A}(\pi))$.*

Theorem 6 is proved by showing that for every BST mergesort algorithm, there is an offline BST algorithm that incurs the same cost as the BST mergesort within a constant factor. Our proof relies on the geometric interpretation of the BST model – instead of directly transforming a BST mergesort into an offline BST algorithm we use arborally satisfied sets as an intermediary. The key ingredient is a transformation of a BST merge algorithm to an offline arborally satisfied set algorithm, which is equivalent to an offline BST algorithm by Demaine et al.'s theorem [18]. The following graphic illustrates the chain of dependencies.

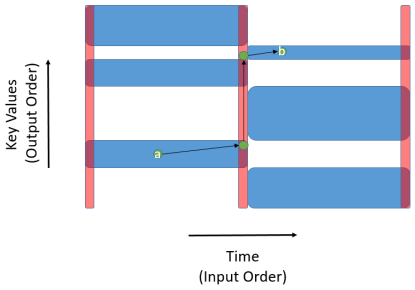


The main idea behind going from the mergesort to an arborally satisfied set is to transform a merge algorithm $\mathcal{M}$ into an algorithm that "merges" two arborally satisfied sets by concatenating them along the time axis (in this paper the x axis) and resolving any unsatisfied rectangles between the two sets, thus producing an arborally satisfied set. This "arboral" mergesort algorithm would by definition be an offline arborally satisfied set algorithm. Ideally this arboral merge would use the same number of accesses as a corresponding BST merge $\mathcal{M}$. The key idea behind our algorithm is to use the keys accessed during the tree merge to arborally satisfy the sets on the two sides, as well as add points to make it easier to satisfy the condition on future merges. In particular, the keys are added in

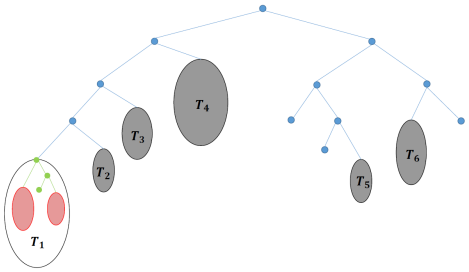
Algorithm 1 arboralMerge$(A, B, \mathcal{M})$
The arboral satisfaction algorithm; also illustrated in Figure 2a.

Input: Two arborally satisfied sets A, B; BST merge algorithm $\mathcal{M}$.
Output: An arborally satisfied set C consisting of the concatenation of A and B as well as additional accesses needed to arborally satisfy the concatenation.

```
1 if A == ∅ then return B ;
2 if B == ∅ then return A ;
3 C ← concatenate A and B on the time axis ;
4 S ← set of keys accessed when merging keys in A and B using M ;
5 access each key in S in the first, middle (rightmost column of A), and end columns of C ;
6 return C ;
```



(a) An illustration of an arboral merge.



(b) A BST separated into a top tree and auxiliary trees.

Figure 2 On the right, an illustration of the merging algorithm shown in Algorithm 1. The blue squares represent members of the two sets being merged, while the red columns (referred to as C_L, C_M, C_R in the proof of Theorem 6) illustrate the additional accesses necessary for the merge. A path drawn from $a \in A$ to $b \in B$ illustrates how the accesses in the middle column ensure the set is arborally satisfied. On the right, a BST with a top tree shown in blue and auxiliary trees T_1 through T_6, where the recursive structure is shown in T_1.

three columns: the leftmost column of the left set, the rightmost column of the right set, and a middle column – we will use the rightmost of the left set, although the leftmost of the right set would also work. Roughly, the accesses are placed down the middle to resolve unsatisfied rectangles, and they are placed down the leftmost and rightmost columns to restore invariants that are useful for future merges. These accesses must by definition form top trees of the two trees being merged. Algorithm 1 shows the merging routine, which is used as a sub-step in an arborally satisfied set algorithm which recursively splits the input set to singletons and then uses Algorithm 1 to merge sub-parts of the input; see Figure 2a for an illustration of the merge step. Since we are adding a constant number of points per access in the mergesort, the total points added is proportional to the cost of the mergesort, which in turn implies an offline BST algorithm with the same cost as the original BST mergesort.

The most difficult part of Theorem 6 is proving correctness of the arboral mergesort – that is, that each execution of the arboral merge routine produces an arborally satisfied set. This will require some more background on arborally satisfied sets.

▶ **Definition 7.** *A **treap** over a set of pairs S is a BST over the first coordinate of each $s \in S$ and a min-heap over the second coordinate. Ties over the second coordinate are permitted and may be broken arbitrarily.*

A treap with ties on the priorities can also be expressed as a **multi-treap** (for multi-node treap), where ties are stored in a **multi-node** that may have more than two children. Child relations must obey an underlying BST structure on the nodes stored within a multi-node; hence a multi-node may have at most one more child than the number of keys in the multi-node. A key component of our proof is that we will define a multi-treap with respect to each side of an arborally satisfied set and then relate these to the BST the mergesort will generate.

▶ **Definition 8.** *Given an arborally satisfied set A, let the left (right) priority be the distance from the left (right) boundary of the first point in the row (closer has higher priority). The* left (right) multi-treap *of A is the multi-treap defined by the (row, priority) pairs.*

Since there can be many points in any given column of an arborally satisfied set, multi-nodes of the multi-treaps can have more than two children.[2]

▶ **Definition 9.** *Given a BST T and an arborally satisfied set A with left (right) multi-treap H_A, T is* left (right) congruent with *A if there is some valid BST structure on H_A (forming a binary subtree within each multi-node) such that the tree structure on H_A is equal to T. T is* doubly *congruent with A if it is both left and right congruent.*

Note that many BSTs can be left (equivalently right) congruent with the same arborally satisfied set A due to equal priorities. Also many arborally satisfied sets can be left (right) congruent with the same BST T. It may seem unlikely that a BST is doubly congruent with a arborally satisfied set, but in our construction we will maintain double congruence, and in particular we will show that the point sets created by Algorithm 1 are doubly congruent to the corresponding tree.

The following observation will be useful for the proof of Theorem 6. It follows from a similar argument to Lemma 2.1 of Demaine et al. [18].

▶ **Observation 10.** *Consider an arborally satisfied set A that is double-congruent with a tree T. Then for any top tree τ of T, if the keys in τ are accessed along either the left or right column of A, or one past the left or right column, the resulting set of points is arborally satisfied.*

Proof. Begin with the case where the keys of τ are accessed one past the leftmost or rightmost column of A. Assume for the sake of contradiction that there exists an unsatisfied rectangle – that is, a rectangle with two points at its corners and no points contained within it – between access $a \in A$ and access $b \in \tau$. Consider the least common ancestor c of a and b, whose key value must be between those of a and b. Since by our assumption, there are no keys accessed between the rectangle defined by a and b, this contradicts the fact that τ is a continuous subtree of T, since c must be accessed in τ to reach b.

This leaves the case where accesses to τ are instead placed on the leftmost or rightmost column of A – that is, in addition to accesses that were already there. Consider an arbitrary access $a \in A$ and any access $b \in \tau$. If the accesses in τ are placed on a new column past the rightmost (leftmost) column of A, there is a monotonic path from a to b with accesses at every corner. If the accesses in τ are imposed on the rightmost (leftmost) column of A instead, the same accesses still form a monotonic path, since this only causes the elimination of one right (left) move. ◀

[2] Demaine et al. [18] define a similar notion when proving that for any arborally satisfied set there is a BST execution with equivalent cost, but only with respect to one side, and only when sweeping column by column.

We now prove correctness of the arboral mergesort algorithm.

▶ **Lemma 11.** *The arboral mergesort algorithm is correct: that is, it returns an arborally satisfied set.*

Proof. We will use the following inductive hypothesis on the arboral merge algorithm (Algorithm 1) to show correctness: Algorithm 1 returns an arborally satisfied set which is double-congruent to the tree T returned by the corresponding BST mergesort algorithm.

Base Case. When the set is just a single point, both arboral satisfaction and double congruence follow trivially.

Inductive Step. The inductive step is broken into several claims, and some new notation is called for. The two arborally satisfied sets being merged are A and B, and by the inductive hypothesis are both arborally satisfied and double-congruent to trees T_A and T_B, respectively. The additional accesses specified by the mergesort are added to three columns. Let C_L, C_R, and C_M denote the set of points which the arboral merge adds along the left, right, and middle columns respectively; see Figure 2a for an illustration. It will also be useful to denote the subset of a C_i ($i \in \{L, R, M\}$) consisting only of accesses to keys in A or B. These subsets are denoted by $C_i(A)$ or $C_i(B)$.

The merge will break A and B into contiguous blocks that are interleaved in key order. As assumed in the model, the block boundaries must be accessed by the merge, and therefore included in the C_i. In general the C_i will include other points as well. The inductive step has to show both that the resulting set is arborally satisfied and is doubly congruent to the merged tree T.

Arboral Satisfaction. Points within A or B are satisfied by the inductive hypothesis. Points both in C_L, C_R, C_M are satisfied by the fact that they access precisely the same keys. This leaves the two more interesting cases: (1) pairs of points one from the previously exiting points (in A or B) and one from the new boundaries C_L, C_R, C_M, and (2) pairs of points one from A and one for B. For the first case, A is double-congruent to tree T_A (by the inductive hypothesis), and $C_i(A)$ is a top tree of A (by construction), so we can apply Observation 10 for points in A and $C_i(A)$. Now since the boundaries of each block of A must be in $C_i(A)$, we can get from a point in A to a point in $C_i(B)$ using a monotonic path by going to a boundary point in $C_i(A)$ and then up or down the column to the point in $C_i(B)$. Symmetrically points in B can get to points in $C_i(B)$ and $C_i(A)$ by a monotonic path. For case (2) consider any point $a \in A$ and point $b \in B$. There is a monotonic path between a and b by composing the monotonic path between a and a boundary point in p_a in $C_m(A)$, between b and a boundary point p_b in $C_m(B)$, and between p_a and p_b, which are in the same column; see Figure 2a.

Double congruency to T. We will show that the set AB returned by the arboral merge algorithm is right congruent to T. Left congruency is true by symmetry. The keys in C_R (those accessed by the merge) correspond to a top tree τ of T. Since all keys in the column C_R have the same highest priority we can organize the root multi-node to match the structure of τ making those nodes congruent. Now consider the subtrees not in τ. They properly are lower in the tree and have equal or lower priority (only equal if they happen to be in the last row). Furthermore the subtrees are separated by keys in τ. Each such subtree either comes completely from T_A or completely from T_B and have the same structure as before the merge (they were not touched by the merge). Furthermore the points from T_A (T_B) only appear in

A (B). This implies the relative priorities have not change for those points when merging into AB. By induction, the trees T_A (T_B) were congruent to A (B) before the merge so the subtrees were congruent and remain congruent after the merge (neither the relative priorities nor tree structure have changed). This implies the whole tree T is congruent with AB. ◀

The proof of Theorem 6 now follows easily.

Proof of Theorem 6. The theorem follows once the cost of the arboral mergesort is shown to be $O(\mathcal{A}(\pi))$. Since the cost of $\mathcal{A}$ is dominated by the cost of each merge execution, and that cost is at most multiplied by six in each call to the arboral merge, the cost of the arboral mergesort is at most $6\mathcal{A}(\pi)$. When the arboral mergesort is transformed into an offline BST algorithm, the cost remains the same for a total cost of $O(\mathcal{A}(\pi))$. ◀

3.2 Partition Sort

We now consider a class of sorting algorithms motivated by quicksort, which we refer to as partition sorts. As in the case of mergesort, we limit ourselves to working with binary trees. However, in this case the trees are not ordered by key, but instead are ordered by input order. The algorithm is like quicksort in that it picks a pivot, partitions the keys on the pivot and recurses. Since we are interested in lower bounds (i.e. showing the cost of partition sort is at least as great as optimal BSTs), we can assume an oracle picks the perfect pivot (e.g., the median). As with mergesort, to achieve better than trivial $O(n \log n)$ bounds it is important that the partition need not visit the whole tree it is partitioning, but rather just some top tree. This allows for sending whole subsequences to the lesser or greater/equal side without visiting all nodes. More precisely here are the definitions of partition and partition sort.

▶ **Definition 12.** *A **BT partition** takes a BT T and for some top tree τ of T returns two BTs T_A, T_B with distinct keys such that for some top trees τ_a of T_A and τ_b of T_B, $\tau = \tau_a \cup \tau_b$, the other subtrees of T appear in either T_A or T_B unchanged, and τ contains the block boundaries of the partitioned output. Furthermore the preordering of the keys in T_A or T_B are a subsequence of the preordering in T (i.e. left-to-right ordering). We assume both partitions are non-empty. The* number of accesses *used by the partition is $|\tau|$.*

▶ **Definition 13.** *A **BT partition sort** on a BT tree T (1) partitions T into T_a and T_b such that for some key k all keys in T_a are less than k and all keys in T_b are greater or equal to k, (2) recurses on each partition, and (3) returns the left and right results appended. The recursion terminates when the tree is of size one. The number of accesses used by the partition sort is the sum of accesses across all partitions.*

Our goal is to show the following theorem, which has the same form as the result for mergesort.

▶ **Theorem 14.** *Let $\mathcal{A}$ be a BT partition sort algorithm that sorts permutation π using $\mathcal{A}(\pi)$ accesses, and let $OPT_{BST}(\pi)$ be the optimal cost of querying π with a BST algorithm. Then $OPT_{BST}(\pi) \in O(\mathcal{A}(\pi))$.*

Our approach is to show a one-to-one correspondence between the tree-based merge and partition sorts.

▶ **Lemma 15.** *For any BT partition sort algorithm $\mathcal{A}$ that sorts permutation π using $\mathcal{A}(\pi)$ accesses, there is a BST mergesort sort algorithm $\mathcal{B}$ that sorts permutation π^{-1} using $\mathcal{B}(\pi^{-1}) = \mathcal{A}(\pi)$ accesses, and vice versa.*

Proof. The idea is to consider running BST mergesort backwards, while reversing the role of time and key order. Consider undoing a merge – i.e. taking the merged tree and partitioning back into its two inputs. Reversing the roles of time and keys, this is equivalent to a BT partition where keys are time order and the partitions is on the first time of the right partition. In particular the size of the top tree and therefore access cost is identical. This continues to be true on the recursive calls. In both cases the base case is of size one. Hence the total access costs of the two algorithms are identical, one applied to the inverse permutation of the other. ◀

Since the size of arborally satisfied sets are invariant under rotation by 90 degrees, reversing the role does not affect the size of the set. Since the proof of Theorem 6 first showed how to map a BST mergesort to an arborally satisfied set and this implied the same bound on a offline BST, this remains true if we rotate the input, arborally satisfy it in the same way, and generate a BST. Theorem 14 follows. Taken together, Theorem 6 and Theorem 14 show the statement in Theorem 1. Although the duality of mergesort and quicksort has been recognized before we are not aware of any formal correspondence such as the one given here.

4 The Log-Interleave Bound

The following two sections contain results that illustrate the utility of the approach shown in Theorem 1: namely, that results in the sorting cost model can directly translate to interesting results in the BST model. In this section we propose an information-theoretic bound on both the cost of accessing a sequence in the BST model and sorting a list in the comparison model. Theorem 17 shows that the log-interleave bound is within a $\lg \lg n$ multiplicative factor of a known lower bound in the BST model. In the next section, we show that there exists a BST mergesort algorithm that sorts any permutation π in $O(\mathrm{LIB}(\pi))$ comparisons, and thus combined with Theorem 6 shows the existence of an offline BST algorithm with the same costs in the BST model.

The log-interleave bound can be thought of as an algorithmic perspective on Wilber's interleave bound. Let P be the static tree with the keys of a permutation π at the bottom. Consider sorting π via mergesort: clearly, each non-leaf vertex of P denotes a merge. The interleave bound charges unit cost for each switch between the right and left subtree during a merge. Another way of looking at this cost is that every continuous run of accesses to the left subtree incurs unit cost. Thus, a mergesort with a merge step that incurred unit cost for each consecutive run – as opposed to the standard mergestep which charges for the size of each run – would sort π using $O(\mathrm{IB}(\pi))$ comparisons.

Lecomte and Weinstein [26] and Chalermsoook et al. [12] independently show that the merge step described above does not exist. However, it is possible to charge the logarithm of the size of each consecutive run, as shown by Brown and Tarjan in [10]. This idea leads us to using such a merge step as an information-theoretic bound, which applies to sorting (sequentially and in parallel), and the BST model. The log-interleave bound is formally defined below; note its similarity to the interleave bound.

▶ **Definition 16.** *Given an access sequence π, fix a static binary tree P with the keys of π at the leaves. For each vertex v_j, query the descendants of v_j in sorted order, then label each with R or L depending on whether it is in the left or right subtree of v_j. Let $S(v_j)$ represent the decomposition of this labeling into the smallest possible number of runs of consecutive accesses to L or R in v_j. Then $LIB(v_j) = \sum_{r_i \in S(v_j)} \lg(|r_i|+1)$ and $LIB(\pi) = \sum_{v \in P} LIB(v_i)$.*

See Figure 3 for an example calculation.

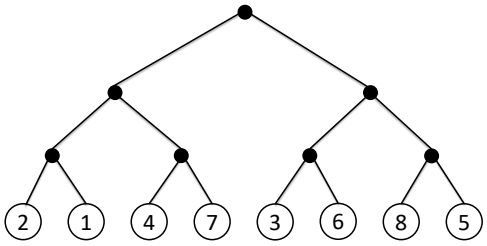


Figure 3 Consider accessing the keys 1-8 in order. For the vertex v_1 at the root of the tree shown here, the labeled access sequence is [L, L, L, R, L, R, R, R]. Since the access sequence switches between the left and right subtree three times, $\mathrm{IB}(v_1) = 3$. Similarly, $\mathrm{LIB}(v_1) = \lg 4 + \lg 2 + \lg 2 + \lg 4$ since the smallest possible decomposition of the labeled access sequence consists of [[L, L, L], [R], [L], [R, R, R]].

A natural question one might ask about a BST algorithm or an adaptive sorting algorithm is how far, in the worst case, is the cost of this algorithm from any known lower bounds? Or, in other words, how close is this algorithm to optimal? In this section, we will settle this question for the log-interleave bound in the BST model, ending in the following theorem:

▶ **Theorem 17.** *For any permutation π, $IB(\pi) \leq LIB(\pi) \in O(\lg\lg n \; IB(\pi))$.*

Our first step is to show that we cannot hope to do better than a $\lg\lg n$ separation; this is stated in the following lemma. This result is similar to the separation result in Theorem 2 of Lecomte and Weinstein [26]; furthermore, the result implies that an online BST algorithm using $\mathrm{LIB}(\pi)$ accesses cannot be dynamically optimal.

▶ **Lemma 18.** *There exists a permutation π such that $LIB(\pi) = \Theta(\lg\lg n \; IB(\pi))$.*

Proof. First we will need to define a particularly useful permutation. The *bit-reversal permutation* π_B on $n = 2^k$ keys is generated by taking a sorted list $[0, 1, \ldots, n]$, writing each key in binary, then reversing the bits of each key. For example, the bit-reversal permutation on 8 keys is $[0, 4, 2, 6, 1, 5, 3, 7]$. Let P be a static tree with keys of π_B at the bottom: then querying its keys in sorted order will switch between the left and right subtree of any $v_j \in P$ on each query. This implies that $\mathrm{IB}(\pi_B) = \Theta(n \lg n)$, thus showing that any BST algorithm will incur this cost when querying π_B.

Consider the permutation π obtained by splitting the sorted list into $n/\lg n$ segments of equal size, and then permuting those $n/\lg n$ segments according to the bit-reversal permutation π_B.

The interleave bound of π will be the same as for a list with $n/\lg n$ elements permuted according to the bit-reversal sequence – that is, $(n/\lg n)\lg(n/\lg n) = O(n)$. In π, every block is of size $\lg n$, so to calculate the log-interleave bound, we multiply by $\lg\lg n$ on all but the bottom $\lg\lg n$ levels. Thus, the log-interleave bound of π is $\Theta(n \lg\lg n)$ while $\mathrm{IB}(\pi) = O(n)$. ◀

Now we have shown there is no possibility of doing better than a $\lg\lg n$ separation, we show that this separation is tight. This starts with the following question: when are the interleave bound and the log-interleave bound farthest apart? It follows from the convexity of the logarithm that for each vertex v_j of a static tree, the interleave bound and the

log-interleave bound are farthest apart when v_j experiences long runs of consecutive accesses to its subtrees (e.g. the list [L, L, L, R, R, R] has fairly different values for its interleave bound and log-interleave bound, but the list [L, R, L, R, L, R] does not).

However, a completely sorted list π_S – translating to the longest run size possible for each vertex of P – has $\mathrm{IB}(\pi_S) = \mathrm{LIB}(\pi_S) = \Theta(n)$. This suggests there must be some intermediate value of the block size that maximizes the difference between the two bounds. As the reader might have inferred from Lemma 18, that size will turn out to be $\lg n$. The next lemma, whose proof follows directly from the convexity of the logarithm, formalizes this intuition.

▶ **Lemma 19.** *For a permutation π, let v be a vertex of the corresponding static tree P such that $IB(v) = S$. Then $LIB(v)$ will differ from $IB(v)$ by the greatest amount when each "run" of L or R in the labeled sequence is the same size.*

Now that we have established that the interleave bound and the log-interleave bound differ the most when all continuous runs are the same size, we move on to ask the following question: how large do the runs of the same size have to be to further maximize this difference? The next lemma shows this fact in the following way: in the inequality below, the expression $S \lg\left(\frac{n}{S}+1\right)$ bounds the log-interleave bound of any π such that $\mathrm{IB}(\pi) = S$. The left-hand expression $c\lg(\lg n+1)\left(S+\frac{n}{\lg n}\right)$ will directly suffice to prove Theorem 17. The proof of the lemma draws out the fact that the two expressions are closest to each other when the size of the continuous runs is $\lg n$.

▶ **Lemma 20.** *For a permutation π, let v be a vertex of the corresponding static tree P such that $IB(v) = S$. Furthermore, let the number of leaves below vertex v be n. Then for some constant c,*

$$c\lg(\lg n+1)\left(S+\frac{n}{\lg n}\right) \geq S\lg\left(\frac{n}{S}+1\right).$$

Proof. Assume for the sake of contradiction that

$$c\lg(\lg n+1)S + c\lg(\lg n+1)\frac{n}{\lg n} < S\lg\left(\frac{n}{S}+1\right).$$

This would imply that each added term is smaller than $S\lg\left(\frac{n}{S}+1\right)$. Begin by examining the case where the first term is smaller than the term on the right:

$$\begin{aligned} \lg(\lg n+1)S &< S\lg\left(\frac{n}{s}+1\right) \\ \implies \lg(\lg n+1) &< \lg\left(\frac{n}{S}+1\right) \\ \implies \lg n &< \frac{n}{S} \\ \implies S &< \frac{n}{\lg n}. \end{aligned}$$

This shows that when $S \geq \frac{n}{\lg n}$, we reach a contradiction and our claim holds. Now, when $S < \frac{n}{\lg n}$, the second term in the sum dominates. When the second term dominates, the expression reads

$$c\lg(\lg n+1)\cdot\frac{n}{\lg n} \geq \frac{n}{\lg n}\lg(\lg n+1)$$

which is self-evidently true for all $c \geq 1$. ◀

Now, these two lemmas are put together to prove Theorem 17.

Proof of Theorem 17. Let P be the static tree corresponding to π, and for each vertex v_i of P, let $S_i = \mathrm{IB}(v_i)$. By Lemma 19, we can assume that if the number of leaves below v_i is n_i, then $\mathrm{LIB}(v_i) = S_i \lg\left(\frac{n_i}{S} + 1\right)$. Then $\mathrm{IB}(\pi) = \sum_{i=1}^{n-1} S_i$. Next, we can use the upper bound on $\mathrm{LIB}(v_i)$ from Lemma 20 to upper bound $\mathrm{LIB}(\pi)$:

$$\begin{aligned}\mathrm{LIB}(\pi) &\leq \sum_{i=1}^{n-1} c \lg\lg n \left(S + \frac{n_i}{\lg n}\right) \\ &= c \lg\lg n \left(\mathrm{IB}(\pi) + \frac{1}{\lg n} \sum_{i=1}^{\lg n} 2^i \frac{n}{2^i}\right) \\ &= c \lg\lg n \left(\mathrm{IB}(\pi) + n\right) = O(\mathrm{IB}(\pi) \lg\lg n).\end{aligned}$$

◀

5 Adaptive Parallel Mergesort

In this section we present a parallel BST mergesort which sorts a permutation π using $O(\mathrm{LIB}(\pi))$ accesses, and the same amount of work. We refer to the algorithm as an *adaptive parallel mergesort*.

First we introduce the data structure used in our mergesort. Given a BST T and a key k, a **split** refers to returning two BSTs, one containing all keys from T which are greater than k, and one containing all keys which are less than k. Given two BSTs T_1, T_2 such that any key in T_1 is greater than every key in T_2, **join** returns a single BST T containing the union of the keys in T_1 and T_2. As previously stated, we assume keys are unique.

The tree used in our mergesort algorithm is a modified red-black tree described by Tarjan and Van Wyck in [36], which they call a *heterogeneous finger search tree*. These trees have the useful property that a key d in a heterogenous finger search tree with n elements can be accessed in time $O(\log(\min(d, n-d)+1))$. This property allowed Tarjan and Van Wyck to devise fast split and join algorithms for heterogenous finger search trees; split runs in amortized time $O(\lg(\min(|T_1|, |T_2|)+1))$ – that is, the logarithm of the size of the smaller tree returned. Join similarly is bounded by amortized time $O(\lg(\min(|T_1|, |T_2|)+1))$ – in this case, the size of the smaller of the two trees being joined together. The worst-case complexity of split and join is $O(\log \max |T_1|, |T_2|)$. As presented in [36], the heterogeneous finger search tree is not strictly a BST as it uses more than one pointer; however, work by [13] shows how it can be converted into using a single pointer with an additional constant factor loss.

The natural parallel algorithm to merge two trees is as follows: starting with two trees, split each tree using the other tree's root; then, recurse in parallel to merge the two left halves and the two right halves, respectively, joining the two at the end. This idea was presented by Blelloch et al. [4], and is shown here in Algorithm 2. This algorithm, however, does not meet the log-interleave bound even if we use heterogeneous finger search trees for the split and join. We therefore modify the algorithm as is shown in Algorithm 3 and illustrated in Figure 4, which follows the same idea with some small modifications. In addition to splitting the second tree T_2 into L_2 and R_2 based on the root of the first tree (T_1), it then splits T_1 by the maximum value of L_2 and the minimum value of R_2 to effectively break T_1 into three parts. The middle part need not be split recursively since it falls between two elements of T_2. This avoids redundant splits.

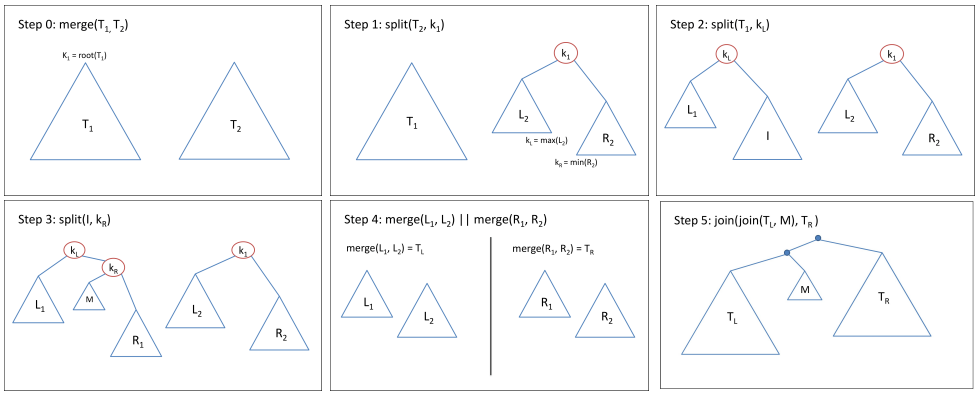

Figure 4 One round of our recursive merge algorithm. The nodes shown in red are the nodes used to split a tree; the small blue nodes denote merges.

Algorithm 2 union(T_1, T_2).
Blelloch et al.'s union algorithm. Here, the function *expose* refers to returning the root and its right and left subtrees.

Input: Two BSTs T_1, T_2 with disjoint keys.
Output: A BST containing the union of the keys of T_1 and T_2

if $T_1 =$ *Leaf* **then return** T_2 ;
else if $T_2 =$ *Leaf* **then return** T_1 ;
else
  $L_1, k_2, R_1 = \text{expose}(T_1)$;
  $L_2, R_2 = \text{split}(T_2, k)$;
  do in parallel
    $T_L = \text{union}(L_1, L_2)$;
    $T_R = \text{union}(R_1, R_2)$;
return *join*(T_L, k_2, T_R);

Algorithm 3 mergeHT(T_1, T_2)
Pseudocode for the merge step of our mergesort.

Input: Two BSTs T_1, T_2
Output: A BST containing the union of the keys of T_1 and T_2

if $T_1 =$ *Leaf* **then return** T_2 ;
else if $T_2 =$ *Leaf* **then return** T_1 ;
else
  $k = \text{root}(T_1)$;
  $L_2, R_2 = \text{split}(T_2, k)$;
  $k_1 = \max(L_2)$; $k_2 = \min(R_2)$;
  $L_1, I = \text{split}(T_1, k_1)$;
  $M, R_1 = \text{split}(I,\ k_2)$;
  do in parallel
    $T_L = \text{merge}(L_1, L_2)$;
    $T_R = \text{merge}(R_1, R_2)$;
return *join*(*join*(T_L, M), T_R);

It is not immediate our modified algorithm's work is bounded by the log-interleave bound, since the set of splits and joins it performs does not neatly correspond to the sums of block sizes at each level in the static tree used to calculate the log-interleave bound. We will show that this different sequence of splits and joins also performs within the log-interleave bound, culminating in the following theorem:

▶ **Theorem 21.** *There exists a parallel mergesort which for any permutation π performs $O(LIB(\pi))$ work with polylogarithmic span.*

Furthermore, since the algorithm proposed is a BST mergesort, it follows from Theorem 6 that there also exists an offline BST algorithm with the same cost in the BST model:

▶ **Corollary 22.** *There exists an offline BST algorithm $\mathcal{A}$ such that $\mathcal{A}(\pi) = O(LIB(\pi))$.*

The proofs of Theorem 21 and Corollary 22 are shown in the full version of the paper.

Parameterized Complexity of Binary CSP: Vertex Cover, Treedepth, and Related Parameters

Hans L. Bodlaender

Abstract

We investigate the parameterized complexity of Binary CSP parameterized by the vertex cover number and the treedepth of the constraint graph, as well as by a selection of related modulator-based parameters. The main findings are as follows:

- Binary CSP parameterized by the vertex cover number is W[3]-complete. More generally, for every positive integer d, Binary CSP parameterized by the size of a modulator to a treedepth-d graph is W[$2d+1$]-complete. This provides a new family of natural problems that are complete for odd levels of the W-hierarchy.
- We introduce a new complexity class XSLP, defined so that Binary CSP parameterized by treedepth is complete for this class. We provide two equivalent characterizations of XSLP: the first one relates XSLP to a model of an alternating Turing machine with certain restrictions on conondeterminism and space complexity, while the second one links XSLP to the problem of model-checking first-order logic with suitably restricted universal quantification. Interestingly, the proof of the machine characterization of XSLP uses the concept of *universal trees*, which are prominently featured in the recent work on parity games.
- We describe a new complexity hierarchy sandwiched between the W-hierarchy and the A-hierarchy: For every odd t, we introduce a parameterized complexity class S[t] with W[t] $\subseteq$ S[t] $\subseteq$ A[t], defined using a parameter that interpolates between the vertex cover number and the treedepth.

We expect that many of the studied classes will be useful in the future for pinpointing the complexity of various structural parameterizations of graph problems.

1 Introduction

The Binary Constraint Satisfaction Problem (BinCSP, for short) is a fundamental problem defined as follows. We are given an undirected graph $G = (V, E)$, called the *primal* or the *Gaifman graph*, where V is a set of variables, each with a prescribed domain of possible

values. Further, each edge uv of G corresponds to a binary constraint that restricts the possible pairs of values that can be assigned to u and v. The task is to decide whether every variable can be mapped to a value from its domain so that all the constraints are satisfied.

Due to immense modeling power, constraint satisfaction problems are of great importance in multiple applications, and the theoretical study of their complexity is a field on its own. In this work we are interested in parameterized algorithms for BinCSP, with a particular focus on structural parameters of the Gaifman graph. An example of such a result is a classic observation, usually attributed to Freuder [32]: using dynamic programming, BinCSP can be solved in time $n^{k+\mathcal{O}(1)}$, where n is the maximum size of a domain and k is the treewidth of the Gaifman graph. In the language of parameterized complexity, this means that BinCSP parameterized by treewidth is *slice-wise polynomial*, or in the complexity class XP.

The class XP is very general and just placing BinCSP parameterized by treewidth within XP does not provide much insight into the actual complexity of the problem. A more detailed study of the parameterizations of BinCSP by pathwidth and by treewidth was recently performed by Bodlaender, Groenland, Nederlof, and Swennenhuis in [11], and by Bodlaender, Groenland, Jacob, Pilipczuk, and Pilipczuk in [10]. In particular, as shown in [11], BinCSP parameterized by pathwidth is complete for XNLP: the class of all parameterized problems that can be solved by a nondeterministic Turing machine using $f(k)\log n$ space and $f(k)\cdot n^{\mathcal{O}(1)}$ time, where k is the parameter and f is a computable function. A "tree variant" of XNLP, called XALP, was studied in [10]; it can be defined using the same model of a Turing machine, except that the machine additionally has access to a stack of unbounded size that can be manipulated by pushing and popping. As proved in [10], BinCSP parameterized by treewidth is complete for XALP. All in all, the recent works [7, 9, 10, 11, 26] present a variety of problems on graphs with linear or tree-like structure that are complete for XNLP and XALP, respectively. This is an evidence that XNLP and XALP capture certain fundamental varieties of computational problems: those amenable to linearly and tree-structured dynamic programming with state space of slice-wise polynomial size.

The contemporary research in parameterized algorithms features many more structural parameters of graphs, besides treewidth and pathwidth. In this work we explore the complexity of BinCSP parameterized by the following parameters of the Gaifman graph: (1) the vertex cover number, (2) the treedepth, and (3) a selection of related modulator-based parameters lying between the vertex cover number and the treedepth.

New completeness results for the W-hierarchy. The W-hierarchy was introduced around thirty years ago in the work by Downey and Fellows that founded the field of parameterized algorithms and complexity. In this hierarchy, we have a collection of classes, including $\mathrm{W}[1] \subseteq \mathrm{W}[2] \subseteq \ldots \subseteq \mathrm{W}[\mathrm{SAT}] \subseteq \mathrm{W}[\mathrm{P}]$; see [20, 21, 30] for an overview and for bibliographic references. A large variety of problems are known to be complete (under fpt reductions) for W[1] and for W[2]. However, for classes W[t] with $t \geqslant 3$, there is so far only a handful of examples of natural problems known to be complete [1, 5, 6, 14, 15, 36]. Our first contribution is to give new examples of complete problems for W[t] for all odd $t \geqslant 3$.

Our first example concerns BinCSP parameterized by the *vertex cover number*: the minimum size of a vertex cover in the Gaifman graph.

▶ **Theorem 1.** *BinCSP parameterized by the vertex cover number of the Gaifman graph is complete for the class* W[3].

It was known that BinCSP parameterized by the vertex cover number is W[1]-hard [29, 44]. The W[3]-completeness is surprising, not only due to the small number of examples of natural W[3]-complete problems, but also because many problems appear to be fixed-parameter tractable or even have a kernel of polynomial size, when the vertex cover number is used as the parameter (e.g., [28, 29, 31, 34]).

For a graph G and a graph class $\mathcal{C}$, a *modulator* to $\mathcal{C}$ in G is a set of vertices W such that $G - W \in \mathcal{C}$. For instance, vertex covers are modulators to the class of edgeless graphs. A *feedback vertex set* is another type of a modulator, now to graphs without cycles, i.e., to forests. The *feedback vertex number* of a graph G is the minimum size of a feedback vertex set in G. We prove that the parameterization by the feedback vertex number yields a much harder problem.

▶ **Theorem 2.** *BinCSP parameterized by the feedback vertex number of the Gaifman graph is* W[SAT]*-hard and in* W[P]*.*

Finally, with similar techniques, we obtain the following completeness results for W[t] for all odd $t \geqslant 3$. Here, *treedepth* is a structural parameter measuring the "depth" of a graph, we will expand on it later on.

▶ **Theorem 3.** *For each integer $d \geqslant 1$, BinCSP is complete for* W[$2d+1$] *when parameterized by the minimum size of a modulator to a graph of treedepth at most d, and when parameterized by the minimum size of a modulator to a forest of depth at most d.*

Interestingly, each increase of the depth of the trees by one corresponds to an increase in the W-hierarchy by two levels: this is because one level of depth in the tree or forest corresponds to a conjunction (looking at all children of a node) with a disjunction (the choice of a value). Theorem 3 can be seen as an interpolation between Theorems 1 and 2: by allowing the forest to have larger and larger depth, we obtain harder and harder parameterized problems. This yields a family of natural complete problems for the odd levels of the W-hierarchy.

Theorem 1 is proved in Section 3, while Theorems 2 and 3 are proved in the full version [12].

Treedepth parameterization: class XSLP. As we argued, the classes XNLP and XALP can be seen as the "natural home" for BinCSP parameterized by pathwidth and treewidth respectively, and for many other problems on "path-like" or "tree-like" graphs. We introduce a new parameterized complexity class XSLP which is the "natural home" for the parameter treedepth instead, reflecting "shallow" graphs (this is what the letter S stands for).

The *treedepth* of a graph G is the minimum depth of a rooted forest F on the same vertex set as G such that every edge of G connects a vertex with its ancestor in F; thus, it is a measure of shallowness of a graph. While treedepth is never smaller than pathwidth, it can be arbitrarily large even on graphs of bounded pathwidth: a path on n vertices has pathwidth 1 and treedepth $\lceil \log_2(n+1) \rceil$. Despite being relatively lesser known than treewidth or pathwidth, treedepth appears naturally in many seemingly disconnected areas. For instance, it features a prominent role in the theory of Sparsity (see [43, Chapters 6 and 7] for an overview), has interesting combinatorics of its own (see e.g. [16, 19, 22, 39]), corresponds to important dividing lines in finite model theory (see e.g. [25, 40]), and governs the parameterized complexity of block-structured integer programming (see [24] for an overview). More importantly for us, a line of work [33, 37, 41, 42, 45, 46] uncovered that for many classic problems, on graphs of low treedepth one can design fixed-parameter algorithms that are both time- and space-efficient, which is conjectured not to be possible for the pathwidth or treewidth parameterizations [46]. This makes treedepth a prime candidate for a parameter that can be interesting from the point of view of BinCSP.

And so, we define two complexity classes: XSLP consists of all parameterized problems that can be reduced to BinCSP parameterized by treedepth in parameterized logspace (that is, in deterministic space $f(k) + \mathcal{O}(\log n)$ for a computable f), while XSLP$^+$ has the same definition, except we consider fpt reductions. This distinction is of technical nature: on one

hand we use parameterized logspace reductions to match the definitions of XALP and XNLP and retain the inclusion XSLP $\subseteq$ XNLP $\subseteq$ XALP, and on the other hand we would like to compare XSLP with the W-hierarchy, which requires closure under fpt reductions. In fact, XSLP$^+ \supseteq$ W[t] for every integer t (this will follows from Proposition 4).

We prove two alternative characterizations of XSLP. The first one is through a machine model: we prove that XSLP can be equivalently defined as problems that can be solved by an alternating Turing machine with the following resource bounds: (1) $f(k)\log n$ bits of nondeterminism, (2) $f(k) + \mathcal{O}(\log n)$ bits of conondeterminism, (3) alternation at most $f(k)$, and (4) working space $f(k) + \mathcal{O}(\log n)$ plus a read-once stack of size $f(k)\log n$ that can be only pushed upon and read only at the end of the computation. See Theorem 10 in Section 4.1 for a formal statement. This reflects the characterization of XALP through alternating Turing machines with different bounds on conondeterminism and the size of a computation tree, see [10, Theorem 1].

The main step in the proof of our machine characterization of XSLP is a regularization lemma for the considered machine model, allowing us to assume that the computation tree has always a very concrete shape. Interestingly, this step crucially uses the existence of fpt-sized *universal trees*, a tool fundamentally underlying the recent advances in the complexity of parity games. While universal trees can be seen only implicitly in the breakthrough work of Calude et al. [13], their central role in the approach was exposed in subsequent works [18, 38].

The second characterization is through model-checking first-order logic, and is inspired by the definition of the A-hierarchy; see [30, Chapter 8]. In essence, we provide a complete problem for XSLP, which amounts to model-checking first-order sentences in which universal quantification must follow a root-to-leaf path in a rooted forest present in the structure. Details and formal statements can be found in Section 4.2.

***d*-fold vertex cover and the S-hierarchy.** We "project" the class XSLP closer to lower levels of the W-hierarchy, thus obtaining a new hierarchy of parameterized classes sandwiched between the W-hierarchy and the A-hierarchy. For this, we introduce the following parameter.

The 1-*fold vertex cover number* of a graph G is simply the number of vertices of G. Inductively, for $d \geqslant 2$, the *d-fold vertex cover number* is the smallest integer k with the following property: there is a subset of vertices $U \subseteq V(G)$ with $|U| \leqslant k$ such that every connected component of $G - U$ has $(d-1)$-fold vertex cover number at most k. Alternatively, we can also define the parameter using a "fattened" variant of elimination trees (the decomposition notion underlying treedepth). Namely, G has d-fold vertex cover number at most k if and only if there is a rooted tree T of depth at most d, and a vertex partition $\{V_t \colon t \in V(T)\}$ of $V(G)$ such that $|V_t| \leqslant k$ for all $t \in V(T)$, and edges in G between vertices of V_s and V_t are only allowed when s and t are equal or are in an ancestor-descendant relationship in T.

We now define the parameterized complexity class[1] S[$2d-1$] as the fpt-closure of BinCSP parameterized by the d-fold vertex cover number, for all integers $d \geqslant 1$. The following result relates the introduced classes to the W-hierarchy, the A-hierarchy, and the class XSLP$^+$.

▶ **Proposition 4.** *For every integer $d \geqslant 1$, we have* W[$2d-1$] $\subseteq$ S[$2d-1$] $\subseteq$ A[$2d-1$] *and* S[$2d-1$] $\subseteq$ XSLP$^+$.

The proof is straightforward and is given in the full version [12].

[1] We remark that there is an already existing concept called the S-hierarchy, related to subexponential parameterized algorithms; see [30, Definition 16.9]. Since we are not aware of any subsequent work on the structure of this hierarchy, we took the liberty of using the same naming scheme for our classes.

While the definition of d-fold vertex cover seems not to have been discussed explicitly in the literature, the idea of alternating deletions of batches of vertices and splitting into connected components is not entirely new, as similar parameters that interpolate between vertex cover and treedepth have previously been studied. For example, 2-fold vertex cover is within a multiplicative factor of two of *vertex integrity*, a parameter that was introduced by Barefoot, Entringer and Swart [4] in 1987 (see [2] for a survey). In the context of block-structure integer programs, the *fracture number* [23] can be seen as an analogue of 2-fold vertex cover, while the concept of *topological height* [24] serves a role similar to that of d in the definition of d-fold vertex cover.

Comparison to List Coloring. The classic List Coloring problem can be interpreted as the special case of BinCSP where every constraint just stipulates that the values assigned to adjacent variables are different from each other. Therefore, a hardness result for List Coloring implies one for BinCSP. Vice versa, we can attempt to turn an instance of BinCSP on graph G into an instance of List Coloring by adding, for each edge uv in G and each forbidden pair of values (a, b), a vertex to G adjacent to u and v with color list $\{a, b\}$. This transformation does not significantly affect graph parameters such as treedepth, treewidth or pathwidth, so hardness and completeness results of BinCSP may also be inherited to List Coloring. However, the transformation may make dramatic changes to other parameters such as vertex cover and vertex modulator to a graph of treedepth at most d, where we can only easily deduce W$[2d-1]$-hardness from our W$[2d+1]$-hardness results. In fact, we separate the two problems with the following result, proved in the full version [12].

▶ **Theorem 5.** *List Coloring is in* W[2] *when parameterized by the vertex cover number and in* W[2d] *when parameterized by the size of a modulator to a treedepth-d graph.*

We believe that due to its robustness, BinCSP better suited to measure the complexity of parameters than List Coloring is. This is also witnessed by the (nearly) tight completeness results presented in Theorems 1, 2, and 3. Table 1 below presents a comparison of the parameterized complexity landscapes of BinCSP and of List Coloring under various structural parameterizations. We discuss this table in the full version [12].

2 Preliminaries

For integers $a \leqslant b$, we write $[a, b]$ for $\{a, a+1, \ldots, b\}$.

Graphs and their parameters. In this paper, we denote the *depth* of a rooted tree as the maximum number of vertices on a path from root to leaf. A *rooted forest* is a collection of rooted trees. The *depth* of a rooted forest is the maximum depth of the trees in the forest.[2]

We use standard graph notation. An *elimination forest* of a graph G, is a rooted forest F with the same vertex set as G, such that for each edge uv of G, u is an ancestor of v or v is an ancestor of u in F. (Note that the forest can contain edges that are not in G.) The *treedepth* of a graph G is the minimum depth of of rooted forest embedding of G.

Let $\mathcal{C}$ be a class of graphs. A *modulator* to $\mathcal{C}$ in a graph G is a set of vertices $W \subseteq V(G)$, such that the graph $G - W$ belongs to $\mathcal{C}$. A *vertex cover* of a graph G is a set of vertices $W \subseteq V(G)$, such that every edge of G has at least one endpoint in W. Note that a set of

[2] The definitions of depth of a tree used in the literature can differ by one. Here we count the number of vertices, e.g., a tree consisting of a single vertex has depth 1.

Table 1 Complexity of BinCSP and List Coloring. Results marked with $*$ are shown in this paper. Some results without a reference are easy to obtain.

Parameter	Binary CSP	List Coloring
number of vertices	W[1]-complete [27, 44]	poly-kernel
vertex cover	W[3]-complete $*$	W[1]-hard [29], in W[2] $*$
feedback vertex set	W[SAT]-hard, in W[P] $*$	W[3]-hard, in W[P] $*$

vertices is a vertex cover if and only if it is a modulator to the class of edgeless graphs, or, equivalently, to the class of graphs with treedepth at most 1. A *feedback vertex set* in a graph G is a modulator to a forest, or, equivalently, a set of vertices that intersects each cycle in G.

Constraint satisfaction problems. We consider the BinCSP problem defined as follows. An instance of BinCSP is a triple

$$I = (G, \{D(u)\colon u \in V(G)\}, \{C(u,v)\colon uv \in E(G)\}),$$

where

- G is an undirected graph, called the *Gaifman graph* of the instance;
- for each $u \in V(G)$, $D(u)$ is a finite set called the *domain* of u; and
- for each $uv \in E(G)$, $C(u,v) \subseteq D(u) \times D(v)$ is a binary relation called the *constraint* at uv. Note that $C(u,v)$ is not necessarily symmetric; throughout this paper, we apply the convention that $C(v,u) = \{(b,a) \mid (a,b) \in C(u,v)\}$.

In the context of a BinCSP instance, we may sometimes call vertices *variables*. A *satisfying assignment* for an instance I is a function η that maps every variable u to a value $\eta(u) \in D(u)$ such that for every edge uv of G, we have $(\eta(u), \eta(v)) \in C(u,v)$. The BinCSP problem asks, for a given instance I, whether I is *satisfiable*, that is, there is a satisfying assignment for I.

The List Coloring problem is a special case of BinCSP defined as follows. An instance consists of a graph G and, for every vertex u of G, a set (*list*) of colors $L(u)$. The question is whether there is a mapping f of vertices to colors such that for every vertex u we have $f(u) \in L(u)$, and for each edge uv of G, we have $f(u) \neq f(v)$. Note that this is equivalent to a BinCSP instance where lists $L(u)$ are the domains, and all constraints are non-equalities: $C(u,v) = \{(a,b) \in L(u) \times L(v) \mid a \neq b\}$ for every edge uv.

Complexity theory. We assume the reader to be familiar with standard notions of the parameterized complexity theory, such as the W-hierarchy or parameterized reductions. For more background, see [17, 20, 21, 30]. Let us recall concepts directly used in this paper.

We say that a parameterized problem Q is in *parameterized logspace* if Q can be decided in (deterministic) space $f(k) + \mathcal{O}(\log n)$, for some computable function f. Note that every problem in parameterized logspace is fixed-parameter tractable, because a Turing machine working in space $f(k) + \mathcal{O}(\log n)$ has $2^{\mathcal{O}(f(k))} \cdot n^{\mathcal{O}(1)}$ configurations, and hence its acceptance can be decided in fixed-parameter time.

An *fpt-reduction* is a parameterized reduction that works in fixed-parameter time. A *pl-reduction* is a parameterized reduction that works in parameterized logspace, that is, can be computed in (deterministic) space $f(k) + \mathcal{O}(\log n)$, for some computable function f.

A Boolean formula is said to be *t-normalized* when it is the conjunction of disjunctions of conjunctions of ... of literals, with t levels of conjunctions or disjunctions. We only consider the case where $t \geqslant 2$, and assume that we start by conjunctions. Note that 2-normalized Boolean formulas are in Conjunctive Normal Form.

In the Weighted t-Normalized Satisfiability problem, we are given a t-normalized Boolean formula F on n variables, and an integer k, and ask if we can satisfy F by setting exactly k of the variables to true, and all other variables to false. This problem is complete for W[t], see e.g. [20, 21]. A t-normalized expression is said to be *anti-monotone* if each literal is the negation of a variable. We use the following result to simplify our proofs.

▶ **Theorem 6** (Downey and Fellows, see [20, 21]). *For every odd $t \geqslant 3$, Weighted Anti-Monotone t-Normalized Satisfiability is complete for W[t].*

We use the following result as starting point for membership proofs.

▶ **Theorem 7** (Downey and Fellows, see [20, 21]). *For every $t \geqslant 2$, Weighted t-Normalized Satisfiability is complete for* W[t].

3 W[3]-completeness for BinCSP parameterized by vertex cover

In this section, we prove Theorem 1. We prove the hardness below and refer to the full version [12] for the proof of membership.

▶ **Lemma 8.** *BinCSP with vertex cover as parameter is* W[3]*-hard.*

Proof. Take an instance of Weighted 3-Normalized Anti-Monotone Satisfiability, i.e., we have a Boolean formula F that is a conjunction of disjunctions of conjunctions of negative literals, and ask if we can satisfy it by setting exactly k variables to true. Suppose $x_1, \ldots, x_n$ are the variables used by F. Suppose F is the conjunction of r disjunctions of conjunctions of negative literals.

We build a graph G as follows. The vertex set $V(G)$ consists of a set $W = \{w_1, \ldots, w_k\}$ of size k, and a set $S = \{v_1, v_2, \ldots, v_r\}$ of size r. The set W will be the vertex cover of G, and S will form an independent set. We add edges from each vertex in W to each other vertex in the graph.

The domain of a vertex $w \in W$ is $D(w) = \{x_1, \ldots, x_n\}$. For distinct $w, w' \in W$, $w' \neq w'$, we set $C(w, w') = \{(x_i, x_j) \mid i \neq j\}$. This enforces that all vertices in W are assigned a different value – this corresponds to setting exactly k variables to true.

Now consider a vertex $v_i \in S$ for $i \in [1, r]$. We say that v_i represents the ith disjunction of conjunctions of literals in F, i.e., each of the disjunctions in the formula is represented by one vertex in the independent set. Suppose that this disjunction has t_i terms (each term is a conjunction of negative literals). We set $D(v_i) = [1, t_i]$, that is, each value for v_i is an integer in $[1, t_i]$.

The intuition is as follows. We set a variable x_i to true, if and only if exactly one vertex in W is assigned x_i. As all vertices in W will get a different value, we set in this way exactly k variables to true. The formula F is the conjunction of r disjunctions; each of these disjunctions is represented by one of the vertices $v_i \in S$. For each v_i, the disjunction represented by v_i must be satisfied, so one of its terms must be satisfied. The value of v_i tells a satisfied term, i.e., if the value of v_i is $j \in [1, t_i]$, then the jth term is satisfied. This is checked by looking at the edges from v_i to the vertices in W.

We now give the constraints that ensure the term is satisfied. Consider a vertex $v_i \in S$ and $w \in W$. Recall that the value of v_i is an integer in $[1, t_i]$ which represents one term in the ith disjunction of F, and that term is a conjunction of a number of negative literals. For $j \in [1, t_i]$ and $j' \in [1, n]$, we have $(j, x_{j'}) \in C(v_i, w)$ if and only if for each literal $\neg x_{j''}$ that appears in the jth term of the ith disjunction of F, $j'' \neq j'$.

We call the constructed graph G and write I for the corresponding instance of BinCSP.

▷ Claim 9. F can be satisfied by setting exactly k variables to true, if and only if I has a satisfying assignment.

Proof of Claim 9. Suppose F can be satisfied by making $x_{i_1}, \ldots, x_{i_k}$ true, and all other literals false. Then assign the vertices in W the values $x_{i_1}, \ldots, x_{i_k}$ successively. The constraints between vertices in W are thus satisfied.

Now consider a vertex $v_i \in S$. Consider the ith term F_i of the (upper level) conjunction of F. This term must be satisfied by the truth assignment. Suppose the term is $F_i = F_{i,1} \vee \cdots \vee F_{i,t_i}$. At least one of the F_{i_j}'s must be satisfied by the truth assignment, say $F_{i,j'}$. Then assign v_i the value j'.

We can verify that the constraints for edges between v_i and each w_j are fulfilled. By assumption, $F_{i,j'}$ holds. It thus cannot contain a negative literal $\neg x_\alpha$, where x_α is set to true. So w_j cannot be assigned x_α when $\neg x_\alpha$ is a literal in $F_{i,j'}$. Thus we found a satisfying assignment for I.

Now, suppose that I has a satisfying assignment. From the constraints between vertices in W, we see that all vertices in W have a different value. Set a variable x_i to true, if and only if a vertex in W has value x_i, and otherwise, set it to false. We have thus set exactly k variables to true.

Consider the ith term of the upper level conjunction of F. Suppose this term is $F_{i,1} \vee \ldots \vee F_{i,t_i}$. Suppose v_i is assigned value j. For each negative literal $\neg x_\alpha$ in the conjunction $F_{i,j}$, by the constraints, we cannot have a vertex in W that is assigned x_α, and thus x_α is set to false. Thus, the term $F_{i,j}$ is satisfied by the truth assignment, and thus F_i is satisfied. As this holds for all conjuncts of F, F is satisfied by the specified assignment. ◁

From Claim 9, we see that we have a parameterized reduction from Weighted Anti-Monotone 3-Normalized Satisfiability to BinCSP with vertex cover as parameter. The result now follows from the W[3]-hardness of Weighted Anti-Monotone 3-Normalized Satisfiability (Theorem 6). ◀

4 XSLP and treedepth

In this section we discuss the class XSLP and its various characterizations. As discussed in Section 1, we actually define two variants of this class, depending on the kind of reductions that we would like to speak about. Let BinCSP/td denote the following parameterized problem. We are given a BinCSP instance I and an elimination forest of the Gaifman graph of I

of depth at most k, which is the parameter. The task is to decide whether I is satisfiable. Then the two variants of XSLP are defined as the closures of this problem under pl- and fpt-reductions, respectively:

$$\text{XSLP} = [\text{BinCSP}/_{\text{td}}]^{\text{pl}} \qquad \text{and} \qquad \text{XSLP}^+ = [\text{BinCSP}/_{\text{td}}]^{\text{fpt}}.$$

That is, XSLP consists of all parameterized problems that are pl-reducible to $\text{BinCSP}/_{\text{td}}$, and XSLP^+ is defined similarly, but with fpt-reductions in mind.

Note that in the $\text{BinCSP}/_{\text{td}}$ problem we assume that a suitable elimination forest is provided on input. This is to abstract away the need of computing such an elimination forest; the complexity of this task is also an interesting question, but lies beyond the scope of this work.

4.1 A machine characterization

We first give a machine characterization of XSLP. We will use a model of an *alternating read-once stack machine*, or *AROSM* for brevity, which we now define. We assume familiarity with standard Turing machines, on which we build our model.

An alternating read-once stack machine M is a Turing machine that has access to three types of memory, each using $\{0, 1\}$ as the alphabet:

- a read-only input tape;
- a working tape; and
- a read-once stack.

The input tape and the working tape are accessed and manipulated as usual, by a head that may move, read, and (in the case of the working tape) write on the tape. The input to the machine is provided on the input tape. On the other hand, the stack is initially empty and the machine may, upon any transition, push a single symbol onto the stack. It cannot, however, read the stack until the final step of the computation. More precisely, the acceptance condition is as follows: The machine has a specified *final state*. Once it is reached, the computation finishes and the machine reads the ith bit of the stack, where i is the number whose binary encoding is the current content of the working tape. If this bit is 1, then M accepts, and otherwise it rejects.

A *configuration* of M is a 5-tuple consisting of the state, the content of the working tape, the content of the stack, and the positions of the heads on the input and the working tape.

Further, M is an *alternating machine*, which means that its states are partitioned into three types: *existential states*, *universal states*, and *deterministic states*. A configuration of a machine is existential/universal/deterministic if its state is so. When the state of the machine is deterministic, there is exactly one transition allowed. At existential and universal states, there are always two transitions allowed; these will be named the 0-*transition* and the 1-*transition*. The acceptance is defined as usual in alternating machines: when in an existential state, M may accept if at least one allowed transition leads to a configuration from which it may accept, and in a universal state we require that both transitions lead to configurations from which M may accept. The notion of a machine deciding a (parameterized) problem is as usual.

The $\forall$ *computation tree* of M for input x is defined as a tree of configurations with the following properties:

- the root is the initial configuration with input x;
- the leaves are configurations with the final state;
- every deterministic and every existential configuration has exactly one child, which is the unique, respectively any of the two configurations to which the machine may transit;

- every universal configuration has exactly two children, corresponding to the two configurations to which the machine may transit.

It follows that M accepts input x if there is a $\forall$ computation tree for input x where every leaf is a configuration in which M accepts. We call such $\forall$ computation trees *accepting*.

A *branch* of a (rooted) tree is a root-to-leaf path. For a $\forall$ computation tree T of machine M, we define the following quantities:

- The *working space* of T is the minimum number i such among configurations present in T, the head on the working tape is never beyond the ith cell.
- The *stack size* of T is the maximum size of the stack among all configurations in T.
- The *nondeterminism* of T is the maximum number of existential configurations on any branch of T.
- The *conondeterminism* of T is the maximum number of universal configurations on any branch of T.
- The *alternation* of a branch of T is the minimum number of blocks into which the branch can be partitioned so that each of the blocks does not simultaneously contain an existential and a universal configuration. The *alternation* of T is the maximum alternation on any branch of T.

We say that a machine M *decides* a parameterized problem Q using certain resources among those described above, if for any input (x, k), we have $(x, k) \in Q$ if and only if there is an accepting $\forall$ computation tree for (x, k) that has the resources bounded as prescribed.

Having all the necessary definitions in place, we can state the main result of this section.

▶ **Theorem 10.** *The following conditions are equivalent for a parameterized problem Q.*

(1) $Q \in \mathrm{XSLP}$*;*

(2) *Q can be decided by an alternating read-once stack machine that for input (x, k) with $|x| = n$, uses working space at most $f(k)+\mathcal{O}(\log n)$, stack size $f(k)\log n$, nondeterminism $f(k)\log n$, co-nondeterminism $f(k)+\mathcal{O}(\log n)$, and alternation $f(k)$, for some computable function f.*

Before we proceed to the proof of Theorem 10, let us discuss the necessity of different resource restrictions described in (2):

- Increasing the working space to $f(k)\log n$ (and thus rendering the stack, the nondeterminism and the co-nondeterminism unnecessary) would make the machine model at least as powerful (and in fact, equivalently powerful) as deterministic Turing machines with $f(k)\log n$ space; this corresponds to a class called XL. As XL^+ (the closure of XL under fpt reductions) contains AW[SAT] [30, Exercise 8.39], the supposition that the amended model is still equivalent to XSLP would imply the inclusion $\mathrm{AW}[\star] \subseteq \mathrm{AW}[\mathrm{SAT}] \subseteq \mathrm{XSLP}^+$. From the logic characterization that will be provided in Section 4.2 it follows that $\mathrm{AW}[\star] \supseteq \mathrm{XSLP}^+$, so in fact we would obtain a collapse $\mathrm{AW}[\star] = \mathrm{AW}[\mathrm{SAT}] = \mathrm{XSLP}^+$.
- If we increase the bound on allowed co-nondeterminism to $f(k)\log n$, thus matching the bound on the allowed nondeterminism, then it is not hard to see that the obtained machine model would be able to solve the model-checking problem for first-order logic on general relational structures, which is AW[$\star$]-complete. Consequently, if the amended machine model was still equivalent to XSLP, we would again obtain equality $\mathrm{AW}[\star] = \mathrm{XSLP}^+$, which we consider unlikely.
- If we let the machine use unbounded nondeterminism, then already for k constant and assuming no use of co-nondeterminism, our machines would be able to solve every problem in NL, including Directed Reachability. If the obtained machine model was still equivalent to XSLP, then Directed Reachability would be reducible (in L) to BinCSP on graphs of constant treedepth. But the latter problem is actually in L, so we would obtain L = NL.

- We believe that increasing the alternation from $f(k)$ to $f(k) + \mathcal{O}(\log n)$ yields a strictly more powerful machine model, though at this point we cannot pinpoint any concrete collapse that would be implied by the converse. However, it is not hard to check that an AROSM with resource bounds as in Theorem 10, but alternation $f(k) + \mathcal{O}(\log n)$, is able to solve BinCSP instances with Gaifman graphs of treedepth as large as $\log n$, but with all domains of size at most k. We do not see how to reduce this problem to BinCSP with domains of unbounded size, but treedepth bounded by $f(k)$.
- It is an interesting question whether the $f(k) \log n$ bound on the stack size can be lifted; that is, whether allowing unbounded stack size strictly increases the power of the considered machine model. On one hand, in all our proofs, the stack is essentially only used to store nondeterministic bits, and in any run there are at most $f(k) \log n$ of them anyway. So if the stack is used only for this purpose, then it is immaterial whether its size is bounded by $f(k) \log n$ or unbounded. On the other hand, the restriction on the stack size plays an important role in the proof of the implication (2) $\Rightarrow$ (1) of Theorem 10. We leave resolving this question open.

The remainder of this section is devoted to the proof of Theorem 10. Naturally, the argument is split into the forward and the backward implication.

We refer to the full version [12] for the proof of the simpler implication (1) $\Rightarrow$ (2), but briefly sketch it here. We use an AROSM to guess a satisfying assignment to the given ${}^{\text{BinCSP}}/_{\text{td}}$ instance, by going top-down through the associated forest. We use nondeterminism to guess the assignment for the next vertex u, and conondeterminism to verify whether the currently guessed partial assignment can be extended to all the subtrees rooted at the children of u.

We now proceed to the more difficult implication (2) $\Rightarrow$ (1) of Theorem 10. The main idea is that we introduce a restricted variant of a *regular* AROSM, which is an AROSM whose $\forall$ computation tree has a very specific shape, computable from k and the length of the input. We will then show two lemmas: (i) for every AROSM there is an equivalent regular one, and (ii) acceptance of a regular AROSM can be reduced to ${}^{\text{BinCSP}}/_{\text{td}}$. The main point in this strategy is that the assumption that the computation tree is fixed allows us to fix it as the elimination tree of the Gaifman graph of the constructed BinCSP instance.

More precisely, we will be working with the *contracted* $\forall$ *computation trees* defined as follows. Let T be a $\forall$ computation tree of an AROSM M, where without loss of generality we assume that the starting state of M is universal. A *universal block* of T is an inclusion-wise maximal subtree A of T such that the root of A is a universal configuration and A does not contain existential configurations. Note that removing all universal blocks from T breaks T into a collection of disjoint paths consisting only of deterministic and existential configurations; these will be called *existential blocks*. The *contraction* of T is the tree T' whose nodes are universal blocks of T, where the ancestor order is naturally inherited from T: one block is an ancestor of the other in T' if this holds for their roots in T. Note that a universal block B is a child of a universal block A in T' if and only if there is an existential block C that connects the root of B with a leaf of A. Thus, the edges of T' are in one-to-one correspondence with the existential blocks of T.

▶ **Definition 11.** *An AROSM M is* regular *if given $(1^n, k)$ one can in parameterized logspace compute a rooted tree $T_{n,k}$ with the following properties:*

- *$T_{n,k}$ has depth at most $f(k)$, for some computable function f; and*
- *for any input (x, k) with $|x| = n$, if M accepts (x, k), then M has a $\forall$ computation tree accepting (x, k) whose contraction is $T_{n,k}$.*

With this definition in place, we can state the two lemmas described before.

▶ **Lemma 12.** *If a parameterized problem Q can be decided by an AROSM M using the resource bounds stated in Theorem 10, then it can also be decided by a regular AROSM M' using such resource bounds.*

▶ **Lemma 13.** *If Q can be decided by a regular AROSM M using the resource bounds stated in Theorem 10, then $Q \in$ XSLP.*

The (2) ⇒ (1) implication of Theorem 10 follows directly by combining the two lemmas above. The proof of Lemma 13 is a conceptually straightforward, though technically a bit involved encoding of a ∀ computation tree of the machine through an instance of BinCSP whose elimination tree is (roughly) $T_{n,k}$. We give this proof in the full version [12]. The proof of Lemma 12 is the interesting part of the argument, as it involves the notion of *universal trees*.

Before we proceed, let us state a simple lemma that is used in our proofs several times. We included a proof in the full version [12] for completeness.

▶ **Lemma 14.** *Suppose T is a rooted tree with N leaves. Then there exists a labelling λ that maps every edge e of T to a binary string $\lambda(e) \in \{0,1\}^\star$ with the following properties:*
- *For every node u, the labels of edges connecting u with its children are pairwise different.*
- *For every leaf ℓ, the total length of labels on the root-to-ℓ path in T is at most $\lceil \log N \rceil$.*

Moreover, given T the labelling λ can be computed in deterministic logarithmic space.

4.1.1 Regularization

We now prove Lemma 12. We need the following definitions. An *ordered tree* is a rooted tree where for every vertex u there is a linear order $\preceq$ on the children of u. An *embedding* of an ordered tree S into an ordered tree T is an injective mapping $\phi\colon V(S) \to V(T)$ such that
- the root of S is mapped to the root of T, and
- for every node u of S, the children of u in S are mapped to distinct children of $\phi(u)$ in T in an order-preserving way: if $v \prec v'$ are distinct children of u in S, then $\phi(v) \prec \phi(v')$.

We will use the following result about the existence of *universal trees*.

▶ **Lemma 15** (follows from Jurdziński and Lazić [38], see also Theorem 2.2 of [18])**.** *For every pair of integers $n, k \in \mathbb{N}$ there exists an ordered tree $U_{n,k}$ such that*
- *$U_{n,k}$ has depth k;*
- *$U_{n,k}$ has at most $2n \cdot \binom{\lceil \log n \rceil + k + 1}{k}$ leaves; and*
- *for every ordered tree T of depth at most k and with at most n leaves, there is an embedding of T into $U_{n,k}$.*

Moreover, given $(1^n, k)$, the tree $U_{n,k}$ can be computed parameterized logspace.

We remark that the claim about the computability of $U_{n,k}$ in parameterized logspace is not present in [18, 38], but follows directly from the recursive construction presented there. In fact, we will also need the following property, which again follows directly from the construction, and which strengthens the embedding property stated in Lemma 15.

▶ **Lemma 16.** *For every node u of $U_{n,k}$, the subtree of $U_{n,k}$ rooted at u is isomorphic to $U_{n',k'}$ for some $n' \leqslant n$ and $k' \leqslant k$; the labeling of nodes of $U_{n,k}$ with suitable numbers n', k' can be computed along with $U_{n,k}$ within the algorithm of Lemma 15. Moreover, if $n_1, \ldots, n_p$ are nonnegative integers such that $n_1 + \ldots + n_p \leqslant n$, then there are distinct children $v_1 \prec v_2 \prec \ldots \prec v_p$ of the root of $U_{n,k}$ such that for every $i \in \{1, \ldots, p\}$, the subtree of $U_{n,k}$ rooted at v_i is isomorphic to $U_{n'_i,k-1}$ for some $n'_i \geqslant n_i$.*

Finally, observe that

$$2n \cdot \binom{\lceil \log n \rceil + k + 1}{k} \leqslant 2n \cdot 2^{\lceil \log n \rceil + k + 1} \leqslant \mathcal{O}(2^k \cdot n^2),$$

hence $U_{n,k}$ has $\mathcal{O}(2^k \cdot n^2)$ leaves.

We proceed to the proof of Lemma 12. Let us fix an AROSM M that on any input (x, k) with $|x| \leqslant n$, uses $f(k) \log n$ nondeterminism, $f(k) + d \log n$ conondeterminism, $f(k)$ alternation, $f(k) + d \log n$ working space, and $f(k) \log n$ stack size, where f is a computable function and $d \in \mathbb{N}$ is a constant. We may assume w.l.o.g. that the starting state of M is universal. Denote $K = f(k)$ and $N = 2^{f(k) + \lceil d \log n \rceil} \leqslant 2^{f(k)+1} \cdot n^d$; then K is an upper bound on the depth and N is an upper bound on the total number of leaves of any $\forall$ computation tree accepting (x, k) within the stipulated resources. By Lemma 15, we may compute the universal tree $U_{N,K}$ in deterministic space $h(k) + \mathcal{O}(\log n)$ for a computable function h. Note that $U_{N,K}$ has $N' = \mathcal{O}(2^K \cdot N^2) \leqslant \mathcal{O}(2^{3f(k)} \cdot n^{2d})$ leaves. The tree $U_{N,K}$ will serve the role of $T_{n,k}$ in the proof. Also, we use Lemma 14 to compute a suitable labeling λ of the edges of $U_{N,K}$ in which the total length of labels on every branch of $U_{N,K}$ is at most $\lceil \log N' \rceil \leqslant 3f(k) + 2d \log n + \mathcal{O}(1)$.

We are left with designing an AROSM M' that is equivalent to M, in the sense that M' accepts input (x, k) if and only if M does, and in such case the contracted $\forall$ computation tree of M' on (x, k) may be $U_{N,K}$. The idea is that machine M' will simulate M while inserting some dummy computation to "fill" the contracted $\forall$ computation tree of M to $U_{N,K}$. However, we will need to be very careful about how the conondeterminism of M is simulated.

A *stackless configuration* is a configuration of M, but without specifying the content of the stack; that is, it consists of the state of M, the content of the working tape, and the positions of the heads on the input and the working tapes. For a universal stackless configuration c of M, we define the *universal block* rooted at c, denoted $U(c)$, as a rooted tree of stackless configurations that is obtained just as the $\forall$ computation tree, except that M starts at c and we do not continue the simulation once the final state or any existential configuration is reached. Note here since M cannot read the stack except for the end of the computation, $U(c)$ is uniquely defined for every stackless configuration c. Thus, the leaves of $U(c)$ are existential or final (stackless) configurations, and whenever c is present in a $\forall$ computation tree T of M, T contains a copy of $U(c)$ rooted at c as a subtree.

The next claim shows that given a stackless configuration c, the universal block $U(c)$ can be computed within the allowed resources.

▷ Claim 17. Given a stackless configuration c of M, the universal block $U(c)$, together with a labelling of its edges with transitions taken, can be computed in deterministic space $h(k) + \mathcal{O}(\log n)$, for some computable h.

Proof. Let $Z = f(k) + \lfloor d \log n \rfloor$. Observe that for every binary string $r \in \{0, 1\}^Z$, we can compute the branch of $U(c)$ that takes the consecutive conondeterministic choices as prescribed by the consecutive bits of r. To do this, just simulate M starting from c and, whenever a conondeterministic choice needs to be made, use the next bit of r to determine how it is resolved. (This simulation stops when an existential or a final configuration is encountered.) Having this subprocedure, the whole $U(c)$ can be easily computed by iterating through consecutive strings $r \in \{0, 1\}^Z$ and outputting the branches of $U(c)$ one after the other. (Strictly speaking, from every next branch we output only the part after diverging from the previous branch.) Finally, note that r can be stored within the allowed space. ◁

With Claim 17 established, we proceed to the construction of M'. For the sake of the proof, suppose M has a $\forall$ computation tree T that is accepting and uses the allowed resources. Machine M' tries to verifies the existence of such T by traversing the universal tree $U_{N,K}$ and guessing, along the way, how the contraction T' of T embeds into $U_{N,K}$. By Lemma 15 we know that such an embedding always exists. The traversal of $U_{N,K}$ will be done in such a way that the contracted $\forall$ computation tree of M' will be always $U_{N,K}$.

At every point of computation, M' stores on its working tape a node u of $U_{N,K}$ and its contracted $\forall$ computation tree from this point on should be the subtree of $U_{N,K}$ rooted at u. Machine M' is always either in the *real mode* or in the *dummy mode*. In the real mode, M' is in the process of guessing a subtree of T. Therefore, then M' holds the following data:

- On the working tape, M' stores a stackless configuration c of M. The reader should think of c as of the configuration of M at the root of a universal block of T.
- On its own stack, M' holds the content of the stack of M.
- Additionally on the working tape, M' stores two integers a and b, denoting the total number of nondeterministic and conondeterministic bits used by M so far, respectively. (In other words, a and b are the total number of existential and universal configurations visited so far on a branch of T.) We maintain the following invariant: the subtree of $U_{N,K}$ rooted at u is $U_{N',K'}$ for some $K' \leqslant K$ and N' such that $N' \geqslant N/2^b$.

Then the task of M' is to verify the existence of a subtree S of a $\forall$ computation tree of M such that

- S has c supplied with the current content of the stack at its root;
- S embeds into the subtree of $U_{N,K}$ rooted at u;
- the nondeterminism and the conondeterminism of S together with a and b add to at most $f(k)\log n$ and $f(k) + d\log n$, respectively; and
- S is accepting, that is, every leaf of S is an accepting configuration.

In the dummy mode, M' is not guessing any part of T, so its task is to perform some meaningless computation in order to make its contracted $\forall$ computation tree equal to the subtree of $U_{N,K}$ rooted at u. So in this mode, M' holds on its working tape only the node u.

We now explain steps taken by M' in the real mode. Given c, M' applies the algorithm of Claim 17 to compute the universal block $U(c)$. (Formally speaking, $U(c)$ is not computed explicitly, as it would not fit within the working space, but at any point a bit from the description of $U(c)$ is needed, we run the algorithm of Claim 17 to compute this bit.) Let $\ell_1, \ldots, \ell_p$ be the leaves of $U(c)$, in the order as they appear in the description of $U(c)$. Informally, we wish to fit in $U(c)$ into the computation tree of M' while keeping enough "space" for the remaining computations M may wish to perform, without knowing how the computation will continue at the leaves. For every $i \in \{1, \ldots, p\}$, let b_i be total number of universal configurations on the branch of $U(c)$ finishing at ℓ_i. By assumption, the subtree of $U_{N,K}$ rooted at u is isomorphic to $U_{N',K'}$ for some $N' \geqslant N/2^b$ and $K' \leqslant K$. Similarly, we would like to find children $v_1 \prec v_2 \prec \ldots \prec v_p$ of u in $U_{N,K}$ such that the subtree rooted at each v_i is isomorphic to $U_{N_i,K'-1}$ where $N_i \geqslant N/2^{b+b_i}$. This follows from Lemma 16: we check that

$$\sum_{i=1}^{p} N/2^{b+b_i} \leqslant N' \sum_{i=1}^{p} 2^{-b_i} = N',$$

where the last equality follows since $U(c)$ is a binary tree. Note that given $b_1, \ldots, b_p$, we may compute the corresponding children $v_1, \ldots, v_p$ with sufficiently large subtrees in logarithmic space greedily: having found v_i, we can set v_{i+1} to be the $\prec$-smallest child v of u such that $v_i \prec v$ and the subtree rooted at v is isomorphic to $U_{N'',K'-1}$ for some $N'' \geqslant m_i$. Hence,

from now on we assume that the children $v_1, \ldots, v_p$ are given to us. (Again, formally, when we need any v_i, we run the logarithmic space algorithm computing $v_1, \ldots, v_p$ to retrieve the sought v_i.)

Machine M' conondeterministically guesses the label $\lambda(uv)$ of an edge uv connecting u with a child v; this can be done using conondeterministic $2|\lambda(uv)| + 1$ bits[3]. Noting that the pair $(u, \lambda(uv))$ uniquely determines v, we can now compute v. We have two cases:

- Suppose $v = v_i$ for some $i \in \{1, \ldots, p\}$. Then M' simulates all transitions of M on the path from c to the leaf ℓ_i in $U(c)$ (this may include some push operations). If ℓ_i is a final configuration, M' finishes the computation and verifies acceptance in the same way M would do. Otherwise, if ℓ_i is an existential configuration, M' further nondeterministically simulates M using its own nondeterminism, until a final or a universal configuration is encountered, or the bound of $f(k) \log n$ on the total number of nondeterministic steps is exceeded (together with a). In case of a final configuration, we do the same as before: machine M' concludes the computation and verifies whether M accepts. In case of a universal configuration, say c', M' moves the currently considered node of $U_{N,K}$ from u to v, and proceeds with working with c' at v. The counters a and b are updated by the total number of nondeterministic and conondeterminisitc bits used between ℓ and c' and between c and ℓ, respectively. Note here that the content of the stack has been appropriately updated while simulating the transitions of M from c to c'.
- Suppose $v \notin \{v_1, \ldots, v_p\}$. Then M' moves the currently considered node of $U_{N,K}$ from u to v, but enters v in the dummy mode.

This concludes the description of the behavior of M' in the real mode.

Finally, when in the dummy mode, machine M' does as follows:

- If u is a leaf, M' just accepts.
- If u is not a leaf, M' conondeterministically chooses a label $\lambda(uv)$ of an edge uv connecting u with a child v, using $2|\lambda(u, v)|+1$ conondeterminstic bits. Then M' computes v, performs a trivial nondeterministic transition, and enters v, again in the dummy mode.

This completes the construction of M'.

From the construction it follows that the contracted $\forall$ computation tree of M' on (x, k) is always $U_{N,K}$, hence M' is regular. Moreover, on every branch M' uses as much nondeterminism as M, that is, at most $f(k) \log n$, while the conondeterminism of M' is bounded by $2\lceil \log N' \rceil + k \leqslant 6f(k) + 4d \log n + k + \mathcal{O}(1)$, by the assumed properties of the labeling λ. The maximum stack length of M' is the same as that of M, while on its working tape, M' holds always at most one configuration of M plus $h(k) + \mathcal{O}(\log n)$ additional bits, for some computable function h. Finally, since every contracted $\forall$ computation tree of M accepting (x, k) within prescribed resources embeds into $U_{N,K}$, it is straightforward to see from the construction that M' accepts (x, k) within the prescribed resources if and only if M does. This concludes the proof of Lemma 12, so the proof of Theorem 10 is also complete.

4.2 A logic characterization

We now provide another characterization of XSLP, by providing a complete problem related to model-checking first-order logic. This reflects the definitions of classes AW[$\star$] and of the A-hierarchy, see [30, Chapter 8].

[3] For instance, the machine can guess consecutive bits of $\lambda(uv)$ interleaved with symbols 0 and 1, where 0 denotes "continue guessing" and 1 denotes "end of $\lambda(uv)$".

We use the standard terminology for relational structures. A (relational) signature is a set Σ consisting of *relation symbols*, where each relation symbol R has a prescribed arity $\mathrm{ar}(R) \in \mathbb{N}$. A Σ-*structure* $\mathbb{A}$ consists of a universe U and, for every relation symbol $R \in \Sigma$, its *interpretation* $R^{\mathbb{A}} \subseteq U^{\mathrm{ar}(R)}$ in $\mathbb{A}$. In this paper we only consider *binary signatures*, that is, signatures where every relation has arity at most 2.

For a signature Σ, we may consider standard first-order logic over Σ-structures. In this logic there are variables for the elements of the universe. Atomic formulas are of the form $x = y$ and $R(x_1, \ldots, x_k)$ for some $R \in \Sigma$ with $k = \mathrm{ar}(R)$, with the obvious semantics. These can be used to form larger formulas by using Boolean connectives, negation, and quantification (both existential and universal).

A Σ-structure $\mathbb{A}$ is called *forest-shaped* if Σ contains a binary relation parent such that $\mathsf{parent}^{\mathbb{A}}$ is the parent relation on a rooted forest with the vertex set being the universe of $\mathbb{A}$, and a unary relation root such that $\mathsf{root}^{\mathbb{A}}$ is the set of roots of this forest. We say that a first-order sentence φ over Σ is $\forall$-*guided* if it is of the form:

$$\varphi \quad = \quad \forall x_1 \exists y_1 \ \ldots \ \forall x_k \exists y_k \ (\mathsf{root}(x_1) \wedge \mathsf{parent}(x_1, x_2) \wedge \ldots \wedge \mathsf{parent}(x_{k-1}, x_k)) \Rightarrow \psi(x_1, y_1, \ldots, x_k, y_k)$$

where ψ is quantifier-free. In other words, φ is in a prenex form starting with a universal quantifier, and moreover we require that the first universally quantified variable is a root and every next universally quantified variable is a child of the previous one. Note that there are no restrictions on existential quantification.

For a binary signature Σ, we consider the problem of model-checking $\forall$-guided formulas on forest-shaped Σ-structures. In this problem we are given a forest-shaped Σ-structure $\mathbb{A}$ and a $\forall$-guided sentence φ, and the question is whether φ holds in $\mathbb{A}$. We consider this as a parameterized problem where $\|\varphi\|$ – the total length of an encoding of the sentence φ – is the parameter.

The following statement provides a characterization of XSLP in terms of the model-checking problem described above.

▶ **Theorem 18.** *There exists a binary signature Σ such that the following conditions are equivalent for a parameterized problem Q.*

(1) $Q \in$ XSLP*;*

(2) Q *can be* pl*-reduced to the problem of model-checking $\forall$-guided sentences on forest-shaped Σ-structures.*

The proof of Theorem 18 can be found in the full version [12], but we sketch it here.

For the (1) $\Rightarrow$ (2) implication, it suffices to pl-reduce $\textsc{BinCSP}/\mathrm{td}$ to the model-checking problem for $\forall$-guided sentences on forest-shaped structures. This is a fairly straightforward construction. Given an instance I of $\textsc{BinCSP}/\mathrm{td}$, we build a relational structure $\mathbb{A}$ consisting of the (given) elimination forest F of the Gaifman graph of I and the disjoint union of domains $D(u)$ of variables u of I. These domains are bound to respective variables using a binary predicate, and there is another binary predicate encoding the constraints. Then it is straightforward to write a $\forall$-guided sentence φ that checks the satisfiability of I in a top-down manner on F: existential variables are used to guess the evaluation of variables of I, while universal variables are used to verify the possibility of extending the current partial evaluation further down.

For the (2) $\Rightarrow$ (1) implication, by Theorem 10 it suffices to design an AROSM M that solves the model-checking problem for $\forall$-guided sentences on forest-shaped Σ-structures within the bounds stipulated in Theorem 10. Machine M uses its conondeterminism and nondeterminism to universally and existentially guess the evaluations of consecutive variables

$x_1, y_1, \ldots, x_k, y_k$, within $2k$ rounds of alternation. Here, the assumption that the input sentence is $\forall$-guided and the input structure is forest-shaped can be used in conjunction with Lemma 14 to bound the total conondeterminism used by $\mathcal{O}(k + \log n)$. Once all variables are evaluated, satisfaction of ψ can be checked within 4 additional rounds of alternation by assuming without loss of generality that ψ is in DNF.

5 Conclusion

In this paper we explored the parameterized complexity of BinCSP for a variety of relatively strong structural parameters, including the vertex cover number, treedepth, and several modulator-based parameters. We believe that together with the previous works on XALP and XNLP [7, 9, 10, 11, 26], our work uncovers a rich complexity structure within the class XP, which is worth further exploration. We selected concrete open questions below.

- In [10, 11], several problems such as Independent Set or Dominating Set, which are fixed-parameter tractable when parameterized by treewidth, were shown to be XALP- and XNLP-complete when parameterized by the *logarithmic* treewidth and pathwidth, which is at most k when the corresponding width measure is at most $k \log n$. Can one prove similar results for the class XSLP and parameterization by logarithmic treedepth?
- Theorem 3 provides natural complete problems only for the odd levels of the W-hierarchy. Similarly, we defined the S-hierarchy only for odd levels. It would be interesting to have a natural description of the situation also for the even levels.
- The characterizations of XSLP given by Theorems 10 and 18 can be "projected" to a rough characterizations of classes S[d] for odd d by stipulating that the alternation is at most d. Unfortunately, this projection turns out not to be completely faithful: the obtained problems do not precisely characterize the class S[d], but lie somewhere between S[$d - \mathcal{O}(1)$] and S[$d + \mathcal{O}(1)$]. Can we provide a compelling description of the levels of the S-hierarchy in terms of machine problems or in terms of model-checking first-order logic?
- What is the complexity of List Coloring parameterized by the vertex cover number? Currently, we know it is W[1]-hard and in W[2]. Similarly, what is the complexity of List Coloring and Precoloring Extension with the minimum size of a modulator to a treedepth-d graph as the parameter?
- Can one obtain a better understanding of the complexity of BinCSP and List Coloring parameterized by the feedback vertex number?

Nondeterministic Interactive Refutations for Nearest Boolean Vector

Andrej Bogdanov

Abstract

Most n-dimensional subspaces $\mathcal{A}$ of $\mathbb{R}^m$ are $\Omega(\sqrt{m})$-far from the Boolean cube $\{-1,1\}^m$ when $n < cm$ for some constant $c > 0$. How hard is it to certify that the Nearest Boolean Vector (NBV) is at least $\gamma\sqrt{m}$ far from a given random $\mathcal{A}$?

Certifying NBV instances is relevant to the computational complexity of approximating the Sherrington-Kirkpatrick Hamiltonian, i.e. maximizing $x^T Ax$ over the Boolean cube for a matrix A sampled from the Gaussian Orthogonal Ensemble. The connection was discovered by Mohanty, Raghavendra, and Xu (STOC 2020). Improving on their work, Ghosh, Jeronimo, Jones, Potechin, and Rajendran (FOCS 2020) showed that certification is not possible in the sum-of-squares framework when $m \ll n^{1.5}$, even with distance $\gamma = 0$.

We present a non-deterministic interactive certification algorithm for NBV when $m \gg n \log n$ and $\gamma \ll 1/mn^{1.5}$. The algorithm is obtained by adapting a public-key encryption scheme of Ajtai and Dwork.

1 Introduction

When can we expect to have a reduction from problem A to problem B? Complexity theory can be used not only to show existence of reductions but also to argue separations. For example, one reason an oracle for factoring is not considered an imminent threat to SAT is that the correctness of prime factorizations can be both proved and refuted, that is (the decision version of) factoring is in NP ∩ coNP.

In general, there cannot be a reduction (of sufficiently low complexity) from A to B if there is a complexity class that (conjecturally) separates the two. For worst-case problems in NP the separating class is often NP ∩ coNP or one of its close relatives (NP ∩ coAM or Statistical Zero-Knowledge).

It is natural to wonder whether analogous separations in average-case complexity can clarify the landscape of reductions within distributional NP; a class of particular importance to cryptography and learning theory. Reductions among non-NP-complete distributional problems do exist, but are few and far between. Notable examples include lattice problems [18, 24, 22, 17]. More recently, a web of reductions was developed to explain the hardness of various statistical inference problems [5].

A handful of average-case NP complete problems were found in the 1980-90s [16, 9]. All these problems are closely related to simulation of Turing Machines, perhaps necessarily so [29]. The conjectured hardness of combinatorial problems like random SAT or planted clique still lacks satisfactory explanation.

In the context of random SAT, Feige, Kim, and Ofek [7] showed that random 3CNF instances with n variables and $m \gg n^{1.4}$ equations admit efficient nondeterministic refutations of satisfiability, that is, belong to Avg-coNP.[1] Although most such instances are unsatisfiable, it is not known how to efficiently certify the lack of a satisfying assignment in the regime $n^{1.4} \ll m \ll n^{1.5}$. On the other hand, when $m \ll n^{1.4}$ not even nondeterministic refutations are known. Thus we do not expect a reduction from random 3SAT with clause-to-variable density $n^{0.41}$ to random 3SAT with density $n^{0.39}$ barring a major algorithmic advance.

Our contribution is an analogous result for the distributional Nearest Boolean Vector to a Subspace problem which was introduced by Mohanty, Raghavendra and Xu [19]. In Theorem 1 we show that for a certain parameter regime in which this problem may be intractable, the problem is in average-case statistical zero-knowledge (Avg-SZK) and therefore admits *interactive* nondeterministic refutations.

1.1 The Nearest Boolean Vector problem

We work with the following formulation of the Nearest Boolean Vector problem:

Nearest Boolean Vector (NBV):
Input: An n-dimensional subspace $\mathcal{A}$ of $\mathbb{R}^m$.
Yes instances: There exists a $v \in \{-1,1\}^m$ such that $\mathrm{dist}(v,\mathcal{A}) \leq \gamma\sqrt{m}$.
No instances: For all $v \in \{-1,1\}^m$, $\mathrm{dist}(v,\mathcal{A}) > \sqrt{m}/2$.

When $n < cm$ for a sufficiently small constant c, most subspaces $\mathcal{A}$ (chosen from the uniform Haar measure) are no instances [19]. We are interested in the errorless average-case complexity of NBV. An efficient average-case algorithm for distributional NBV can be viewed as an efficiently computable certificate that most subspaces are far from the Boolean cube.

When $\gamma < 1/2$, NBV is in NP. Several works [19, 8, 23] provide evidence that it is intractable on average in the regime $m \ll n^2$.

1.2 Our Result

We give a reduction from distributional NBV to the Statistical Distance to Uniform (SDU) problem. The input to SDU is a sampler of outputs in $\{0,1\}^n$, the YES instances are samplers whose outputs are $1-\delta$ far from uniform, and NO instances are samplers whose values are δ close to uniform. For $\delta = 1/3$ SDU is in the class Statistical Zero Knowledge (SZK) [26], which is a subclass of coAM.[2]

[1] Their result was recently extended to the semi-random model [12] in which the formula is arbitrary and only the literals are polarized randomly.

[2] When $\delta = 1/n$, SDU is in the more restricted class Non-Interactive Statistical Zero-Knowledge (NISZK) [10]. AvgNISZK membership can also be obtained for smaller γ.

▶ **Theorem 1.** *Let C be a sufficiently large constant and $\epsilon \geq 2^{-n/C}$. For all but an ϵ-fraction of instances, NBV with parameters $m = Cn \log n$ and $\gamma = 1/Cmn^{3/2} \log^{1/2}(n/\epsilon)$ is in* AvgSZK.

The proof is given in Section 3. In Section 5 we outline a tentative approach for improving the completeness error γ.

When ϵ is polynomial in n, SZK membership holds for all but a $n^{-O(1)}$ fraction of instances and the approximation factor γ has value $\tilde{\Theta}(1/mn^{3/2})$. When ϵ is $2^{-\Omega(n)}$ then the fraction of instances is exponential, but $\gamma = \Theta(1/mn^2)$.

2 Background and Overview

2.1 Average-case refutations

Refutations come up naturally in the study of combinatorial optimization. A worst-case approximation algorithm A for a minimization problem P is required to output a value within a factor of c of the optimum on all instances. Such an algorithm provides an efficient refutation of the claim

$$x \text{ has a solution of value at most } A(x)/c \tag{1}$$

for every instance x.

When efficient refutations are hard to obtain for all x it may be natural to relax the condition to hold for most x. An average-case refutation should still certify (1), but it is now allowed to fail on some small fraction of inputs x.

For many natural distributions, the optimum is tightly concentrated around its expectation. For example, the maximum number of satisfiable clauses in random 3SAT with sufficiently large clause-to-variable density is close to 7/8 on most instances. In particular, an average-case refutation must certify that most instances are not satisfiable, but it should be allowed to output "I don't know" on a small fraction of inputs. This motivates the following definition:

▶ **Definition 2.** *A refutation R with failure rate ϵ for distributional (promise) problem f is an algorithm that outputs "no" or "I don't know", is always correct ($R(x) = f(x)$ or "I don't know"), and outputs "I don't know" on at most an ϵ-fraction of inputs.*

While efficient deterministic or randomized refutations are needed for the design of approximation algorithms, in this work we are interested in the existence of nondeterministic (coNP-type) refutations. Such refutations yield efficiently *verifiable* certificates of (1) on most inputs. As a consequence of Theorem 1 we have

▶ **Corollary 3.** *There is a efficient nondeterministic interactive refutation for NBV with failure rate $\epsilon \geq 2^{-n/C}$ and parameters $m = Cn \log n$, $\gamma = 1/Cmn^{3/2} \log^{1/2}(n/\epsilon)$.*

2.2 Refutations in the Sum-of-Squares Framework

The sum-of-squares (SoS) framework is an incomplete but poweful framework for refuting optimization problems. It has been used to argue efficient refutations do not exist for problems such as clique [3]. The most notable incorrect prediction of SoS is on random 3LIN with perfect completeness [11, 27]. In that case not only do refutations exist but they can be found by Gaussian elimination.

In contrast, the nondeterministic refutations of Feige, Kim, and Ofek arise as solutions to the level-$O(n^{2\delta})$ SoS relaxation of random 3SAT with n variables and m constraints. This may be viewed as evidence that SoS correctly predicts refutability in problems that are immune to Gaussian elimination "attacks".

2.3 Sherrington-Kirkpatrick and Nearest Boolean Vector

The negative energy of the Sherrington-Kirkpatrick Hamiltonian at zero-temperature is the value

$$SK(M) = \min \frac{1}{\sqrt{n}} \cdot x^T M x \qquad \text{subject to } x \in \{\pm 1/\sqrt{n}\}^n$$

for a matrix M sampled from the Gaussian Orthogonal Ensemble. It can be efficiently certified that $SK(M) \leq 2 + \epsilon$ for every $\epsilon > 0$ and most matrices M via the relaxation

$$SK(M) \leq \min_{\|u\|=1} \frac{1}{\sqrt{n}} \cdot u^T M u = \lambda_1(M), \tag{2}$$

where $\lambda_1(M)$ is the largest eigenvalue of M, which is known to not exceed $2 + \epsilon$ for most matrices M.

Parisi [21] conjectured and Talagrand [28] proved that $SK(M)$ is in fact strictly smaller than 2 for most matrices M. The true value for most M is concentrated around Parisi's constant $P_* \approx 1.526$. More recently Montanari [20] found an algorithm that finds a solution x for which $x^T M x \leq P_* - \epsilon$ for most matrices M and proved its correctness under some plausible conjecture.

Mohanty, Raghavendra, and Xu [19] ask whether Montanari's algorithm can be matched with an efficient certificate that $SK(M) \leq P_* + \epsilon$ for most matrices M. Together with Montanari's algorithm, this would give an errorless heuristic for calculating $SK(M)$ up to lower-order terms. As a first step they show that SK reduces to the potentially more tractable Nearest Boolean Vector Problem.

Mohanty, Raghavendra, and Xu prove that for all $c, \gamma > 0$ there exists an $\epsilon > 0$ such that if NBV with parameters $m/n = c$ and γ admits efficient refutations than so does the claim $SK(M) \leq 2 - \epsilon$ for most M. Moreover, for sufficiently small c, most subspaces $\mathcal{A}$ are no-instances of NBV.

However, their main evidence for refutability of NBV is negative: They show that no refutations can be obtained from the natural degree-4 SoS relaxation of NBV for any constant c, even in case of perfect completeness $\gamma = 0$. A refutation algorithm for $\gamma = 0$ is merely required to certify that no Boolean vector belongs to the subspace $\mathcal{A}$. The SoS hardness regime was later extended to $m \ll n^{3/2}$ and to degree-$n^{\Omega(1)}$ SoS by Ghosh et al. [8]. It is believed that it can be further extended up to $m < n^2/4$, as (heuristically) suggested by calculations of the low-degree likelihood ratio (see Potechin et al. [23]).

Theorem 1 has no bearing on the complexity of certifying that $SK(M) \leq 2$ for most M. To obtain an improvement over the spectral certificate (2) the completeness error γ would have to be constant, or at least $m^{-\epsilon}$ for some small ϵ.

2.4 Algorithms for NBV

When $m \gg n^2$ and γ is a sufficiently small constant it is plausible that NBV can be efficiently solved by linearization. Represent $\mathcal{A}$ as the column span of B for some $m \times n$ matrix B. Consider the objective

$$\text{minimize } \sum_{i=1}^{m} \big(\langle B_i, x\rangle^2 - 1\big)^2 \quad \text{over } x \in \mathbb{R}^n, \tag{3}$$

where B_i is the i-th row of B. If $\mathcal{A}$ had a Boolean vector $\langle B_i, x\rangle = \pm 1$ the value of this objective would be zero. We suspect that for most matrices B it should be lower bounded by

$\Omega(m)$. If (3) were efficiently computable its value would be the required certificate. Although this is unlikely, the same argument can be applied to its linearization in which degree-2 monomials $x_i x_j$ are represented by variables y_{ij}:

$$\text{minimize} \sum_{i=1}^{m} \left(\sum_{j,k=1}^{n} B_{ij} B_{ik} y_{jk} - 1 \right)^2 \quad \text{over } y \in \mathbb{R}^{n(n+1)/2}, \tag{4}$$

which is a convex quadratic objective and therefore efficiently minimizable.

In the case of perfect completeness, $\gamma = 0$ NBV reduces to the Shortest Vector Problem (SVP) in lattices with approximation factor exponential in the dimension and can therefore be solved by the LLL algorithm [15] for any $m > n$. Here is an outline of the (standard) reduction R. Let the columns of $C \in \mathbb{R}^{m \times (m-n)}$ be a random orthonormal basis of the dual subspace $\mathcal{A}^{\perp}$. Consider the lattice $\mathcal{L}$ spanned by the rows of the $m \times (2m - n)$ matrix $C' = [\delta I_m | C]$ for $\delta = 2^{-2m^2}$. If $\mathcal{A}$ contained a Boolean vector x then $C'x$ would be a vector of length $\delta\sqrt{m}$ in $\mathcal{L}$. If not, by a union bound there is unlikely to exist a vector $x \in \{-2^m, \ldots, 2^m\}^m$ for which $\|Cx\| < 2^m \delta$ so the shortest vector in $\mathcal{L}$ has length at least $2^m \delta$.

2.5 Nondeterministic refutations for NBV

This reduction R extends to almost-perfect completeness $\gamma = 2^{-\Theta(m^2)}$. It is tempting to conjecture for $m \gg n \log n$ that there is a constant d such that R reduces NBV with parameter $\gamma = m^{-d}$ to SVP with approximation factor $\sqrt{m}$, which is a coNP problem [1]. Should such a reduction exist it would imply efficient nondeterministic refutations for NBV.

We were unable to prove the soundness of R in this parameter regime. Our preliminary calculations indicate that $\mathcal{L}$ may contain unusually short vectors for most instances $\mathcal{A}$ of NBV.

Instead, we prove Theorem 1 by adapting a public-key encryption scheme of Ajtai and Dwork [2] (see [4] for a "modern" description) into the desired reduction from NBV to SDU.

2.6 Refutations, SZK, and Public-key Encryption

The *chosen plaintext attack* security notion for one-bit encryption with public key PK and encryption algorithm Enc posits that the distributions $(PK, Enc(PK, 0))$ and $(PK, Enc(PK, 1))$ are computationally indistinguishable. In contrast, functionality requires that they be statistically distinguishable by the decryption algorithm.

The security of several public-key encryption candidates is argued using a model (fake) public-key distribution FK with the property that PK and FK are computationally indistinguishable while $(FK, Enc(FK, 0))$ and $(FK, Enc(FK, 1))$ are statistically indistinguishable. This proof strategy yields a reduction from distinguishing real and model public keys to SDU.

The security proof for the Ajtai-Dwork (AD) and Bogdanov et al.'s (BCHR) pancake encryptions are of this type. In BCHR, the model public key FK is a sequence m of independent standard n-dimensional Gaussians, while in the real public key PK an almost-periodic component is planted in a secret direction s of $\mathbb{R}^n$. If the almost-periodic component is concentrated around the values -1 and 1, the row-span of PK can be viewed as a yes-instance of NBV.

To turn this distinguisher between PK and FK into a refutation, we observe that the encryption remains functional even for a worst-case choice of PK that satisfies some efficiently verifiable conditions (the largest and smallest singular values of PK are pseudorandom). By

verifying these conditions the reduction from NBV to SDU ensures that *all* yes-instances of NBV map to yes-instances of SDU, while affecting only a small fraction of no-instances, thus providing interactive remoteness certificates for most instances of NBV.

The BCHR encryption and security proof suggest the following visualization of the remoteness certificates. If a random matrix FK is multiplied on the right by a random $x \sim \{\pm 1\}^m$ the output $FK \cdot x$ is close to a random Gaussian point in $\mathbb{R}^n$ (see Fact 17). On the other hand, $PK \cdot x$ is concentrated around "pancakes" perpendicular to the secret direction s. To certify remoteness, the verifier asks the prover to furnish an $x \in \{\pm 1\}^m$ close to a random Gaussian point g in $\mathbb{R}^n$. Unless g happens to land close to a pancake the prover will fail on an no- instance PK of NBV.

A fatal weakness of BCHR encryption is that it is insecure unless $m \gg n^2$, a setting of parameters in which NBV is tractable. In contrast, security of AD can be proved when $m = O(n \log n)$. This improvement is obtained by modifying the encryption from $\mathrm{round}(PK \cdot x)$ to $\mathrm{round}(\sigma A \cdot x) \bmod \mathcal{P}(B)$, where $PK = [A|B]$ with $A \in \mathbb{R}^{(m-n)\times n}$ and $B \in \mathbb{R}^{n\times n}$ is the public key matrix, $\mathcal{P}(B)$ is the parallelepiped spanned by the columns of B, and σ is a suitable scaling factor. Reduction 1 in Section 3 implements this security proof (in a different basis which is more suitable for analysis), again by imposing some efficiently verifiable conditions that hold for typical yes-instances but for none of the no-instances of NBV.

3 Refutation via Lattice Smoothing

We represent the random subspace $\mathcal{A}$ as the row space of a random $n \times m$ matrix $[A|B']$ of independent normal entries. It is sufficient to specify these entries up to $O(\log n)$ bits of precision. We carry out our analyses assuming infinite precision. It will be clear from the calculations that the additional effect of rounding the entries of A does not affect correctness.

For a real number x let $x = \lfloor x \rceil + \{x\}$ be its unique representation with $\lfloor x \rceil \in \mathbb{Z}$ and $\{x\} \in [-1/2, 1/2)$. Let $\{x\}_p$ be the multiple of $1/p$ in $[-1/2, 1/2)$ closest to $\{x\}$. The notation extends to vectors and matrices entrywise.

▷ Fact 4. (a) $|\{x\}| \le |x|$ and (b) $|\{x + y\}| \le |\{x\}| + |\{y\}|$.

We choose the modulus p to equal $Cn\sqrt{m}$ for a sufficiently large constant C. Let $\sigma = (1/\pi)\sqrt{n \ln(12mn/\epsilon + 2n)}$.

Reduction 1: On input $[A|B']$, $A \in \mathbb{R}^{n\times(m/2)}$, $B' \in \mathbb{R}^{n\times(m/2)}$,

1 Find a submatrix B of B' with smallest singular value at least $1/\sqrt{n}$.
2 If step 1 is unsuccessful, fail.
3 If any column of A has norm more than $2\sqrt{n}$, fail.
4 Otherwise, output the sampler S that maps $x \sim \{\pm 1\}^{m/2}$ to $\{\{\sigma B^{-1} A\}_p x\} \in \frac{1}{p}\mathbb{Z}_p^n$.

A naive implementation of step 1 would split B' into m/n candidate matrices B and attempt to find one with singular value $1/\sqrt{n}$, resulting in failure rate $\epsilon = 2^{-O(m/n)}$ which is $n^{-O(1)}$ when $m = O(n \log n)$. In Section 4 we design a greedy procedure for choosing B that improves the failure rate to $2^{-\Omega(n)}$.

Theorem 1 follows from Claims 5 and 8.

▷ Claim 5. Assume $\epsilon > 2^{-\Omega(n)}$. For all but an ϵ-fraction of instances $[A|B']$ the output of S is 1/3-close to a uniformly random element of $\frac{1}{p}\mathbb{Z}_p^n$.

▷ Fact 6 (Smoothing). [18, Lemmas 3.3 and 4.1] If all columns of $B \in \mathbb{R}^{n\times n}$ have norm at most b, g is standard normal in $\mathbb{R}^n$, and $\sigma \geq (b/2\pi)\sqrt{\ln(n/\epsilon + 2n)}$, then $\{\sigma B^{-1} g\}$ is ϵ-close to a uniform random point in $[-1/2, 1/2)^n$.

▷ Fact 7 (Leftover hash lemma). [13] If $C \sim \mathbb{Z}_p^{n\times m}$ is a random matrix and $x \in \mathbb{Z}_p^m$ be a random vector uniformly distributed on some set of size M then (C, Cx) is $\sqrt{p^n/M}$-close to uniformly random.

Proof of Claim 5. By Proposition 9 B can be found (efficiently) except with probability $\exp(-\Omega(m))$. By large deviation bounds all columns of B have norm at most $2\sqrt{n}$ except with probability $2^{-\Omega(n)}$. By our choice of parameters, both conditions are satisfied except with probability $2^{-\Omega(m)} + 2^{-\Omega(n)} \leq \epsilon/2$. Assuming this we argue the conclusion holds even when conditioning on B.

For each column a_i of A, $\sigma a_i \in \mathbb{R}^n$ is a normal vector of zero mean and covariance σI. By smoothing Fact 6, $\{\sigma B^{-1} a_i\}$ is $\epsilon/4m$-close to a uniform point in $[-1/2, 1/2)^n$. Therefore $C = \{\sigma B^{-1} A\}_p$ is $\epsilon/12$-close to a random matrix in $\frac{1}{p}\mathbb{Z}_p^{(m/2)\times n}$. By Fact 7, (C, Cx) is $\epsilon/12 + \sqrt{p^n/2^{m/2}}$-close to random. By our choice of parameters, $\epsilon/12 + \sqrt{p^n/2^{m/2}} \leq \epsilon/6$. By Markov's inequality the output of the sampler is 1/3-close to random except with probability $\epsilon/2$ over the choice of A, and therefore except with probability ϵ over the choice of A and B'. ◁

▷ Claim 8. If $[A|B']$ is a yes instance of NBV with parameters $m > Cn \log n$ and $\gamma < 1/Cmn^{3/2} \log^{1/2}(n/\epsilon)$, either the reduction fails, or the output of S is 2/3-far from random.

Proof. As $[A|B']$ is a yes instance of NBV there exists a witness $w \in \mathbb{R}^n$ such that $w[A|B'] = v + e$, where $v \in \{\pm 1\}^m$ and $\|e\| \leq \gamma\sqrt{m}$. Let D be the distinguisher that on input $y \in \frac{1}{p}\mathbb{Z}_p^n$ accepts if $|\{\langle wB, y\rangle\}| < 1/24$.

Assume y is uniform in $\frac{1}{p}\mathbb{Z}_p^n$. We show D accepts y with probability at most 1/6. We can write y as $\{u\}_p$ where u is uniform in $[0, 1)^n$. Let $e' = y - u$ and let v_B and e_B be the projections of v and e on the columns indexed by B. Then

$$\langle wB, y\rangle = \langle v_B + e_B, u + e'\rangle = \langle v_B, u\rangle + \langle v_B, e'\rangle + \langle e_B, y\rangle$$

The random variable $\{\langle v_B, u\rangle\}$ is uniform in $[-1/2, 1/2)$, so $|\{\langle v_B, u\rangle\}| > 1/12$ with probability 5/6. If this happens, by the triangle inequality,

$$\begin{aligned}
|\{\langle wB, y\rangle\}| &\geq |\{\langle v_B, u\rangle\}| - |\langle v_B, e'\rangle| - |\langle e_B, y\rangle| \\
&\geq 1/12 - \|v_B\|\|e'\| - \|e_B\|\|y\| \\
&\geq 1/12 - n/p - \gamma\sqrt{mn} \\
&> 1/24
\end{aligned}$$

and D rejects y.

Now assume the reduction does not fail so that $\|B^{-1}\| \leq \sqrt{n}$ and all columns of A and B have norm at most $2\sqrt{n}$. We will show that D accepts $y = \{\{\sigma B^{-1} A\}_p x\}$ with probability at least 5/6. Therefore D distinguishes this distribution from the uniform one, so the two must be 2/3-far.

Let $E = \{\sigma B^{-1} A\}_p - \{\sigma B^{-1} A\}$. Then

$$\{\sigma B^{-1} A\}_p = \{\sigma B^{-1} A\} + E = \sigma B^{-1} A - \lfloor \sigma B^{-1} A \rfloor + E.$$

Since x is integral,

$$y = \{\{\sigma B^{-1} A\}_p x\} = \{\sigma B^{-1} A x + E x\}.$$

Therefore

$$\langle wB, y\rangle = \langle wB, \sigma B^{-1}Ax\rangle + \langle wB, Ex\rangle - \langle wB, f\rangle,$$

where $f = \lfloor \sigma B^{-1}Ax + Ex \rceil$. The first term equals

$$\langle wB, \sigma B^{-1}Ax\rangle = \sigma\langle wA, x\rangle = \sigma\langle v_A, x\rangle + \sigma\langle e_A, x\rangle,$$

where v_A and e_A are the projections of v and e on the coordinates indexed by the columns of A. The third term equals

$$\langle wB, f\rangle = \langle v_B, f\rangle + \langle e_B, f\rangle.$$

As $\sigma\langle v_A, x\rangle$ and $\langle v_B, f\rangle$ are integers,

$$\begin{aligned}
|\{\langle wB, y\rangle\}| &\le |\sigma\langle e_A, x\rangle| + |\langle wB, Ex\rangle| + |\langle e_B, f\rangle| \\
&\le \sigma\|e_A\|\|x\| + \|wB\|\|Ex\| + \|e_B\|\|f\| \\
&\le \sigma\|e_A\|\|x\| + (\|v_B\| + \|e_B\|)\|Ex\| + \|e_B\|(\sigma\|B^{-1}\|\|Ax\| + \|Ex\| + \sqrt{n}) \\
&\le \sigma\gamma m + (\sqrt{n} + \gamma\sqrt{m})(\sqrt{mn}/p) + \gamma\sqrt{m}(\sigma\cdot\sqrt{n}\cdot\|Ax\| + \sqrt{mn}/p + \sqrt{n}).
\end{aligned}$$

As Ax is a random ± 1 sum of vectors of norm at most $2\sqrt{n}$, its expected squared norm is mn, so its norm is at most $3\sqrt{mn}$ with probability at least $5/6$. Since $\gamma < 1/Cmn^{3/2}\log^{1/2}(n/\epsilon)$, $p > Cn\sqrt{m}$, and so $p > C\gamma m\sqrt{n}$, each term on the right hand side is less than $1/72$ (if C is sufficiently large). Then the left hand side is less than $1/24$ and D accepts y. ◁

4 Well-conditioned submatrices of random matrices

We now present and analyze the simple greedy algorithm used in step 1 in Reduction 1.

▶ **Proposition 9.** *Let $B \in \mathbb{R}^{m\times n}$ be a random Gaussian matrix with $m > Cn$. The probability that B contains a square submatrix with smallest singular value at least $1/\sqrt{n}$ is $1 - \exp(-\Omega(m))$. Moreover this submatrix can be found efficiently.*

Think of the column vectors of B as a stream of random normal vector samples. The matrix A is constructed incrementally column by column, starting with the empty matrix. After $k-1$ columns of A have been chosen, the next sample from the stream is considered as a candidate for the k-th column. It is rejected unless

$$\rho = \sum_{i=1}^{k} \frac{1}{\sigma_k^2} \le \frac{k}{n-k+1}, \tag{5}$$

where $\sigma_1, \ldots, \sigma_k$ are the singular values of A.

Once all n columns of A have been chosen, (5) guarantees that the sum of inverse squares of the singular values is at most n, so the smallest singular value will be at least $\sqrt{n}$ as desired. It remains to argue that no more than $m-n$ rejections happen except with probability $\exp(-\Omega(m))$.

Evolution of ρ

We analyze the evolution of ρ as columns are being added to A. Let A_k be any non-singular $n \times k$ matrix. Then

$$\rho(A_k) = \frac{\sum_{i=1}^{k}\prod_{j\ne i}\sigma_j^2}{\prod_{i=1}^{k}\sigma_i^2} = -\frac{\chi_k'(0)}{\chi_k(0)},$$

where $\chi_k(\lambda) = \det(A_k^\top A_k - \lambda I)$. Given A_k, let A_{k+1} be the random matrix obtained by appending a random normal column x to A_k.

Let $L \in \mathbb{R}^{k\times k}$ be an orthogonal matrix such that $L^\top A_k^\top A_k L = \operatorname{diag}(\sigma_1^2, \ldots, \sigma_k^2)$. It can be obtained from the singular value decomposition of A_k. The matrix $L' \in \mathbb{R}^{(k+1)\times(k+1)}$ given by $L' = \operatorname{diag}(L, 1)$ is also orthogonal and

$$A_{k+1}L' = \begin{bmatrix} A_k & x \end{bmatrix} \cdot \begin{bmatrix} L & \\ & 1 \end{bmatrix} = \begin{bmatrix} A_k L & x \end{bmatrix}$$

Since the columns of $A_k L$ are orthogonal of length $\sigma_1, \ldots, \sigma_k$, the columns of

$$A_k L \operatorname{diag}(\sigma_1^{-1}, \ldots, \sigma_k^{-1})$$

can be completed to an orthonormal basis C. The change of variables

$$y^\top = x^\top C$$

is then an isometry, so $y_1, \ldots, y_n$ are independent standard normals, and $\|y\| = \|x\|$. Then

$$L'^\top A_{k+1}^\top A_{k+1} L' = \begin{bmatrix} \sigma_1^2 & & & & \sigma_1 y_1 \\ & \sigma_2^2 & & & \sigma_2 y_2 \\ & & \ddots & & \vdots \\ & & & \sigma_k^2 & \sigma_k y_k \\ \sigma_1 y_1 & \sigma_2 y_2 & \ldots & \sigma_k y_k & \|y\|^2 \end{bmatrix}$$

Therefore

$$\begin{aligned} \chi_{k+1}(\lambda) &= \det(A_{k+1}^\top A_{k+1} - \lambda I) \\ &= \det(L'^\top A_{k+1}^\top A_{k+1} L' - \lambda I) \\ &= (\|y\|^2 - \lambda)\prod_{i=1}^{k}(\sigma_i^2 - \lambda) - \sum_{i=1}^{k}\sigma_i^2 y_i^2 \prod_{j\neq i}(\sigma_j^2 - \lambda) \\ &= \chi_k(\lambda)\left(\|y\|^2 - \lambda - \sum_{i=1}^{k}\frac{\sigma_i^2 y_i^2}{\sigma_i^2 - \lambda}\right). \end{aligned}$$

We obtain the following recurrences:

$$\chi_{k+1}(0) = \chi_k(0)\|y^{\perp k}\|^2$$

$$\chi'_{k+1}(0) = \chi'_k(0)\|y^{\perp k}\|^2 - \chi_k(0)\left(1 + \sum_{i=1}^{k}\frac{y_i^2}{\sigma_i^2}\right),$$

where $y^{\perp k} = (y_{k+1}, \ldots, y_n)$.

▷ Claim 10. If $(n-k+1)\chi'_k(0) + k\chi_k(0) \geq 0$ then

$$\mathrm{E}\big[(n-k)\chi'_{k+1}(0) + (k+1)\chi_{k+1}(0)\big|A_k\big] \geq 0.$$

The claim follows from linearity of expectation using the facts $\mathrm{E}[y_i^2] = 1$ and $\mathrm{E}\|y^{\perp k}\|^2 = k$.

Proof of Proposition 9. We show that the number of samples required for each column of A is dominated by a geometric random variable whose success probability is some absolute constant $p_\star$. The expected number of samples required is then at most $n/p_\star$. By large deviation bounds for geometric random variables [14] the probability that more than Cn samples are required is then at most $\exp(-\Omega(Cnp_\star))$, assuming $C > 1/p_\star$.

For the first column of A to fulfill (5) its squared norm needs to be at least n. This is at least $p_\star$ by Corollary 12 (with $a_1 = \cdots = a_n = 1$ and $b = 0$).

Now suppose (5) holds after the k-th column was added. Fix A_k and let X be the random variable $(n-k)\chi'_{k+1}(0) + (k+1)\chi_{k+1}(0)$. By Claim 10 $\mathrm{E}[X] \geq 0$. The random variable X is of the form in Corollary 12 so $\Pr(X > \mathrm{E}[X]) \geq p_\star$. Once a column x has been picked so that $X \geq 0$, the invariant (5) will hold for the matrix $A_{k+1} = [A_k\ x]$. ◀

4.1 Anticoncentration

The concentration Q of a real-valued random variable X is $Q(X,h) = \sup_x \Pr(x \leq X \leq x+h)$.

▶ **Proposition 11.** *There exists an absolute constant C such that if $X_1, \ldots, X_n$ are independent mean zero, unit variance random variables such that $Q(X_i, h) \leq 3/4$ for all i and some $h \leq 1/4C$ then*

$$\Pr\big(a_1X_1 + \cdots + a_nX_n > 0\big) \geq \frac{h^2}{32 + 4h^2}.$$

for all $a_1, \ldots, a_n$.

▶ **Corollary 12.** *There is an absolute constant $p_\star$ so that for every n and $a_1, \ldots, a_n, b$,*

$$\Pr\big(a_1Z_1^2 + \cdots + a_nZ_n^2 + b \geq \mu\big) \geq p_\star,$$

where $Z_1, \ldots, Z_n$ are independent normals and $\mu = a_1 + \cdots + a_n + b$.

Proof. Apply Proposition 11 to the random variables $Y_i = (X_i^2 - 1)/\sqrt{2}$ which have mean zero and unit variance. The condition $Q(Y_i, h) \leq 3/4$ is satisfied for all $h \leq 0.2$. ◀

Proof of Proposition 11. Let $X = a_1X_1 + \cdots + a_nX_n$. We may assume X has unit variance. By Rogozin's inequality [25],

$$Q(X,H) \leq CH\Big(\sum a_i^2(1 - Q(a_iX_i, a_ih))\Big)^{-1/2} = 2CH \leq 2Ch,$$

where $H = h\max_i|a_i| \leq h$. Applying Claim 13 we get

$$\Pr[X > 0] \geq \frac{1}{t+h}(h(1-2Ch) - 2/t) = \frac{h/2 - 2/t}{t+h}.$$

Choosing $t = 8/h$ we get $\Pr(X > 0) \geq h^2/(32 + 4h^2)$. ◀

▷ Claim 13. For every zero-mean, unit-variance X, every $\lambda > 0$, and every $t \geq 1$

$$\Pr[X > 0] \geq \frac{1}{t+h}\big(h \cdot \Pr(-h < X \leq 0) - 2/t\big).$$

Proof. Let $p = \Pr(X \in (0,t])$ and $q = \Pr(X \in (-h, 0])$. Then

$$\begin{aligned}\mathrm{E}[X] &\leq -h\Pr(X \leq -h) + 0\Pr(-h < X \leq 0) + t\Pr(0 < X \leq t) + \mathrm{E}[X1(X > t)] \\ &\leq -h \cdot (1 - q - p) + t \cdot p + \mathrm{E}[X1(X > t)].\end{aligned}$$

As $\mathrm{E}[X] = 0$,

$$p \geq \frac{1}{t+h}\big(h(1-q) - \mathrm{E}[X1(X > t)]\big).$$

By Claim 14, $\mathrm{E}[X1(X > t)] \leq \mathrm{E}[|X|1(|X| > t)] \leq 2/t$. ◁

▷ Claim 14. For every zero-mean, unit-variance X and every $t \geq 1$,

$$\mathrm{E}\big[|X|1(|X| > t)\big] \leq 2/t.$$

Proof.

$$\begin{aligned}
\mathrm{E}\big[|X|1(|X| > t)\big] &= \int_0^\infty \Pr(|X|1(|X| > t) > x)dx \\
&= \int_0^t \Pr(|X| > t)dx + \int_t^\infty \Pr(|X| > x)dx \\
&\leq \int_0^t (1/t^2)dx + \int_t^\infty (1/x^2)dx \\
&= 2/t.
\end{aligned}$$

The inequality is Chebyshev's. ◁

5 Refutation via Boolean combinations

Theorem 1 was proved by adapting the Ajtai-Dwork encryption scheme into a refutation algorithm for NBV. In this Section we carry out an analogous analysis for the "pancake encryption" of Bogdanov, Cueto Noval, Hoffmann, and Rosen (BCHR).

Their public key is also computationally indistinguishable from a random subspace of $\mathbb{R}^m$. The dimension of this subspace is, however, only $o(\sqrt{m})$. As a consequence, the resulting refutation only applies to a regime of NBV that is efficiently tractable.

While BCHR becomes insecure when $n \gg \sqrt{m}$, we believe that a modification of it may be secure up to $n = m^{1-o(1)}$. The advantage of the BCHR-based reduction over Theorem 1 is that it applies to larger completeness error γ.

▶ **Theorem 15.** *For every constant ϵ there exists a constant C such that for all but an ϵ-fraction of instances, average-case NBV with parameters $m = C(n \log n)^2$ and $\gamma = 1/C\sqrt{m}$ is in SZK.*

Let Z be a normal random variable and let $\zeta_1 < \cdots < \zeta_r$ be the unique numbers such that $\Pr(Z \leq \zeta_i) = (2i+1)/2r$. The Gaussian rounding $\mathrm{round}_r \colon \mathbb{R} \to \{\zeta_1, \ldots, \zeta_r\}$ is the function $\mathrm{round}_r(z) = \zeta_i$ where i is the unique index for which $\lceil r \cdot \Pr(Z \leq z) \rceil = \lceil r \cdot \Pr(Z \leq \zeta_i) \rceil$ (see Figure 1). For $z \in \mathbb{R}^n$ let $\mathrm{round}_r \colon \mathbb{R}^n \to \{\zeta_1, \ldots, \zeta_r\}^n$ be given by $\mathrm{round}_r(z) = (\mathrm{round}_r(z_1), \ldots, \mathrm{round}_r(z_n))$. Ser $r = \max\{Cm, Cn^2/\gamma^2\}$.

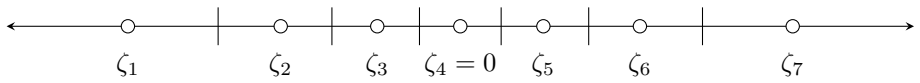

Figure 1 The function round_r for $r = 7$. All intervals have equal Gaussian measure. The values in the i-th interval round to ζ_i.

Reduction 2: On input $A \in \mathbb{R}^{m \times n}$,

1 If the largest singular value of A is more than $2\sqrt{m}$, fail.
2 If the smallest singular value of A is less than $\sqrt{m}/4$, fail.
3 Otherwise, output the sampler S that maps $x \sim \{\pm 1/\sqrt{m}\}^m$ to $\mathrm{round}_r(Ax)$.

Theorem 15 follows from Claims 16 and 19.

▷ Claim 16. For every ϵ there is a C so that for a $1-\epsilon$ fraction of instances $A \in \mathbb{R}^{m\times n}$, where $m = (Cn\log n)^2$, the output of S is 2/3-close to random.

▷ Fact 17. [4] The distribution $(A, \mathrm{round}_r(Ax))$ is $\sqrt{4en\ln r/\sqrt{m}}$-close to (A,ζ), where ζ is uniform over rounded values and independent of A.

▷ Fact 18. [6] Assume $m > 2n$. The largest and smallest singular values of A is at most $2\sqrt{n}$ and at least $\sqrt{n}/4$, except with probability $\exp(-\Omega(n))$.

Proof of Claim 16. By Fact 17, the joint distribution of A and the output of the sampler is $O(C^{-1/2})$-close to uniform. Therefore for all but $O(C^{-1/2})$ choices of A the output is 2/3-close to uniform. By a Chernoff bound and Fact 18 at most $2^{-\Omega(m)}$ other inputs A cause the reduction to fail. ◁

▷ Claim 19. If A is a yes instance of NBV with $\gamma < 1/C\sqrt{m}$, either Reduction 2 fails, or the output of S is 2/3-far from random.

▷ Fact 20. [4] For sufficiently large r, $\mathrm{round}_r(z)$, $z\in\mathbb{R}$ is $r^{-1/2}$-close to z unless $|z| > t$ for t such that $\Pr(|Z| > t) \le 3(r\ln r)^{-1/2}$, where Z is normal in $\mathbb{R}$.

Proof of Claim 19. Let $w\in\mathbb{R}^n$ be the witness for which $wA = v + e$ where $v\in\{\pm1\}^m$ and $\|e\| \le \gamma\sqrt{m}$. Let D be the distinguisher that, given ζ, accepts if $|\{\sqrt{m}\langle w,\zeta\rangle\}| \le 1/48$.

Assuming the reduction did not fail, by the assumption on singular values,

$$\frac{1}{4} \le \frac{\|v\| - \|e\|}{2\sqrt{m}} \le \|w\| \le \frac{\|v\| + \|e\|}{\sqrt{m}/4} \le 8.$$

If ζ is random, we argue that D rejects with probability at least 5/6. we can write $\zeta = \mathrm{round}_r(g)$ for a normal $g\in\mathbb{R}^n$. Let $e = \mathrm{round}_r(g) - g$. Then $\sqrt{m}\langle w,\zeta\rangle = \sqrt{m}\langle w,g\rangle + \sqrt{m}\langle w,e\rangle$. The random variable $\sqrt{m}\langle w,g\rangle$ is a univariate normal with standard deviation at least $\sqrt{m}\|w\| \ge \sqrt{m}/4$. By Fact 6, $\{\sqrt{m}\langle w,g\rangle\}$ is $2^{-\Omega(m)} < 1/24$ close to uniform in $[-1/2, 1/2)$. In particular, $|\{\sqrt{m}\langle w,g\rangle\}| > 1/24$ except with probability $11/12 - 1/24$. By Fact 20, $\|e\|_\infty \le r^{-1/2}$ except with probability $3n(r\ln r)^{-1/2} < 1/24$. Both events happen with probability at least 5/6. Assuming this,

$$|\{\sqrt{m}\langle w,\zeta\rangle\}| > 1/24 - |\{\sqrt{m}\langle w,e\rangle\}| \ge 1/24 - \sqrt{m}\|w\|\|e\| > 1/48$$

because $\sqrt{m}\|w\|\|e\| \le 8\sqrt{m}r^{-1/2}$ and D rejects.

If ζ is the output of the sampler we argue that the distinguisher accepts it with probability at least 8/9:

$$|\{\sqrt{m}\langle w,Ax\rangle\}| = |\{\sqrt{m}\langle v+e,x\rangle\}| = |\{\sqrt{m}\langle v,x\rangle + \sqrt{m}\langle e,x\rangle\}| = \sqrt{m}|\langle e,x\rangle| \tag{6}$$

because v and $\sqrt{m}x$ are integral. As x is random, $\mathrm{E}[\langle e,x\rangle^2] = \|e\|^2/m$. By Markov's inequality, $|\langle e,x\rangle| \le 3\|e\|/\sqrt{m}$ except with probability 1/9. If this holds (6) is at most $3\|e\| \le 3\gamma\sqrt{m}$.

As the largest singular value of A is at most $2\sqrt{m}$, all entries of Ax are between -2 and 2. By Fact 20, $\|\mathrm{round}_r(Ax) - Ax\|_\infty \le nr^{-1/2}$. Therefore

$$|\{\sqrt{m}\langle w, \mathrm{round}_r(Ax) - Ax\rangle\}| \le \sqrt{m}\|w\|\|\mathrm{round}_r(Ax) - Ax\| \le 8\sqrt{m}nr^{-1/2} \le \gamma\sqrt{m}.$$

Together with (6), $|\{\sqrt{m}\langle w,Ax\rangle\}| \le 4\gamma\sqrt{m} \le 1/48$. ◁

Abstract

The 2-Vertex-Connected Spanning Subgraph problem (2VCSS) is among the most basic NP-hard (Survivable) Network Design problems: we are given an (unweighted) undirected graph G. Our goal is to find a subgraph S of G with the minimum number of edges which is 2-vertex-connected, namely S remains connected after the deletion of an arbitrary node. 2VCSS is well-studied in terms of approximation algorithms, and the current best (polynomial-time) approximation factor is 10/7 by Heeger and Vygen [SIDMA'17] (improving on earlier results by Khuller and Vishkin [STOC'92] and Garg, Vempala and Singla [SODA'93]).

Here we present an improved 4/3 approximation. Our main technical ingredient is an approximation preserving reduction to a conveniently structured subset of instances which are "almost" 3-vertex-connected. The latter reduction might be helpful in future work.

1 Introduction

Real-world networks are prone to failures. For this reason it is important to design them so that they are still able to support a given traffic despite a few (typically temporary) failures of nodes or edges. The basic goal of survivable network design is to construct cheap networks which are resilient to such failures.

Most natural survivable network design problems are NP-hard, and a lot of work was dedicated to the design of approximation algorithms for them. One of the most basic survivable network design problems is the 2-Vertex-Connected Spanning Subgraph problem (2VCSS). Recall that an (undirected) graph $G = (V, E)$ is k-vertex-connected (kVC) if, after removing any subset W of at most $k - 1$ nodes (with all the edges incident to them), the residual graph $G[V \setminus W]$ is connected. In particular, in a 2VC graph G we can remove any single node while maintaining the connectivity of the remaining nodes (intuitively, we can tolerate a single node failure). In 2VCSS we are given a 2VC (unweighted) undirected graph $G = (V, E)$, and our goal is to compute a minimum cardinality subset of edges $S \subseteq E$ such that the (spanning) subgraph (V, S) is 2VC.

2VCSS is NP-hard: indeed an n-node graph G admits a Hamiltonian cycle iff it contains a 2VC spanning subgraph with n edges. Czumaj and Lingas [13] proved that the problem is APX-hard, hence most likely it does not admit a PTAS. A 2-approximation for 2VCSS can be obtained in different ways. For example one can compute an (open) ear decomposition of

the input graph and remove the trivial ears (containing a single edge). The resulting graph is 2VC and contains at most $2(n-1)$ edges (while the optimum solution must contain at least n edges). The first non-trivial 5/3 approximation was obtained by Khuller and Vishkin [28]. This was improved to 3/2 by Garg, Vempala and Singla [20] (see also an alternative 3/2 approximation by Cheriyan and Thurimella [11]). Finally Heeger and Vygen [24] presented the current-best 10/7 approximation[1]. Our main result is as follows (please see Section 2 for an overview of our approach):

▶ **Theorem 1.** *There is a polynomial-time $\frac{4}{3}$-approximation algorithm for 2VCSS.*

1.1 Related Work

An undirected graph G is k-edge-connected (kEC) if it remains connected after removing up to $k-1$ edges. The 2-Edge-Connected Spanning Subgraph problem (2ECSS) is the natural edge-connectivity variant of 2VCSS, where the goal is to compute a 2EC spanning subgraph with the minimum number of edges. Like 2VCSS, 2ECSS does not admit a PTAS unless $P = NP$ [13]. It is not hard to compute a 2 approximation for 2ECSS. For example it is sufficient to compute a DFS tree and augment it greedily. Khuller and Vishkin [27] found the first non-trivial 3/2-approximation algorithm. Cheriyan, Sebö and Szigeti [10] improved the approximation factor to 17/12. This was further improved to 4/3 in two independent and drastically different works by Hunkenschröder, Vempala and Vetta [25] and Sebö and Vygen [34]. The current best and very recent $\frac{118}{89} + \varepsilon < 1.326$ approximation is due to Garg, Grandoni and Jabal Ameli [19]. Our work exploits several ideas from the latter paper. The k-Edge Connected Spanning Subgraph problem (kECSS) is the natural generalization of 2ECSS to any connectivity $k \geq 2$ (see, e.g., [11, 17]).

A major open problem in the area is to find a better than 2 approximation for the weighted version of 2ECSS. This is known for the special case with 0-1 edge weights, a.k.a. the Forest Augmentation problem, by the recent work by Grandoni, Jabal-Ameli and Traub [21] (see also [2, 7, 6] for the related Matching Augmentation problem).

A problem related to kECSS is the k-Connectivity Augmentation problem (kCAP): given a k-edge-connected undirected graph G and a collection of extra edges L (*links*), find a minimum cardinality subset of links L' whose addition to G makes it $(k+1)$-edge-connected. It is known [14] that kCAP can be reduced to the case $k = 1$, a.k.a. the Tree Augmentation problem (TAP), for odd k and to the case $k = 2$, a.k.a. the Cactus Augmentation problem (CacAP), for even k. Several approximation algorithms better than 2 are known for TAP [1, 8, 9, 15, 16, 22, 29, 30, 31], culminating with the current best 1.393 approximation by Cecchetto, Traub and Zenklusen [5]. Till recently no better than 2 approximation was known for CacAP (excluding the special case where the cactus is a single cycle [18]): the first such algorithm was described by Byrka, Grandoni and Jabal Ameli [4], and later improved to 1.393 in [5]. In a recent breakthrough by Traub and Zenklusen, a better than 2 (namely 1.694) aproximation for the weighted version of TAP was achieved [35] (later improved to $1.5 + \varepsilon$ in [36]). Partial results in this direction where achieved earlier in [1, 12, 16, 22, 32].

[1] Before [24] a few other papers claimed even better approximation ratios [23, 26], however they have been shown to be buggy or incomplete, see the discussion in [24].

1.2 Preliminaries

We use standard graph notation. For a graph $G = (V, E)$, we let $V(G) = V$ and $E(G) = E$ denote its nodes and edges, resp. For $W \subseteq V$ and $F \subseteq E$, we use the shortcuts $G \setminus F := (V, E \setminus F)$ and $G \setminus W := G[V \setminus W]$. For a subgraph G', a node v and an edge e, we also use the shortcuts $v \in G'$ and $e \in G'$ meaning $v \in V(G')$ and $e \in E(G')$, resp. Throughout this paper we sometimes use interchangeably a subset of edges F and the corresponding subgraph (W, F), $W = \{v \in V : v \in f \in F\}$. The meaning will be clear from the context. For example, we might say that $F \subseteq E$ is 2VC or that F contains a connected component. In particular, we might say that $S \subseteq E$ is a 2VC spanning subgraph. Also, given two subgraphs G_1 and G_2, by $G' = G_1 \cup G_2$ we mean that G' is the subgraph induced by $E(G_1) \cup E(G_2)$. We sometimes represent paths and cycles as sequence of nodes. A k-vertex-cut of G is a subset W of k nodes such that $G[V \setminus W]$ has at least 2 connected components. A node defining a 1-vertex-cut is a cut vertex.

By $\mathsf{OPT}(G) \subseteq E(G)$ we denote an optimum solution to a 2VCSS instance G, and let $\mathsf{opt}(G) := |\mathsf{OPT}(G)|$ be its size. All the algorithms described in this paper are deterministic.

The proofs that are omitted here due to space constraints will appear in the journal version of the paper (see also [3]).

2 Overview of Our Approach

In this section we sketch the proof of our 4/3-approximation (Theorem 1). The details and proofs which are omitted here will be given in the following technical sections.

Our result relies on 3 main ingredients. The first one is an approximation-preserving (up to a small additive term) reduction of 2VCSS to instances of the same problem on properly *structured* graphs, which are "almost" 3VC in a sense described later (see Section 2.1).

At this point we compute a minimum-size 2-edge-cover H similarly to prior work: this provides a lower bound on the size of the optimal solution. For technical reasons, we transform H into a *canonical* form, without increasing its size (see Section 2.2).

The final step is to convert H into a feasible solution S. Starting from $S = H$, this is done by iteratively adding edges to and removing edges from S in a careful manner. In order to take the size of S under control, we assign 1/3 credits to each edge of the initial S, and use these credits to pay for any increase in the number of edges of S (see Section 2.3). We next describe the above ingredients in more detail.

2.1 A Reduction to Structured Graphs

Our first step is an approximation-preserving (up to a small additive factor) reduction of 2VCSS to instances of the same problem on properly *structured* graphs. This is similar in spirit to an analogous reduction for 2ECSS in [19]. In particular we exploit the notion of irrelevant edges and isolating cuts defined in that paper. We believe that our reduction might be helpful also in future work.

In more detail, we can get rid of the following *irrelevant* edges.

▶ **Lemma 2** (irrelevant edge). *Given a 2VC graph G, let $e = uv \in E(G)$ be such that $\{u, v\}$ is a 2-vertex-cut (we call e* irrelevant*). Then every optimal 2VCSS solution for G does not contain e.*

Proof. We will need the following observation:

▶ **Fact 3.** *Suppose that a minimal solution S to 2VCSS on a graph G contains a cycle C. Then S does not contain any chord f of C. Indeed, otherwise consider any open ear decomposition*[2] *of S which uses C as a first ear. Then f would be a trivial ear (consisting of a single edge) of the decomposition, and thus $S \setminus \{f\}$ would also be 2VC, contradicting the minimality of S.*

Let $H \subseteq E$ be any optimal (hence minimal) solution to 2VCSS on G. Assume by contradiction that H contains an irrelevant edge $e = uv$. Removing u and v splits H into different connected components $C_1, \ldots, C_k$, with $k \geq 2$. Each one of those components has edges u_iu, v_iv in H, where $u_i, v_i \in C_i$ for $i \in \{1, \ldots, k\}$, otherwise H would contain a cut vertex. Let P_1 be a path from u_1 to v_1 in C_1, and P_2 be a path from v_2 to u_2 in C_2. Then e is a chord of the cycle $P_1 \cup P_2 \cup \{uu_1, v_1v, vv_2, u_2u\}$, contradicting the minimality of H by Fact 3. ◀

We can enforce (see later) that our graph G is "almost" 3VC, in the sense that the only 2-vertex-cuts of G are a very specific type of *isolating* cuts defined as follows.

▶ **Definition 4** (isolating cut)**.** *Given a 2-vertex-cut $\{u, v\}$ of a graph G, we say that this cut is* isolating *if $G \setminus \{u, v\}$ has exactly two connected components, one of which consisting of* 1 *node. Otherwise the cut is* non-isolating*.*

Assuming that there are no non-isolating cuts, we can avoid the following local configuration: this will be helpful in the rest of our analysis.

▶ **Definition 5** (removable 5-cycle)**.** *We say that a 5-cycle C of a 2VC graph G is* removable *if it has at least two vertices of degree 2 in G.*

▶ **Lemma 6.** *Given a 2VC graph G without non-isolating cuts and with at least* 6 *nodes. Let C be a removable 5-cycle of G. Then in polynomial time one can find an edge e of C such that there exists an optimum solution to 2VCSS on G not containing e (we say that e is a* removable *edge).*

Proof. Assume $C = v_1v_2v_3v_4v_5$. If C has two vertices of degree 2 that are adjacent in C, namely v_1 and v_2, then $\{v_3, v_5\}$ is a non-isolating cut of G, a contradiction. Thus we can assume that C has exactly two non-adjacent vertices of degree 2, say v_1 and v_3 w.l.o.g.

We will show that the edge $e = v_4v_5$ is the desired removable edge. Let H be an optimal 2VCSS solution for G that uses the edge v_4v_5. Observe that in this case since v_1 and v_3 have degree 2, then H must contain all the edges of C.

To complete the argument we show that there exists an edge $f \in E(G) \setminus E(H)$, such that v_4v_5 is a chord of a cycle in $H' := H \cup \{f\}$: hence we can remove v_4v_5 from H' using Fact 3 to obtain an alternative optimum solution not containing v_4v_5.

Let $H'' = H \setminus \{v_4v_5\}$. There is no cycle C' in H'' that contains both v_4 and v_5, otherwise v_4v_5 is a chord of C' in H, contradicting the minimality of H by Fact 3. Therefore if we remove v_2 from H'', there must be no paths from v_4 to v_5. This means that there is a partition of $V(G) \setminus \{v_2\}$ into non-empty sets V_1 and V_2 such that, $\{v_3, v_4\} \in V_1$, $\{v_1, v_5\} \in V_2$ and there is no edge in H'' between V_1 and V_2. Since $|V(G)| \geq 6$, then we can assume w.l.o.g that $|V_1| \geq 3$.

[2] An ear-decomposition of an undirected graph G is a sequence of paths or cycles $P_0, \ldots, P_k$ (ears) spanning $E(G)$ such that P_0 is a cycle and P_i, $i \geq 1$, has its internal nodes disjoint from $V_{i-1} := V(P_0) \cup \ldots \cup V(P_{i-1})$ and its endpoints (or one node if P_i is a cycle) in V_{i-1}. We say that an ear-decomposition is open if P_i is a path, for $i \geq 1$. Every 2VC graph admits an open ear decomposition [33, Chapter 15].

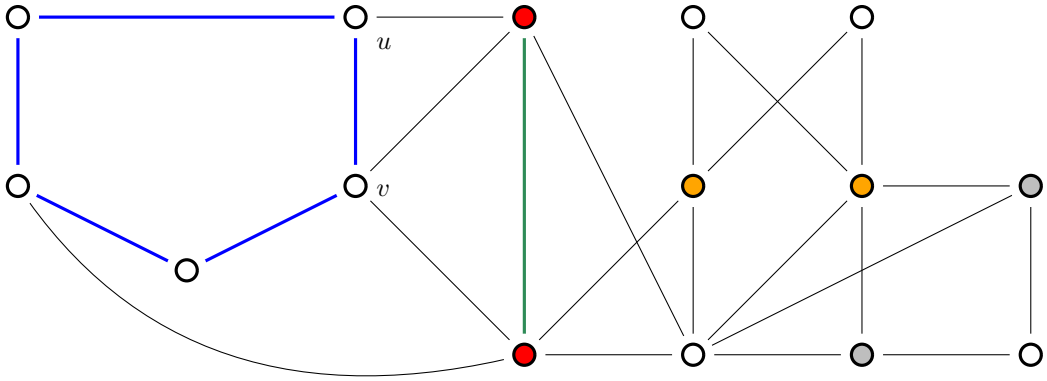

Figure 1 The cycle induced by the blue edges is a removable cycle, since it has two vertices of degree 2 in G. The edge uv is removable. The red and orange (resp. gray) pairs of vertices form a non-isolating (resp. isolating) cut. The green edge is irrelevant.

There must be an edge $f = u_1u_2 \in E(G)$ such that $u_1 \in V_1 \setminus \{v_3, v_4\}$ and $u_2 \in V_2$, otherwise $\{v_2, v_4\}$ is a non-isolating cut in G, a contradiction. Now we show that f is the desired edge. We claim that there exists a path P_1 in $H[V_1 \setminus \{v_3\}]$ between u_1 and v_4. Since H is 2VC, there exists a path P_1 between u_1 and v_4 not using v_2. Such path does not use v_3 either since this node is adjacent only to v_2 and v_4, and $u_1 \notin \{v_3, v_4\}$. If P_1 is not contained in $H[V_1]$, it would need to use at least two edges between V_1 and V_2 in H, however we argued before that H contains only one such edge, namely v_4v_5. Symmetrically, we claim that there exists a path P_2 in $H[V_2 \setminus \{v_1\}]$ between u_2 and v_5. Notice that $u_2 = v_5$ is possible, in which case the claim trivially holds. Hence next assume $u_2 \neq v_5$. Observe that $u_2 \neq v_1$ since u_2 is adjacent to $u_1 \notin \{v_2, v_5\}$. Thus, the claim about P_2 follows symmetrically to the case of P_1. Altogether, v_4v_5 is a chord of the cycle $P_1 \cup P_2 \cup \{f\} \cup C \setminus \{v_4v_5\}$ in $H' = H \cup \{f\}$, which implies the lemma. ◀

We are now ready to define a structured graph and to state our reduction to such graphs.

▶ **Definition 7** (structured graph). *A 2VC graph G is structured if it does not contain: (1) Irrelevant edges; (2) Non-isolating cuts; (3) Removable 5-cycles.*

▶ **Lemma 8.** *Given a constant $1 < \alpha \leq \frac{3}{2}$, if there exists a polynomial-time algorithm for 2VCSS on a structured graph G that returns a solution of cost at most $\max\{\mathsf{opt}(G), \alpha \cdot \mathsf{opt}(G) - 2\}$, then there exists a polynomial-time α-approximation algorithm for 2VCSS.*

We remark that any $\alpha - \varepsilon$ approximation of 2VCSS on structured graphs, for an arbitrarily small constant $\varepsilon > 0$, immediately implies an algorithm of the type needed in the claim of Lemma 8: indeed, instances with $\mathsf{opt}(G) \leq \max\{\frac{2}{\varepsilon}, \frac{2}{\alpha-1}\}$ can be solved exactly in constant time by brute force.

The algorithm at the heart of our reduction is algorithm RED given in Algorithm 1. Lines 1-2 solve by brute force instances with few nodes. Lines 3-4, 5-10, and 11-12 get rid recursively of irrelevant edges, non-isolating vertex cuts and removable 5-cycles, resp. When Line 13 is reached, the graph is structured and therefore we can apply a black-box algorithm ALG for structured instances of 2VCSS.

It is easy to see that the algorithm runs in polynomial time.

Algorithm 1 Reduction from arbitrary to structured instances of 2VCSS. Here G is 2VC and ALG is an algorithm for structured instances that returns a solution of cost at most $\max\{\mathsf{opt}(G), \alpha \cdot \mathsf{opt}(G) - 2\}$ for some $1 < \alpha \leq \frac{3}{2}$.

1: **if** $|V(G)| < \max\{6, \frac{2}{\alpha-1}\}$ **then**
2: Compute OPT(G) by brute force (in constant time) and **return** OPT(G)
3: **if** G contains an irrelevant edge **then**
4: **return** RED$(G \setminus \{e\})$
5: **if** G contains a non-isolating vertex cut $\{u, v\}$ **then**
6: let $(V_1, V_2), 2 \leq |V_1| \leq |V_2|$, be a partition of $V(G) \setminus \{u, v\}$ such that there are no edges between V_1 and V_2 in $G \setminus \{u, v\}$
7: let G_1 be the graph resulting from G by contracting V_2 into one node v_2 and G_2 the graph resulting from G by contracting V_1 into one node v_1 (keeping one copy of parallel edges in both cases)
8: let $H_1 =$ RED(G_1) and $H_2 =$ RED(G_2)
9: let E_1 (resp. E_2) be the two edges of H_1 (resp., H_2) with endpoints in v_2 (resp., v_1)
10: **return** $H := (H_1 \setminus E_1) \cup (H_2 \setminus E_2)$
11: **if** G contains a removable 5-cycle **then**
12: let e be the removable edge (found via Lemma 6) in that cycle and **return** RED$(G \setminus \{e\})$
13: **return** ALG(G)

▶ **Lemma 9.** RED(G) *runs in polynomial time in* $|V(G)|$ *if* ALG *does so.*

Proof. Let $n = |V(G)|$. First observe that each recursive call, excluding the corresponding subcalls, can be executed in polynomial time. In particular, we can find one irrelevant edge, if any, in polynomial time by enumerating all the possible 2-vertex-cuts. Furthermore, we can find some removable 5-cycle, if any, in polynomial time by enumerating all 5-cycles. Then, by Lemma 6, we can indentify a removable edge in such cycle. We also remark that in Lines 4 and 12 we remove one edge, and we never increase the number of edges. Hence the corresponding recursive calls increase the overall running time by a polynomial factor altogether.

It is then sufficient to bound the number $f(n)$ of recursive calls where we execute Lines 6-10 starting from a graph with n nodes. Consider one recursive call on a graph G with n nodes, where the corresponding graph G_1 has $5 \leq k \leq n/2 + 2$ nodes. Notice that G_2 has $n - k + 4$ nodes. Thus one has $f(n) \leq \max_{5 \leq k \leq n/2+2}\{f(k) + f(n - k + 4)\}$, which implies that $f(n)$ is polynomially bounded. ◀

Let us next show that RED produces a feasible solution.

▶ **Lemma 10.** *Given a 2VC graph* G, RED(G) *returns a feasible 2VCSS solution for* G.

Proof. Let us prove the claim by induction on $(|V(G)|, |E(G)|)$ in lexicographic order. The base cases are given when RED(G) executes Lines 2 or 13: in these cases RED clearly returns a feasible solution. Consider an instance G where RED(G) does not execute those lines (in the root call), and assume the claim holds for any instance G' where $(|V(G')|, |E(G')|)$ is strictly smaller than $(|V(G)|, |E(G)|)$ in lexicographic order. By Lemma 2, when RED recurses at Line 4, the graph $G \setminus \{e\}$ is 2VC, hence the recursive call returns a 2VC spanning subgraph by inductive hypothesis. A similar argument holds when Line 12 is executed, this time exploiting Lemma 6.

It remains to consider the case when Lines 6-10 are executed. Notice that both G_1 and G_2 are 2VC. In this case we can assume by inductive hypothesis that both H_1 and H_2 are 2VC. Consider any $w_1 \in V_1$. Since H_1 is 2VC, H_1 contains 2 vertex disjoint paths from w_1 to v_2. Notice that both u and v must be the second last node in exactly one such path, hence in particular there exist two (internally) vertex-disjoint paths P_{w_1u} and P_{w_1v} in H over the nodes $V_1 \cup \{u, v\}$ from w_1 to u and v, resp. Symmetrically, for each $w_2 \in V_2$ there exist two vertex disjoint paths P_{w_2u} and P_{w_2v} in H over the nodes $V_2 \cup \{u, v\}$ from w_2 to u and v, resp.

For any $w_1 \in V_1$ and $w_2 \in V_2$, the w_1-w_2 paths $P_{w_1u} \cup P_{w_2u}$ and $P_{w_1v} \cup P_{w_2v}$ in H are vertex disjoint. Similarly, for any $w_1 \in V_1$ and $w_2 \in V_2$, $P_{w_1u} \cup P_{w_1v}$ and $P_{w_2u} \cup P_{w_2v}$ are vertex disjoint u-v paths in H. Given $w_1 \in V_1$ and $w_1' \in V_1 \cup \{u, v\}$, consider the two vertex disjoint paths in H_1 between them. If these paths do not contain v_2, then they also belong to H. Otherwise exactly one of those paths contains the subpath $P' = uv_2v$: by replacing P' with $P_{w_2u} \cup P_{w_2v}$ for an arbitrary $w_2 \in V_2$, one obtains two vertex disjoint w_1-w_1' paths in H. A symmetric argument holds for $w_2 \in V_2$ and $w_2' \in V_2 \cup \{u, v\}$.

Assume to get a contradiction that H has a cut vertex w. If $w \in \{u, v\}$, then w is also a cut vertex in either H_1 or H_2. Thus we can assume w.l.o.g. $w \in V_1$. Consider the components resulting of removing the vertex w from H. If one of this components does not contain u nor v then w is also a cut vertex in H_1. Thus removing w from H yields two connected components C_u, C_v, with $u \in C_u, v \in C_v$. But since $w \in V_1$, no edge from H_2 present in H is removed by deleting w. In particular, there is a path from u to v in H, contradicting the fact that w is a cut vertex. ◀

It remains to analyze the approximation factor of RED.

▶ **Lemma 11.** $|\mathsf{RED}(G)| \leq \begin{cases} \mathsf{opt}(G), & \text{if } |V(G)| < \max\{6, \frac{2}{\alpha-1}\}; \\ \alpha \cdot \mathsf{opt}(G) - 2, & \text{if } |V(G)| \geq \max\{6, \frac{2}{\alpha-1}\}. \end{cases}$

Proof. We prove the claim by induction on $(|V(G)|, |E(G)|)$ in lexicographic order. The base cases correspond to the execution of Lines 2 and 13. Here the claim trivially holds. The claim holds by inductive hypothesis and by Lemmas 2 and 6 when Lines 4 and 12, resp., are executed. Notice that the 6 that appears in the max in the claim of the lemma is meant to guarantee that the conditions of Lemma 6 are satisfied.

It remains to consider the case when Lines 6-10 are executed. Let OPT be a minimum 2VC spanning subgraph of G, and OPT_i be an optimal 2VCSS solution for G_i, $i \in \{1, 2\}$. We will later show

$$|\mathsf{OPT}| = |\mathsf{OPT}_1| + |\mathsf{OPT}_2| - 4. \tag{1}$$

Notice that since $|H_i \cap E_i| = 2$ for $i \in \{1, 2\}$ and $H_1 \setminus E_1$ and $H_2 \setminus E_2$ are edge-disjoint, we have $|H| = |H_1| + |H_2| - 4$.

Notice that, for $|V_i| \geq \frac{2}{\alpha-1}$, one has $|\mathsf{OPT}_i| \leq \alpha|\mathsf{OPT}_i| - 2$. We now distinguish a few cases.

If $|V_2| < \max\{6, \frac{2}{\alpha-1}\}$, then $|H| = |H_1| + |H_2| - 4 = |\mathsf{OPT}_1| + |\mathsf{OPT}_2| - 4 = |\mathsf{OPT}|$.

If $|V_1| \geq \max\{6, \frac{2}{\alpha-1}\}$, then $|H| = |H_1| + |H_2| - 4 \leq \alpha|\mathsf{OPT}_1| - 2 + \alpha|\mathsf{OPT}_2| - 2 - 4 \leq \alpha(|\mathrm{OPT}_1| + |\mathrm{OPT}_2|) - 8 \leq \alpha|\mathsf{OPT}| + 4\alpha - 8 \leq \alpha|\mathsf{OPT}| - 2$. The last inequality uses the assumption $\alpha \leq 3/2$.

Finally, if $|V_1| < \max\{6, \frac{2}{\alpha-1}\}$ and $|V_2| \geq \max\{6, \frac{2}{\alpha-1}\}$, we have $|H| = |H_1| + |H_2| - 4 \leq |\mathsf{OPT}_1| + \alpha|\mathsf{OPT}_2| - 2 - 4 = (1-\alpha)|\mathsf{OPT}_1| + \alpha(|\mathsf{OPT}_1| + |\mathsf{OPT}_2|) - 6 \leq (1-\alpha)|\mathsf{OPT}_1| + 4\alpha + \alpha|\mathsf{OPT}| - 6 \leq \alpha|\mathsf{OPT}| - 2$. The last inequality holds since $|\mathsf{OPT}_1| \geq |V(G_1)| \geq 5$ and $\alpha > 1$.

It remains to prove (1). Let E_1 be the two edges of G_1 with endpoints in v_2 and E_2 be the two edges of G_2 with endpoints in v_1. Observe that E_i coincides with the E_i defined in Line 9. By the same argument as in the proof of Lemma 10, one has that $(\mathsf{OPT}_1 \setminus E_1) \cup (\mathsf{OPT}_2 \setminus E_2)$ is a 2VC spanning subgraph of G. Notice that $\mathsf{OPT}_1 \setminus E_1$ and $\mathsf{OPT}_2 \setminus E_2$ are edge-disjoint and that $|E_i \cap \mathsf{OPT}_i| = |E_i| = 2$ for $i \in \{1, 2\}$. Using this two facts we get that $|\mathsf{OPT}| \leq |(\mathsf{OPT}_1 \setminus E_1) \cup (\mathsf{OPT}_2 \setminus E_2)| = |\mathsf{OPT}_1| + |\mathsf{OPT}_2| - 4$.

For the other direction, assume by contradiction that $|\mathsf{OPT}| < |\mathsf{OPT}_1| + |\mathsf{OPT}_2| - 4$. Notice that $E(G) = (E(G_1) \setminus E_1) \dot\cup (E(G_2) \setminus E_2)$ and thus $\mathsf{OPT} = ((E(G_1) \setminus E_1) \cap \mathsf{OPT}) \dot\cup ((E(G_2) \setminus E_2) \cap \mathsf{OPT})$. Thus we have that either $|(E(G_1) \setminus E_1) \cap \mathsf{OPT}| < |\mathsf{OPT}_1| - 2$ or $|(E(G_2) \setminus E_2) \cap \mathsf{OPT}| < |\mathsf{OPT}_2| - 2$. Assume w.l.o.g. that $|(E(G_1) \setminus E_1) \cap \mathsf{OPT}| < |\mathsf{OPT}_1| - 2$. Then $((E(G_1) \setminus E_1) \cap \mathsf{OPT}) \cup \{uv_2, vv_2\}$ is a 2VC spanning subgraph of G_1 of cardinality less than $|\mathsf{OPT}_1|$, a contradiction. (1) follows. ◀

2.2 A Canonical 2-Edge-Cover

It remains to give a good enough approximation algorithm for structured graphs. The first step in our algorithm (similarly to prior work on related problems [6, 19, 25]) is to compute (in polynomial time [33, Chapter 30]) a minimum-cardinality 2-edge-cover[3] H of G. It is worth to remark that $|H| \leq \mathsf{opt}(G)$: indeed the degree of each node in any 2VC spanning subgraph of G must be at least 2.

For technical reasons, we transform H, without increasing its size, into another 2-edge-cover which is *canonical* in the following sense. We need some notation first. If a connected component of H has at least 6 edges we call it a *large component*, and otherwise a *small component*. Let C be a large component of H. We call every maximal 2VC subgraph of C a *block*, and every edge of C such that its removal splits that component into two connected components a *bridge*. Notice that every edge of C is either a bridge or belongs to some block in that component. Also, every edge of C belongs to at most one block, thus there is a unique partition of the edges of C into blocks and bridges (but a node of C might belong to multiple blocks and to multiple bridges). Observe that C is 2VC iff it has exactly one block. If C is large but not 2VC we call it a *complex component*. If a block B of a complex component C contains only one cut vertex of C, we say that B is a *leaf-block* of C. Notice that since H is a 2-edge-cover, C must have at least 2 leaf blocks.

▶ **Definition 12** (Canonical 2-Edge-Cover). *A 2-edge-cover S of a graph G is* canonical *if: (1) Every small component of S is a cycle; (2) For any complex component C of S, each leaf-block B of C has at least 5 nodes.*

▶ **Lemma 13.** *Given a minimum 2-edge-cover H of a structured graph G, in polynomial time one can compute a* canonical *2-edge-cover S of G with $|S| = |H|$.*

Proof. We start with $S := H$. At each step if there are edges $e \in E(G) \setminus E(S)$ and $e' \in E(S)$, such that $S' := S \cup \{e\} \setminus \{e'\}$ is a 2-edge-cover that has fewer connected components than S or it has the same number of connected components as S but has fewer bridges and blocks in total than S, then we replace S by S'. This process clearly terminates within a polynomial number of steps, returning a 2-edge-cover S of the same size as the initial H (hence in particular S must be minimal).

[3] A 2-edge-cover H of a graph G is a subset of edges such that each node v of G has at least 2 edges of H incident to it.

Let us show that the final S satisfies the remaining properties. Assume by contradiction that S has a connected component C with at most 5 edges that is not a cycle. By a simple case analysis C must be a 4-cycle plus one chord f. However this contradicts the minimality of S by Fact 3.

Finally assume by contradiction that S has a complex component C, with a leaf-block B such that B has at most 4 nodes. By the minimality of S, B must be a 3-cycle or a 4-cycle. Let $B = v_1 \dots v_k$, $k \in \{3, 4\}$, and assume w.l.o.g. that v_1 is the only cut-vertex of C that belongs to B. In this case we show that there must exist an edge $e = uz \in E(G)$ such that $u \in \{v_2, v_k\}$ and $z \notin B$. If this is not true then for $k = 3$, v_1 is a cut-vertex in G, and for $k = 4$, $\{v_1, v_3\}$ form a non-isolating cut, leading to a contradiction in both cases. Consider $S' := S \cup \{e\} \setminus \{uv_1\}$. Note that S' is a 2-edge-cover of the same size as S. Since uv_1 belongs to a cycle of S, then the number of connected components in S' is not more than in S. If $z \notin C$ the number of connected components of S' is less than in S, which is a contradiction. Otherwise the number of connected components of S and S' is the same. Now in S' all the bridges and the blocks of S that shared an edge with any path from u to z in $S \setminus \{uv_1\}$ become part of the same block and all the other bridges and blocks remain the same. This is a contradiction as the total number of bridges and blocks of S' is less than in S. ◀

2.3 A Credit-Based Argument

Next assume that we are given a minimum-cardinality canonical 2-edge-cover H of a structured graph G. Observe that, for $|H| \leq 5$, H is necessarily a cycle of length $|H|$ by the definition of canonical 2-edge-cover and a simple case analysis. In particular H is already a feasible (and optimal) solution. Therefore we next assume $|H| \geq 6$. Starting from $S = H$, we will gradually add edges to (and sometimes remove edges from) S, until S becomes 2VC. In order to keep the size of S under control, we use a credit-based argument similarly to prior work [6, 19, 21]. At high level, the idea is to assign a certain number of credits $\mathsf{cr}(S)$ to S. Let us define the cost of S as $\mathsf{cost}(S) = |S| + \mathsf{cr}(S)$. We guarantee that for the initial value of S, namely $S = H$, $\mathsf{cost}(S) \leq \frac{4}{3}|H|$. Furthermore, during the process $\mathsf{cost}(S)$ does not increase.

During the process we maintain the invariant that S is canonical. Hence the following credit assignment scheme is valid for any intermediate S:

1. To every small component C of S we assign $\mathsf{cr}(C) = |E(C)|/3$ credits.
2. Each large component C receives $\mathsf{cr}(C) = 1$ credits.
3. Each block B receives $\mathsf{cr}(B) = 1$ credits.
4. Each bridge b receives $\mathsf{cr}(b) = 1/4$ credits.

We remark that each large connected component C of S which is 2VC, receives one credit in the role of a component, and one additional credit in the role of a block of that component. Let $\mathsf{cr}(S) \geq 0$ the total number of credits assigned to the subgraphs of S. It is not hard to show that the initial cost of S is small enough.

▶ **Lemma 14.** $\mathsf{cost}(H) \leq \frac{4}{3}|H|$.

Proof. Let us initially assign $\frac{1}{4}$ credits to the bridges of H and $\frac{1}{3}$ credits to the remaining edges. Hence we assign at most $\frac{|H|}{3}$ credits in total. We next redistribute these credits so as to satisfy the credit assignment scheme.

Each small component C retains the credits of its edges. If C is large and 2VC then it has exactly one block B. Since $|E(C)| \geq 6$, its edges have at least 2 credits, so we can assign 1 credit to C and 1 to B.

Now consider a complex component C of H. The bridges keep their own credits. Since H is a 2-edge-cover and C is complex, then C has at least 2 leaf-blocks B_1 and B_2. By the definition of canonical, B_1 and B_2 have at least 5 nodes (hence edges) each. Therefore

together they have at least $\frac{10}{3} > 3$ credits, which is sufficient to assign one credit to C, B_1 and B_2. Any other block B of C (which has at least 3 edges) keeps the credits of its edges, hence at least 1 credit. Observe that $\mathsf{cost}(H) = |H| + \mathsf{cr}(H) \leq \frac{4}{3}|H|$ as desired. ◀

As mentioned before, starting from $S = H$, we will transform S without increasing its cost $\mathsf{cost}(S)$ until it becomes a single large component C that is 2VC (and thus it has exactly one block B) and therefore a 2VC spanning subgraph of G. Notice that at the end of the process $\mathsf{cr}(S) = \mathsf{cr}(C) + \mathsf{cr}(B) = 2$, hence $|S| = \mathsf{cost}(S) - 2 \leq \frac{4}{3}|H| - 2$. Combining this with the trivial case for $|H| \leq 5$, we obtain the following lemma.

▶ **Lemma 15.** *Given a canonical minimum 2-edge-cover H of a structured graph G, one can compute in polynomial time a 2VCSS solution S for G with $|S| \leq \max\{|H|, \frac{4}{3}|H| - 2\}$.*

Given the above results, it is easy to prove Theorem 1.

Proof of Theorem 1. By Lemma 8 it is sufficient to compute a solution of cost at most $\max\{\mathsf{opt}(G), \frac{4}{3} \cdot \mathsf{opt}(G) - 2\}$ on a structured graph G. We initially compute a canonical minimum 2-edge-cover H of G via Lemma 13. Then we apply Lemma 15 to obtain a 2VCSS solution S with $|S| \leq \max\{|H|, \frac{4}{3}|H| - 2\} \leq \max\{\mathsf{opt}(G), \frac{4}{3}\mathsf{opt}(G) - 2\}$. Clearly all steps can be performed in polynomial time. ◀

It remains to discuss the proof of Lemma 15 (assuming $|H| \geq 6$), which is the most technical part of our paper. The construction at the heart of the proof consists of a few stages. Recall that we start with a 2-edge-cover $S = H$, and then gradually transform S without increasing $\mathsf{cost}(S)$.

In the first stage of our construction we remove from S all the small components with the exception of the following type of 4-cycles that require a separate argument in the following.

▶ **Definition 16** (pendant 4-cycle)**.** *Let S be a 2-edge-cover of a graph G and C' be a large component of S. We say that a connected component C of S is a* pendant 4-cycle *(of C') if C is a 4-cycle and all the edges of G with exactly one endpoint in C have the other endpoint in C'.*

▶ **Lemma 17.** *Let G be a structured graph and H be a canonical minimum 2-edge cover of G, with $|H| \geq 6$. In polynomial time one can compute a canonical 2-edge-cover S of G such that the only small components of S are pendant 4-cycles and $\mathsf{cost}(S) \leq \mathsf{cost}(H)$.*

In the second stage of our construction we reduce to the case where S consists of large 2VC components only.

▶ **Lemma 18.** *Let G be a structured graph and S be a canonical 2-edge-cover of G such that the only small components of S are pendant 4-cycles. In polynomial time one can compute a canonical 2-edge-cover S' of G such that all the connected components of S' are 2VC and large, and $\mathsf{cost}(S') \leq \mathsf{cost}(S)$.*

At this point we can exploit the following definition and lemma from [19] to construct the desired 2VC spanning subgraph.

▶ **Definition 19** (Nice Cycle)**.** *Let $\Pi = (V_1, \ldots, V_k)$, $k \geq 2$, be a partition of the node-set of a graph G. A nice cycle N of G w.r.t. Π is a subset of edges with endpoints in distinct subsets of Π such that: (1) N induces one cycle of length at least 2 in the graph obtained from G by collapsing each V_i into a single node; (2) given the two edges of N incident to some V_i, these edges are incident to distinct nodes of V_i unless $|V_i| = 1$.*

▶ **Lemma 20** ([19]). *Let $\Pi = (V_1, \dots, V_k)$, $k \geq 2$, be a partition of the node-set of a 2VC graph G. In polynomial time one can compute a nice cycle N of G w.r.t. Π.*

▶ **Lemma 21.** *Let G be a structured graph and S be a 2-edge-cover of G such that all the connected components of S are 2VC and large. In polynomial time one can compute a 2VCSS solution S' for G with $\mathsf{cost}(S') \leq \mathsf{cost}(S)$.*

Proof. Initially set $S' = S$. Consider the partition $\Pi = (V_1, \dots, V_k)$ of $V(G)$ where V_i is the set of vertices of the 2VC component C_i of S'. If $k = 1$, S' already satisfies the claim. Otherwise, using Lemma 20 we can compute a nice cycle N of G w.r.t. Π. Let us replace S' with $S'' := S' \cup N$. W.l.o.g assume N is incident to $V_1, ..., V_r$ for some $2 \leq r \leq k$. Then in S'' the nodes $V_1 \cup \ldots \cup V_r$ belong to a unique (large) 2VC connected component C'. Furthermore $\mathsf{cost}(S') - \mathsf{cost}(S'') = \sum_{i=1}^{r}(\mathsf{cr}(C_i) + \mathsf{cr}(B_i)) - \mathsf{cr}(C') - \mathsf{cr}(B') - r = 2r - 2 - r \geq 0$, where B_i is the only block of the component C_i and B' the only block of C'. By iterating the process for a polynomial number of times one obtains a single 2VC component, hence the claim. ◀

The proof of Lemma 15 follows by chaining Lemmas 17, 18, and 21, and by the previous simple observations.

Abstract

Many streaming algorithms provide only a high-probability relative approximation. These two relaxations, of allowing approximation and randomization, seem necessary – for many streaming problems, both relaxations must be employed simultaneously, to avoid an exponentially larger (and often trivial) space complexity. A common drawback of these randomized approximate algorithms is that independent executions on the same input have different outputs, that depend on their random coins. *Pseudo-deterministic* algorithms combat this issue, and for every input, they output with high probability the same "canonical" solution.

We consider perhaps the most basic problem in data streams, of counting the number of items in a stream of length at most n. Morris's counter [CACM, 1978] is a randomized approximation algorithm for this problem that uses $O(\log \log n)$ bits of space, for every fixed approximation factor (greater than 1). Goldwasser, Grossman, Mohanty and Woodruff [ITCS 2020] asked whether pseudo-deterministic approximation algorithms can match this space complexity. Our main result answers their question negatively, and shows that such algorithms must use $\Omega(\sqrt{\log n / \log \log n})$ bits of space.

Our approach is based on a problem that we call *Shift Finding*, and may be of independent interest. In this problem, one has query access to a shifted version of a known string $F \in \{0,1\}^{3n}$, which is guaranteed to start with n zeros and end with n ones, and the goal is to find the unknown shift using a small number of queries. We provide for this problem an algorithm that uses $O(\sqrt{n})$ queries. It remains open whether $\text{poly}(\log n)$ queries suffice; if true, then our techniques immediately imply a nearly-tight $\Omega(\log n / \log \log n)$ space bound for pseudo-deterministic approximate counting.

1 Introduction

Computing over data streams is a rich algorithmic area that has developed enormously, and actually started with the simple-looking problem of approximate counting [28]. Let us first recall the streaming model: The input is a stream, i.e., a sequence of items, and the goal is to compute a pre-defined function of these items, such as the number of items (or number of the distinct items), while making one sequential pass over the stream (or sometimes a few passes). Many useful functions actually depend on the items as a multiset, i.e., ignoring their order, or even only on their frequencies (like the famous ℓ_p-norm of the frequency vector). Another possible goal is to produce a sample, rather than computing a function, e.g., to produce a uniformly random item.

The primary measure of efficiency for streaming algorithms is their space complexity, and for many problems, researchers have designed space-efficient algorithms, often with space complexity that is even polylogarithmic in the input size. However, this comes at a price – these algorithms are usually randomized (and not deterministic) and/or compute an approximate solution (rather than exact one). In fact, oftentimes both relaxations are needed in order to achieve low space complexity. For example, to count the number of items in a stream of length at most n, there is a randomized approximation algorithm using $O(\log\log n)$ bits of space, but algorithms that are exact or deterministic must use $\Omega(\log n)$ bits [28]. Another example is the ℓ_2-norm of the frequency vector of items from a ground set $[d]$ (or equivalently, of a d-dimensional vector under a sequence of additive updates) – there is a randomized approximation algorithm that uses $O(\log d)$ bits of space, but algorithms that are exact or deterministic must use $\Omega(d)$ bits of space [1].

Gat and Goldwasser [9] initiated the study of *pseudo-deterministic* algorithms, which informally means that when run (again) on the same input, with high probability they produce exactly the same output. This notion combats a potential issue with randomized algorithms, that independent executions on the same input might return different outputs, depending on the algorithm's coin tosses. Many known streaming algorithms suffer from this issue, which is a serious concern for some users and applications. Pseudo-deterministic algorithms were later considered in the streaming model by Goldwasser, Grossman, Mohanty and Woodruff [16], and these are formally defined as follows.

▶ **Definition 1.1.** *A streaming algorithm A is* pseudo-deterministic *(PD) if there is a function $F(\cdot)$ defined on inputs of A (streams), such that for every stream σ,*

$$\Pr[A(\sigma) = F(\sigma)] \geq 9/10,$$

where the probability is over the random choices of the algorithm. We shall refer to F as the canonical function *of algorithm A.*[1]

We focus on *estimation problems*, which ask to approximate a numerical value, and are very popular in the streaming model. For such problems, the notion of PD relaxes the exact setting and the deterministic one, since exact algorithms have one canonical output (the

[1] The canonical function F depends on the order arrival of the stream items. In an alternative definition, the canonical function depends on the items only as a multiset, i.e., ignoring their order in the stream. These two definitions are equivalent in the setting of approximate counting, which is the focus of our work.

Table 1 Known space bounds (in bits) for 2-approximate counting in a stream of length at most n. Folklore bounds are stated without a reference.

Algorithms	Upper bound	Lower bound
Exact or deterministic	$O(\log n)$	$\Omega(\log n)$
Randomized and approximate	$O(\text{loglog}\, n)$ [28]	$\Omega(\text{loglog}\, n)$ [29]
Pseudo-deterministic	$O(\log n)$	$\Omega(\sqrt{\log n/\text{loglog}\, n})$ [Thm. 1.2]

exact numerical value), and hence they are PD. Thus the known lower bounds for these settings do not apply for PD algorithms, and a central question, identified in [16], remains open:

Are there efficient PD streaming algorithms for estimation problems?

Currently, no lower bounds are known for natural estimation problems, although for several search problems, like reporting an element from a stream with deletions (equivalently, an index from the support of the frequency vector), it is known that lower bounds for deterministic algorithms extend to PD algorithms [16].

1.1 Main Result: Approximate Counting

Perhaps the most basic problem in the streaming model is to count the number of stream items. Exact counting, i.e., computing the number of items exactly, requires $\Theta(\log n)$ bits of space when the stream has length at most n, even for randomized algorithms with some error probability. Work by Morris [28], later refined in [8, 18, 29], showed that the number of stream items can be $(1+\epsilon)$-approximated with probability $9/10$ using $O_\epsilon(\text{loglog}\, n)$ bits of space, where $\epsilon > 0$ is arbitrary but fixed. Throughout, we refer to multiplicative approximation, and use the notations $O_c(\cdot)$ and $\Omega_c(\cdot)$ to hide factors that are polynomial in c. Morris's algorithm has found many applications, both in theory and in practice [27, 29]. An open question stated explicitly by Goldwasser, Grossman, Mohanty and Woodruff [16] is whether there is a PD algorithm for this problem using $O(\text{loglog}\, n)$ bits of space. We answer their question negatively, by proving the following lower bound.

▶ **Theorem 1.2** (Main Result). *For every $c, n > 1$, every PD streaming algorithm that c-approximates the number of items in a stream of length at most $(c+1)n$ must use $\Omega_c(\sqrt{\log n/\text{loglog}\, n})$ bits of space.*

To be more precise, our lower bound is actually $\Omega\big(\frac{\log n}{\sqrt{\log n \,\text{loglog}(cn)}+\log c}\big)$, which is still $\Omega(\sqrt{\frac{\log n}{\text{loglog}\, n}})$ as long as $c < 2^{\sqrt{\log n \,\text{loglog}\, n}}$. Previously, there was a large gap for this problem, between $O(\log n)$ bits (by a deterministic algorithm) and $\Omega(\text{loglog}\, n)$ bits (from the randomized setting) [29]. See Table 1 for a summary of the known bounds.

Our proof analyzes the promise variant of c-approximate counting for streams of length at most $(c+1)n$, which we denote by $\Pi^{AC}_{c,n}$; this variant asks to distinguish whether the number of stream items is $\le n$ or $> cn$ (see Definition 2.1). A crucial property of PD algorithms is that they have to be PD also for inputs in the range $[n+1, cn]$ (i.e., outside the promise). We rely on this property of PD algorithms to prove the following result, which immediately yields Theorem 1.2 as a corollary.

▶ **Theorem 1.3** (Main Result). *For every $c, n > 1$, every PD streaming algorithm for problem $\Pi^{AC}_{c,n}$ must use $\Omega_c(\sqrt{\log n / \log\log n})$ bits of space.*

Our proof of Theorem 1.3 appears in Section 4. It is based on a problem that we call Shift Finding, which may be of independent interest, as it is very natural and likely to find connections to other problems. In addition, it can potentially lead to a near-tight $\Omega(\log n/ \log\log n)$ lower bound for PD streaming, by simply improving our algorithmic result for Shift Finding. A very recent independent work by Grossman, Gupta and Sellke [20] shows a tight $\Omega(\log n)$ bound for $\Pi^{AC}_{c,n}$, using a very different technique, which views the PD streaming algorithm as a Markov chain with a limited number of states.

1.2 Main Technique: The Shift Finding Problem

Our main result relies on *algorithms* for the shift Finding problem $\Pi^{SF}_{c,n}$, which is defined below. Let us first introduce some basic terminology. A function $F : [m] \to \{0, 1\}$ can also be viewed as a string $F \in \{0, 1\}^m$, and vice versa, and we sometimes use these interchangeably. Given $s \in [0, n]$, let the shifted version of this F be the function $F_s : x \mapsto F(s + x)$, with a properly restricted domain, see Section 2.

▶ **Definition 1.4** (Shift Finding). *Let $c, n > 1$. In problem $\Pi^{SF}_{c,n}$, the input is a string $P \in \{0, 1\}^{(c-1)n}$, and one has query access to a string F_{s^*} that is the concatenation of $n - s^*$ zeros, then P, and finally s^* ones, for an unknown $s^* \in [0, n]$. Thus, a query for $x \in [0, cn]$ returns $F_{s^*}(x)$. The goal is to output s^*.*

The measure of complexity of an algorithm for this problem is the number of queries that it makes to F_{s^*}. A randomized algorithm is required to be correct (in its output s^*) with probability 9/10.

This problem may be also of independent interest. In a different variant of shift finding, the input is a random string $c \in \{0, 1\}^n$ and a vector x that is obtained from the string c by a cyclic shift τ and some noise (random bit flips), and the goal is to compute the shift τ with high probability. This problem is related to GPS synchronization, see [23, 2] for more details. There is a sublinear time algorithm for this problem, running in time roughly $O(n^{0.641})$ [2]. One main difference is that in our Definition 1.4, one string is completely known to the algorithm, and the only concern is the number of queries to the second string.

1.2.1 Connection to PD Counting

We show that an algorithm for Shift Finding ($\Pi^{SF}_{c,n}$) implies a space lower bound for PD streaming algorithm for counting ($\Pi^{AC}_{c,n}$).

▶ **Theorem 1.5.** *Let $c, n > 1$, and suppose that the Shift Finding problem $\Pi^{SF}_{c,n}$ admits a randomized algorithm that makes at most $q = q(c, n)$ queries (possibly adaptive). Then, every PD streaming algorithm for the approximate counting problem $\Pi^{AC}_{c,n}$ must use $\Omega(\frac{\log n}{\log q})$ bits of space.*

It immediately follows that if the Shift Finding problem $\Pi^{SF}_{c,n}$ can be solved using polylog(n) queries (for fixed $c > 1$), then PD approximate counting requires $\Omega(\frac{\log n}{\log\log n})$ bits of space. However, our current upper bound for Shift Finding is $q = O(\sqrt{cn})$ queries (Theorem 1.8) and is not strong enough to yield a nontrivial lower bound for PD approximate counting.

Therefore, to prove our main lower bound (Theorem 1.3), we revert to a generalization of Theorem 1.5 where the Shift Finding algorithm is still given an instance of problem $\Pi^{SF}_{c,n}$ (namely, a string F and query access to F_{s^*}), but reports a small set $R \subset [0, n]$ (say of size

$|R| \leq t$) that contains the unknown shift (i.e., $s^* \in R$). This algorithm may be randomized provided that it is PD, and its canonical function maps each instance of problem $\Pi^{SF}_{c,n}$ to a set R of size t that contains s^*.

▶ **Theorem 1.6.** *Let $c, n > 1$, and suppose there is a PD algorithm Q that, given an instance of problem $\Pi^{SF}_{c,n}$, makes at most $q = q(c,n)$ queries (possibly adaptive) to F_{s^*} and its canonical function M maps the input to a set $R \subset [0,n]$ of size $t = t_c(n)$ that contains s^*. Then every PD streaming algorithm for problem $\Pi^{AC}_{c,n}$ must use $\Omega(\frac{\log(n/t)}{\log q})$ bits of space.*

We use Theorem 1.6, (more precisely its proof arguments rather than its statement) to prove our main result (Theorem 1.3), see Section 4. At a high level, the proof of Theorem 1.3 proceeds by splitting into two cases, depending on the canonical function F. Roughly speaking, in one case we show a Shift Finding algorithm that returns a set of size $t = n/2^{\sqrt{\log n}}$ using $q = O(\log n)$ queries by binary search, and in the other case an algorithm to find the shift (i.e., $t = 1$) with probability $9/10$ using $q = 2^{\sqrt{\log n}}$ uniformly random queries.

As a corollary of Theorem 1.5, we get that the *tracking* version of approximate counting must use $\Omega(\log n)$ bits of space, which is tight with a straightforward deterministic counting. Tracking means that the algorithm produces an output after every stream item rather than at the end of the stream, and with probability $9/10$, all the outputs are simultaneously correct (i.e., approximate the number of items seen so far).

▶ **Corollary 1.7** (Tracking). *For every $c, n > 1$, every PD tracking algorithm that c-approximates the number of items in a stream of length $(c+1)n$ must use $\Omega(\log n)$ bits of space.*

In contrast, for standard randomized algorithms, there is a tracking algorithm for $(1+\epsilon)$-approximate counting that uses $O_\epsilon(\log\log n)$ bits of space, for any fixed $\epsilon > 0$ [29]. Corollary 1.7 follows by an easy modification of the proof of Theorem 1.5. That proof uses $O(\log q)$ repetitions of a PD streaming algorithm, and then employs a union bound on q input streams, which is not necessary for tracking algorithms and thus the bound follows.

A more direct argument is essentially by equivalence to exact counting. For a stream with $s < n$ items, the state of a PD tracking algorithm with canonical function F can be used to compute s, as follows. Simulate insertion of more items to the stream until the output of the algorithm changes to 1 (which corresponds to the first 1 in F_s), from which s can be computed.

1.2.2 An Algorithm for Shift Finding

Consider a special case of the Shift Finding problem $\Pi^{SF}_{c,n}$, where the input string P is a run of zeros followed by a run of ones (viewed as a function, it is a step function); then the algorithm can perform a binary search using $O(\log(cn))$ queries, and find the unique location where F_{s^*} switches from value 0 to 1, and hence recover s^*. At the other extreme, suppose the input string P is random; then with high probability every set of $O(\log n)$ queries from P (and thus from F_{s^*}) will be answered differently (viewed as a string in $\{0,1\}^{O(\log n)}$). Based on these observations, one may hope that problem $\Pi^{SF}_{c,n}$ admits an algorithm that makes polylog(cn) queries. We leave this as an open question and prove a weaker bound of $O(\sqrt{cn})$ queries.

▶ **Theorem 1.8** (Shift Finding Algorithm). *There is a deterministic algorithm for problem $\Pi^{SF}_{c,n}$ that makes $O(\sqrt{cn})$ queries.*

A key observation in our result, that may be useful in future work, is that for every shift s^* there is a "short witness" that uses exactly 2 queries. We formalize this as verifying a given guess s for the shift s^*.

▶ **Lemma 1.9** (Short Witness). *There is a deterministic algorithm that, given as input an instance of problem $\Pi^{SF}_{c,n}$ and $s < n$, makes 2 queries to F_{s^*} and returns "yes" if $s = s^*$ and "no" otherwise.*

The proofs of Theorem 1.8 and Lemma 1.9 appear in Section 5. At a high level, the Shift Finding algorithm in Theorem 1.8 queries the set $\{F_{s^*}(0), F_{s^*}(\sqrt{cn}), F_{s^*}(2\sqrt{cn}), ..., F_{s^*}(cn)\}$, and then uses the short witness (Lemma 1.9) to check every feasible $s \in [n]$ (i.e., that agrees with the query answers). Following an observation by Peter Kiss, we are able to improve our Shift Finding algorithm to use only $O((cn)^{1/3} \log n)$ queries; details omitted.

1.3 Related Work

Pseudo-deterministic algorithms

The notion of pseudo-deterministic algorithms was introduced by [9] (they originally called them Bellagio algorithms), followed by a long sequence of works that studied it in different models [13, 19, 14, 30, 24, 15, 5, 31, 11, 21, 12, 16, 26, 6, 17, 10, 7]. In the streaming and sketching models, [16] proved strong lower bounds for finding a non-zero entry in a vector (given in a stream with deletions), and for sketching ℓ_2-norms. Another related setting is that of sublinear time computation. Under certain assumptions, PD algorithms (in the sublinear time region) were shown to admit the following relation with deterministic algorithms – if for a certain problem there is a PD algorithm using q queries, then there is a deterministic algorithm using $O(q^4)$ queries [13]. The techniques of [13] do not seem to extend to streaming algorithms.

Adaptive adversarial streams

In this setting, the stream items are chosen adversarially and depend on past outputs of the streaming algorithm (i.e., the stream is adaptive) [3]. This model is considered to be between PD algorithms and the standard randomized setting, in the sense that for streams of length m, amplifying a PD algorithm to success probability $1 - \frac{1}{10m}$ (by $O(\log m)$ repetitions and taking the median) guarantees (by a union bound) that the algorithm outputs the canonical solution after every stream item with probability 9/10, thus the adversary acts as an oblivious one (the adversary knows in advance the output of the streaming algorithm, which is the canonical function). For approximate counting, adaptive streams and standard (oblivious) streams are equivalent (since the stream items are identical) and thus admit an algorithm using $O(\log\log n)$ bits of space.

There is a vast body of work designing algorithms for adaptive streams, but not much is known in terms of lower bounds. Lower bounds are known for some search problems, like finding a spanning forest in a graph undergoing edge insertions and deletions, but also for graph coloring [4]. Regarding estimation problems, the only lower bound we are aware of is for some artificial problem [25]. Recently, Stoeckl [32] showed a lower bound on streaming algorithms that use a bounded amount of randomness, conditioned on a lower bound for PD algorithms. In the related model of linear sketching, Hardt and Woodruff [22] showed lower bounds on the dimensions of sketching algorithms, which applies to many classical problems, like ℓ_p-norm estimation and heavy hitters.

2 Preliminaries

▶ **Definition 2.1** (Approximate counting). *Let $c, n > 1$. In problem $\Pi^{AC}_{c,n}$, the input is a stream of $l \leq (c+1)n$ identical items. The goal is to output 0 if $l \leq n$ and 1 if $l > cn$ (and otherwise the output can be either 0 or 1).*

Let A be a PD algorithm for problem $\Pi^{AC}_{c,n}$, and let $F : [0, (c+1)n] \to \{0,1\}$ be the canonical function of A. Thus, there is a fixed string $P \in \{0,1\}^{(c-1)n}$ such that

$$F(x) = \begin{cases} 0 & \text{if } x \in [0, n]; \\ 1 & \text{if } x \in [cn+1, (c+1)n]; \\ P(x-n) & \text{otherwise.} \end{cases}$$

For $s^* \in [0, n]$, let $F_{s^*} : [0, (c+1)n - s^*] \to \{0,1\}$ be a shifted version of F, namely the function $F_{s^*} : x \mapsto F(s^* + x)$. We use these notations throughout the paper.

Our proofs are based on a reduction from a simple one-way communication problem, called MESSAGE and denoted Π^{MSG}_{Σ}, where Alice's input x is from an alphabet Σ that is fixed in advance, Bob has no input, and the goal is that Bob outputs x with probability at least 2/3. It is well known that this problem requires $\Omega(\log|\Sigma|)$ bits of communication, even for randomized protocols using shared randomness. We provide a proof for completeness.

▶ **Lemma 2.2.** *For every alphabet Σ, every one-way communication protocol (even with shared randomness) for problem Π^{MSG}_{Σ} must use $\Omega(\log|\Sigma|)$ bits of communication.*

Proof. Let $\mathcal{A}$ be a protocol for problem Π^{MSG}_{Σ}. For a random string r representing the randomness of $\mathcal{A}$, let $\Sigma_r \subset \Sigma$ be the set of all $s \in \Sigma$ for which Bob correctly recovers s. Let r^* be a string maximizing $|\Sigma_r|$, then by averaging, $|\Sigma_{r^*}| \geq \frac{2}{3}|\Sigma|$. Consider an instance of $\mathcal{A}$ that uses r^* as its random string. Assume by contradiction that the number of communication bits is less than $\log|\Sigma_{r^*}|$, then by the pigeonhole principle there are two distinct inputs $s, s' \in \Sigma_{r^*}$ such that $\mathcal{A}(s)$ and $\mathcal{A}(s')$ result in the same message. Bob then cannot distinguish between (i.e., has the same output distribution for) s and s', a contradiction. Hence, the number of bits of communication is at least $\log|\Sigma_{r^*}| = \Omega(\log|\Sigma|)$. ◀

3 Lower Bounds for PD Approximate Counting via Shift Finding

In this section, we prove Theorem 1.5. The proof involves three problems from different settings: (a) PD approximate counting in the streaming model; (b) Shift Finding in the query-access model; and (c) MESSAGE in one-way communication with shared randomness. The proof essentially shows that if there is an algorithm for Shift Finding that makes only q queries and also a streaming algorithm for PD approximate counting that uses b bits of space, then MESSAGE can be solved using $O(b \log q)$ bits of communication. Combining this bound with the well-known lower bound for MESSAGE in Lemma 2.2 yields a lower bound for b.

A core idea in the proof is that an execution of a PD streaming algorithm A for the approximate counting problem $\Pi^{AC}_{c,n}$ on a stream with s^* insertions, can be used (even without knowing s^*, by making additional insertions and then querying the streaming algorithm A) to provide query access to the shifted function $F_{s^*} : x \mapsto F(s^* + x)$. This query access, along with a query-efficient algorithm for the Shift Finding problem $\Pi^{SF}_{c,n}$, is then used to solve an instance of the MESSAGE problem Π^{MSG}_{Σ}.

In fact, we prove the following theorem, which holds for each string F separately (rather than a bound that depends on the worst-case F), and yields Theorem 1.5 as an immediate corollary.

▶ **Theorem 3.1.** *Let A be a PD streaming algorithm for problem $\Pi^{AC}_{c,n}$, where $c, n > 1$, and let $F : [0, (c+1)n] \to \{0,1\}$ be the canonical function of A. Suppose that Shift Finding with respect to this specific F (the problem of finding an unknown shift $s^* \in [n]$ with probability at least $9/10$ given query access to F_{s^*}) admits a randomized algorithm that makes at most $q = q(F)$ (possibly adaptive) queries. Then the streaming algorithm A must use $\Omega(\frac{\log n}{\log q})$ bits of space.*

Proof. Define algorithm A' to be an amplification of A to success probability $1 - 1/(10q)$, by running $O(\log q)$ independent repetitions and reporting their majority. Assume there exists an algorithm Q that for every $s^* \in [n]$, makes at most $q = q(F)$ queries to F_{s^*} (possibly adaptive) and outputs s^* with probability at least $9/10$.

Consider an instance of problem Π^{MSG}_{Σ} with alphabet $\Sigma = [0, n]$, and consider the following protocol for it. Alice starts an execution of the streaming algorithm A' using the shared randomness, then takes her input $s^* \in \Sigma$ and makes s^* stream insertions to algorithm A', and finally sends the state (memory contents) of A' to Bob.

Bob continues the execution of the streaming algorithm A' (using the shared randomness), and uses it to provide query access to F_{s^*}, as follows. In order to query F_{s^*} at any index x, Bob makes a fresh copy A_0 of the streaming algorithm A', insert x stream items to algorithm A_0 and then reads its output. With probability at least $1 - 1/(10q)$, the answer that Bob gets is indeed $F_{s^*}(x)$ (because the number of items inserted to this instance of the algorithm is $x + s^*$). Bob uses this query access and his knowledge of F to simulate algorithm Q (with the goal of recovering s^*).

Consider Bob's simulation of algorithm Q. If Q was executed with true query access to F_{s^*}, then it would have had success probability $9/10$, and would have made a sequence of queries X_Q to F_{s^*}. This sequence X_Q depends only on F_{s^*} and the coin tosses of algorithm Q. In particular, revealing X_Q (i.e., conditioned on X_Q) does not affect the coins of the streaming algorithm A', and it still succeeds with probability at least $1 - 1/(10q)$. We can thus apply a union bound to conclude that algorithm A' succeeds on all queries $x \in X_Q$ (i.e., outputs the corresponding $F_{s^*}(x)$) with probability at least $1 - q \cdot \frac{1}{10q} = 9/10$. Hence, when Bob simulates algorithm Q using the streaming algorithm A', with probability $9/10$ (over the coins of A') the execution is identical to running algorithm Q with true access to F_{s^*}, which itself succeeds with probability $9/10$. By a union bound, with probability $8/10$ both algorithm Q and the streaming algorithm A' succeed, in which case Bob recovers s^*, and therefore this communication protocol solves problem Π^{MSG}_{Σ} with alphabet $\Sigma = [0, n]$.

By Lemma 2.2, the message Alice sends must contain $\Omega(\log n)$ bits, and thus the streaming algorithm A' must use $\Omega(\log n)$ bits of space. Recall that algorithm A' consists of $O(\log q)$ copies of the streaming algorithm A and thus algorithm A must use $\Omega(\frac{\log n}{\log q})$ bits of space. ◀

4 Lower Bound for PD Approximate Counting

In this section, we prove Theorem 1.3, i.e., for every $c, n > 1$, we prove that every PD streaming algorithm for the approximate counting problem $\Pi^{AC}_{c,n}$ must use $\Omega_c(\sqrt{\frac{\log n}{\log\log n}})$ bits of space.

Let F be the canonical function of a PD streaming algorithm for problem $\Pi^{AC}_{c,n}$. Our analysis is split into two cases depending on F, which informally correspond to whether a fixed pattern (like "01") appears in the string F at most t times or not. These cases are analyzed using Theorems 1.6 and 3.1. The overall bound will be derived by optimizing the threshold t between the two cases to roughly $t = n/2^{\sqrt{\log n}}$.

4.1 Scenario One

In this scenario, there is a specific pattern in F that appears at most t times, where $t = t_c(n)$ will be set at the end of our proof. We first consider the pattern "01" in F, which corresponds to $x \in [0, (c+1)n-1]$ such that $F(x) = 0$ and $F(x+1) = 1$, and later generalize this pattern to a broader family.

▶ **Lemma 4.1.** *If the pattern "01" appears at most t times in F, then every PD streaming algorithm for problem $\Pi^{AC}_{c,n}$ whose canonical function is F must use $\Omega(\frac{\log(n/t)}{\log\log(cn)})$ bits of space.*

Proof. The proof is by a reduction from problem MESSAGE, similarly to the proof of Theorem 3.1. Perhaps the most delicate part is the definition of an alphabet Σ for the MESSAGE problem Π^{MSG}_{Σ}, and it proceeds as follows.

Given $s \in [n]$, consider the following execution of Binary Search on the function F_s. Initialize $l = 0$ and $r = cn + 1$, and at every iteration query $F_s(\lfloor \frac{l+r}{2} \rfloor)$; if $F_s(\lfloor \frac{l+r}{2} \rfloor) = 0$, then $l \leftarrow \lfloor \frac{l+r}{2} \rfloor$, otherwise $r \leftarrow \lfloor \frac{l+r}{2} \rfloor$. These iterations maintain the invariant that $F_s(l) = 0$ and $F_s(r) = 1$, and after at most $\log(cn)$ iterations arrive at $r = l + 1$ with the pattern "01". Define a mapping $M : [n] \to [cn]$ such that $M(s)$ is the location where the binary search finds a "01" in F_s, i.e., the final index l; thus $F(s + M(s)) = 0$ and $F(s + M(s) + 1) = 1$.

In order to define an alphabet Σ, consider a partitioning of $[n]$ to buckets, defined such that items s, s' are from the same bucket B if and only if they are mapped to the same value $M(s) = M(s')$. For every bucket B and every $s, s' \in B$, we know from above that $F(s' + M(s)) = 0$ and $F(s' + M(s) + 1) = 1$, so there are at most t possibilities for s' (one of which is $s' = s$), and thus the size of the bucket $|B| \leq t$. Define $\Sigma \subset [n]$ by taking one representative from each bucket. Thus, every $s_1 \neq s_2 \in \Sigma$ satisfy $M(s_1) \neq M(s_2)$ and $|\Sigma| \geq n/t$.

Let A be a streaming algorithm whose canonical function is F and let algorithm A' be an amplification of algorithm A that succeeds with probability $1 - 1/(10\log(cn))$ (by making $O(\log\log(cn))$ repetitions and taking the majority). Consider an instance of the MESSAGE problem Π^{MSG}_{Σ}, and proceed similarly to the proof of Theorem 3.1. We provide a self-contained analysis for completeness. Alice and Bob perform the following protocol. Alice starts an execution of algorithm A' using the shared randomness. For input $s^* \in \Sigma$, she inserts s^* stream items to algorithm A' and sends the state (memory contents) of this algorithm A' to Bob. In order to get query access to F_{s^*} at index x, Bob makes a fresh copy A_0 of algorithm A', continues the algorithm's execution (using the shared randomness), inserts x stream items to algorithm A_0 and finally reads its output. Bob uses this query access to simulate the Binary Search algorithm on F_{s^*} (with the goal of recovering $M(s^*)$). He then infers which bucket corresponds to his result, and outputs the representative of that bucket (which is s^* if he recovers $M(s^*)$).

If the Binary Search algorithm were executed with true query access to F_{s^*}, then it would have output $M(s^*)$ and would have made a sequence of queries X_{BS} to F_{s^*}. This sequence depends only on F_{s^*}, and in particular independent of the random coins of algorithm A'. Thus by a union bound, algorithm A' succeeds on all queries $x \in X_{BS}$ (i.e. outputs the corresponding $F_{s^*}(x)$) with probability at least $1 - \log(cn) \cdot 1/(10\log(cn)) = 9/10$. Hence,

when Bob simulates the Binary Search algorithm using the streaming algorithm A', then with probability 9/10 the execution is identical to running the Binary Search algorithm with true query access to F_{s^*}. Thus with this probability 9/10, Bob recovers $M(s^*)$, and hence outputs s^*, which concludes the correctness analysis of the communication protocol.

By Lemma 2.2, the message Alice sends must contain $\Omega(\log|\Sigma|) \geq \Omega(\log(n/t))$ bits, and thus algorithm A' must use $\Omega(\log(n/t))$ bits of space. Recall that algorithm A' is made of $O(\text{loglog}(cn))$ copies of algorithm A and thus algorithm A must use $\Omega(\frac{\log(n/t)}{\text{loglog}(cn)})$ bits of space. ◀

▶ Remark 4.2. This proof can be easily generalized to prove Theorem 1.6. The first extension is by replacing the Binary Search algorithm and the corresponding buckets with any deterministic algorithm Q that returns a subset containing s^*. In order to generalize Q to any PD algorithm Y, consider the canonical function of Y instead of the mapping M, and apply the same proof. It holds because the crucial property of the Binary Search algorithm was the existence of the mapping M. Then by an additional union bound, both algorithms Q and A' succeed with probability 8/10 (as in the proof of Theorem 3.1).

We now generalize Lemma 4.1 to a larger family of patterns in F, where each pattern is characterized by a parameter $k \in [n]$, and appears at index $x \in [0, (c+1)n - k]$ such that $F(x) = 0$ and $F(x+k) = 1$. These patterns are allowed to overlap with each other (for different values of k). Denote such a pattern by "$0?^{k-1}1$", where each question mark can represent either 0 or 1, and the number of question marks is $k-1 < n$. A copy of this pattern can be found in $O(\log \frac{n}{k})$ queries to F_{s^*} by a binary search on the grid $(0, k, ..., \lceil \frac{cn}{k} \rceil k)$, since $F_{s^*}(0) = 0$ and $F_{s^*}(\lceil \frac{cn}{k} \rceil k) = 1$. Hence, if there exists k for which this pattern appears at most t times in F, then the communication protocol above can be adjusted to imply that algorithm A must use at least $\Omega(\frac{\log(n/t)}{\text{loglog}(cn/k)}) \geq \Omega(\frac{\log(n/t)}{\text{loglog}(cn)})$ bits of space. The only change in the proof is in the number of queries that Bob makes, which affects the number of repetitions in algorithm A', and thus only affects the loglog term.

▶ **Corollary 4.3.** *If for some $k \leq n$ the pattern "$0?^{k-1}1$" appears at most t times in F, then every PD streaming algorithm for problem $\Pi^{AC}_{c,n}$ whose canonical function is F, must use $\Omega(\frac{\log(n/t)}{\text{loglog}(cn)})$ bits of space.*

4.2 Scenario Two

In this scenario, for every $k \leq n$ the pattern "$0?^{k-1}1$" appears at least t times in F.

▶ **Lemma 4.4.** *If for all $k \in [n]$, the pattern "$0?^{k-1}1$" appear at least t times in F, then every PD streaming algorithm for problem $\Pi^{AC}_{c,n}$ whose canonical function is F, must use $\Omega(\frac{\log n}{\log(cn/t)+\text{loglog}\, n})$ bits of space.*

Proof. In this case, there is an algorithm for the Shift Finding problem $\Pi^{SF}_{c,n}$ using $q = O(\frac{cn \log n}{t})$ queries to F_{s^*}, as follows.

1. let $S = [0, n]$
2. repeat the following $\frac{10cn \log n}{t}$ times:
   a. pick $r \in [cn]$ uniformly at random and query $F_{s^*}(r)$
   b. let $S \leftarrow \{s \in S : \ F(s+r) = F_{s^*}(r)\}$
3. if $|S| = 1$, return $s \in S$; else return FAIL

The final set S clearly contains the shift s^*. It remains to show that all $s \neq s^*$ are removed from the set S with high probability.

Fix $s \in [n], s \neq s^*$. There are t values for $r \in [cn]$ for which $F(s^*+r) \neq F(s+r)$, as follows. Assume without loss of generality that $s^* < s$ and denote $k = s - s^* \in [n]$. Let l be a location that corresponds to the pattern "$0?^{k-1}1$" in F, i.e. $F(l) = 0$ and $F(l+k) = 1$. If $l \in [s^*+1, s^*+cn]$, then there is $r \in [cn]$ such that $s^* + r = l$, for which $F(s^*+r) = 0 \neq F(l+k) = F(s+r)$. There are at least t locations for this pattern (i.e. possible values for l), thus it remains to show that indeed $l \in [s^*+1, s^*+cn]$. It must be that $l + k > n$ since $F(x) = 0$ for all $x \leq n$, and similarly $l \leq cn$ since $F(x) = 1$ for all $x > cn$. Hence $l \in [n-k+1, cn] \subset [s^*+1, s^*+cn]$, and thus there are t values for $r \in [cn]$ for which $F(s^*+r) \neq F(s+r)$ (each value for r corresponds to a possible value for l).

Thus, in each repetition, s is removed from the set S with probability at least $\frac{t}{cn}$. The probability s is not removed after $\frac{10cn\log n}{t}$ repetitions is $(1-\frac{t}{cn})^{(10cn\log n)/t} < \frac{1}{n^2}$. By a union bound, all $s \neq s^*$ are removed with probability $1 - \frac{1}{n}$, which concludes the correctness analysis of the algorithm for problem $\Pi^{SF}_{c,n}$.

By Theorem 3.1, every PD streaming algorithm for the approximate counting problem $\Pi^{AC}_{c,n}$ with a canonical function F must use $\Omega(\frac{\log n}{\log((cn\log n)/t)})$ bits of space. ◀

4.3 Concluding the Proof of Theorem 1.3

Concluding the two scenarios, set $t = n/2^{\sqrt{\log n \cdot \log\log(cn)}}$ and get by Corollary 4.3 and Lemma 4.4 that every PD streaming algorithm for the approximate counting problem $\Pi^{AC}_{c,n}$ must use

$$\Omega(\min\{\tfrac{\log(n/t)}{\log\log(cn)}, \tfrac{\log n}{\log((cn/t)\log n)}\}) = \Omega(\tfrac{\log n}{\sqrt{\log n \log\log(cn)} + \log c})$$

bits of space, which boils down to $\Omega(\sqrt{\frac{\log n}{\log\log n}})$ for $c < 2^{\sqrt{\log n \log\log n}}$.

5 Shift Finding Algorithm

One can hope to prove tighter lower bounds for PD streaming algorithms for the approximate counting problem $\Pi^{AC}_{c,n}$, and a possible approach is by solving the Shift Finding problem $\Pi^{SF}_{c,n}$ using polylog n queries. Recall that in problem $\Pi^{SF}_{c,n}$, the input is a string $P \in \{0,1\}^{(c-1)n}$, which can be represented by a string F which is a concatenation of n zeros, P and then n ones; and query access to a shifted version of F with shift s^*, denoted F_{s^*}. As stated in Theorem 1.8, we show a deterministic algorithm for problem $\Pi^{SF}_{c,n}$ using $O(\sqrt{cn})$ queries (Algorithm 1), and we leave open the question whether it is the right bound. The proof relies on an efficient verification algorithm that for input s, uses 2 queries and returns "yes" if and only if $s = s^*$, as stated in Lemma 1.9 and described next.

Proof of Lemma 1.9. Denote by $l \in [n+1, cn+1]$ the smallest number such that $F(l) = 1$, and by $r \in [n, cn]$ the largest number such that $F(r) = 0$. For input $s \in [0, n]$, the verification algorithm returns "no" if $F_{s^*}(l-s) = 0$ or $F_{s^*}(r-s) = 1$, and otherwise returns "yes".

If $s = s^*$, then $F_{s^*}(x-s) = F(x)$ and the verification algorithm outputs "yes". If $s > s^*$, then $s^* - s + l < l$ and thus $F_{s^*}(l-s) = F(s^*-s+l) = 0$ and the verification algorithm outputs "no". Similarly, if $s < s^*$ then $F_{s^*}(r-s) = 1$ and the verification algorithm outputs "no". ◀

▶ Remark 5.1. There is a randomized algorithm for problem $\Pi^{SF}_{c,n}$ using $\tilde{O}_c(\sqrt{n})$ queries that is similar to the proof of Theorem 1.3 in Section 4. It proceeds by considering those two scenarios. In scenario one, instead of constructing the set Σ, query witnesses for all the t

possible shifts using $2t$ queries and hence recover the unknown shift s^*. In scenario two, the proof of Theorem 1.3 shows how to find the unknown shift s^* in $O(\frac{cn}{t}\log n)$ queries with high probability. Hence, by setting $t = \sqrt{cn\log n}$, this algorithm finds the unknown shift in $O(\max\{t+\log(cn), \frac{cn}{t}\log n\}) \leq O(\sqrt{cn\log n})$ queries with high probability.

Next is a slight improvement, a deterministic algorithm in $O(\sqrt{cn})$ queries, proving Theorem 1.8.

Algorithm 1 Deterministic Shift Finding in $O(\sqrt{cn})$ queries.

Input: n, c, F and query access to F_{s^*}
Output: s^*

1: $Q \leftarrow (F_{s^*}(0), F_{s^*}(\sqrt{cn}), F_{s^*}(2\sqrt{cn}), ..., F_{s^*}(cn))$
2: let $S \leftarrow \left\{s \in [0,n] : \forall i \in [0,\sqrt{cn}], F_s(i\sqrt{cn}) = Q(i)\right\}$ ▷ i.e. the set of all shifts that could have produced Q
3: **for** $s \in S$ **do**
4: check the witness of s
5: **if** $s = s^*$ **then** return s

▶ **Lemma 5.2.** *The set S in Algorithm 1 is of size $O(\sqrt{cn})$.*

Proof. Assume by contradiction that $|S| \geq \sqrt{cn}+1$. Hence by the pigeonhole principle, there exists $s_1 < s_2 \in S$ such that $s_1 = s_2 \mod \sqrt{cn}$. Hence for all $i \in [0, \sqrt{cn} - \frac{s_2-s_1}{\sqrt{cn}}]$,

$$Q(i) = F_{s_2}(i\sqrt{cn}) = F_{s_1}(s_2 - s_1 + i\sqrt{cn}) = Q(\tfrac{s_2-s_1}{\sqrt{cn}} + i),$$

where the first and last transitions hold since $s_1, s_2 \in S$ and $\frac{s_2-s_1}{\sqrt{cn}}$ is an integer number, and the second transition is by definition. Thus Q has a period of length $\frac{s_2-s_1}{\sqrt{cn}} \leq \lfloor\frac{s_2}{\sqrt{cn}}\rfloor$. However, for $i \in [\sqrt{cn} - \lfloor\frac{s_2}{\sqrt{cn}}\rfloor + 1, \sqrt{cn}]$ the values that Q get are $Q(i) = F_{s_2}(i\sqrt{cn}) = 1$ since $s_2 + i\sqrt{cn} \geq cn$; thus all entries in Q are equal 1, which contradicts the fact that $Q(0) = 0$, and thus completes the proof. ◀

Algorithm 1 returns the shift s^* since $s^* \in S$ and by the correctness of the verifier in Lemma 1.9. The number of queries Algorithm 1 makes is $O(|S| + |Q|) = O(\sqrt{cn})$, which proves Theorem 1.8.

Minimum Chain Cover in Almost Linear Time

Manuel Cáceres
Department of Computer Science, University of Helsinki, Finland

Abstract

A minimum chain cover (MCC) of a k-width directed acyclic graph (DAG) $G = (V, E)$ is a set of k chains (paths in the transitive closure) of G such that every vertex appears in at least one chain in the cover. The state-of-the-art solutions for MCC run in time $\tilde{O}(k(|V| + |E|))$ [Mäkinen et at., TALG], $O(T_{MF}(|E|) + k|V|)$, $O(k^2|V| + |E|)$ [Cáceres et al., SODA 2022], $\tilde{O}(|V|^{3/2} + |E|)$ [Kogan and Parter, ICALP 2022] and $\tilde{O}(T_{MCF}(|E|) + \sqrt{k}|V|)$ [Kogan and Parter, SODA 2023], where $T_{MF}(|E|)$ and $T_{MCF}(|E|)$ are the running times for solving maximum flow (MF) and minimum-cost flow (MCF), respectively.

In this work we present an algorithm running in time $O(T_{MF}(|E|) + (|V| + |E|) \log k)$. By considering the recent result for solving MF [Chen et al., FOCS 2022] our algorithm is the first running in almost linear time. Moreover, our techniques are deterministic and derive a deterministic near-linear time algorithm for MCC if the same is provided for MF. At the core of our solution we use a modified version of the mergeable dictionaries [Farach and Thorup, Algorithmica], [Iacono and Özkan, ICALP 2010] data structure boosted with the SIZE-SPLIT operation and answering queries in amortized logarithmic time, which can be of independent interest.

1 Introduction

Computing a minimum-sized set of chains covering all vertices of a DAG $G = (V, E)$ is a well known poly-time solvable problem [15, 18], with many applications in widespread research fields such as bioinformatics [34, 7, 13, 4, 8, 32]. Here we call such an object a *minimum chain cover* (an MCC) $\mathcal{C}$ containing k chains $\mathcal{C} = \{C_1, \ldots, C_k\}$, which are paths in the transitive closure of G. The *size* k of an MCC is known as the *width* of G and equals the maximum number of pairwise unreachable vertices (antichain) of G, by Dilworth's theorem [15] on partially ordered sets (posets).

The history of MCC. It was Fulkerson [18] in the 1950s the first to show a poly-time algorithm for posets (transitive DAGs). His algorithm reduces the problem to finding a maximum matching in a bipartite graph with $2|V|$ vertices and $|E|$ edges, and thus can be

solved in $O(|E|\sqrt{|V|})$ time by using the Hopcroft-Karp algorithm [21][1]. Improvements on these ideas were derived in the $O(|V|^2 + k\sqrt{k}|V|)$ and $O(\sqrt{|V|}|E| + k\sqrt{k}|V|)$ time algorithms of Chen and Chen [10, 11], and the $O(k|V|^2)$ time algorithm of Felsner et al. [17]. In the same article, Felsner et al. showed a combinatorial approach to compute a *maximum antichain* (MA) in near-linear time for the cases $k = 2, 3, 4$, which was latter generalized to $O(f(k)(|V| + |E|))$ [5], $f(k)$ being an exponential function. State-of-the-art approaches improve exponentially on its running time dependency on k. These approaches solve the strongly related problem of *minimum path cover* (MPC). An MPC $\mathcal{P}$ is a minimum-sized set of *paths* covering the vertices of G, and thus it is also a valid chain cover. Moreover, since every MCC can be transformed into an MPC (by connecting consecutive vertices in the chains), the *size* of an MPC also equals the width k.

The state-of-the-art for MCC. Mäkinen et al. [29] provided an algorithm for MPC, running in time $O(k(|V| + |E|) \log |V|) = \widetilde{O}(k(|V| + |E|))$ while Cáceres et al. [6] presented the first $O(k^2|V| + |E|)$ parameterized linear time algorithm. Both algorithms are based on a classical reduction to *minimum flow* [30], which we will revisit later. In the same work, Cáceres et al. [6] showed how to compute an MPC in time $O(T_{MF}(|E|) + ||\mathcal{P}||)$ and a MA in time $O(T_{MF}(|E|))$, where $T_{MF}(|E|)$ is the running time for solving *maximum flow* (MF) and $||\mathcal{P}||$ is the total length of the reported MPC. As such, by using the recent result for MF of Chen et al. [9] we can solve MPC and MA in (almost) optimal (input+output size) time. However, the same does not apply to MCC as the total length of an MCC can be exactly $|V|$ (e.g. by removing repeated vertices) while the total length of an MPC can be $\Omega(k|V|)$ in the worst case, as shown in Figure 1.

The $k|V|$ barrier was recently overcame by Kogan and Parter [26, 27] by reducing the total length of an MPC. They obtain this improvement by using *reachability shortcuts* and by devising a more involved reduction to *minimum cost flow* (MCF). Their algorithms run in time $\widetilde{O}(|E| + |V|^{3/2})$ [26] and $\widetilde{O}(\sqrt{k}|V| + |E|^{1+o(1)})$ [27] using the MCF algorithms of Bran et al. [35] and Chen et al. [9], respectively.

In this paper we present an algorithm for MCC improving its running time dependency on k exponentially w.r.t. the state-of-the-art.

▶ **Theorem 1.** *Given a k-width DAG $G = (V, E)$ we can compute a minimum chain cover in time $O(T_{MF}(|E|) + (|V| + |E|) \log k)$, where $T_{MF}(|E|)$ is the time for solving maximum flow.*

Thus by applying the flow algorithm of Chen et al. [9] we solve the problem in almost-linear time for the first time.

▶ **Corollary 2.** *Given a k-width DAG $G = (V, E)$ we can compute a minimum chain cover in time $O(|E|^{1+o(1)})$ w.h.p.*

Moreover, our solution in Theorem 1 uses a MF solver as a black box and it is deterministic otherwise. Therefore, we provide a deterministic MCC solution in *near-linear time* if one is found for MF. At the core of our solution we use mergeable dictionaries boosted with the SIZE-SPLIT operation to efficiently transform the flow outputted by the MF solver into an MCC. *Mergeable dictionaries* is a data structure maintaining a dynamic partition $\mathcal{K}$ of the natural numbers $\{1, \ldots, k\}$ (the reuse of k is intentional as this is how our approach will use the data structure), starting from the partition $\mathcal{K} = \{\{1, \ldots, k\}\}$ and supporting the following operations, for $K, K_1, K_2 \in \mathcal{K}$:

[1] Recent fast solutions for maximum matching do not speed up this approach as one needs to compute the transitive closure of the DAG first.

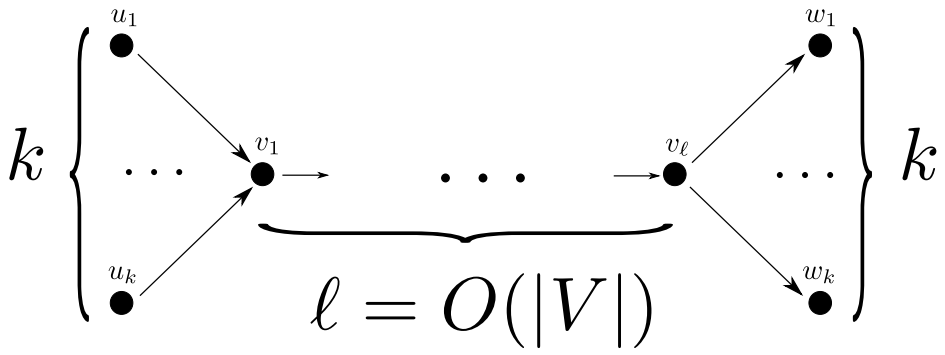

Figure 1 Example k-width DAG where every MPC $\mathcal{P}$ has total length $||\mathcal{P}|| = \Omega(k|V|)$. Indeed, every path in an MPC must start from some u_i and traverse the middle path $v_1, \ldots, v_\ell$ until reaching some w_j, since otherwise it is not possible to cover the rest of the graph minimally. Moreover, if $k = \ell = |V|/3$, then $||\mathcal{P}|| = \Omega(|V|^2)$. On the other hand, there is always an MCC $\mathcal{C}$ of total size $||\mathcal{C}|| = |V|$ (in this case only one of the chains cover the vertices of the middle path).

- SEARCH(K, j): returns $\max_{i \in K, i \leq j} i$ if any such element exists[2].
- MERGE(K_1, K_2): replaces K_1 and K_2 by $K_1 \cup K_2$ in $\mathcal{K}$.
- SPLIT(K, j): replaces K by $K' = \{i \in K \mid i \leq j\}$ (only if $K' \neq \emptyset$) and $K \setminus K'$ (only if $K \neq K'$) in $\mathcal{K}$.

Note that the MERGE operation does not assume that $\max_{i \in K_1} i < \min_{i \in K_2} i$ (sets are non-overlapping) as generated by the SPLIT operation. If the previous condition (or the analogous $\max_{i \in K_2} i < \min_{i \in K_1} i$) is assumed, the operation is known as JOIN. Mergeable dictionaries have applications in Lempel-Ziv decompression [16, 3, 31], mergeable trees [19] and generalizations of union-find-split [28]. In this paper we show how to modify them to obtain a fast MCC algorithm. Next, we review the different approaches used to implement mergeable dictionaries in the literature.

Mergeable dictionaries. The first efficient implementation of mergeable dictionaries can be derived[3] from the *segment merge* strategy proposed by Farach and Thorup [16] to efficiently MERGE two self-balanced binary search trees, assuming that operations SEARCH, SPLIT and JOIN are implemented in logarithmic time. The authors showed how to implement the MERGE operation by minimally SPLITing both sets into non-overlapping sets and pairwise JOINing the resulting parts. They proved that after $|V|+|E|$ operations (the abuse of notation is again intentional) their strategy works in $O(\log k \cdot \log(|V| + |E|))$ amortized time per operation. Later, Iacono and Özkan [22] presented a mergeable dictionaries implementation running in $O(\log k)$ amortized time per operation, based on biased skip lists [1]. The same amortized running time was later achieved by Karczmarz [24] with a very simple approach using tries [14] to represent the sets.

[2] This query is also known as *predecessor* query in the literature.
[3] The authors of [16] do not define mergeable dictionaries formally.

Our algorithm for MCC computes a minimum flow f^* encoding an MPC and then extracts an MCC from f^* by processing G in topological order and querying mergeable dictionaries boosted with the SIZE-SPLIT operation. Formally, we require the following operations, for $K, K_1, K_2 \in \mathcal{K}, s \in \{1, \ldots, |K| - 1\}$:

- SOME(K): returns some element $i \in K$.
- MERGE(K_1, K_2): replaces K_1 and K_2 by $K_1 \cup K_2$ in $\mathcal{K}$.
- SIZE-SPLIT(K, s): replaces K by $K' \subseteq K, |K'| = s$ and $K \setminus K'$ in $\mathcal{K}$.

In Section 3 we show how to implement these operations in $O(\log k)$ amortized time each. Then, in Section 4 we show our MCC algorithm using the previously described data structure. Besides the theoretical improvement already explained, we highlight the simplicity of our solutions, both in our proposal for boosted mergeable dictionaries as well as in our algorithm for MCC.

2 Notation and preliminaries

Graphs. For a vertex $v \in V$ we denote $N^-(v)$ ($N^+(v)$) to be the set of *in(out)-neighbors* of v that is $N^-(v) = \{u \in V \mid (u, v) \in E\}$ ($N^+(v) = \{w \in V \mid (v, w) \in E\}$). A v_1v_ℓ-path is a sequence of vertices $P = v_1, \ldots, v_\ell$ such that $(v_i, v_{i+1}) \in E$ for $i \in \{1, \ldots, \ell - 1\}$, in this case we say that v_1 *reaches* v_ℓ. We say that P is *proper* if $\ell \geq 2$ and that P is a cycle if $v_1 = v_\ell$. A *directed acyclic graph* (DAG) is a graph without proper cycles. In a DAG we can compute, in linear time [23, 33], a *topological order* $v_1, \ldots, v_{|V|}$ of its vertices such that for every $i < j$, $(v_j, v_i) \notin E$. In this paper we assume that G is a DAG and since our algorithms run in time $\Omega(|V| + |E|)$, we assume that an input *topological order* is given. A chain is a sequence of vertices $C = v_1, \ldots, v_{\ell'}$ such that for each $i \in \{1, \ldots, \ell' - 1\}$ v_i reaches v_{i+1}. We denote $|C| = \ell'$ to the length of the chain. A *chain cover* $\mathcal{C}$ is a set of chains such that every vertex appears in some chain of $\mathcal{C}$. We say that it is a *chain decomposition* if every vertex appears in exactly one chain of $\mathcal{C}$ and a *path cover* if every chain of $\mathcal{C}$ is a path, in this case we denote it $\mathcal{P}$ instead. We denote $||\mathcal{C}||$ to the total length of a chain cover that is $||\mathcal{C}|| = \sum_{C \in \mathcal{C}} |C|$. An antichain is a subset of vertices $A \subseteq V$ such that for $u, v \in A, u \neq v$, u does not reach v. The minimum size of a chain cover is known as the *width* of G and we denote it k.

Flows. Given a function of *demands* $d : E \to \mathbb{N}_0$ and $s, t \in V$, an *st-flow* is a function $f : E \to \mathbb{N}_0$ satisfying *flow conservation* that is $inFlow_v := \sum_{u \in N^-(v)} f(u, v) = \sum_{w \in N^+(v)} f(v, w) := outFlow_v$ for each $v \in V \setminus \{s, t\}$, and *satisfying the demands* that is $f(e) \geq d(e)$ for each $e \in E$. A *flow decomposition* of k (the reuse of notation is again intentional) paths of f is a collection $\mathcal{D} = P_1, \ldots, P_k$ of st-paths such that for each edge $e \in E$, $f(e) = |\{P_i \in \mathcal{D} \mid e \in P_i\}|$.[4] The *size* $|f|$ of f is defined as the net flow entering t (equivalently exiting s by flow conservation) that is $|f| = inFlow_t - outFlow_t$. The problem of *minimum flow* looks for a feasible st-flow of minimum size. Finding an MPC can be reduced to decompose a specific minimum flow [30], we will revisit this reduction in Section 4. The same techniques applied for the problem of *maximum flow* can be used in the context of the minimum flow problem [12, 2]. In fact, for MPC one can directly apply a maximum flow algorithm with *capacities* at most $|V|$ [6, Theorem 2.2 (full version)].

[4] This is a simplified definition of flow decomposition which suffices for our purposes.

Data structures. A *self-balancing binary search tree* such as an AVL-tree or a red-black tree [20] is a binary search tree supporting operations SEARCH, SPLIT and JOIN in logarithmic time each (in the worst case). A (binary) *trie* [14] is a binary tree representing a set of integers by storing their *binary representation* as *root-to-leaf* paths of the trie. In our tries all root-to-leaf paths have the same length $\lfloor \log k \rfloor + 1$. For a data structure supporting a set of operations, and a potential function ϕ capturing the state of the data structure, we say that the *amortized* time of an operation equals to its (worst-case) running time plus the change $\Delta\phi$ in the potential triggered by the operation. If we apply a sequence of $O(|V| + |E|)$ operations whose amortized time is $O(\log k)$ the total (worst-case) running time is $O((|V| + |E|) \log k)$.

3 Mergeable dictionaries with SIZE-SPLIT

We show how to implement the *boosted* mergeable dictionaries supporting operations SOME, MERGE and SIZE-SPLIT in $O(\log k)$ amortized time each. To achieve this result we modify an existing solution of mergeable dictionaries implementing operations SEARCH, MERGE and SPLIT by adding the SELECT operation. Formally for $K \in \mathcal{K}, s \in 1, \ldots, |K|$,

- SELECT(K, s): returns the s-th smallest element in K.

With the SELECT operation we can use (normal) mergeable dictionaries to implement SOME and SIZE-SPLIT as follows:

- SOME$(K) \leftarrow$ SEARCH(K, k).
- SIZE-SPLIT$(K, s) \leftarrow$ SPLIT$(K$,SELECT$(K, s))$.

While for SOME it suffices to do a SEARCH with a known upper bound (recall that k is the maximum element in the universe considered), in the case of SIZE-SPLIT we can first SELECT the corresponding pivot and use this pivot to SPLIT the set by its value, obtaining the desired sizes for the split.

This reduction allows us to obtain the boosted mergeable dictionaries by simply implementing the SELECT operation with logarithmic amortized cost (SIZE-SPLIT can be seen as one call to SELECT followed by a separate call to SPLIT). Moreover, if the implementation of SELECT does not modify the data structure (and thus the potential ϕ), its amortized time equals its (worst-case) running time (as ϕ does not change). We show that this is indeed the case in both the segment merge strategy of Farach and Thorup [16], and the trie implementation of Karczmarz [24], the latter achieving the desired running time.

The mergeable dictionaries based on segment merge represent each set as a self-balancing binary search tree. As such, the SELECT operation can be implemented in $O(\log k)$ time by storing the sub-tree sizes at every node of the tree, which can be maintained (updated when the tree changes) in the same (worst-case) running time as the normal operations of the tree (see e.g. [25]).

Similarly, the implementation of Karczmarz [24] represents every set as a trie of its elements. As discussed in Section 2, a trie stores its elements as their binary representation encoded as (equal length) root-to-leaf paths of the trie. For example, if $k = 6$ the corresponding binary representation of 3 is 011, which is represented as the root-to-leaf path following the left child, then its right child and then its right child. Analogous to binary search trees, the nodes of a trie can be augmented to store the number of leaves in their respective sub-trees. If such augmentation of a trie is performed, then the operation SELECT can be implemented in $O(\log k)$ (worst-case) time similar to the implementation on binary search trees, since the leaves in the trie follow the same order as the elements they represent:

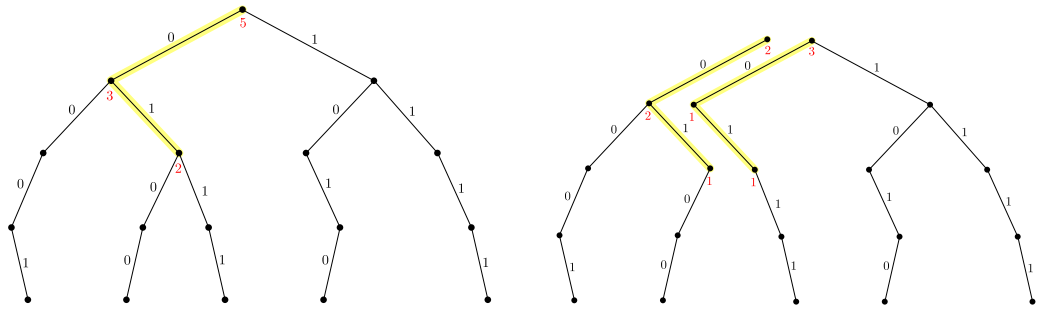

Figure 2 Result of calling SIZE-SPLIT($K = \{1, 4, 7, 10, 15\}, 2$) on a trie representation of boosted mergeable dictionaries. The binary representation of numbers in the set are spelled as root-to-leaf paths of the trie. Some number of leaves' counters are written in red under their respective nodes. Those counters are used to answer $4 \leftarrow \text{SELECT}(K, 2)$. After this, $\text{SPLIT}(K, 4)$ is performed. The path P representing the longest prefix (01) between the binary representations of 4 (0100) and 7 (0111) is highlighted in yellow. The right figure shows the end result, note that only the counters in the nodes of P change.

for a query SELECT(s) on a trie node, it suffices to look at the number of leaves l (elements) under the left child, if $l \geq s$ we continue to the left child answering SELECT(s), otherwise we continue to the right child answering SELECT($s - l$).

Karczmarz [24] showed that SPLIT(K, j) can be performed by finding the root-to-node path P corresponding to the longest common prefix between the binary representations of SEARCH(K, j) and of the smallest value greater than j in K. It then splits the trie by removing the right children of the nodes of P (to form K') and then joining those nodes as right children of a copy of P (to create $K \setminus K'$). Note that this procedure can be easily augmented to maintain the number of leaves under each node: only the nodes in P (and in its copy) decrease their value by the number of leaves of their lost children. Figure 2 shows an example of the SPLIT operation. MERGE(K_1, K_2) is implemented as a simple recursive algorithm that at every step keeps one of the (common) nodes and then merges the corresponding left and right sub-trees (if one of those sub-trees is empty then it just keeps the other sub-tree, we refer to the original work [24] for details). In this case the maintenance of the number of leaves can be performed when returning from the recursive calls: simply recompute the number of leaves as the sum of the number of leaves of their two children. Each of these computations is a constant time operation, and thus they do not change the asymptotic running time of MERGE. We then obtain the following lemma.

▶ **Lemma 3.** *There exists a data structure maintaining a dynamic partition $\mathcal{K}$ of $\{1, \ldots, k\}$ starting from $\mathcal{K} = \{\{1, \ldots, k\}\}$ and answering operations SOME, MERGE and SIZE-SPLIT such that for a sequence of $n = \Omega(k)$ operations[5] it answers in total $O(n \log k)$ time.*

Proof. We first note that operations SOME, MERGE and SIZE-SPLIT can be implemented in the same asymptotic (worst-case) running time as operations SEARCH, MERGE and SPLIT in the data structure of Karczmarz [24], respectively. Indeed, as previously discussed, SOME is implemented as one call to SEARCH, MERGE is implemented in the same way as in [24] but taking care of the number-of-leaves counters' updates which does not affect the asymptotic running time, and SIZE-SPLIT is implemented as one call to SELECT (in

[5] This requirement comes from the fact that mergeable dictionaries actually start from an empty collection of sets, however, one can create the singleton sets and merge then in total $O(k \log k)$ time.

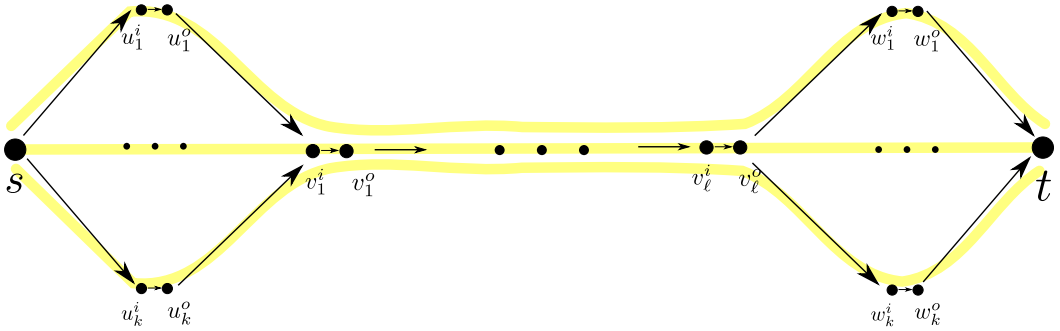

Figure 3 Flow reduction (demands are not shown) of the graph of Figure 1 and a minimum flow on it. Only edges with positive flow are shown. The flow is implicitly presented as a flow decomposition showing every path highlighted in yellow, this flow decomposition corresponds to an MPC of the original DAG.

$O(\log k)$ time) followed by one call to SPLIT (also in $O(\log k)$ time). For the amortized analysis we reuse the potential function used by Karczmarz [24], namely, the number of nodes on all tries. Operations SOME and MERGE follow the same potential change as in [24] and thus have an $O(\log k)$ amortized running time. Finally, since SELECT does not change the total number of nodes (nor any of the tries) the potential change of a SIZE-SPLIT is the same as the one of a SPLIT, that is $O(\log k)$ as in [24]. The lemma follows by using the amortized running times of the data structure's operations. ◀

4 An almost linear time algorithm for MCC

We show how to use Lemma 3 to obtain a fast MCC algorithm. Our algorithm computes a minimum flow f^* encoding an MPC of G and then uses the data structure from Lemma 3 to efficiently extract an MCC from f^*. Next, we describe the well known [30] reduction from MPC to MF by following the notation of [6, Section 2.3 (full version)].

Given the DAG G we build its *flow reduction* $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ as the graph obtained by adding a global source s, a global sink t and splitting every vertex $v \in V$ into two copies connected by an edge. Additionally, the first copy, v^i, is connected from the in-neighbors of v and the second copy, v^o, is connected to the out-neighbors of v. Formally, $\mathcal{V} = \{s, t\} \cup \{v^i \mid v \in V\} \cup \{v^o \mid v \in V\}$, and $\mathcal{E} = \{(s, v^i) \mid v \in V\} \cup \{(v^o, t) \mid v \in V\} \cup \{(v^i, v^o) \mid v \in V\} \cup \{(u^o, v^i) \mid (u, v) \in E\}$. Note that $|\mathcal{E}| = O(|V| + |E|)$, and that $\mathcal{G}$ is also a DAG. We also define demands on the edges, $d : \mathcal{E} :\to \mathbb{N}_0$, as 1 if the edge is of the form (v^i, v^o), and 0 otherwise. Intuitively, the demands *require* that at least one unit of flow goes through every vertex (of G), which directly translates into to the path cover condition of covering each vertex with at least one path. In fact, every flow decomposition (recall Section 2) of a feasible st-flow f of $\mathcal{G}, d$ corresponds to a path cover of G of size $|f|$. Moreover, every decomposition of a minimum flow f^* of $\mathcal{G}, d$ corresponds to an MPC of G, and thus $k = |f^*|$ [6, Section 2.3 (full version)]. Figure 3 illustrates these ideas with an example.

Since every vertex cannot belong to more than $|V|$ paths in an MPC, the problem can be reduced to maximum flow [2, Theorem 3.9.1]. We summarize these results in the following lemma.

Algorithm 1 Non-optimized pseudocode for our MCC algorithm. A naive implementation of this algorithm obtains an $O(||\mathcal{P}||)$ running time as explained in this manuscript.

Input: A directed acyclic graph $G = (V, E)$.
Output: A minimum chain decomposition $\mathcal{C} = C_1, \ldots, C_k$ of G.

```
(G, d) ← Build the flow reduction of G detailed in Section 4
f*, k = |f*| ← Use Lemma 4 to obtain a minimum flow of (G, d)
Initialize C_i as an empty list for i ∈ {1, ..., k}
I_s ← {1, ..., k}
for v ∈ V in topological order do
    I_v ← Take f*(s, v^i) elements from I_s
    for u^o ∈ N^-(v^i) do
        I_uv ← Take f*(u^o, v^i) elements from I_u
        I_v ← I_v ∪ I_uv
    i ← Choose an element from I_v
    C_i.append(v)
return C_1, ..., C_k
```

▶ **Lemma 4** (Adaptation of [6, Theorem 2.2 (full version)]). *We can compute a flow f^* of $\mathcal{G}, d$ such that every flow decomposition of f^* corresponds to an MPC of G, in time $O(T_{MF}(|E|))$, where $T_{MF}(|E|)$ is the time for solving maximum flow.*

A decomposition algorithm is simple in this case: start from s and follow a path P of positive flow edges until arriving at t, and then update f^* decreasing the flow on the edges of P by one. Repeat this process until no flow remains. The st-paths obtained during the decomposition can be easily transformed into an MPC $\mathcal{P}$ of G (trim s and t and replace v^i, v^o by v on each path, see e.g. [27]).

If implemented carefully (see e.g. [26, Lemma 1.11 (full version)]), the previous algorithm runs in time $O(||\mathcal{P}||)$ and it outputs a valid MCC $\mathcal{P}$ (recall that every MPC is an MCC). However, as shown in Figure 1, $||\mathcal{P}||$ can be $\Omega(k|V|)$ in the worst case. Our algorithm overcomes this barrier by instead directly extracting (from f^*) a minimum chain decomposition (MCD, recall Section 2) and thus its total length is exactly $|V|$.

The main idea to extract an MCD $\mathcal{C} = C_1, \ldots, C_k$ from f^* is to compute, for each vertex $v \in \mathcal{V}$, the set $I_v \subseteq \{1, \ldots, k\}$ of indices such that v would belong to paths $\mathcal{P}_v = \{P_i \mid i \in I_v\}$ in a flow decomposition $\mathcal{D} = P_1, \ldots, P_k$ of f^*. Note that $I_s = I_t = \{1, \ldots, k\}$ by construction of $\mathcal{G}, d$. To efficiently compute these sets, we process the vertices in a topological order of $\mathcal{G}$, for example $s, v_1^i, v_1^o, \ldots, v_{|V|}^i, v_{|V|}^o, t$ (recall that a topological order $v_1, \ldots, v_{|V|}$ of G is assumed as input). When processing vertex v we compute I_v as follows: for every $u \in N^-(v)$ we *take* (exactly) $f^*(u, v)$ elements from I_u, let us denote I_{uv} to these elements. Then, we compute I_v as the *union* $\bigcup_{u \in N^-(v)} I_{uv}$. And finally, we *take an arbitrary element* $i \in I_v$ and append v to C_i. Algorithm 1 shows a pseudocode for this algorithm.

Note that vertices are added to their respective chains in the correct order since they are processed in topological order.

Moreover, since indices are moved from one vertex to the other only if there is an edge between them, consecutive vertices are always connected by a path in G, and thus the lists C_i correspond to proper chains. Finally, adding each vertex to only one such chain ensures that the end result is indeed an MCD (every vertex in exactly one chain).

An important aspect of the algorithm is that exactly $f^*(u^i, v^i)$ ($f^*(s, v^i)$) elements are *taken out* of I_u (I_s). This step is always possible thanks to flow conservation of f^*.

Algorithm 2 Our MCC algorithm running in time $O(T_{MF}(|E|) + (|V| + |E|) \log k)$, where $T_{MF}(|E|)$ is the time for solving maximum flow. The algorithm uses the boosted mergeable dictionaries from Section 3.

Input: A directed acyclic graph $G = (V, E)$.
Output: A minimum chain decomposition $\mathcal{C} = C_1, \ldots, C_k$ of G.

```
(G, d) ← Build the flow reduction of G detailed in Section 4
f*, k = |f*| ← Use Lemma 4 to obtain a minimum flow of (G, d)
Initialize C_i as an empty list for i ∈ {1, ..., k}
Initialize mergeable dictionaries maintaining a partition of {1, ..., k}
I_s ← {1, ..., k}
for v ∈ V in topological order do
    I_v, I_s ← SIZE-SPLIT(I_s, f*(s, v^i))
    for u^o ∈ N^-(v^i) do
        I_uv, I_u ← SIZE-SPLIT(I_u, f*(u^o, v^i))
        I_v ← MERGE(I_v, I_uv)
    i ← SOME(I_v)
    C_i.append(v)
return C_1, ..., C_k
```

▶ **Lemma 5.** *Given a k-width DAG $G = (V, E)$ as input, Algorithm 1 computes a minimum chain decomposition $\mathcal{C} = C_1, \ldots, C_k$ of G.*

Proof. By Lemma 4, every flow decomposition of f^* corresponds to an MPC of G. We prove that each C_i is a chain of V, since every vertex is added to exactly one C_i we conclude that $\mathcal{C} = C_1, \ldots, C_k$ is a minimum chain decomposition. Inductively, if v is added after v' in chain C_i, then v' reaches v in G. Indeed, $i \in I_v$ and in particular $i \in I_u$ for some $u \in N^-(v)$, and inductively v' reaches u in G and thus also reaches v. ◀

Moreover, since only splits and unions are performed, the sets I_v's and I_{uv}'s form a partition of $\{1, \ldots, k\}$ at any point during the algorithm's execution.

A simple implementation of sets I_v's and I_{uv}'s as linked lists, allows us to perform the unions and element picks in constant time, but the splits in $O(f^*(u^o, v^i))$ (and $O(f^*(s, v^i))$) time each, and thus in $O\left(\sum_{v \in V} \left(f^*(s, v^i) + f^*(v^o, t)\right) + \sum_{(u,v) \in E} f^*(u^o, v^i)\right) = O(||\mathcal{P}||)$ time in total. However, we can implement the sets I_v's and I_{uv}'s as boosted mergeable dictionaries from Section 3 to speed up the total running time. Algorithm 2 shows the final result.

▶ **Theorem 1.** *Given a k-width DAG $G = (V, E)$ we can compute a minimum chain cover in time $O(T_{MF}(|E|) + (|V| + |E|) \log k)$, where $T_{MF}(|E|)$ is the time for solving maximum flow.*

Proof. The correctness of the algorithm follows from the previous discussion and Lemma 5 since Algorithm 2 is an implementation of Algorithm 1. Building the flow reduction takes $O(|V| + |E|)$ time and obtaining the minimum flow f^* takes $O(T_{MF}(|E|))$ time by Lemma 4. The rest of the running time is derived from the calls to the mergeable dictionaries' operations. SOME is called $O(|V|)$ times while SIZE-SPLIT and MERGE are called once per edge in the flow reduction that is $O(|\mathcal{E}|) = O(|V| + |E|)$ times. By applying Lemma 3 the total time of the $O(|V| + |E|)$ operation calls is $O((|V| + |E|) \log k)$. ◀

We finish our paper by encapsulating our result into a tool that can be used to efficiently extract a set of vertex-disjoint chains $\mathcal{C}$, encoding a set of paths $\mathcal{P}$, from a flow f that encodes $\mathcal{P}$ as a flow decomposition. If the problem can be modeled as a maximum flow/minimum cost flow problem, the result of Chen et al. [9] allows us to solve such problems in almost linear time. As a simple example, we could solve the ℓ-cover problem (find a set of ℓ vertex-disjoint chains covering the most vertices) in almost linear time.

▶ **Corollary 6.** *Let $G = (V, E)$ be a DAG, and $f : E \to \mathbb{N}_0$ a flow encoding a set of $|f|$ paths $\mathcal{P}$ of G as a flow decomposition into weight-1 paths. In $O((|V| + |E|) \log |f|)$ time, we can compute a set of $|f|$ vertex-disjoint chains $\mathcal{C}$ of G, which can (alternatively) be obtained by removing repeated vertices from $\mathcal{P}$.*

Abstract

Estimating the ground state energy of a local Hamiltonian is a central problem in quantum chemistry. In order to further investigate its complexity and the potential of quantum algorithms for quantum chemistry, Gharibian and Le Gall (STOC 2022) recently introduced the *guided local Hamiltonian problem (GLH)*, which is a variant of the local Hamiltonian problem where an approximation of a ground state (which is called a guiding state) is given as an additional input. Gharibian and Le Gall showed quantum advantage (more precisely, BQP-completeness) for GLH with 6-local Hamiltonians when the guiding state has fidelity (inverse-polynomially) close to 1/2 with a ground state.

In this paper, we optimally improve both the locality and the fidelity parameter: we show that the BQP-completeness persists even with 2-local Hamiltonians, and even when the guiding state has fidelity (inverse-polynomially) close to 1 with a ground state. Moreover, we show that the BQP-completeness also holds for 2-local physically motivated Hamiltonians on a 2D square lattice or a 2D triangular lattice. Beyond the hardness of estimating the ground state energy, we also show BQP-hardness persists when considering estimating energies of *excited* states of these Hamiltonians instead. Those make further steps towards establishing *practical quantum advantage* in quantum chemistry.

1 Introduction

Simulation of physical systems is one of the originally envisioned applications of quantum computing [12, 13]. Quantum chemistry, in particular, has seen much activity on this front in recent years, e.g. [1, 4, 5, 24, 29, 31]. There, a central goal is to estimate the ground state energy of a given k-local Hamiltonian H, denoted the *k-local Hamiltonian problem (k-LH)*. Roughly, for this problem, a k-local Hamiltonian $H = \sum_i H_i$ on n qubits is a $2^n \times 2^n$ Hermitian matrix, specified succinctly via "local quantum clauses" H_i acting on $k \in O(1)$ qubits each. The eigenvalues of H are the discrete energy levels of the corresponding quantum system. In particular, the smallest eigenvalue, which we denote $\lambda_0(H)$, is called the ground state energy. An eigenvector corresponding to $\lambda_0(H)$ is called a ground state, and describes a state of the quantum system in the energy configuration $\lambda_0(H)$. Note that k-LH strictly generalizes classical k-SAT, in that any instance of the latter can be embedded into the former.

Unfortunately, it is nowadays well-known that estimating ground state energies of local Hamiltonians is QMA-complete [23]. This hardness persists, moreover, even in the bosonic [32] and fermionic settings [30]. Thus, assuming BQP $\neq$ QMA, one cannot hope for an efficient algorithm for k-LH on *all* k-local Hamiltonians.

What actually happens in practice

In an attempt to bypass worst-case hardness results, in practice the quantum chemistry community often adopts the following two-step procedure:

- (Step 1: Ground state approximation) A classical heuristic algorithm is applied to obtain a "guiding state" $|\psi\rangle$, which is hoped to have "good" fidelity with a ground state.
- (Step 2: Ground state energy approximation) The guiding state $|\psi\rangle$ is used in Quantum Phase Estimation (QPE) [22] to efficiently compute the corresponding ground state energy [2, 4]. (A more recent approach is based on variational quantum algorithms, aimed more at near-term hardware (see [9] for a survey), but which is heuristic in nature (unlike QPE).)

Two comments: (1) There is something special about Step 2 – it is a unique strength of quantum computers to be able to resolve an eigenvalue (within additive $1/\mathrm{poly}(n)$ precision) of a (sparse) Hermitian matrix given just an *approximation* $|\psi\rangle$ to the corresponding eigenvector (via QPE)![1] Indeed, the closely related task of (sparse) matrix inversion, which can be solved efficiently on a quantum computer coherently by diagonalizing the matrix and "manually" inverting its eigenvalues via postselection, is BQP-complete [19]. (2) In general, one does *not* expect a good[2] guiding state for arbitrary local Hamiltonian H to exist, as this would imply QCMA = QMA. And even if such a guiding state *did* exist, finding it can still be hard. For example, minimizing $\mathrm{tr}(H\rho)$ over the "simplest" quantum ansatz of tensor product states, i.e. $\rho = \rho_1 \otimes \rho_2 \otimes \cdots \otimes \rho_n$ for $\rho_i \in \mathcal{L}(\mathbb{C}^2)$, remains NP-hard (seen by letting H be a diagonal Hamiltonian encoding a classical 3-SAT instance).

---

[1] Actually, quantum computers can efficiently prepare a ground state with fidelity $1-1/\exp(n)$ given access to a guiding state $|u\rangle$ that has inverse polynomial fidelity with a ground state $|g\rangle$ (i.e. $|\langle u|g\rangle| \geq 1/\mathrm{poly}(n)$) using quantum amplitude amplification for local Hamiltonians that have inverse-polynomial spectral gaps [26].

[2] "Good" here meaning a state $|\psi\rangle$ with inverse polynomial fidelity with a ground state, and with a succinct classical description allowing $|\psi\rangle$ to be prepared efficiently.

Directions for study

With Steps 1 and 2 above in mind, in order to practically obtain a quantum advantage for quantum chemistry problems, there are two branches of study necessary:

- (Step 1: Ground state approximation) Here, the best one can hope for is fast algorithms tailored to physically motivated *special cases* of Hamiltonians H (either heuristic or worst-case poly-time complexity). This is arguably the bottleneck for fast quantum algorithms outperforming classical techniques [25].
- (Step 2: Ground state energy approximation) A thorough complexity theoretic understanding of which Hamiltonian families provably permit quantum computers to outperform classical ones, assuming a good guiding state has been found (in Step 1).

In [15], the formal study of the second step above was initiated. Specifically, the *Guided k-local Hamiltonian problem (k-GLH)* was introduced, which is stated roughly as follows (formally given in Definition 6): Given a k-local Hamiltonian H, an appropriate "representation" of a guiding state $|\psi\rangle$ with δ-fidelity with the ground space of H, and real thresholds $\beta > \alpha$, estimate the ground state energy of H. Then, two results were shown:

- For any constant k, k-GLH can be efficiently solved *classically* within *constant* precision, i.e. for $\beta - \alpha \in \Theta(1)$ and $\delta \in \Theta(1)$.
- In contrast, 6-GLH is BQP-hard for *inverse polynomial* precision, i.e. $\beta - \alpha \geq 1/\text{poly}(n)$, and $\delta = 1/\sqrt{2} - 1/\text{poly}(n)$.

The latter regime of inverse-polynomial precision turns out to be the relevant one for solving quantum chemistry problems in practice – the desired "chemical accuracy" is about 1.6 millihartree (which is constant relative to an unnormalized Hamiltonian), which upon renormalization of the Hamiltonian (as done here) yields the claimed inverse polynomial precision. This BQP-hardness result thus gives theoretical evidence for the superiority of quantum algorithms for chemistry.

Four important problems were left open in [15]: Is k-GLH still BQP-hard with larger δ, and in particular for δ arbitrarily close to 1? Is k-GLH still BQP-hard for $k < 6$? Is k-GLH still BQP-hard for estimating the excited state energies? Is k-GLH still BQP-hard for physically motivated Hamiltonians?

This work

In this work, we continue the agenda toward Step 2 above by resolving these four open questions. Here are our main contributions:

- First, we show that BQP-hardness continues to hold even for $\delta = 1 - 1/\text{poly}(n)$, i.e. even when we are promised the guiding state $|\psi\rangle$ is a remarkably good approximation to the ground state.
- Second, we show that BQP-hardness continues to hold even for $k = 2$. (Note that for $k = 1$, the problem can be solved efficiently classically, even without a guiding state.)
- Third, we extend the BQP-hardness results to the case when one is interested in estimating energies of excited states, rather than just the groundstate. Interestingly, we are only able to show BQP-completeness in this setting by showing that the first point holds, i.e. the BQP-hardness in the regime $\delta \in [\frac{1}{2} + \Omega(1/poly(n)), 1 - \Omega(1/poly(n))]$.
- Fourth, we prove hardness results for *physically motivated* Hamiltonians. They include XY model (constraints of the form $XX + YY$), Heisenberg model (constraints of the form $XX + YY + ZZ$), the antiferromagnetic XY model and the antiferromagnetic Heisenberg model (i.e. "Quantum Max Cut" [16]). In contrast, the BQP-hardness construction of [15] is arguably artificial, because they used the circuit-to-Hamiltonian construction of [23] and query Hamiltonian construction of [3].

To formalize the third direction, we introduce the *Guided k-Local Hamiltonian Low Energy*-problem (k-GLHLE) in which the guiding state has δ-fidelity with the c'th excited state of H and the problem is to estimate the c'th excited state energy of H (for a formal definition, see Definition 6). Then, the four contributions above are summarized in the following theorem.

▶ **Theorem 1** (Main result). *For any $\delta \in (0, 1 - \Omega(1/\mathrm{poly}(n)))$, constant $k \geq 2$ and some integer $0 \leq c \leq \mathcal{O}(poly(n))$, there exist $a, b \in [-1, 1]$ with $b - a \in \Omega(1/\mathrm{poly}(n))$ such that k-GLHLE is* BQP*-hard. Moreover, it is still* BQP*-hard if the 2-local Hamiltonian is restricted to any of the following families of Hamiltonians:*

- *non-2SLD Hamiltonian on a 2D square lattice*
- *antiferromagnetic Heisenberg model*
- *antiferromagnetic XY model on a 2D triangular lattice.*

Here, the "non-2SLD" Hamiltonians are, roughly, 2-local Hamiltonians that cannot be diagonalized via single-qubit unitaries (see Definition 5 for the formal definition). (The term 2SLD is short for "the 2-local parts of all interactions in the set are simultaneously locally diagonalizable".) It was originally introduced in the Hamiltonian complexity classification of Cubitt and Montanaro [10]. The XY model and the Heisenberg model are examples of non-2SLD Hamiltonians.

Techniques

Now let us explain our technical contributions. Our first result is the improvement of the fidelity δ (Proposition 7 in Section 3). The construction of [15] cannot exceed $\delta = 1/2$, but we achieve the fidelity $\delta = 1 - 1/\mathrm{poly}(n)$. Let us explain why the construction of [15] cannot exceed the fidelity $\delta = 1/2$. Their construction for the BQP-hardness result is the following local Hamiltonian

$$H = \frac{\alpha + \beta}{2} I \otimes |0\rangle\langle 0| + H' \otimes |1\rangle\langle 1|,$$

where $\beta - \alpha > 1/\mathrm{poly}(n)$ and H' is a certain local Hamiltonian whose lowest eigenvalue is $\leq \alpha$ in the YES case and is $\geq \beta$ in the NO case. It is clear that a ground state of H is $|\psi\rangle \otimes |1\rangle$ in the YES case, where $|\psi\rangle$ is a ground state of H'. For the NO case, a ground state is $|0...0\rangle \otimes |0\rangle$. It can then be easily observed that the optimal guiding state (i.e. the guiding state that has the maximum fidelity with ground states *in both the YES and the NO cases*) is written as $|\phi\rangle \otimes |+\rangle$ for a certain choice of $|\phi\rangle$, which shows that the fidelity cannot exceed $1/2$ in this construction.

To overcome the problem, we use the perturbation theory approaches of [21, 7]. In particular, we use first-order perturbation theory, either using the general Schrieffer-Wolf transform framework of [7] or a more first-principles approach via the Projection Lemma. The main idea is to use a large energy penalty term to rule out all low-energy states which do not look like "history states". We then show that the corresponding guiding state can be chosen as the semi-classical subset state introduced in [15] (see Definition 2 in Section 2). To obtain this, we notice that the ground state of our Hamiltonian is gapped and unique. This is because we are doing a reduction from BQP (as opposed to QMA). In other words, there is no QMA "proof" to be plugged into the history state construction, and therefore there is a unique low-energy history state. In sum, via perturbation theory, we are able to *directly* approximate the ground state with a guiding state in *both* YES and NO cases, as opposed to the block encoding approach of [15], which used equally weighted orthogonal subspaces to *separately* encode the YES and NO cases, respectively.

Our second result is BQP-hardness of k-GLH for $k = 2$ (Propositions 9 in Section 3). Here, the universal simulation setup of [11, 33] cannot be directly applied, because although their results can approximately preserve the ground space of the input Hamiltonian, it was not known whether semi-classical subset states can be mapped to semi-classical subset states under such simulation frameworks, and the latter is essential for guiding states used in GLH. We show that this is indeed the case. In particular, we show that the original semi-classical subset state of the input 5-GLH instance is mapped to a state with polynomially many ancilla qubits in the low-energy subspace of the simulating 2-local Hamiltonian.

Our third result is the BQP-hardness for physically motivated 2-local Hamiltonians (Proposition 10 and Proposition 12). The main obstacle here is that ground states of physically motivated 2-local Hamiltonians are not known to be guided by semi-classical subset states. To solve the problem, we introduce another class of semi-classical states which we call *semi-classical encoded states* (see Definition 3 in Section 2). Intuitively, semi-classical encoded states are states constructed from semi-classical subset states by applying a local isometry on each qubit. Although semi-classical encoded states are more general than semi-classical subset states, they still allow succinct descriptions and efficient classical sampling algorithms (Lemma 4). For us, it is essential that semi-classical encoded states are closed under the applications of the local encoding of states during the perturbative simulations. We show that semi-classical encoded states indeed satisfy this property, and therefore can guide ground states of physically motivated 2-local Hamiltonians. The semi-classical encoded states newly introduced in this paper are of independent interest, and seem to have many other interesting applications.

Finally, our fourth result is to extend the k-GLH problem to the question of excited state energy estimation, we call this the *Guided k-Local Hamiltonian Low Energy* (k-GLHLE) problem. In Ref. [20], the authors show that determining the cth excited state energy of a k-local Hamiltonian ($k \geq 3$), where $c = \text{poly}(n)$, is QMA-complete – even if all the $c - 1$ energy eigenstates and corresponding energies are known. In their construction, they embed a k-local Hamiltonian H, encoding the QMA computation, in a Hamiltonian H' living on a larger Hilbert space. This allows them to add up to polynomial number of artificial eigenstates to H' below the groundstate of H. Finding the c'th eigenvalue of H' is then just as hard as finding the groundstate of H. We show that this construction translates to the setting with guiding states. As a bonus, we also show that the unguided problem is QMA-hard for $k = 2$, which was left open in [20].

Open questions

There are many open questions surrounding GLH, as well as the more general important goal of solving quantum chemistry problems on quantum computers. For example, we have shown BQP-hardness of GLH for physically motivated Hamiltonians such as those with Heisenberg interactions. An important next step would be to show BQP-hardness for the specific types of fermionic Hamiltonians which are currently being studied in the quantum chemistry literature. Another subtle but important point is that, technically, the level of precision required for GLH in quantum chemistry scales as $1/n$, while the hardness promise gap scales as $o(1/n)$ in [15] and the present paper. Can this be improved to $\Theta(1/n)$? A positive resolution to the quantum PCP conjecture would presumably, in turn, allows one to obtain hardness for gap $\Theta(1)$. Absent this, we are unaware of any circuit-to-Hamiltonian construction which is able to achieve $O(1/n)$ promise gap. Moreover, as mentioned earlier, the main bottleneck for quantum chemistry on quantum computers is the arduous task of *finding* a good guiding state (if it even exists!). Can good heuristics be designed for this?

Efforts to date suggest the answer so far is negative [25]. Finally, more interestingly (but more challengingly), can one show *rigorous* poly-time guiding-state computation algorithms for the specific families of Hamiltonians considered in the quantum chemistry literature?

2 Preliminaries

Notation

We denote by $[M]$ the set $\{1, \ldots, M\}$. We write $\lambda_i(A)$ to denote the ith eigenvalue of a Hermitian matrix A, ordered in non-decreasing order, with $\lambda_0(A)$ denoting the smallest eigenvalue (ground energy). We denote $\mathrm{eig}(A) = \{\lambda_0(A), \ldots, \lambda_{\dim(A)-1}(A)\}$ for the (ordered) set of all eigenvalues of A.

2.1 Semi-classical states

In this section, we formally introduce the guided local Hamiltonian problem. We first define two classes of semi-classical states. The term "semi-classical" is motivated by the requirement for such states that they should be efficiently described (as an input of the problem) and efficiently samplable.[3]

▶ **Definition 2** (Semi-classical subset state). *We say that a normalized state $|u\rangle \in \mathbb{C}^{2^n}$ is a semi-classical subset state if there is a subset $S \subseteq \{0,1\}^n$ with $|S| = \mathrm{poly}(n)$ such that*

$$|u\rangle = \frac{1}{\sqrt{|S|}} \sum_{x \in S} |x\rangle \,.$$

A semi-classical subset state can be efficiently described by the description of S. It is clear that we can efficiently sample from the probability distribution that outputs $x \in \{0,1\}^n$ with probability $|\langle x|u\rangle|^2$, i.e. according to the uniform distribution over S.

We next introduce a generalized version of a semi-classical subset state.

▶ **Definition 3** (Semi-classical encoded state). *We say that a normalized state $|u\rangle \in \mathbb{C}^{2^m}$, for $n < m \in \mathcal{O}(n)$, is a semi-classical encoded state if there is a subset $S \subseteq \{0,1\}^n$ with $|S| = \mathrm{poly}(n)$ and a set of isometries $V_1, V_2, ..., V_n$, where each of V_i maps a 1-qubit state to an $\mathcal{O}(1)$-qubit state, such that*

$$|u\rangle = \frac{1}{\sqrt{|S|}} \sum_{x \in S} V_1(|x_1\rangle) \otimes V_2(|x_2\rangle) \otimes \cdots \otimes V_n(|x_n\rangle).$$

A semi-classical encoded state is indeed a semi-classical subset state if the encoding is trivial (i.e. $V_1 = V_2 = \cdots = V_n = I$). A semi-classical encoded state can be described by the description of S and isometries $V_1, V_2 ..., V_n$. We can also efficiently sample from the semi-classical encoded state as we show in the following lemma.

▶ **Lemma 4.** *Given the description of an m-qubit semi-classical encoded state $|u\rangle$, we can classically efficiently sample from the probability distribution that outputs $x \in \{0,1\}^m$ with probability $|\langle x|u\rangle|^2$.*

[3] The requirement of sampling access for a guiding state is motivated by the existence of an efficient classical algorithm for the GLH problem with constant precision, given a guiding state with sampling access, as shown in [15]. One type of a semi-classical state we use in this paper is a polynomial-size variant of the notion of subset states, first introduced in [18].

Proof. Assume we are given the description, $S \subseteq \{0,1\}^n$ and $V_1, V_2, ..., V_n$, of the semi-classical encoded state

$$|u\rangle = \frac{1}{\sqrt{|S|}} \sum_{x \in S} V_1(|x_1\rangle) \otimes V_2(|x_2\rangle) \otimes \cdots \otimes V_n(|x_n\rangle).$$

Let $P(y_0, y_1, ..., y_{i-1}) = |(\langle y_0, y_1, ..., y_{i-1}| \otimes I)\,|u\rangle\,|^2$ be the probability that the measurement outcome of the first i qubits of $|u\rangle$ in the computational basis is $y_0, y_1, ..., y_{i-1}$. For each $i \in [m]$, we can efficiently calculate $P(y_0, y_1, ..., y_{i-1})$ because $|S| = \text{poly}(n)$ and $V_1(|x_1\rangle) \otimes V_2(|x_2\rangle) \otimes \cdots \otimes V_n(|x_n\rangle)$ is a product state of $\mathcal{O}(1)$-qubit states. Then, we can also efficiently calculate the conditional probability

$$P(z|y_0, y_1, ..., y_{i-1}) = \frac{P(y_0, y_1, ..., y_{i-1}, z)}{P(y_0, y_1, ..., y_{i-1})}.$$

If the bits $y_0, y_1, ..., y_{i-1}$ have already been sampled, we compute $P(z|y_0, y_1, ..., y_{i-1})$ and sample the next bit by tossing the coin with bias $P(0|y_0, y_1, ..., y_{i-1})$. In this way, we can classically efficiently sample from the probability distribution that outputs x with probability $|\langle x|u\rangle|^2$. ◀

2.2 Non-2SLD Hamiltonian and geometry of interaction

To state the result, we introduce some families of Hamiltonians. Given a set of (at most) two-body interactions $\mathcal{S} = \{h_\alpha\}$, $\mathcal{S}$-Hamiltonian refers to the family of Hamiltonians that can be written in the form

$$H = \sum_{\langle i,j \rangle \in E} J_{i,j} h^{(i,j)}_{\alpha_{i,j}}, \tag{1}$$

where $J_{i,j} \in \mathbb{R}$, $h^{(i,j)}_{\alpha_{i,j}}$ is two-local interaction chosen from $\mathcal{S}$ and E is the set of edges that represents the connectivity of interaction [10]. If the connectivity of two-body interaction is restricted to a 2D square lattice, we call such a family $\mathcal{S}$-Hamiltonian on a 2D square lattice. We also introduce the notion of 2SLD and non-2SLD:

▶ **Definition 5** (2SLD interaction [10]). *Suppose $\mathcal{S}$ is a set of interactions at most 2 qubits. We say that $\mathcal{S}$ is 2SLD if there exists $U \in \text{SU}(2)$, such that for all $h_i \in \mathcal{S}$,*

$$U^{\otimes 2} h_i (U^\dagger)^{\otimes 2} = \alpha_i Z \otimes Z + A_i \otimes I + I \otimes B_i,$$

where $\alpha_i \in \mathbb{R}$ and A_i, B_i are arbitrary single-qubit Hamiltonians.

A set $\mathcal{S}$ is non-2SLD if it is not 2SLD. In particular, such non-2SLD $\mathcal{S}$ includes the following physically motivated[4] Hamiltonians:

- $\{Z, X, ZZ, XX\}$ ($ZZXX$ interaction [6])
- $\{Z, X, ZX, XZ\}$ (ZX interaction [6])
- $\{XX + YY\}$ (general XY interaction)
- $\{XX + YY + ZZ\}$ (general Heisenberg interaction).

If there is only a single type of interaction (like $\mathcal{S} = \{XX + YY + ZZ\}$), the Hamiltonian is called *semi-translationally-invariant*. (Interaction strength can differ in each term.)

[4] For clarity, in [10] and here, all hardness results require *non-uniform* weights on constraints. It is an open question whether one can obtain (say) QMA-hardness results with uniform (i.e. unit weight) constraints for such models. This remains an interesting open question, as many-body physicists typically utilize unit weights to model physical systems.

Restriction on the sign of the interaction

We also introduce a further restricted class of $\mathcal{S}$-Hamiltonian in which all the signs of the coefficients are promised to be non-negative (i.e. all of $J_{i,j}$ in eq. (1) must satisfy $J_{i,j} \geq 0$). We call such a family of Hamiltonians as $\mathcal{S}^+$-Hamiltonian following [28]. In [28], the following results are shown:

- $\{\alpha XX + \beta YY + \gamma ZZ\}^+$-Hamiltonian is QMA-complete if $\alpha + \beta > 0$, $\alpha + \gamma > 0$ and $\beta + \gamma > 0$ hold.
- $\{\alpha XX + \beta YY + \gamma ZZ\}^+$-Hamiltonian is QMA-complete if the interactions are restricted to the edges of a 2D triangular lattice if $\alpha XX + \beta YY + \gamma ZZ$ is not proportional to $XX + YY + ZZ$ in addition to the condition that $\alpha + \beta > 0$, $\alpha + \gamma > 0$ and $\beta + \gamma > 0$ hold.

The first type of $\mathcal{S}^+$-Hamiltonian includes the antiferromagnetic Heisenberg model ($\{XX + YY + ZZ\}^+$-Hamiltonian) and the antiferromagnetic XY model ($\{XX + YY\}^+$-Hamiltonian) as important special cases. The antiferromagnetic XY model (unlike the antiferromagnetic Heisenberg model) remains QMA-complete if its geometric interaction is restricted to a 2D triangular lattice as it is included in the second type of $\mathcal{S}^+$-Hamiltonian above.

3 GLHLE hardness constructions

We next define the guided local Hamiltonian low energy (GLHLE) problem, which can be viewed as a generalization of GLH by considering arbitrary eigenstates of Hamiltonians[5]. For an n-qubit Hamiltonian H, we denote Π_c the projector onto the space spanned by the states of H that have energy $\lambda_c(H)$.

▶ **Definition 6** (Guided Local Hamiltonian Low Energy). *GLHLE*(k, c, a, b, δ)

Input: *A k-local Hamiltonian H on n qubits such that $\|H\| \leq 1$ and the description of a semi-classical encoded state $|u\rangle \in \mathbb{C}^{2^n}$, a constant $c \in \mathbb{N}_{\geq}0$.*

Promise: $\|\Pi_c |u\rangle\|^2 \geq \delta$, *where Π_c denotes the projection on the subspace spanned by the cth eigenstates, ordered in order of non-decreasing energy, of H, and either $\lambda_c(H) \leq a$ or $\lambda_c(H) \geq b$ holds.*

Goal: *Decide whether $\lambda_c(H) \leq a$ or $\lambda_c(H) \geq b$.*

The proof of Theorem 1 consists of five parts: first, we show that 5-local GLH with $\delta = 1 - \Omega(1/\text{poly}(n))$ fidelity is BQP-hard. Then, we show how to extend this result to the BQP-hardness of the 6-local GLHLE problem. Next, we improve the locality parameter and show a reduction from 6-local GLHLE to 2-local GLHLE. Simultaneously we show that this also holds when we restict the Hamiltonians to be non$-2SLD$ $\mathcal{S}$-Hamiltonian on a $2D$ square lattice. Finally, we show that BQP-hardness persists if we restrict the family of Hamiltonians to be $\{XX + YY + ZZ\}^+$-Hamiltonians, or $\{XX + YY\}^+$-Hamiltonians on a $2D$ triangular lattice.

We state these five parts as propositions and prove them one by one, from this our main result (Theorem 1) follows.

[5] This definition of GLH is very similar to the definition of GLH$^*(k, a, b, \delta)$ in [15]. The difference is that while the guiding states used in [15] are restricted to semi-classical subset states (Definition 2), in our definition we use the more general concept of semi-classical encoded states (Definition 3). Note that our BQP-hardness result for general 2-local Hamiltonians (Proposition 9) actually holds even when the guiding state is a semi-classical subset state. Proposition 9, which optimally improves both the locality and fidelity parameters of [15], therefore holds in exactly the same setting as [15]. We use semi-classical encoded states only to show BQP-hardness for further restricted families of Hamiltonians (Propositions 10 and 12).

3.1 Increasing the allowed fidelity

The first proposition focuses on increasing the allowed fidelity of the guiding state with the ground state of the Hamiltonian of interest (and hence $c = 0$).

▶ **Proposition 7.** *For any $\delta \in (0, 1 - \Omega(1/\mathrm{poly}(n)))$, there exist $a, b \in [0,1]$ with $b - a \in \Omega(1/\mathrm{poly}(n))$ such that the problem GLHLE$(5, 0, a, b, \delta)$ is* BQP*-hard. Moreover, it is still* BQP*-hard with the additional two promises that*

1. *H has a non-degenerate ground state separated from the first excited state by a spectral gap $\gamma \in \Omega(1/\mathrm{poly}(n))$ in both the cases $\lambda_0(H) \leq a$ and $\lambda_0(H) \geq b$.(We call such instances γ-gapped* GLH(k, a, b, δ)*.)*
2. *The guiding state is restricted to be a semi-classical subset state.*

Proof. Let $\Pi = (\Pi_{\mathrm{yes}}, \Pi_{\mathrm{no}})$ be a promise problem in BQP, and $x \in \{0,1\}^n$ be an input. Let $U_x = U_m U_{m-1} ... U_1$ be a quantum circuit that decides x consisting of $m = \mathrm{poly}(n)$ gates. U_x acts on $|x\rangle_A \otimes |0...0\rangle_B$ where A denotes the n-qubit input register and B denotes the poly-size ancilla register. By measuring the output register of $U_x |x\rangle_A \otimes |0...0\rangle_B$, the quantum verifier outputs 1 with probability at least α if $x \in \Pi_{\mathrm{YES}}$ (at most β if $x \in \Pi_{\mathrm{NO}}$, respectively). We may assume $\alpha = 1 - 2^{-n}$ and $\beta = 2^{-n}$ via the standard error reduction for BQP.

Consider a pre-idled quantum verifier $\tilde{U}_x \coloneqq U_x I \cdots I$, where I is the identity gate. The $\tilde{U}_x$ consists of $M \coloneqq m + N$ gates, where N is the number of idling steps. ($N = \mathrm{poly}(n)$ is taken properly later.) Consider Kitaev's [23] 5-local circuit-to-Hamiltonian construction with an additional scaling factor:

$$H \coloneqq \Delta(H_{\mathrm{in}} + H_{\mathrm{prop}} + H_{\mathrm{stab}}) + H_{\mathrm{out}}. \tag{2}$$

Here,

$$H_{\mathrm{in}} \coloneqq (I - |x\rangle\langle x|)_A \otimes (I - |0...0\rangle\langle 0...0|)_B \otimes (|0\rangle\langle 0|)_C \tag{3}$$

$$H_{\mathrm{out}} \coloneqq |0\rangle\langle 0|_{\mathrm{out}} \otimes |M\rangle\langle M|_C \tag{4}$$

$$H_{\mathrm{stab}} \coloneqq \sum_{j=1}^{M-1} |0\rangle\langle 0|_{C_j} \otimes |0\rangle\langle 0|_{C_{j+1}} \tag{5}$$

$$H_{\mathrm{prop}} \coloneqq \sum_{t=1}^{M} H_t, \text{where} \tag{6}$$

$$H_t \coloneqq -\frac{1}{2} U_t \otimes |t\rangle\langle t-1|_C - \frac{1}{2} U_t^\dagger \otimes |t-1\rangle\langle t|_C + \frac{1}{2} I \otimes (|t\rangle\langle t|_C + |t-1\rangle\langle t-1|_C). \tag{7}$$

It is known that the non-degenerate and zero-energy ground space of $H_0 \coloneqq H_{\mathrm{in}} + H_{\mathrm{prop}} + H_{\mathrm{stab}}$ is spanned by $|\psi_{\mathrm{hist}}\rangle$, where

$$|\psi_{\mathrm{hist}}\rangle \coloneqq \frac{1}{\sqrt{M+1}} \sum_{t=0}^{M} \tilde{U}_t \tilde{U}_{t-1} \cdots \tilde{U}_1 |x\rangle_A \otimes |0...0\rangle_B \otimes |t\rangle_C .$$

It is also known that the smallest non-zero eigenvalue of H_0 is larger than $\pi^2/(64M^2)$ [17, Lemma 2.2] (based on [14, Lemma 3]).

We apply the Schrieffer-Wolf transformation for this H by taking sufficiently large Δ. Note that $H_{\mathrm{out}} = |0\rangle\langle 0| \otimes I \otimes |M\rangle\langle M|$ and $\|H_{\mathrm{out}}\| = 1$. We would take

$$\Delta \geq 16 \cdot 64 M^2 / \pi^2.$$

Then, H has a one-dimensional ground space spanned by a ground state $|g\rangle$. In the following, we analyze the fidelity between $|g\rangle$ and $|\psi_{\mathrm{hist}}\rangle$, and the eigenvalue of $|g\rangle$ in the YES and NO cases.

Analysis of fidelity

Using Equation (12) of Appendix B , the bound

$$\| |g\rangle - |\psi_{\text{hist}}\rangle \| \in \mathcal{O}\left((\Delta/M^2)^{-1}\right)$$

holds. Let us introduce the following state:

$$|u\rangle := \frac{1}{\sqrt{N}} \sum_{t=1}^{N} |x\rangle_A \otimes |0...0\rangle_B \otimes |t\rangle_C .$$

This is a semi-classical subset state. This state satisfies

$$|\langle u|\psi_{\text{hist}}\rangle|^2 = \frac{N}{m+N+1}.$$

Therefore, for any positive polynomial r, we can take sufficiently large $N, \Delta \in \mathcal{O}(\text{poly}(n))$ so that $|\langle u|g\rangle|^2 \geq 1 - 1/r(n)$.

Analysis of eigenvalue

Next, we see the ground state energy of H in both the YES case and the NO case. The first-order effective Hamiltonian is given by

$$H_{\text{eff},1} = |\psi_{\text{hist}}\rangle \langle\psi_{\text{hist}}| H_{\text{out}} |\psi_{\text{hist}}\rangle \langle\psi_{\text{hist}}| .$$

The history state is defined as

$$|\psi_{\text{hist}}\rangle = \frac{1}{\sqrt{M+1}} \sum_{t=1}^{M} \tilde{U}_t \cdots \tilde{U}_1 |x\rangle_A \otimes |0...0\rangle_B \otimes |t\rangle_C$$

and

$$\langle\psi_{\text{hist}}| H_{\text{out}} |\psi_{\text{hist}}\rangle = \frac{1}{M+1} \langle x,0| U_x^\dagger (|0\rangle\langle 0|_{\text{out}} \otimes I) U_x |x,0\rangle .$$

The eigenvalue of $H_{\text{eff},1}$ is given by $\langle\psi_{\text{hist}}| H_{\text{out}} |\psi_{\text{hist}}\rangle$ and this is $\mathcal{O}((\Delta/M^2)^{-1}) = \mathcal{O}(1/\text{poly}(n))$-close to the ground state energy of H using Equation (11).

It can be verified that $\langle\psi_{\text{hist}}| H_{\text{out}} |\psi_{\text{hist}}\rangle \leq (1-\alpha)/(M+1)$ if U_x accepts x with probability at least α and $\langle\psi_{\text{hist}}| H_{\text{out}} |\psi_{\text{hist}}\rangle \geq (1-\beta)/(M+1)$ if U_x accepts x with probability at most β. As we have mentioned earlier, we can assume $\alpha = 1 - 2^{-n}$ and $\beta = 2^{-n}$. Therefore, the ground state energy a of H lies in the range of $0 \pm \mathcal{O}((\Delta/M^2)^{-1})$ if $x \in \Pi_{\text{yes}}$ and the ground state energy b of H lies in the range of $1/(M+1) \pm \mathcal{O}((\Delta/M^2)^{-1})$ if $x \in \Pi_{\text{no}}$.

We also see the spectral gap between the ground state and any excited state in both the YES and NO cases. We first see the NO case. As we have shown, the ground state energy lies in $\frac{1-2^n}{M+1} \pm \mathcal{O}((M^2/\Delta))$. In $H = \Delta(H_{\text{in}} + H_{\text{prop}} + H_{\text{stab}}) + H_{\text{out}}$, the eigenvalues of $\Delta(H_{\text{in}} + H_{\text{prop}} + H_{\text{stab}})$ is perturbed at most $\|H_{\text{out}}\| = 1$. Therefore, the smallest non-zero eigenvalue of H is larger than $(\Delta\pi^2)/(64M^2) - 1$. The spectral gap in the NO case is therefore

$$\mathcal{O}\left(\frac{\Delta}{M^2}\right) - 1 - \left(\frac{1-2^{-n}}{M+1} + \mathcal{O}\left(\frac{M^2}{\Delta}\right)\right).$$

The ground state energy in the YES case is smaller than that in the NO case. Therefore, we can take sufficiently large $\Delta \in \text{poly}(n)$ so that H has inverse-polynomial spectral gap and $b - a \in \Omega(1/\text{poly}(n))$. Finally, we can normalize H by a polynomially large factor, which concludes the proof. ◀

3.2 Extending to excited states

The next proposition extends the result to excited states, at the cost of increasing the locality of the construction by one.

▶ **Proposition 8.** *For any $\delta \in \Omega(0, 1 - 1/poly(n))$ there exist $a, b \in [-1, 1]$ with $b - a \in \Omega(1/poly(n))$ and some number $0 \leq c \leq poly(n)$ such that GLHLE$(6, c, a, b, \delta)$ is* BQP*-hard even when,*

1. *the c'th eigenvalue of H, $\lambda_c(H)$, is non-degenerate and is separated by a gap $\gamma \in \Omega(1/poly(n))$ from both $\lambda_{c-1}(H)$ and $\lambda_{c+1}(H)$. (We call such instances γ-gapped GLHLE(k, c, a, b, δ).)*
2. *The guiding state is restricted to be a semi-classical subset state.*

Proof. We will reduce directly from the BQP-complete Hamiltonian H as defined in Eq. (2). Again, let $|u\rangle$ be a semi-classical guiding state such that $|\langle u|\psi_0\rangle| \geq \zeta$. Consider the following 6-local Hamiltonian $H^{(c)}$ on $n+1$ qubits[6]:

$$H^{(c)} = H^{(z)} \otimes |0\rangle\langle 0| + H^{(s)} \otimes |1\rangle\langle 1|, \tag{8}$$

where

$$H^{(z)} = \sum_{i=0}^{d} 2^i |1\rangle\langle 1|_i + \sum_{i=d+1}^{n} 2^{d+1} |1\rangle\langle 1|_i - \left(c - \frac{1}{2}\right) I,$$
$$H^{(s)} = \frac{1}{2} \frac{H + I/4}{\|H\| + 1/4} - \frac{1}{4} I,$$

where we have that $d = \lceil \log_2(c) \rceil$. $H^{(z)}$ has exactly c states with negative energy, with the smallest eigenvalue being $-c + \frac{1}{2}$ and the largest eigenvalue value at $\sum_{i=0}^{d} 2^i + \sum_{i=d+1}^{n} 2^{d+1} - \left(c - \frac{1}{2}\right) = 2^{d+1} + 2^{d+1}(n-d) - \frac{1}{2} - c$. The spectrum jumps in integer steps of 1, and has as largest negative (resp. smallest non-negative) energy value $-\frac{1}{2}$ (resp. $\frac{1}{2}$). Since $\text{eig}(H^{(s)}) \in [-1/4, 1/4]$, we must have that $H^{(s)}$ sits precisely at the c'th excited state level (or $c+1$'th eigenstate level) in $H^{(c)}$. Therefore, given a guiding state $|u\rangle$ for H such that $|\langle u|\psi_0\rangle| \geq \delta$, one has that the guiding state $|u^{(c)}\rangle = |u\rangle \otimes |1\rangle$ is also semi-classical and must have $|\langle u^{(c)}|\psi_c^{(c)}\rangle| \geq \delta$, where $|\psi_c^{(c)}\rangle$ denotes the cth excited state of $H^{(c)}$. Since this construction of $H^{(c)}$ and $|u^{(c)}\rangle$ provides a polynomial time reduction from an instance of GLH(k, a, b, δ) to one of GLHLE(k, c, a, b, δ), whenever $c = \mathcal{O}(\text{poly}(n))$, we must have that GLHLE(k, c, a, b, δ) is BQP-hard whenever $k \geq 6$. The gap between $\lambda_c(H^{(c)}) - \lambda_{c-1}(H^{(c)}) = \frac{1}{4}$ and the gap between $\lambda_{c+1}(H^{(c)}) - \lambda_c(H^{(c)}) = \gamma$ as before. The norm of the new Hamiltonian is bounded by $|H^{(c)}| = \mathcal{O}(\text{poly}(n))$, hence after normalisation we retain $\lambda_c(H^{(c)}) - \lambda_{c-1}(H^{(c)}) \geq \lambda_{c+1}(H^{(c)}) - \lambda_c(H^{(c)}) = \Omega(1/\text{poly}(n))$. ◀

3.3 Locality reduction and reduction to physically motivated Hamiltonians via strong Hamiltonian simulation

The next two propositions bring (i) the locality k down to 2 and (ii) extend the result to any of non-2SLD $\mathcal{S}$-Hamiltonian on a 2D square lattice.

[6] Note that this gadget can be trivially changed such that estimating the n highest energy states is BQP-hard.

▶ **Proposition 9.** *Any γ-gapped GLHLE(k, c, a, b, δ) with $k \in \mathcal{O}(1)$, $b - a \in \Omega(1/\mathrm{poly}(n))$, $\delta \in (0, 1-\Omega(1/\mathrm{poly}(n)))$, $0 \leq c \leq$ poly(n), and $\gamma \in \Omega(1/\mathrm{poly}(n))$ with a guiding semi-classical subset state can be reduced to γ'-gapped GLHLE$(2, c, a', b', \delta')$ with $b' - a' \in \Omega(1/\mathrm{poly}(n))$, $\delta' \in (0, 1 - \Omega(1/\mathrm{poly}(n)))$ and $\gamma' \in \Omega(\mathrm{poly}(n))$, and with a guiding semi-classical subset state in polynomial time.*

▶ **Proposition 10.** *Any γ-gapped GLHLE(k, c, a, b, δ) with $k \in \mathcal{O}(1)$, $b - a \in \Omega(1/\mathrm{poly}(n))$, $\delta \in (0, 1 - \Omega(1/\mathrm{poly}(n)))$, $0 \leq c \leq$ poly(n) and $\gamma \in \Omega(1/\mathrm{poly}(n))$, and with a guiding semi-classical subset state can be reduced to γ'-gapped GLHLE$(2, c, a', b', \delta')$ with $b' - a' \in \Omega(1/\mathrm{poly}(n))$, $\delta' \in (0, 1 - \Omega(1/\mathrm{poly}(n)))$ and $\gamma' \in \Omega(\mathrm{poly}(n))$ in polynomial time whose Hamiltonian is restricted to any of non-2SLD $\mathcal{S}$-Hamiltonian on a 2D square lattice.*

Proof of Propositions 9 and 10. Let H and $|u\rangle$ be arbitrary inputs of GLHLE(k, c, a, b, δ) with $k \in \mathcal{O}(1)$, $b - a \in \Omega(1/\mathrm{poly}(n))$, $\delta \in (0, 1 - \Omega(1/\mathrm{poly}(n)))$. From Theorem 15 (in Appendix A.1), we can efficiently find a non-2SLD $\mathcal{S}$-Hamiltonian H' on a 2D square lattice that is a strong (Δ, η, ϵ)-simulation of H given the description of H. We take $\epsilon < (b - a)/2$, $b' = b - \epsilon$, $a' = a + \epsilon$ and $\Delta = \mathcal{O}(\epsilon^{-1}\|H\|^2 + \eta^{-1}\|H\|)$ so that $\lambda_c(H') \leq a'$ if $\lambda_c(H) \leq a$, and $\lambda_c(H') \geq b'$ if $\lambda_c(H) \geq b'$ while $b' - a' \in \Omega(1/\mathrm{poly}(n))$.

We have shown the *existence* of desirable eigenvectors in the simulated Hamiltonian. What remains to show is that (i) the encoded state of $|u\rangle$ still has $1 - 1/\mathrm{poly}(n)$ fidelity with c'th excited state of H' and (ii) the encoded state is still a semi-classical subset state after the simulation by a 2-local Hamiltonian (for concluding Proposition 9) , and (iii) the encoded state is still a semi-classical encoded state after the simulation by an arbitrary non-2SLD $\mathcal{S}$-Hamiltonian on a 2D square lattice (for concluding Proposition 10).

(i) Verification of the fidelity. The fidelity can be analyzed by the following lemma:

▶ **Lemma 11** (Simulation of the gapped excited state)**.** *Suppose the c'th excited state $|g\rangle$ of H is non-degenerate and separated from both the $c-1$'th excited state and $c+1$'th excited state by a gap γ. Suppose H' is a (Δ, η, ϵ)-simulation of H such that $2\epsilon < \gamma$. Then H' has a non-degenerate c'th excited state $|g'\rangle$ and*

$$\|\mathcal{E}_{\mathrm{state}}(|g\rangle) - |g'\rangle\| \leq \eta + \mathcal{O}(\gamma^{-1}\epsilon).$$

Proof. This is a slight modification of Lemma 2 of [8]. First, the non-degeneracy of the c'th excited state of H' follows because the i'th smallest eigenvalues of H and H' differs at most ϵ for all $0 \leq i \leq \dim(H) - 1$, and ϵ satisfies $2\epsilon < \gamma$. Consider H as an unperturbed Hamiltonian and $V \coloneqq \tilde{\mathcal{E}}^\dagger H' \tilde{\mathcal{E}} - H$ as a perturbation. Then, the perturbed Hamiltonian $H + V = \tilde{\mathcal{E}}^\dagger H' \tilde{\mathcal{E}}$ has a non-degenerate c'th excited state $\tilde{\mathcal{E}}_{\mathrm{state}}(|g'\rangle)$. The first-order perturbation theory for eigenvectors gives $\| |g\rangle - \tilde{\mathcal{E}}^\dagger_{\mathrm{state}}(|g'\rangle)\| \in \mathcal{O}(\gamma^{-1}\epsilon)$. Therefore, it follows that $\|\tilde{\mathcal{E}}_{\mathrm{state}}(|g\rangle) - |g'\rangle\| = \|\tilde{\mathcal{E}}_{\mathrm{state}}(|g\rangle) - \tilde{\mathcal{E}}_{\mathrm{state}}(\tilde{\mathcal{E}}^\dagger_{\mathrm{state}}(|g'\rangle))\| \in \mathcal{O}(\gamma^{-1}\epsilon)$ using that $\tilde{\mathcal{E}}_{state}$ is an isometry and $|g'\rangle \in \mathrm{Im}(\tilde{\mathcal{E}}_{state})$. Finally, by using $\|\mathcal{E}_{state} - \tilde{\mathcal{E}}_{state}\| \leq \eta$, $\|\mathcal{E}_{\mathrm{state}}(|g\rangle) - |g'\rangle\| \leq \eta + \mathcal{O}(\gamma^{-1}\epsilon)$ follows. ◀

Using Lemma 11, we can take sufficiently small ϵ and η to ensure $\|\mathcal{E}_{\mathrm{state}}(|u\rangle) - |g'\rangle\| \leq \delta' = \delta - 1/\mathrm{poly}(n)$. Because the Hamiltonian simulation is efficient, the operator norm $\|H'\|$ and the number of qubits of H' is in poly(n).

(ii) Verification of the semi-classical property for Proposition 9. We start from a semi-classical subset state $|u\rangle = 1/\sqrt{|S|}\sum_{x\in S}|x\rangle$. We show that after the simulation of the original k-local Hamiltonian H where $k \in \mathcal{O}(1)$ by an 2-local Hamiltonian, the corresponding encoding $\mathcal{E}_{\mathrm{state}}(|u\rangle)$ is still a semi-classical subset state.

In order to simulate the k-local Hamiltonian by a 2-local Hamiltonian (that has no restriction on the family of Hamiltonian), it is enough to use mediator qubit gadgets that attach $|0\rangle$ states for mediator qubits (called subdivision and 3-to-2 gadgets [27]). A k-local term can be simulated by $(\lceil k/2 \rceil + 1)$-local terms using the subdivision gadget. Moreover, subdivision gadgets can be applied to each of the terms of the Hamiltonian in parallel [28, 11]. Therefore, we can reduce a k-local Hamiltonian to a 3-local Hamiltonian by $\mathcal{O}(\log k)$ rounds of applications of the subdivision gadgets. Then we can use the 3-to-2 gadgets in parallel to reduce to a 2-local Hamiltonian. In the corresponding encoding of states of this procedure, polynomially many $|0\rangle$ states are attached to the original state. Clearly, by attaching polynomially many $|0\rangle$ states, a polynomial-size subset state is mapped to another polynomial-size subset state:

$$\frac{1}{\sqrt{|S|}} \sum_{x \in S} |x\rangle \to \frac{1}{\sqrt{|S|}} \sum_{x \in S} |x\rangle |0\rangle^{\otimes \mathrm{poly}(n)} = \frac{1}{\sqrt{|S|}} \sum_{x \in S \times \{0 \ldots 0\}} |x\rangle .$$

This concludes the proof of Proposition 9.

(iii) Verification of the semi-classical property for Proposition 10. We proceed to show that starting from a semi-classical subset state $|u\rangle$, the resulting state is a semi-classical encoded state when we simulate the original Hamiltonian by a non-2SLD $\mathcal{S}$-Hamiltonian on a 2D square lattice. There are three types of encodings used in the simulation:

- **Mediator qubits.** In this encoding, some simple ancilla states are attached to the original state.
- **Subspace encoding.** In this encoding, a local isometry is applied to the original state.
- **Local Unitaries.** In this encoding, local unitary $U \otimes U \otimes \cdots \otimes U$, where each of U acts on one qubit, is applied to the original state.

We restate the chain of Hamiltonian simulations of Appendix C:

Arbitrary k-local Hamiltonian
↓ (1) Mediator qubits. (Attach a semi-classical subset state $|\alpha\rangle$.)
Spatially sparse 5-local Hamiltonian
↓ (2) Mediator qubits. (Attach polynomially many $|+_y\rangle$ states.)
Spatially sparse 10-local real Hamiltonian
↓ (3) Mediator qubits. (Attach polynomially many $|0\rangle$ or $|1\rangle$ states.)
Spatially sparse 2-local Pauli interactions with no Y-terms
↓ (4) Subspace encoding.
Spatially sparse $\mathcal{S}_0 = \{XX + YY + ZZ\}$ or $\{XX + YY\}$ Hamiltonian
↓ (5) Mediator qubits. (Attach polynomially many $|0\rangle$ or $|1\rangle$ states.)
$\mathcal{S}_0$-Hamiltonians on a 2D square lattice
↓ (6) Mediator qubits, Subspace encoding, and local unitary.
Arbitrary non-2SLD $\mathcal{S}$-Hamiltonian on a 2D square lattice

In step (1), a semi-classical subset state is attached to a semi-classical subset state $|u\rangle$. The resulting state is also a semi-classical subset state:

$$\begin{aligned} |u\rangle = \frac{1}{\sqrt{|S|}} \sum_{x \in S} |x\rangle \to & \frac{1}{\sqrt{|S|}} \sum_{x \in S} |x\rangle \otimes \frac{1}{\sqrt{|S'|}} \sum_{x' \in S'} |x'\rangle \\ & = \frac{1}{\sqrt{|S||S'|}} \sum_{x \in S \times S'} |x\rangle . \end{aligned} \tag{9}$$

The resulting state after the encodings of steps (2)∼(4) is a semi-classical encoded state because in these steps, a tensor product of single-qubit states is attached to a semi-classical subset state and then the state is encoded by a local isometry. By further performing a local encoding to the semi-classical encoded state, the resulting state is also a semi-classical encoded state. This concludes the proof of Proposition 10. ◀

Finally, we show a BQP-hardness result for the antiferromagnetic Hamiltonian.

▶ **Proposition 12.** *For any $\delta \in (0, 1 - \Omega(1/\mathrm{poly}(n)))$, there exist $a, b \in [0, 1]$ with $b - a \in \Omega(1/\mathrm{poly}(n))$ and $0 \leq c \leq \mathcal{O}(poly(n))$ such that the problem GLHLE$(2, c, a, b, \delta)$ with $b - a \in \Omega(1/\mathrm{poly}(n))$ is* BQP*-hard for Hamiltonians that are restricted to either $\{XX+YY+ZZ\}^+$-Hamiltonian, or $\{XX+YY\}^+$-Hamiltonian on a 2D triangular lattice.*

Proof. We first prove the case of $\{XX+YY+ZZ\}^+$-Hamiltonian. This can be reduced from the GLHLE problem of $\{XX+YY+ZZ\}$-Hamiltonian with a semi-classical encoded state as a guiding state, which is shown to be BQP-hard in Proposition 10. The $\{XX+YY+ZZ\}$-Hamiltonian can be simulated by $\{XX+YY+ZZ\}^+$-Hamiltonian using the "basic gadget" (this is a type of a mediator qubit gadget) of [28]. In the corresponding encoding of the state, a tensor product of two-qubit states is attached to the original state. This encodes a semi-classical encoded state to another semi-classical encoded state. The reason is as follows. Let us denote the attached tensor product of polynomially many two-qubit states as

$$|\phi_1\rangle \otimes |\phi_2\rangle \otimes \cdots |\phi_m\rangle = V_1' |0\rangle \otimes V_2' |0\rangle \otimes \cdots V_m' |0\rangle ,$$

where $|\phi_1\rangle , ..., |\phi_m\rangle$ are two-qubit states and $V_1', ..., V_m'$ are isometries such that $V_i' |0\rangle = |\phi_i\rangle$ for each $i \in [m]$. Then, the original semi-classical encoded state represented by a polynomial-size subset S and a local isometry $V_1 \otimes V_2 \otimes \cdots \otimes V_n$ is mapped to a semi-classical encoded state represented by a subset $S \times \{0...0\}$ and a local isometry $V_1 \otimes \cdots \otimes V_n \otimes V_1' \otimes \cdots \otimes V_m'$. This concludes the case of $\{XX+YY+ZZ\}^+$-Hamiltonian.

We next show the BQP-hardness of the GLHLE problem of $\{XX+YY\}^+$-Hamiltonian on a 2D triangular lattice with a semi-classical encoded state. We show a reduction from the GLHLE problem of $\{XX+YY\}$-Hamiltonian on a 2D square lattice with a semi-classical encoded state as a guiding state, which is shown to be BQP-hard in Proposition 10. It is shown in [28] how to simulate $\{XX+YY\}$-Hamiltonian on a 2D square lattice by $\{XX+YY\}^+$-Hamiltonian on a 2D triangular lattice by using mediator qubit gadgets. The corresponding encoding is just attaching a product state of polynomially many $\mathcal{O}(1)$-qubit states to the original guiding state. Therefore, the original semi-classical encoded state is mapped to another semi-classical encoded state (by a similar reason as in the case of $\{XX+YY+ZZ\}^+$-Hamiltonian). ◀

A Approximate Hamiltonian simulation

A.1 Introduction of approximate Hamiltonian simulation

While in the QMA-hardness reduction it suffices to focus only on the eigenvalues in the simulation, in the reduction of GLH it is also important to know how the eigenvectors change in the perturbative simulation. It is convenient to introduce the notion of *approximate Hamiltonian simulation* to show the reduction of GLH.

▶ **Definition 13** (Approximate Hamiltonian simulation [11], [33]). *We say that an m-qubit Hamiltonian H' is a (Δ, η, ϵ)-simulation of an n-qubit Hamiltonian H if there exists a local encoding $\mathcal{E}(M) = V(M \otimes P + \bar{M} \otimes Q)V^\dagger$ such that*

1. *There exists an encoding $\tilde{\mathcal{E}}(M) = \tilde{V}(M \otimes P + \bar{M} \otimes Q)\tilde{V}^\dagger$ such that $\tilde{\mathcal{E}}(\mathbb{1}) = P_{\leq\Delta(H')}$ and $\|\tilde{V} - V\| \leq \eta$, where $P_{\leq\Delta(H')}$ is the projector onto the subspace spanned by eigenvectors of H' with eigenvalue below Δ,*
2. *$\|H'_{\leq\Delta} - \tilde{\mathcal{E}}(H)\| \leq \epsilon$, where $H'_{\leq\Delta} \coloneqq P_{\leq\Delta(H')}H'$.*

Here, V is a local isometry that can be written as $V = \bigotimes_i V_i$ where each V_i is an isometry acting on at most 1 qubit, and P and Q are locally orthogonal projectors (i.e. for all i there exist orthogonal projectors P_i and Q_i acting on the same subsystem as V_i such that $P_iQ_i = 0$, $P_iP = P$ and $Q_iQ = Q$) such that $P + Q = I$, and $\bar{M}$ is the complex conjugate of M. Moreover, we say that the simulation is efficient if m and $\|H'\|$ are at most $\mathcal{O}(\mathrm{poly}(n, \eta^{-1}, \epsilon^{-1}, \Delta))$, and the description of H' can be computable in $\mathrm{poly}(n)$ time given the description of H.

We approximately simulate the original Hamiltonian H in the low-energy subspace of H'. There is a corresponding encoding of a state which can be taken as

$$\mathcal{E}_{\mathrm{state}}(\rho) = V(\rho \otimes \sigma)V^\dagger$$

for σ such that $P\sigma = \sigma$ (if $P \neq 0$). If ρ is the eigenvector of H with eigenvalue α, then $\mathcal{E}_{\mathrm{state}}(\rho)$ is approximately the eigenvector of H' with eigenvalue $\alpha' \in [\alpha - \epsilon, \alpha + \epsilon]$.

In [33], it is shown that there exist families of Hamiltonians that can efficiently simulate any $\mathcal{O}(1)$-local Hamiltonians. They call such families of Hamiltonians *strongly universal Hamiltonians.*[7] We use the construction of strongly universal Hamiltonians of [33] to show Proposition 9. Formally, the strong (and weak) universality is defined as follows:

▶ **Definition 14** (Strong and weak universality [33]). *A family of Hamiltonians $\mathcal{H} = \{H_m\}$ is weakly universal if given any $\Delta, \eta, \epsilon > 0$, any $\mathcal{O}(1)$-local, n-qubit Hamiltonian can be (Δ, η, ϵ)-simulated. Such a family is strongly universal if the simulation is always efficient.*

The following result is shown in [33]:

▶ **Theorem 15** ([33]). *Any non-2SLD $\mathcal{S}$-Hamiltonian on a 2D-square lattice is strongly universal.*

B Schrieffer-Wolf transformation for 1-dimensional gapped ground space

Let us introduce the Schrieffer-Wolf transformation and its approximation [7] which we use in the proof. We only consider the case when the unperturbed Hamiltonian has 1-dimensional ground space.

Let H_0 be a Hamiltonian that has 1-dimensional ground space spanned by $|g_0\rangle$ whose energy is 0. Let us assume that the smallest non-zero eigenvalue of H_0 is larger than one. Consider the following (perturbed) Hamiltonian: $H = \Delta H_0 + V$. We shall always assume that $\|V\| \leq \Delta/2$ in the following. Then, there is only one eigenvector (which we denote $|g\rangle$) of H with eigenvalue lying in the interval of $[-\Delta/2, \Delta/2]$ (Lemma 3.1 of [7]).

Then, the Schrieffer-Wolf (SW) transformation is defined as a unitary U_{SW} that maps the ground space of H to that of H_0. That is, $U_{\mathrm{SW}}|g\rangle = |g_0\rangle$. The Hamiltonian

$$H_{\mathrm{eff}} = \Pi_0 U_{\mathrm{SW}}(\Delta H_0 + V)U_{\mathrm{SW}}^\dagger \Pi_0$$

is called the effective low-energy Hamiltonian. Here, Π_0 is the projector onto the ground space of H_0. The eigenvector of H_{eff} is $|g_0\rangle$ and the eigenvalue is the same as the eigenvalue of $|g\rangle$ with respect to H.

Next, we show how to approximate U_{SW} and H_{eff}. We only need the simplest first-order approximation in the proof of Proposition 7. In the following, we further assume $\|V\| \leq \Delta/16$. Then, it is known that

$$\|I - U_{\mathrm{SW}}\| \in \mathcal{O}(\Delta^{-1}\|V\|) \tag{10}$$

and

$$\|H_{\mathrm{eff}} - \Pi_0 V \Pi_0\| \in \mathcal{O}(\Delta^{-1}\|V\|^2) \tag{11}$$

hold (Lemma 3.4 [7], Lemma 4 [8]). This means that I and $\Pi_0 V \Pi_0$ work as the first-order approximation of U_{SW} and H_{eff}, respectively. The derivation and the forms of the higher-order terms can be found in [7]. From eq. (10), it follows that

$$\| \, |g\rangle - |g_0\rangle \, \| = \left\| (I - U_{\mathrm{SW}}^\dagger)\, |g_0\rangle \right\| \in \mathcal{O}(\Delta^{-1}\|V\|). \tag{12}$$

It follows from eq. (11) that the ground state energy of H differs at most $\mathcal{O}(\Delta^{-1}\|V\|^2)$ from the eigenvalue of $H_{\mathrm{eff},1} \coloneqq \Pi_0 V \Pi_0$ (restricted to the space spanned by $|g_0\rangle$).

[7] It would be possible to show Theorem 1 by modifying the verifier circuit $\tilde{U}_x$ following [27] to make the constructed Hamiltonian spatially sparse. We believe Proposition 9 is interesting because the reduction holds for arbitrary $\mathcal{O}(1)$-local Hamiltonian even if it is not originally spatially sparse.

C Encoding of states for strong Hamiltonian simulation

We sketch the construction of the strong Hamiltonian simulation introduced in [33]. The simulation mainly consists of two parts. First, they construct spatially sparse 5-local Hamiltonian [27] using a quantum phase estimation circuit and its modification. This procedure may be thought of as a "Hamiltonian-to-circuit" (then goes back to Hamiltonian by circuit-to-Hamiltonian) construction. Then, they perturbatively simulate the spatially sparse Hamiltonian with known techniques in the literature [27, 11, 28]. In the following, we overview their construction.

(1) Arbitrary k-local Hamiltonian $\rightarrow$ spatially sparse 5-local Hamiltonian ([33])

Let H be a target $\mathcal{O}(1)$-local Hamiltonian. Assume that H can be written as $H = \sum_i E_i |\psi_i\rangle \langle\psi_i|$ where $\{E_i\}$ and $\{|\psi_i\rangle\}$ are the eigenvalues and eigenvectors of H. In [33], they showed that there is a spatially sparse quantum circuit $U_{\mathrm{PE}}^{\mathrm{sparse}}$ that approximately estimates the energy of H, i.e.

$$U_{\mathrm{PE}}^{\mathrm{sparse}} \sum_i c_i |\psi_i\rangle |0^m\rangle \approx \sum_i c_i |\psi_i\rangle |\tilde{E}_i\rangle |other\rangle ,$$

where $\{c_i\}$ are arbitrary coefficients and $\{|\tilde{E}_i\rangle\}$ are approximations of $\{E_i\}$.

The circuit $U_{\mathrm{PE}}^{\mathrm{sparse}}$ is implemented first by constructing $U_{\mathrm{NN}}^{\mathrm{sparse}}$ that consists of 1D nearest-neighborhood interaction. Then, $U_{\mathrm{NN}}^{\mathrm{sparse}}$ is converted into a spatially sparse circuit using ancilla qubits and swap gates.

Then they combine uncomputation and idling to construct

$$U = (\mathrm{Idling})(U_{\mathrm{PE}}^{\mathrm{sparse}})^\dagger (\mathrm{Idling}) U_{\mathrm{PE}}^{\mathrm{sparse}} .$$

They apply circuit-to-Hamiltonian construction for this U to construct spatially sparse 5-local Hamiltonian H_{circuit}. They use first-order perturbation theory to show that H_{circuit} simulates H in its low-energy subspace. The encoding of H_{circuit} to the low energy subspace of H is approximated by the map: $H \rightarrow H \otimes |\alpha\rangle \langle\alpha|$. Here, $|\alpha\rangle$ is a subset state with poly(n)-size subset S' that is related to the history state of the idling steps after uncomputation. For detail, see the proof of Proposition 2 of [33]. Then, the corresponding encoding of the state is

$$|u\rangle \rightarrow |u\rangle \otimes |\alpha\rangle .$$

The encoded state is also a semi-classical subset state if $|u\rangle$ is a semi-classical subset state.

(2) Spatially sparse 5-local Hamiltonian $\rightarrow$ Spatially sparse 10-local real Hamiltonian (Lemma 22 of [11])

In this simulation, the state is encoded by attaching polynomially many $|+_y\rangle$ where $|+_y\rangle$ is the $+1$ eigenvector of Pauli Y matrix:

$$|u\rangle \rightarrow |u\rangle \otimes |+_y\rangle \otimes \cdots \otimes |+_y\rangle . \tag{13}$$

This encoding does not map a semi-classical subset state into a semi-classical state but maps into a semi-classical encoded state. The reason is as follows. Let V_y be a unitary such that $|+_y\rangle = V_y |0\rangle$, and $|u\rangle = 1/\sqrt{|S|} \sum_{x\in S} |x\rangle$. Then, the right side of eq. (13) can be written as

$$|u\rangle \otimes |+_y\rangle \otimes \cdots \otimes |+_y\rangle = \frac{1}{\sqrt{|S|}} \sum_{x\in S\times\{0\ldots0\}} I \otimes \cdots \otimes I \otimes V_y \otimes \cdots \otimes V_y |x\rangle .$$

This is a semi-classical encoded state with a subset $S \times \{0...0\}$ and a local isometry (this is indeed a local unitary) $I \otimes \cdots \otimes I \otimes V_y \otimes \cdots \otimes V_y$.

(3) Spatially sparse 10-local real Hamiltonian → Spatially sparse 2-local Pauli interactions with no Y-terms ([27, 10])

This can be done first by simulating the 10-local real Hamiltonian with 11-local Hamiltonian whose Pauli decomposition does not contain any Pauli Y terms [11, Lemma 40]. In the corresponding encoding, $|1\rangle$ states are attached for the polynomially many mediator qubits introduced in the simulation. Then, we can use subdivision gadgets and 3-to-2 gadgets [27]. In this simulation, polynomially many mediator qubits are introduced, and the encoding of states is just to add $|0\rangle$ states for each of the mediator qubits. The resulting Hamiltonian can be written in the form $\sum_{i<j}\alpha_{ij}A_{ij}+\sum_k(\beta_k X_k+\gamma_k Z_k)$, where A_{ij} is one of the interactions of X_iX_j, X_iZ_j, Z_iX_j or Z_iZ_j.

(4) Subspace encoding for spatially sparse $\mathcal{S}_0=\{XX+YY+ZZ\}$ or $\{XX+YY\}$ Hamiltonian (Theorem 42 of [11])

We have already obtained 2-local Hamiltonian in the form $\sum_{i<j}\alpha_{ij}A_{ij}+\sum_k(\beta_k X_k+\gamma_k Z_k)$. Then we show how to simulate this Hamiltonian with arbitrary non-2SLD $\mathcal{S}$-Hamiltonians. We first consider $\mathcal{S}_0$ Hamiltonian, where $\mathcal{S}_0=\{XX+YY+ZZ\}$ or $\mathcal{S}_0=\{XX+YY\}$. In this simulation, we use subspace encoding in which the *logical qubit* of the original Hamiltonian is encoded into four *physical qubits*. Consider the simulation by Heisenberg interaction $\{XX+YY+ZZ\}$ for example. Each logical qubit is encoded into 4 qubit state by an isometry that is defined as

$$V|0\rangle=|0_L\rangle=|\Psi_-\rangle_{13}|\Psi_-\rangle_{24} \tag{14}$$

$$V|1\rangle=|1_L\rangle=\frac{2}{\sqrt{3}}|\Psi_-\rangle_{12}|\Psi_-\rangle_{34}-\frac{1}{\sqrt{3}}|\Psi_-\rangle_{13}|\Psi_-\rangle_{24}, \tag{15}$$

where $|\Psi_-\rangle=(|01\rangle-|10\rangle)/\sqrt{2}$. For details, see [11, Theorem 42]. The encoding of states for XX+YY interaction is the same. A semi-classical encoded state is clearly mapped to a semi-classical encoded state by applying a local isometry of the corresponding subspace encoding.

(5) Spatially sparse $\mathcal{S}_0$-Hamiltonian → $\mathcal{S}_0$-Hamiltonians on a 2D square lattice (Lemma 47 of [11])

This simulation can be done using three perturbative gadgets called subdivision, fork, and crossing gadgets. All of these gadgets attach a mediator qubit for each use of the gadgets. $\mathcal{O}(1)$ rounds of parallel use of perturbative gadgets are sufficient to simulate a spatially sparse $\mathcal{S}_0$-Hamiltonian by a $\mathcal{S}_0$-Hamiltonians on a 2D square lattice, which prevents the interaction strength to grow exponentially. (For general interaction graphs, $\mathcal{O}(\log n)$ rounds of perturbative simulations are necessary.)

(6) $\mathcal{S}_0$-Hamiltonian on 2D square lattice → Arbitrary non-SLD $\mathcal{S}$-Hamiltonian on a 2D square lattice (Theorem 43 of [11])

Finally, this simulation is similarly done by using variants of mediator qubit gadgets or subspace encoding gadgets as well as applying local unitaries.[8]

[8] Applying local unitaries means to simulate H by $U^{\otimes n}H(U^\dagger)^{\otimes n}$ where U acts on one qubit. The corresponding encoding of state is $\mathcal{E}_{state}(|\psi\rangle)=U^{\otimes n}|\psi\rangle$.

Planar #CSP Equality Corresponds to Quantum Isomorphism – A Holant Viewpoint

Jin-Yi Cai

Ben Young[1]
Department of Computer Sciences, University of Wisconsin-Madison, WI, USA

Abstract

Recently, Mančinska and Roberson proved [11] that two graphs G and G' are *quantum isomorphic* if and only if they admit the same number of homomorphisms from all *planar* graphs. We extend this result to planar #CSP with any pair of sets $\mathcal{F}$ and $\mathcal{F}'$ of real-valued, arbitrary-arity constraint functions. Graph homomorphism is the special case where each of $\mathcal{F}$ and $\mathcal{F}'$ contains a single symmetric 0-1-valued binary constraint function. Our treatment uses the framework of planar Holant problems. To prove that quantum isomorphic constraint function sets give the same value on any planar #CSP instance, we apply a novel form of *holographic transformation* of Valiant [13], using the quantum permutation matrix $\mathcal{U}$ defining the quantum isomorphism. Due to the noncommutativity of $\mathcal{U}$'s entries, it turns out that this form of holographic transformation is only applicable to planar Holant. To prove the converse, we introduce the quantum automorphism group $\mathrm{Qut}(\mathcal{F})$ of a set of constraint functions/tensors $\mathcal{F}$, and characterize the intertwiners of $\mathrm{Qut}(\mathcal{F})$ as the signature matrices of planar Holant$(\mathcal{F} \mid \mathcal{EQ})$ quantum gadgets. Then we define a new notion of (projective) connectivity for constraint functions and reduce arity while preserving the quantum automorphism group. Finally, to address the challenges posed by generalizing from 0-1 valued to real-valued constraint functions, we adapt a technique of Lovász [9] in the classical setting for isomorphisms of real-weighted graphs to the setting of quantum isomorphisms.

1 Introduction

Graph Homomorphism and #CSP

A homomorphism from graph K to graph X is an edge-preserving map from the vertex set $V(K)$ of K to the vertex set $V(X)$ of X. A well-studied problem in complexity theory is to count the number of distinct homomorphisms from K to X, which can be expressed as

$$\sum_{\sigma: V(K) \to V(X)} \prod_{(u,v) \in E(K)} (A_X)_{\sigma(u),\sigma(v)},$$

[1] Corresponding author

the value of the *partition function* of X evaluated on K, where A_X is the adjacency matrix of X. From this perspective, graph homomorphism naturally generalizes to a counting constraint satisfaction problem (#CSP) by replacing $\{A_X\}$ with a set $\mathcal{F}$ of $\mathbb{R}$ or $\mathbb{C}$-valued *constraint functions* on one or more inputs from a finite domain $V(\mathcal{F})$, and replacing K with a set of constraints and variables, where each constraint applies a constraint function to a sequence of variables. The problem is to compute the partition function, which is the sum over all variable assignments of the product of the constraint function evaluations. Letting $V(\mathcal{F}) = V(X)$ and the constraint and variable sets be $E(K)$ and $V(K)$, respectively, with each edge/constraint applying A_X to its two endpoints, we recover the special case of counting homomorphisms from K to X.

Bulatov [2] proved that every problem #CSP($\mathcal{F}$), parameterized by a finite set $\mathcal{F}$ of 0-1-valued constraint functions, is either (1) solvable in polynomial-time or (2) #P-complete. Dyer and Richerby [6] proved that this *complexity dichotomy* has a decidable criterion. This dichotomy was further extended to nonnegative real-valued, and then to all complex-valued constraint functions [5, 4]. When we restrict to planar #CSP instances (for which the bipartite constraint-variable incidence graph is planar), a further *complexity trichotomy* is known for the Boolean domain (where $V(\mathcal{F}) = \{0, 1\}$) [7], that there are exactly three classes: (1) polynomial-time solvable; (2) #P-hard for general instances but solvable in polynomial-time over planar structures; and (3) #P-hard over planar structures. Furthermore, Valiant's holographic algorithm with matchgates [13] is universal for all problems in class (2): *Every* #P-hard #CSP problem that is solvable in polynomial-time in the planar setting is solvable by this one algorithmic strategy. However, for planar #CSP on domains of size greater than 2, a full complexity classification is open.

Holant Problems

We carry out much of our work in the planar Holant framework from counting complexity, which we find natural to this theory, and of which planar #CSP itself is a special case. Like a #CSP problem, a Holant problem is parameterized by a set $\mathcal{F}$ of constraint functions. The input to a planar Holant problem is a *signature grid*, a planar graph where each edge represents a variable and every vertex is assigned a constraint function from $\mathcal{F}$. A vertex's constraint function is applied to its incident edges. This is dual to the #CSP view of graph homomorphism, where each edge is a (necessarily binary) constraint and each vertex is a variable. As with #CSP, the computational problem is to compute the Holant value – the sum over all variable (edge) assignments, of the product of the evaluations of the constraint functions. A (planar) *gadget* is a (planar) Holant signature grid with a number of *dangling* edges, representing external variables. Each gadget has an associated *signature matrix*, which stores the Holant value for each fixed assignment to the dangling edges. The study of Holant problems is motivated by Valiant's *holographic transformations* [13], which are certain Holant value-preserving transformations of the constraint functions by invertible matrices.

Classical and Quantum Isomorphism

As suggested above, one can view a q-vertex real-weighted graph X, via its adjacency matrix $A_X \in \mathbb{R}^{q\times q}$, as an $\mathbb{R}$-valued binary (i.e. two input variables) constraint function. Two q-vertex graphs X and Y are isomorphic if one can apply a permutation to the rows and columns of A_X to obtain A_Y. Equivalently, if we convert A_X and A_Y to vectors $a_X, a_Y \in \mathbb{R}^{q^2}$, there is a permutation matrix P satisfying $P^{\otimes 2}a_X = a_Y$. For n-ary constraint functions $F, G \in \mathbb{R}^{[q]^n}$, where $[q] = \{1, 2, \ldots, q\}$, a natural generalization applies. F and G are isomorphic if there is a permutation matrix P satisfying $P^{\otimes n}f = g$, where $f, g \in \mathbb{R}^{q^n}$ are the vector versions of F and G.

Quantum isomorphism of (undirected, unweighted) graphs, introduced in [1], is a relaxation of classical isomorphism. Graphs X and Y are *quantum isomorphic* if there is a perfect winning strategy in a two-player *graph isomorphism game* in which the players share and can perform measurements on an entangled quantum state. This condition is equivalent to the existence of a *quantum permutation matrix* matrix $\mathcal{U}$ – a relaxation of a permutation matrix whose entries do not necessarily commute – satisfying $\mathcal{U}^{\otimes 2}a_X = a_Y$ [10]. Analogously to classical isomorphism, in this work we define n-ary constraint functions F and G to be *quantum isomorphic* if there is a quantum permutation matrix $\mathcal{U}$ satisfying $\mathcal{U}^{\otimes n}f = g$. Sets $\mathcal{F}$ and $\mathcal{G}$ of constraint functions of equal cardinality are quantum isomorphic if there is a single quantum permutation matrix defining a quantum isomorphism between every pair of corresponding functions in $\mathcal{F}$ and $\mathcal{G}$.

In [8], Lovász proved that two graphs are isomorphic if and only if they admit the same number of homomorphisms from every graph. Fifty years later, Mančinska and Roberson [11] proved that two graphs are *quantum* isomorphic if and only if they admit the same number of homomorphisms from all *planar* graphs. We generalize this result to #CSP and sets of constraint functions. We achieve this via graph combinatorics, results from quantum group theory, and a novel form of holographic transformation, establishing new connections between planar Holant, #CSP, quantum permutation matrices, and quantum isomorphism.

While quantum permutation matrices, quantum isomorphism, and other quantum constructions in this paper are somewhat abstract and technical, we believe it is precisely these concepts' abstractness that makes the connections we develop between them and the very concrete, combinatorial concept of planarity so fascinating and potentially fruitful. Our result that quantum isomorphism exactly captures planarity could lead to entirely novel, algebraic methods of studying the complexity of planar #CSP and Holant.

Our Results

Our main result is the following theorem, a broad extension of the main result of Mančinska and Roberson [11], recast into the well-studied Holant and #CSP frameworks.

▶ **Theorem** (Theorem 9, informal). *Sets $\mathcal{F}$ and $\mathcal{G}$ of $\mathbb{R}$-valued constraint functions are quantum isomorphic iff the partition function of every planar #CSP($\mathcal{F}$) instance is preserved upon replacing every constraint function in $\mathcal{F}$ with the corresponding function in $\mathcal{G}$.*

Our general constraint functions add significant complexity relative to the graph homomorphism special case in [11], since, unlike unweighted graph adjacency matrices, they can be (1) asymmetric (i.e. permuting the argument order affects their value), (2) n-ary, for $n > 2$, and (3) arbitrary real-valued. Each of these three extensions adds intricacies and challenges not present in [11], which we address with novel approaches that reveal new, deeper connections between quantum permutation matrices and planar graphs.

First, in Subsection 3.1 we give a procedure for decomposing any planar Holant signature grid corresponding to a planar #CSP instance into a small set of simple gadgets. Here arise the first new complications associated with higher-arity signatures. The dangling edges of simple gadgets extracted from the signature grid may not be oriented correctly, so we must use certain other gadgets to pivot them to the correct orientation, respecting planarity.

With some preparation in Subsection 3.2, we prove the quantum Holant theorem in Subsection 3.3. The forward direction of Theorem 9 is a direct corollary, giving a more graphical and more intuitive proof than that of the graph homomorphism special case in [11]. The gadget decomposition gives an expression for the Holant value as a product of the component gadgets' signature matrices. So, assuming $\mathcal{F}$ and $\mathcal{G}$ are quantum isomorphic, we

use the quantum permutation matrix $\mathcal{U}$ defining the quantum isomorphism as a *quantum holographic transformation*, inserting tensor powers of $\mathcal{U}$ and its inverse between every pair of signature matrices in the product without changing the Holant value. Then a sequence of these holographic transformations converts every signature in $\mathcal{F}$ to the corresponding signature in $\mathcal{G}$. The quantum holographic transformation does not work on general signature grids, since viewing $\mathcal{U}$ itself as a constraint function in the signature grid is not in general well-defined, as $\mathcal{U}$'s entries do not commute and the partition function does not specify an order to multiply the constraint function evaluations. However, the planarity of the signature grid and the resulting gadget decomposition and matrix product expression for the Holant value implicitly provide a multiplication order. Quantum holographic transformations apply to the planar version of the general Holant problem parameterized by a set $\mathcal{F}$ of constraint functions (not just the special case of #CSP), and should be of independent interest.

The success of the quantum holographic transformation for asymmetric signatures is also dependent on the fact that the holographic transformation action of a quantum permutation matrix is invariant under gadget rotations and reflections. The asymmetry and rotation and reflection issues are only relevant in the context of planar signature grids, since in nonplanar grids, one can simply cross and twist the incident edges to achieve the desired input order. Hence this is another interesting connection between quantum permutation matrices and the structural properties of planar graphs.

In Section 4, to prove the reverse direction of Theorem 9, we turn to the theory of quantum groups [15, 14]. We introduce the quantum automorphism group $\mathrm{Qut}(\mathcal{F})$ of a set $\mathcal{F}$ of signatures, an abstraction of the classical automorphism group satisfying many of the same properties. Using the planar gadget decomposition, we prove that the signature matrices of planar Holant gadgets in the context of $\#\mathrm{CSP}(\mathcal{F})$, a very concrete, combinatorial concept, exactly capture the abstract *intertwiner space* of $\mathrm{Qut}(\mathcal{F})$. A natural approach to the rest of the proof breaks down for constraint functions of arity > 2. Hence we introduce a method to reduce a constraint function's arity while maintaining its inclusion in the original intertwiner space. Then we say a constraint function is *projectively connected* if this procedure yields a connected graph upon reaching arity 2. Finally, we show that if $\mathcal{F}$ and $\mathcal{G}$ are projectively connected and the quantum automorphism group of the disjoint union of $\mathcal{F}$ and $\mathcal{G}$ maps a "vertex" of $\mathcal{F}$ to a "vertex" of $\mathcal{G}$, then $\mathcal{F}$ and $\mathcal{G}$ are quantum isomorphic (analogous to the familiar classical fact for graphs). For 0-1 valued functions, Mančinska and Roberson [11] ensured connectivity by taking complements. However, for real-valued functions F and G this method does not work: we cannot take the complement to assume they are projectively connected. Instead, we adapt to the quantum setting a technique of Lovász [9] in the classical setting for real-weighted graphs, and extract a quantum isomorphism to complete the proof.

All of the above results extend to sets of constraint functions over $\mathbb{C}$ that are closed under conjugation and for which the quantum isomorphism respects conjugation (both properties are trivially satisfied by constraint functions over $\mathbb{R}$). In the full version, our proof is carried out in this setting. In this extended abstract, we specialize to constraint functions over $\mathbb{R}$.

In Appendix A, we give an alternate approach for enforcing constraint function connectivity due to Roberson [12], which adds new binary connected constraint functions to $\mathcal{F}$ and $\mathcal{G}$ rather than modify the existing constraint functions to be projectively connected. We explore two further topics in the full version. First, we extend the connection between quantum isomorphism and nonlocal games. We define graph isomorphism games for real-weighted directed graphs and prove the following generalization of a result in [11]: real-weighted graphs F and G admit the same number of homomorphisms from all planar graphs if and only if there is a perfect quantum commuting strategy for the (F, G)-isomorphism game. Second,

we discuss how pivoting dangling edges around a gadget and horizontally reflecting gadgets, graphical manipulations that arise naturally throughout our work, correspond to the dual and adjoint operations in the pivotal dagger category of gadgets.

We hope that our results, in particular the quantum holographic transformation technique in Theorem 18, will lead to further applications of quantum group theory in the study of planar #CSP and Holant complexity.

2 Preliminaries

Constraint functions and #CSP

▶ **Definition 1** (Constraint function, $V(F)$, $V(\mathcal{F})$). *A tensor $F \in \mathbb{R}^{[q]^n}$, for $q, n \geq 1$, is a* constraint function *of domain size q and arity n. For $\mathbf{x} \in [q]^n$, we write $F_{\mathbf{x}} = F_{x_1,\ldots,x_n} = F(x_1, \ldots, x_n) \in \mathbb{R}$. We write $V(F)$ for $[q]$, thus $F \in \mathbb{R}^{V(F)^n}$. Whenever we specify a set $\mathcal{F}$ of constraint functions, it is assumed that all $F \in \mathcal{F}$ have the same domain, which we call $V(\mathcal{F})$, with $|V(\mathcal{F})| = q$.*

▶ **Definition 2** (#CSP, Z). *A* #CSP problem *#CSP($\mathcal{F}$) is parameterized by a set $\mathcal{F}$ of constraint functions. A* #CSP($\mathcal{F}$) instance *K is defined by a pair (V, C), where V is a set of variables and C is a multiset of* constraints*. Each constraint $c = (F^c, v_{c_1}, \ldots, v_{c_{n_F}})$ consists of a constraint function $F^c \in \mathcal{F}$ and an ordered tuple of variables to which F is applied. The* partition function *Z, on input #CSP($\mathcal{F}$) instance K, outputs*

$$Z(K) = \sum_{\sigma: V \to V(\mathcal{F})} \prod_{(F^c, v_{c_1}, \ldots, v_{c_{n_F}}) \in C} F^c(\sigma(v_{c_1}), \ldots, \sigma(v_{c_{n_F}})).$$

▶ **Definition 3** (Compatible constraint function sets, $K_{\mathcal{F}\to\mathcal{G}}$). *Let $\mathcal{F} = \{F_i\}_{i\in[t]}$, $\mathcal{G} = \{G_i\}_{i\in[t]}$ be two sets of constraint functions on the same domain $[q]$. $\mathcal{F}$ and $\mathcal{G}$ are* compatible *if, for all $i \in [t]$, F_i and G_i have common arity n_i. Call F_i and G_i* corresponding *constraint functions.*

For compatible $\mathcal{F}$ and $\mathcal{G}$ and any #CSP($\mathcal{F}$) instance K, define a #CSP($\mathcal{G}$) instance $K_{\mathcal{F}\to\mathcal{G}}$ by replacing every constraint $(F_i, v_{i_1}, \ldots, v_{i_{n_i}})$ of K with the corresponding constraint $(G_i, v_{i_1}, \ldots, v_{i_{n_i}})$.

Often it will be useful to "flatten" a constraint function F into a matrix:

▶ **Definition 4** ($F^{m,d}$, f). *For $F \in \mathbb{R}^{[q]^n}$ and any $m, d \geq 0$, $m + d = n$, let $F^{m,d} \in \mathbb{R}^{[q^m]\times[q^d]}$ be the $q^m \times q^d$ matrix defined by $F^{m,d}_{x_1\ldots x_m, x_n\ldots x_{m+1}} = F(x_1, \ldots, x_n)$, where $x_1 \ldots x_m \in \mathbb{N}$ is the base-q integer with the most significant digit x_1, and similarly for $x_n \ldots x_{m+1}$ (in decreasing index). We write $f = F^{n,0} \in \mathbb{R}^{q^n}$; it is called the* signature vector *of F.*

Quantum permutation matrices and quantum isomorphism

A core construction in this work is the *quantum permutation matrix*, a generalization of classical permutation matrix, whose entries come from an arbitrary C^*-algebra rather than $\{0, 1\}$. For the purposes of this work, one can view a C^*-algebra as simply an abstraction of $\mathbb{C}$, equipped with an involution $*$ analogous to conjugation, and whose elements, critically, do not necessarily commute. More generally, one can think of a C^*-algebra as the algebra of bounded operators on a Hilbert space.

▶ **Definition 5** (Quantum permutation matrix). *A matrix $\mathcal{U} = (u_{ij})$ with entries from a C^*-algebra with unit element $\mathbf{1}$ is called a* quantum permutation matrix *if it satisfies the following conditions for all i, j:*

- $u_{ij}^2 = u_{ij} = u_{ij}^*$;
- $\sum_j u_{ij} = \sum_i u_{ij} = \mathbf{1}$.

If the C^*-algebra in question is $\mathbb{C}$, then the first condition implies $\mathcal{U}$ is a 0-1 matrix, and then the second condition implies $\mathcal{U}$ is a classical permutation matrix. Hence the abstraction of $\mathbb{C}$ to an arbitrary C^*-algebra is one of the many abstractions from "classical" to "quantum" constructions throughout this work.

Recall that graphs X and Y with adjacency matrices $A_X, A_Y \in \{0,1\}^{[q]\times[q]}$ are classically isomorphic if and only if $PA_X = A_Y P$ for some classical permutation matrix P. Hence we say X and Y are *quantum isomorphic* ($X \cong_{qc} Y$) [1, 10] if there is a quantum permutation matrix $\mathcal{U}$ satisfying $\mathcal{U}A_X = A_Y\mathcal{U}$. Equivalently, $\mathcal{U}^{\otimes 2}a_X = a_Y$, where $a_X, a_Y \in \{0,1\}^{q^2}$ are the signature vectors of A_X and A_Y. Hence the following definition is a generalization of quantum graph isomorphism to higher-arity constraint functions over $\mathbb{R}$.

▶ **Definition 6** ($\cong_{qc}$). *$F, G \in \mathbb{R}^{[q]^n}$ are* quantum isomorphic *($F \cong_{qc} G$) if there is a $q \times q$ quantum permutation matrix $\mathcal{U}$ satisfying $\mathcal{U}^{\otimes n} f = g$. Compatible sets $\mathcal{F}$ and $\mathcal{G}$ of constraint functions are* quantum isomorphic *($\mathcal{F} \cong_{qc} \mathcal{G}$) if there is a $q \times q$ quantum permutation matrix $\mathcal{U}$ satisfying $\mathcal{U}^{\otimes \operatorname{arity}(F_i)} f_i = g_i$ for every i.*

Holant, gadgets and signature matrices

A Holant problem Holant($\mathcal{F}$), like a #CSP problem, is parameterized by a set $\mathcal{F}$ of constraint functions, usually called *signatures*. The input to Holant($\mathcal{F}$) is a *signature grid* Ω, which consists of an underlying multigraph X with vertex set V and edge set E. Each vertex $v \in V$ is assigned a signature $F_v \in \mathcal{F}$ of arity $\deg(v)$. The incident edges $E(v) = (e_1^v, \ldots, e_{\deg(v)}^v)$ of v are input variables to F_v taking values in $V(\mathcal{F})$. We use Pl-Holant($\mathcal{F}$) to specify that input signature grids must have planar underlying multigraphs. For planar Holant, the input variables of F_v are labeled in cyclic order starting with one particular edge, labeled with a diamond. The output on input Ω is

$$\operatorname{Holant}_\Omega(\mathcal{F}) = \sum_{\sigma: E \to V(\mathcal{F})} \prod_{v \in V} F_v(\sigma|_{E(v)}), \tag{1}$$

where $F_v(\sigma|_{E(v)}) = (F_v)(\sigma(e_1^v), \ldots, \sigma(e_{\deg(v)}^v))$. For sets $\mathcal{F}$ and $\mathcal{G}$ of signatures, define the problem Holant($\mathcal{F} \mid \mathcal{G}$) as follows. A signature grid in the context of Holant($\mathcal{F} \mid \mathcal{G}$) has a bipartite underlying multigraph with bipartition $V = V_1 \sqcup V_2$ such that the vertices in V_1 and V_2 are assigned signatures from $\mathcal{F}$ and $\mathcal{G}$, respectively.

The Holant problems in this work always include the following set of signatures.

▶ **Definition 7** (E_n, $\mathcal{EQ}$). *For fixed q, define the 0-1-valued* equality *constraint function $E_n \in \mathbb{R}^{[q]^n}$ by $E_n(x_1, \ldots, x_n) = 1$ iff $x_1 = \ldots = x_n$. Define $\mathcal{EQ} = \bigcup_n E_n$.*

To each #CSP($\mathcal{F}$) instance $K = (V, C)$ we associate a signature grid Ω_K in the context of Holant($\mathcal{F} \mid \mathcal{EQ}$) defined as follows: For every constraint $c \in C$, if c applies function F of arity n, create a degree-n vertex assigned F, called a *constraint vertex*. For each variable $v \in V$, if v appears in the mulitset of constraints $C_v \subseteq C$, create a degree-$|C_v|$ vertex assigned $E_{|C_v|} \in \mathcal{EQ}$, called an *equality vertex*, and edges (v, c) for every $c \in C_v$ such that the cyclic order of edges incident to each constraint vertex matches the order of variables in the constraint. Any edge assignment σ must assign all edges incident to an equality vertex the same value (or else the term corresponding to σ is 0), so we can view σ as #CSP variable assignent. Hence $Z(K) = \operatorname{Holant}_{\Omega_K}(\mathcal{F} \mid \mathcal{EQ})$.

For example, to compute the number of homomorphisms $K \to X$, consider a $\#\mathrm{CSP}(A_X)$ instance where the vertices of K are variables and each edge of K is a constraint applying function $A_X \in \mathbb{R}^{V(X)^2}$ (X's adjacency matrix) to the edge's two endpoints. The corresponding Holant signature grid Ω_K starts with underlying graph K, with K's vertices assigned the appropriate equality signature from $\mathcal{EQ}$, and we subdivide each of K's edges by placing degree-2 constraint vertices, assigned signature A_X, connected to the labeled equality vertices. See Figure 1. We always depict equality and constraint vertices as circles and squares, respectively.

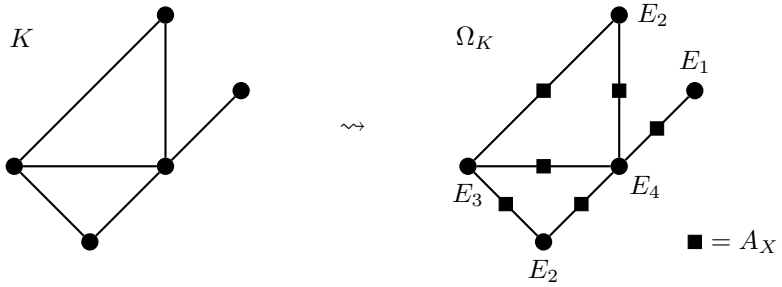

Figure 1 A graph K and the corresponding Holant$(A_X \mid \mathcal{EQ})$ signature grid Ω_K for computing the number of homomorphisms from K to X. Square vertices are assigned signature A_X.

Generalizing graph homomorphism to #CSP entails replacing A_X with an arbitrary set $\mathcal{F}$ of constraint functions, and replacing the degree-2 vertices assigned A_X with arbitrary-degree vertices assigned signatures from $\mathcal{F}$.

▶ **Definition 8** (Planar #CSP instance). *A #CSP instance K is* planar *if the underlying multigraph of the corresponding Holant signature grid Ω_K is planar.*

We now have the notation to state our main theorem.

▶ **Theorem 9** (Main result). *Let $\mathcal{F}$, $\mathcal{G}$ be compatible sets of constraint functions. Then $\mathcal{F} \cong_{qc} \mathcal{G}$ if and only if $Z(K) = Z(K_{\mathcal{F}\to\mathcal{G}})$ for every planar $\#CSP(\mathcal{F})$ instance K.*

If $\mathcal{F} = \{A_X\}$ and $\mathcal{G} = \{A_Y\}$, then Theorem 9 specializes to the result of [11]: graphs X and Y are quantum isomorphic iff they admit the same number of homomorphisms from every planar graph K.

▶ **Definition 10** (Gadget). *A* gadget *is a Holant signature grid equipped with an ordered set of dangling edges (edges with only one endpoint), defining external variables.*

Our gadgets will be in the context of Pl-Holant$(\mathcal{F} \mid \mathcal{EQ})$*, the Holant problem equivalent to $\#CSP(\mathcal{F})$. In this case, we specify that all dangling edges must be attached to equality vertices (vertices assigned signatures in $\mathcal{EQ}$).*

See Figures 2 and 3 for examples of gadgets in the context of Pl-Holant$(\mathcal{F} \mid \mathcal{EQ})$. We draw dangling edges lighter and thinner than internal edges.

▶ **Definition 11** ($M(\mathbf{K})$). *Let $\mathbf{K}$ be a gadget with n dangling edges and containing signatures of domain size q. For any $m, d \geq 0$, $m + d = n$, define $\mathbf{K}$'s (m, d)-*signature matrix *$M(\mathbf{K}) \in \mathbb{R}^{q^m \times q^d}$ by letting $M(\mathbf{K})_{\mathbf{x},\mathbf{y}}$ be the Holant value when the first m dangling edges (called* output *dangling edges) are assigned $x_1, \ldots, x_m$ and the last d dangling edges (called* input *dangling edges) are assigned $y_d, \ldots, y_1$. We draw the output/input dangling edges to the left/right of the gadget.*

▶ **Definition 12.** *Gadget $\mathbf{K}$ is* planar *if the underlying multigraph has an embedding with no edges (dangling or not) crossing, and the dangling edges are in cyclic order in the outer face.*

For a plane embedding of a planar gadget, we draw its output and input dangling edges on the left in order from top to bottom and on the right in order from bottom to top, respectively. For a gadget's signature matrix, observe that we consider the input dangling edges in reverse order, so from top to bottom. This definition preserves planarity of $\circ$:

▶ **Definition 13** (Gadget $\circ, \otimes, \dagger$). *For a gadget* $\mathbf{K}$ *with* $m+d$ *dangling edges, write* $\mathbf{K} \in \mathfrak{G}(m,d)$ *to mean we consider* $\mathbf{K}$ *with* m *output and* d *input dangling edges.*

- *For* $\mathbf{K} \in \mathfrak{G}(m,d), \mathbf{L} \in \mathfrak{G}(d,w)$*, define the composition* $\mathbf{K} \circ \mathbf{L} \in \mathfrak{G}(m,w)$ *by connecting each input dangling edge of* $\mathbf{K}$ *with the corresponding output dangling edge of* $\mathbf{L}$*. If* $\circ$ *creates adjacent vertices assigned* $E_a, E_b \in \mathcal{EQ}$*, we contract the edge between them, merging them into a single vertex assigned* E_{a+b-2}*. This does not change the Holant value.*
- *For* $\mathbf{K} \in \mathfrak{G}(m_1,d_1), \mathbf{L} \in \mathfrak{G}(m_2,d_2)$*, define the tensor product* $\mathbf{K} \otimes \mathbf{L} \in \mathfrak{G}(m_1+m_2, d_1+d_2)$ *by placing* $\mathbf{K}$ *above* $\mathbf{L}$*.*
- *For* $\mathbf{K} \in \mathfrak{G}(m,d)$*, define the (conjugate) transpose* $\mathbf{K}^\dagger \in \mathfrak{G}(d,m)$ *by reflecting* $\mathbf{K}$*'s underlying multigraph horizontally.*

See Figure 2. It is well known that applying the $\circ, \otimes, \dagger$ operations to gadgets corresponds to applying these operations to their signature matrices. See e.g. [3].

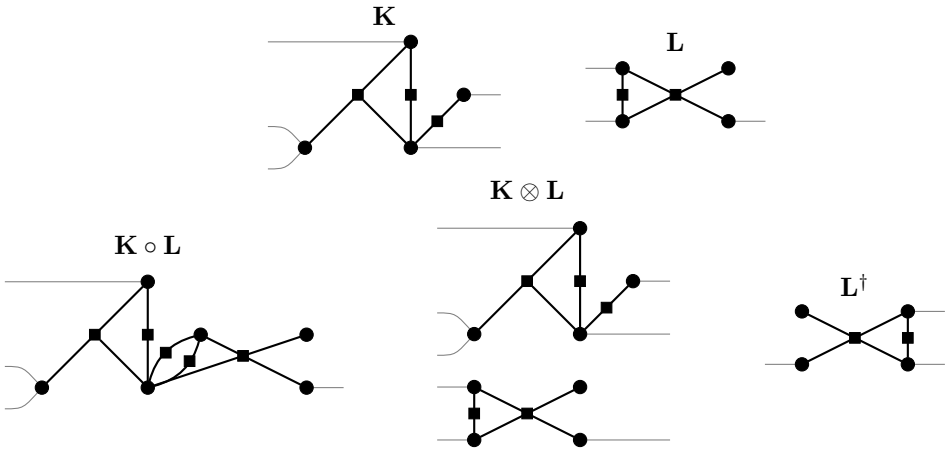

Figure 2 Operations on gadgets $\mathbf{K}$ and $\mathbf{L}$ in the context of Pl-Holant($\mathcal{F} \mid \mathcal{EQ}$).

3 Quantum Isomorphism Implies Planar #CSP Equivalence

3.1 The Planar Gadget Decomposition

Throughout, let $F \in \mathbb{R}^{[q]^n}$ denote a constraint function in $\mathcal{F}$, a set of constraint functions.

▶ **Definition 14** ($\mathcal{P}_\mathcal{F}$, $\mathcal{P}_\mathcal{F}(m,d)$). *Let* $\mathcal{P}_\mathcal{F}$ *be the collection of all planar gadgets in the context of* Holant($\mathcal{F} \mid \mathcal{EQ}$)*. Recall that all dangling edges of such a gadget are attached to vertices assigned signatures in* $\mathcal{EQ}$*.*

Let $\mathcal{P}_\mathcal{F}(m,d) \subseteq \mathcal{P}_\mathcal{F}$ *be the subset of gadgets with* m *output and* d *input dangling edges.*

The discussion after Definition 7 constructs a Pl-Holant($\mathcal{F} \mid \mathcal{EQ}$) instance modelling any given planar #CSP($\mathcal{F}$) instance. One can easily invert this construction to produce a planar #CSP($\mathcal{F}$) instance modelling any given Pl-Holant($\mathcal{F} \mid \mathcal{EQ}$) instance. Hence the signature grids underlying $\mathcal{P}_\mathcal{F}(m,d)$ are exactly the set of signature grids Ω_K corresponding to planar #CSP($\mathcal{F}$) instances.

We next introduce two families of fundamental gadgets in $\mathcal{P}_\mathcal{F}$. See Figure 3.

▶ **Definition 15** ($\mathbf{E}^{m,d}$, $\mathbf{F}^{m,d}$). *For $m, d \geq 0$, let $\mathbf{E}^{m,d}$ be the gadget consisting of a single vertex, assigned E_{m+d}, with m output and d input dangling edges.*

For $m, d \geq 0$ and $(m+d)$-ary signature function F, let $\mathbf{F}^{m,d}$ be the gadget consisting of a central degree-$(m+d)$ vertex assigned F, and m left and d right "arms", each with a vertex assigned E_2 with an output or input dangling edge, respectively. Define $\mathbf{I} = \mathbf{E}^{1,1}$.

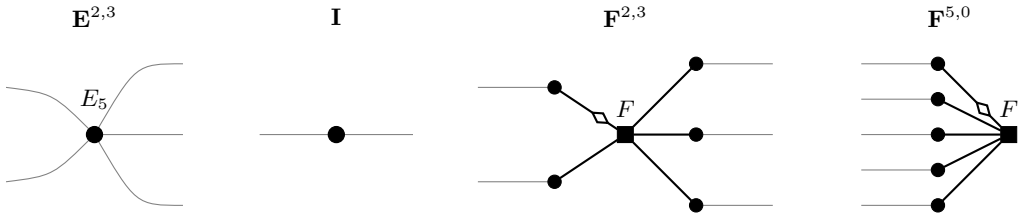

Figure 3 Examples of the fundamental gadgets $\mathbf{E}^{m,d}$ and $\mathbf{F}^{m,d}$. The diamond indicates the first input to asymmetric F.

Observe that $M(\mathbf{E}^{m,d}) = E^{m,d}$ and $M(\mathbf{F}^{m,d}) = F^{m,d}$; in particular $M(\mathbf{F}^{n,0}) = f$.

The next lemma addresses a key new issue raised by viewing our higher-arity constraint functions as explicit vertices in the signature grid. Section 4 requires all $\mathbf{F}$ gadgets to be in the form $\mathbf{F}^{m+d,0}$, but the decomposition procedure below produces gadgets $\mathbf{F}^{m,d}$ for arbitrary m and d (see Figure 5). Hence we must pivot $\mathbf{F}^{m,d}$'s dangling edges between input and output. $\mathbf{E}^{2,0}, \mathbf{E}^{0,2}, \mathbf{I} \in \langle \mathbf{E}^{1,0}, \mathbf{E}^{1,2} \rangle_{\circ,\otimes,\dagger}$ (the closure of $\{\mathbf{E}^{1,0}, \mathbf{E}^{1,2}\}$ under $\circ, \otimes, \dagger$), so we apply a procedure like the one in Figure 4.

▶ **Lemma 16.** *Let F be an n-ary constraint function. Then $\mathbf{F}^{m,d} \in \langle \mathbf{E}^{1,0}, \mathbf{E}^{1,2}, \mathbf{F}^{n,0} \rangle_{\circ,\otimes,\dagger}$ for all $m + d = n$.*

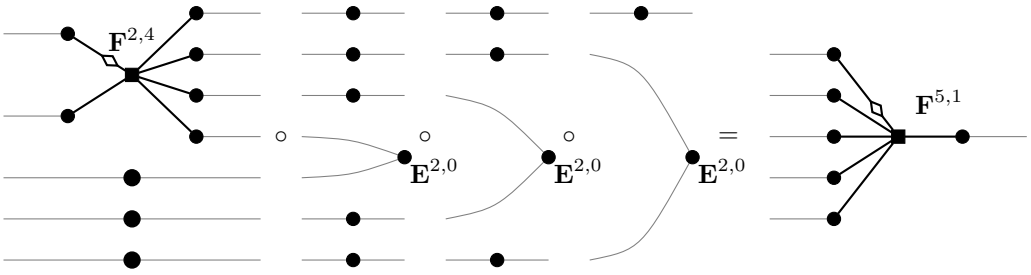

Figure 4 $(\mathbf{F}^{2,4} \otimes \mathbf{I}^{\otimes 3}) \circ (\mathbf{I}^{\otimes 3} \otimes \mathbf{E}^{2,0} \otimes \mathbf{I}^{\otimes 2}) \circ (\mathbf{I}^{\otimes 2} \otimes \mathbf{E}^{2,0} \otimes \mathbf{I}) \circ (\mathbf{I} \otimes \mathbf{E}^{2,0}) = \mathbf{F}^{5,1}$.

Next we show that any planar Holant($\mathcal{F} \mid \mathcal{EQ}$) gadget can be decomposed into the $\mathbf{F}^{\text{arity}(F),0}$ gadgets containing the signatures in $\mathcal{F}$, and two small equality gadgets.

▶ **Theorem 17.** $\mathcal{P}_{\mathcal{F}} = \langle \mathbf{E}^{1,0}, \mathbf{E}^{1,2}, \{\mathbf{F}^{\text{arity}(F),0} \mid F \in \mathcal{F}\} \rangle_{\circ,\otimes,\dagger}$.

The reverse inclusion follows from the fact that $\circ, \otimes, \dagger$ preserve planarity. The idea for the forward inclusion is to decompose an arbitrary $\mathbf{K} \in \mathcal{P}_{\mathcal{F}}$ into a composition of copies of $\mathbf{E}^{m,d}$ and appropriate $\mathbf{F}^{m,d}$, tensored with copies of $\mathbf{I}$. We use Lemma 16 to convert each $\mathbf{F}^{m,d}$ to $\mathbf{F}^{n,0}$. To extract an equality or constraint vertex, we apply one of the two extraction procedures shown in Figure 5, or their horizontal reflections. The extraction procedures guarantee that remaining gadget is still planar, bipartite, and has all dangling edges incident to equality vertices (i.e. is in $\mathcal{P}_{\mathcal{F}}$), so we apply induction.

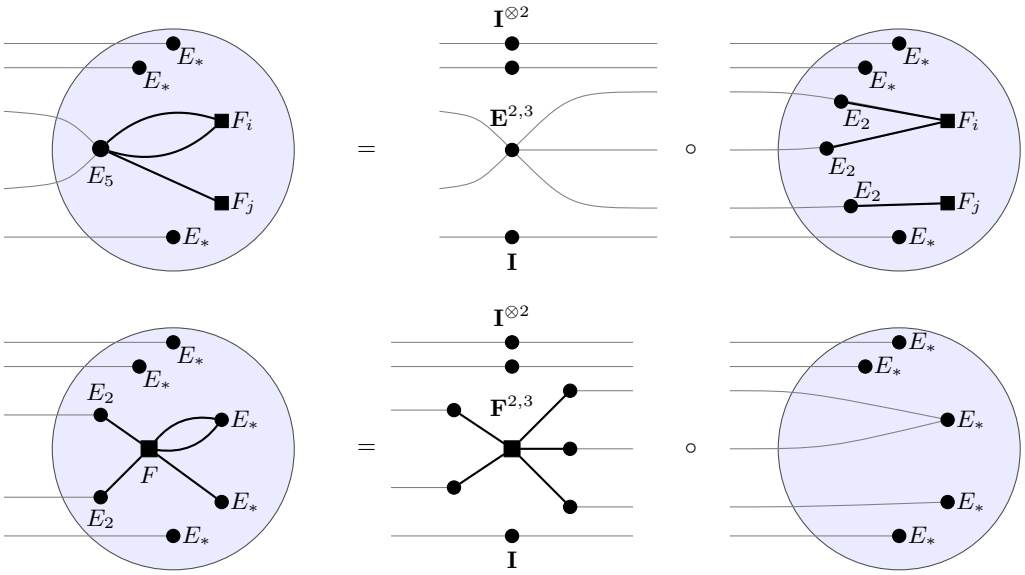

Figure 5 Extracting an equality (top) or constraint vertex from a planar Holant($\mathcal{F} \mid \mathcal{EQ}$) gadget.

3.2 Gadgets and quantum permutation matrices

The quantum Holant theorem, proved in Subsection 3.3, stems from viewing the quantum permutation matrix $\mathcal{U}$ itself as a signature in a Holant signature grid, indicated by a triangle vertex ▲. An immediate corollary of this theorem is one half of our main result Theorem 9: Planar #CSP instances with quantum isomorphic signature sets have the same partition function value. The proof of this result via the quantum Holant theorem is graphical and more intuitive than the proof in [11] of the graph homomorphism special case, and ties quantum isomorphism into the well-studied Holant framework. Furthermore, the graphical calculus of the quantum Holant theorem nicely highlights one of the key new difficulties of our generalization: unlike constraint functions derived from homomorphisms to undirected graphs (the case considered in [11]), general constraint functions F can be *asymmetric*: F's value is not necessarily preserved under permutation of its inputs. By planarity, permutations that cross F's input edges are not allowed, but the dihedral group actions – rotations and reflection – are allowed. Define the rotated constraint function $F^{(r)}$ for $r \in [\text{arity}(F)]$ by $F^{(r)}(x_1, \ldots, x_n) = F(x_{r+1}, \ldots, x_n, x_1, \ldots, x_r)$ and the reflected constraint function $F^\dagger$ by $F^\dagger(x_1, \ldots, x_n) = F(x_n, \ldots, x_1)$. Assuming F and G are quantum isomorphic, that is, $\mathcal{U}^{\otimes n} f = g$, it is not *a priori* obvious (due to noncommutativity), but true, that

$$\mathcal{U}^{\otimes n} f = g \iff \mathcal{U}^{\otimes n} f^{(r)} = g^{(r)} \text{ and } \mathcal{U}^{\otimes n} f = g \iff \mathcal{U}^{\otimes n} f^\dagger = g^\dagger. \tag{2}$$

The quantum Holant theorem uses $\mathcal{U}$ to transform each F in the Holant signature grid into G (via the assumption $\mathcal{U}^{\otimes n} f = g$), and since the signatures $F^{(r)}$ and $F^\dagger$ may appear in the signature grid in place of F, the theorem's success is dependent on the identities (2).

The bottom two panes of Figure 6 below illustrate a case of (2) for 5-ary f and g. The fact that Figure 6 uses $\mathbf{F}^{2,3}$ and $\mathbf{G}^{2,3}$ (with signature matrices $F^{2,3}$ and $G^{2,3}$) in place of $\mathbf{F}^{5,0}$ and $\mathbf{G}^{5,0}$ (with signature vectors f and g) is due to the additional useful identity

$$\mathcal{U}^{\otimes n} f = g \iff \mathcal{U}^{\otimes m} F^{m,d} (\mathcal{U}^{\otimes d})^\dagger = G^{m,d} \text{ for any } m + d = n, \tag{3}$$

illustrated in the upper right pane of Figure 6.

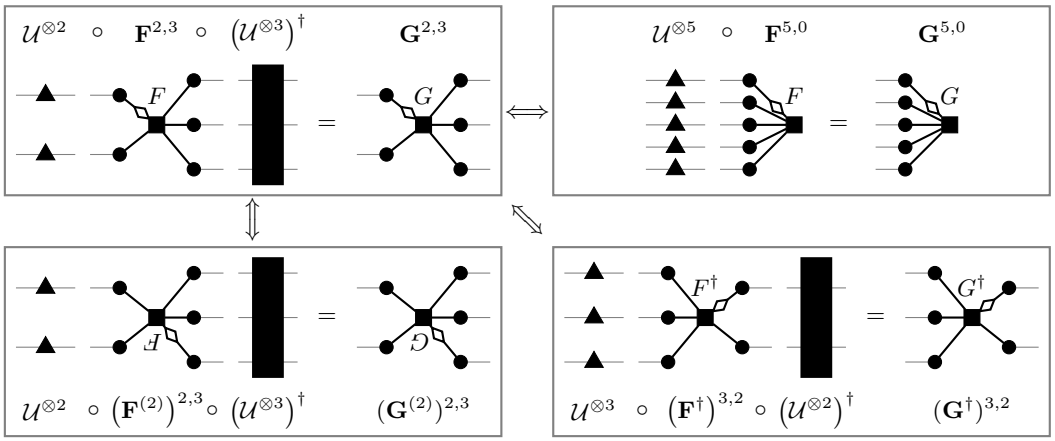

Figure 6 The "action" of $\mathcal{U}$ transforming F to G is preserved under (clockwise from top right) edge pivoting, signature reflection, and signature rotation. $(\mathcal{U}^{\otimes n})^\dagger$ is drawn as a black box, since, due to noncommutativity, $(\mathcal{U}^{\otimes n})^\dagger \neq (\mathcal{U}^\dagger)^{\otimes n}$ in general.

3.3 The Quantum Holant Theorem

The quantum Holant theorem gives a quantum version of *holographic transformation*. A holographic transformation [13] transforms one Holant signature grid Ω into another Ω' resulting in the same Holant value. For a set $\mathcal{F}$ of signatures and an invertible $T \in \mathbb{C}^{q \times q}$, write $T\mathcal{F} = \{T^{\otimes k} f \mid F \in \mathcal{F} \text{ has arity } k\}$. Define $\mathcal{F}T$ similarly. Valiant's Holant Theorem in [13] states that $\text{Holant}_\Omega(\mathcal{F} \mid \mathcal{G}) = \text{Holant}_{\Omega'}(T\mathcal{F} \mid \mathcal{G}T^{-1})$, for any Ω and sets of signatures $\mathcal{F}, \mathcal{G}$, where Ω' is constructed from Ω by replacing every signature in $\mathcal{F}$ or $\mathcal{G}$ with the corresponding transformed signature.

The Holant signature grids Ω_K and $\Omega_{K_{\mathcal{F}\to\mathcal{G}}}$ satisfying $Z(K) = \text{Pl-Holant}_{\Omega_K}(\mathcal{F} \mid \mathcal{EQ})$ and $Z(K_{\mathcal{F}\to\mathcal{G}}) = \text{Pl-Holant}_{\Omega_{K_{\mathcal{F}\to\mathcal{G}}}}(\mathcal{G} \mid \mathcal{EQ})$ are the same, up to replacement of every signature $F \in \mathcal{F}$ by the corresponding signature $G \in \mathcal{G}$. Assuming $\mathcal{F} \cong_{qc} \mathcal{G}$, there is a quantum permutation matrix $\mathcal{U}$ satisfying $\mathcal{U}^{\otimes n} f = g$ for every $F \in \mathcal{F}$ and corresponding $G \in \mathcal{G}$. This suggests we perform a *quantum* holographic transformation using $\mathcal{U}$. A calculation shows that $E^{0,n} = E^{0,n}\mathcal{U}^{\otimes n}$ for every n and any quantum permutation matrix $\mathcal{U}$. As $\mathcal{U}^{-1} = \mathcal{U}^\dagger$ is a quantum permutation matrix, $(\mathcal{EQ})\mathcal{U}^{-1} = \mathcal{EQ}$. Then the Holant theorem setting T to $\mathcal{U}$ seems to give

$$Z(K) = \text{Holant}_{\Omega_K}(\mathcal{F} \mid \mathcal{EQ}) = \text{Holant}_{\Omega_{K_{\mathcal{F}\to\mathcal{G}}}}(\mathcal{G} \mid \mathcal{EQ}) = Z(K_{\mathcal{F}\to\mathcal{G}}) \tag{4}$$

for any, not necessarily planar, #CSP($\mathcal{F}$) instance K. However, this cannot be true. If $\mathcal{F} = \{F\}$ and $\mathcal{G} = \{G\}$, where F and G are symmetric, binary, and 0-1 valued, (4) implies that the graphs with adjacency matrices F and G admit the same number of homomorphisms from any graph, giving $F \cong G$, a classical result of Lovász [8]. In other words, any quantum isomorphic graphs are classically isomorphic. But this is known to be false – see e.g. [1]. The main reason for this failure is the noncommutativity of $\mathcal{U}$'s entries.

When Ω_K is planar, however, this can be rescued by using the decomposition procedure for Ω_K in the proof of Theorem 17, which produces a sequence of gadgets whose signature matrices multiply to the Holant value. This defines an order of Ω_K's vertices, giving a globally consistent way in which $\mathcal{U}$'s entries are multiplied, for the partition function (sum of product expression). We will use $\mathcal{U}$ as a "quantum holographic transformation" by inserting $\mathcal{U}^{\otimes k}$ and its inverse $(\mathcal{U}^{\otimes k})^\dagger$ between every pair of these gadgets, converting every $F \in \mathcal{F}$ to the corresponding $G \in \mathcal{G}$ and preserving $\mathcal{EQ}$.

▶ **Theorem 18** (Quantum Holant Theorem). *Let $\mathcal{U}$ be a $q \times q$ quantum permutation matrix, and let $\mathcal{F}$ and $\mathcal{UF}$ be compatible sets of domain-q real-valued signatures. Then for every* Pl-Holant($\mathcal{F}$) *signature grid Ω,*

$$\text{Pl-Holant}_{\Omega}(\mathcal{F}) = \text{Pl-Holant}_{\Omega'}(\mathcal{UF}),$$

where Ω' is constructed from Ω by replacing every signature in $\mathcal{F}$ with the corresponding signature in $\mathcal{UF}$.

We omit its proof in this extended abstract. The main idea is to perform successive quantum holographic transformations using $\mathcal{U}$; the "pushing through" a set of $\mathcal{U}$'s as tensor powers is illustrated in Figure 7. Since the central gadget may be $\left(\mathbf{F}_i^{(r)}\right)^{m_i,d_i}$ or $\left(\mathbf{F}_i^{\dagger}\right)^{m_i,d_i}$ (depending on the orientation of F in the signature grid) rather than simply $\mathbf{F}^{m_i+d_i,0}$, the identities (2) and (3) illustrated in Figure 6 are necessary.

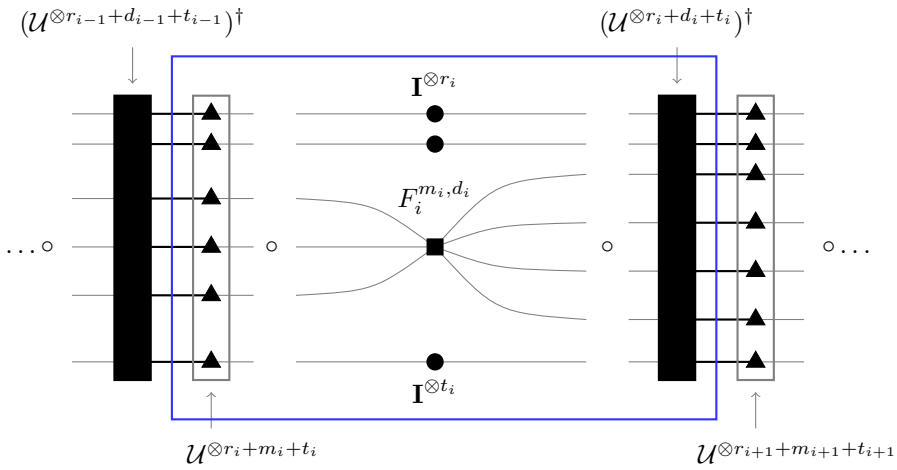

Figure 7 A visualization of a step in the proof of the quantum Holant theorem. We insert factors of the form $I = (\mathcal{U}^{\otimes k})^{\dagger}\mathcal{U}^{\otimes k}$ between every pair of gadgets $\mathbf{I}^{\otimes r_i} \otimes \mathbf{F}_i^{m_i,d_i} \otimes \mathbf{I}^{\otimes t_i}$, then apply gadget composition associativity. The resulting gadget in the blue box is $\mathbf{I}^{\otimes r_i} \otimes \mathbf{G}_i^{m_i,d_i} \otimes \mathbf{I}^{\otimes t_i}$.

Observe that, unlike other results in this work, the quantum Holant theorem is not only applicable to Pl-Holant($\mathcal{F} \mid \mathcal{EQ}$), but more generally to Pl-Holant($\mathcal{F}$) for *any* signature set $\mathcal{F}$. Since holographic transformations are an indespensable tool for the study of Holant problems, and planar Holant is the subject of much active research, the quantum Holant theorem should be of independent interest.

▶ **Corollary 19.** *Let $\mathcal{F}$ and $\mathcal{G}$ be compatible sets of constraint functions. If $\mathcal{F} \cong_{qc} \mathcal{G}$, then $Z(K) = Z(K_{\mathcal{F}\to\mathcal{G}})$ for every planar #CSP($\mathcal{F}$) instance K.*

4 Planar #CSP Equivalence Implies Quantum Isomorphism

The Quantum Automorphism Group

The most abstract construction in this work is the quantum automorphism group Qut($\mathcal{F}$) of a constraint function set $\mathcal{F}$. We omit the full formal definition here, as understanding it is not relevant to the rest of the work.

▶ **Definition 20** ($\mathrm{Qut}(\mathcal{F})$). *For a set $\mathcal{F}$ of constraint functions with $|V(\mathcal{F})| = q$, the* quantum automorphism group $\mathrm{Qut}(\mathcal{F})$ *of $\mathcal{F}$ is defined by the universal*[2] *C^*-algebra $C(\mathrm{Qut}(\mathcal{F}))$ generated by the entries of a $q \times q$ matrix $\mathcal{U} = (u_{ij})$ subject to the relations specifying that $\mathcal{U}$ is a quantum permutation matrix and $\mathcal{U}^{\otimes \mathrm{arity}(F)} f = f$ for every $F \in \mathcal{F}$.*

Observe that, just as $\mathcal{U}^{\otimes \mathrm{arity}(F)} f = g$ defines a quantum isomorphism between F and G, $\mathcal{U}^{\otimes \mathrm{arity}(F)} f = f$ defines quantum automorphisms of F. It is helpful, and sufficient for our purposes, to identify $\mathrm{Qut}(\mathcal{F})$ with $\mathcal{U}$ and $C(\mathrm{Qut}(\mathcal{F}))$, thought of as the algebra of continuous functionals on $\mathrm{Qut}(\mathcal{F})$. Indeed, if $\mathcal{U}$'s entries commute, then $C(\mathrm{Qut}(\mathcal{F}))$ concretizes as the algebra of continuous functionals on the classical automorphism group $\mathrm{Aut}(\mathcal{F})$. Thus the relationship between $\mathrm{Qut}(\mathcal{F})$ and $\mathrm{Aut}(\mathcal{F})$ is analogous to the relationship between quantum and classical permutation matrices: the former is an abstraction of the latter, sharing many familiar properties and constructions.

One such construction is the *orbits* of $\mathrm{Qut}(\mathcal{F})$ on the domain $V(\mathcal{F})$ [10]. If $\mathcal{U}$ is the quantum permutation matrix defining $\mathrm{Qut}(\mathcal{F})$, then $x, y \in V(\mathcal{F})$ are in the same orbit of $\mathrm{Qut}(\mathcal{F})$ if and only if $u_{xy} \neq 0$ (one can draw an analogy with the orbits of $\mathrm{Aut}(\mathcal{F})$ on $V(\mathcal{F})$ by viewing u_{xy} as corresponding to the automorphisms mapping x to y).

Another such construction is the *intertwiner space* of $\mathrm{Qut}(\mathcal{F})$.

▶ **Definition 21** ($C_{\mathrm{Qut}(\mathcal{F})}(m,d)$, $C_{\mathrm{Qut}(\mathcal{F})}$). $C_{\mathrm{Qut}(\mathcal{F})}(m,d) = \{M \in \mathbb{C}^{q^m \times q^d} \mid \mathcal{U}^{\otimes m} M = M \mathcal{U}^{\otimes d}\}$ *is the space of* (m,d)-intertwiners *of* $\mathrm{Qut}(\mathcal{F})$, *and* $C_{\mathrm{Qut}(\mathcal{F})} = \bigcup_{m,d} C_{\mathrm{Qut}(\mathcal{F})}(m,d)$.

Observe that the equation $\mathcal{U}^{\otimes m} M = M \mathcal{U}^{\otimes d}$ resembles, after multiplying by $(\mathcal{U}^{\otimes d})^{-1} = (\mathcal{U}^{\otimes d})^\dagger$, the equation $\mathcal{U}^{\otimes m} F^{m,d} \left(\mathcal{U}^{\otimes d}\right)^\dagger = G^{m,d}$ characterizing quantum isomorphism of F and G (recall (3)). Hence it is reasonable to assume that $C_{\mathrm{Qut}(\mathcal{F})}$ consists of gadget signature matrices. The next lemma, proved in the full version using techniques from quantum group theory, is a step towards this conclusion.

▶ **Lemma 22.** $C_{\mathrm{Qut}(\mathcal{F})} = \langle E^{1,0}, E^{1,2}, \{f \mid F \in \mathcal{F}\} \rangle_{+,\circ,\otimes,\dagger}$.

Note that the RHS of Lemma 22 is the linear span of the signature matrices of the gadgets in the RHS of Theorem 17. This observation motivates the following definition.

▶ **Definition 23** ($\mathfrak{Q}^{\mathcal{P}}_{\mathcal{F}}(m,d)$). *A* planar (m,d)-quantum $\mathcal{F}$-gadget *is a finite linear combination of gadgets in $\mathcal{P}_{\mathcal{F}}(m,d)$ with coefficients in $\mathbb{C}$. Let $\mathfrak{Q}^{\mathcal{P}}_{\mathcal{F}}(m,d)$ be the collection of all planar (m,d)-quantum $\mathcal{F}$-gadgets. Extend the signature matrix function M linearly to $\mathfrak{Q}^{\mathcal{P}}_{\mathcal{F}}(m,d)$.*

Applying M to quantum $\mathcal{F}$-gadgets composed of gadgets on the RHS of Theorem 17 yields the RHS of Lemma 22, so we have the following key connection between the planar gadget decomposition and the intertwiners of $\mathrm{Qut}(\mathcal{F})$.

▶ **Theorem 24.** $C_{\mathrm{Qut}(\mathcal{F})}(m,d) = \{M(\mathbf{Q}) \mid \mathbf{Q} \in \mathfrak{Q}^{\mathcal{P}}_{\mathcal{F}}(m,d)\}$ *for every $m, d \in \mathbb{N}$.*

Say a #CSP instance $K = (V, C)$ is 1-*labeled* if there is a distinguished *labeled* variable $v \in V$. For $x \in V(\mathcal{F})$, let Z^x be the partition function on 1-labeled instances, defined identically to Z, except only summing over those $\sigma : V \to V(\mathcal{F})$ such that $\sigma(v) = x$. A 1-labeled #CSP($\mathcal{F}$) instance K with labeled variable v corresponds to a Holant($\mathcal{F} \mid \mathcal{EQ}$) gadget $\mathbf{K}$ with a single dangling edge incident to the equality vertex constructed from v. For $x \in V(\mathcal{F})$, $M(\mathbf{K})_x = Z^x(K)$. Then the connection between intertwiners and gadget signature matrices established in Theorem 24 yields the following lemma, a quantum analogue of several similar classical results for graph homomorphism, including [9, Lemma 2.4].

▶ **Lemma 25.** *$x, y \in V(\mathcal{F})$ are in the same orbit of $\mathrm{Qut}(\mathcal{F})$ if and only if $Z^x(K) = Z^y(K)$ for all 1-labeled planar #CSP($\mathcal{F}$) instances K.*

[2] A "universal" C^*-algebra is roughly analogous to the generator-and-relation presentation of a group.

Arity Reduction and Projective Connectivity

For n-ary constraint functions, the remaining results require n-dimensional generalizations of orbits. However, such higher-dimensional orbits are not known to exist for $n > 2$. This is another new difficulty posed by our extension of binary graph homomorphism to higher-arity functions. We overcome it by the following arity-reduction technique.

▶ **Lemma 26.** *Let F be an n-ary constraint function with $n > 2$ and let $\mathcal{U}$ define* $\mathrm{Qut}(\{F\})$*, so $\mathcal{U}^{\otimes n} f = f$. Define an arity-$(n-1)$ constraint function F' by $F'_{x_2,\ldots,x_n} = \sum_{x_1} F_{x_1,x_2,\ldots,x_n}$. Then $\mathcal{U}^{\otimes n-1} f' = f'$ (where f' is the vectorization of F').*

After $n-2$ applications of Lemma 26, the resulting binary constraint function is the adjacency matrix of a $\mathbb{R}$-weighted graph. We would like this $\mathbb{R}$-weighted graph to be *connected*, meaning the transitive closure of the relation $\sim$ on $V(X)$ defined by $x \sim y \iff X_{xy} \neq 0$ has only a single equivalence class. We define connnectivity for higher-arity tensors motivated by Lemma 26. For $n \geq 2$, an n-ary constraint function F is *projectively connected* if the $\mathbb{R}$-weighted graph X defined by $X_{uv} = \sum_{x_1,\ldots,x_{n-2}} F_{x_1,\ldots,x_{n-2},u,v}$ is connected.

▶ **Definition 27** ($\oplus$)**.** *Let $F \in \mathbb{R}^{V(F)^n}, G \in \mathbb{R}^{V(G)^n}$ be constraint functions of the same arity n. The* direct sum *$F \oplus G \in \mathbb{R}^{(V(F) \sqcup V(G))^n}$ of F and G is defined for all $\mathbf{x} \in (V(F) \sqcup V(G))^n$ by setting $(F \oplus G)_{\mathbf{x}}$ to be $F_{\mathbf{x}}$ or $G_{\mathbf{x}}$ if $\mathbf{x} \in V(F)^n$ or $\mathbf{x} \in V(G)^n$, respectively, and 0 otherwise. For constraint function sets $\mathcal{F}$ and $\mathcal{G}$ of size s, define $\mathcal{F} \oplus \mathcal{G} = \{F_i \oplus G_i \mid i \in [s]\}$.*

For $n = 2$ and 0-1 valued F and G, the direct sum is the disjoint union of the graphs whose adjacency matrices are F and G. Projective connectivity is desirable due to the following lemma, an extension of [10, Theorem 4.5] to higher arity, and an analogue of the fact that, for connected graphs X and Y, if there exist vertices $x \in V(X)$ and $y \in V(Y)$ in the same orbit of the automorphism group of the disjoint union of X and Y, then $X \cong Y$.

▶ **Lemma 28.** *Let $\mathcal{F}$ and $\mathcal{G}$ be constraint function sets with domains $V(\mathcal{F})$ and $V(\mathcal{G})$, respectively, and further assume that $\mathcal{F}$ and $\mathcal{G}$ contain a pair of corresponding projectively connected constraint functions. If there are some $\hat{x} \in V(\mathcal{F})$, $\hat{y} \in V(\mathcal{G})$ in the same orbit of* $\mathrm{Qut}(\mathcal{F} \oplus \mathcal{G})$*, then $\mathcal{F} \cong_{qc} \mathcal{G}$.*

The proof of Lemma 28 proceeds roughly as follows. Let $\mathcal{U}$ define $\mathrm{Qut}(\mathcal{F} \oplus \mathcal{G})$, and let F and G be the corresponding projectively connected constraint functions in $\mathcal{F}$ and $\mathcal{G}$, respectively. Summing out all but two indices of $F \oplus G$ (as in Lemma 26), we obtain a $\mathbb{R}$-weighted graph Z whose subgraphs induced by $V(F)$ and $V(G)$ are connected, and such that $\mathcal{U}^{\otimes 2} z = z$. Then, following the proof of [10, Theorem 4.5], we extract from Z enough information about $\mathcal{U}$ to show that its quarter submatrix $(u_{xy})_{x \in V(X), y \in V(Y)}$ is itself a quantum permutation matrix, defining a quantum isomorphism between $\mathcal{F}$ and $\mathcal{G}$.

Finally, we come to the proof of the reverse implication of Theorem 9. Lemma 28 assumes $\mathcal{F}$ contains a projectively constraint function, which in general is not true. For (unweighted) graphs, one can take the complement to assume the graphs are connected, but this trick does not apply to our $\mathbb{R}$-weighted constraint functions. Instead, we adapt an idea from Lovász's proof of [9, Corollary 2.6], which is roughly the *classical* case of Theorem 9 restricted to positive-real-weighted graphs. The idea is to add a new vertex to each graph, each adjacent to all other vertices by edges of the same nonzero weight. The new vertices are the targets of a result analogous to Lemma 25, each graph is now connected, and by symmetry of the new vertices, their addition preserves isomorphism. Somewhat remarkably, the same idea applies to quantum isomorphism of higher-arity constraint functions.

▶ **Lemma 29.** *Let $\mathcal{F}$ and $\mathcal{G}$ be compatible sets of constraint functions. If $Z(K) = Z(K_{\mathcal{F}\to\mathcal{G}})$ for every planar #CSP($\mathcal{F}$) instance K, then $\mathcal{F} \cong_{qc} \mathcal{G}$.*

We now present a proof sketch of Lemma 29. See the full version for a full proof. Let 0_F and 0_G be new domain elements. For each $F \in \mathcal{F}$, $G \in \mathcal{G}$, define constraint functions F' and G' on $V(\mathcal{F}) \sqcup \{0_F\}$ and $V(\mathcal{G}) \sqcup \{0_G\}$, by letting

$$F'_{\mathbf{x}} = \begin{cases} F_{\mathbf{x}} & \mathbf{x} \in V(\mathcal{F})^n \\ \gamma & \mathbf{x} = (0_F, 0_F, \ldots, 0_F, c),\ c \neq 0_F \\ 0 & \text{otherwise} \end{cases};\quad G'_{\mathbf{x}} = \begin{cases} G_{\mathbf{x}} & \mathbf{x} \in V(\mathcal{G})^n \\ \gamma & \mathbf{x} = (0_G, 0_G, \ldots, 0_G, c),\ c \neq 0_G \\ 0 & \text{otherwise} \end{cases}$$

for some fixed $\gamma \in \mathbb{R} \setminus \{0\}$. Let $\mathcal{F}' = \{F' \mid F \in \mathcal{F}\}$, $\mathcal{G}' = \{G' \mid G \in \mathcal{G}\}$, with $V(\mathcal{F}') = V(\mathcal{F}) \sqcup \{0_F\}$ and $V(\mathcal{G}') = V(\mathcal{G}) \sqcup \{0_G\}$.

F' and G' are designed to simultaneously satisfy three properties. First, defining $\mathbb{R}$-weighted graphs X' and Y' from F' and G' by summing the first $n-2$ indices as in Lemma 26, we have $X'_{0_F v} = \gamma \neq 0$ for every $v \in V(X') \setminus \{0_F\}$, and similarly for Y'. Thus X' and Y' are connected, so F' and G' are projectively connected.

Second, we wish to obtain $Z^{0_F}(K) = Z^{0_G}(K)$ for every planar 1-labeled #CSP($\mathcal{F}' \oplus \mathcal{G}'$) instance $K = (V, C)$. Then Lemma 25 asserts that 0_F and 0_G are in the same orbit of $\mathrm{Qut}(\mathcal{F}' \oplus \mathcal{G}')$, Hence, since F' and G' are projectively connected, $0_F \in V(\mathcal{F}')$, and $0_G \in V(\mathcal{G}')$, Lemma 28 gives $\mathcal{F}' \cong_{qc} \mathcal{G}'$. Let $K = (V, C)$. To obtain $Z^{0_F}(K) = Z^{0_G}(K)$, consider the following. Let v_0 be the labeled variable in V. When v_0 takes value $0_F \in V(\mathcal{F}')$, all variables must take values in $V(\mathcal{F}')$ (otherwise the assignment contributes 0 to the partition function, as $F' \oplus G'$ takes value 0 unless its inputs are all in $V(\mathcal{F}')$ or all in $V(\mathcal{G}')$). Furthermore, by construction of $\mathcal{F}'$, any constraint function applied to variable v_0 evaluates to 0 unless most of its other arguments also take value 0_F. This fixes more variables to 0_F, and the effect cascades to other constraint functions applied to those variables and so on. Any nonzero constraint with a variable fixed to 0_F always evaluates to γ. Let D be the set of such constraints. Remaining constraints in $C \setminus D$ apply some F' to inputs in only $V(\mathcal{F})$, so F', by construction, acts as the original F. Therefore, the sub-instance of K induced by constraints $C \setminus D$ is effectively a planar #CSP($\mathcal{F}$) instance, so $Z^{0_F}(K)$ is expressible as $\gamma^{|D|}$ times the sum of $Z(K')$ for various planar #CSP($\mathcal{F}$) instances K'. Similarly, by the symmetry of $\mathcal{F}'$ and $\mathcal{G}'$, $Z^{0_G}(K)$ is expressible as $\gamma^{|D|}$ times the sum of $Z(K'')$ for matching planar #CSP($\mathcal{G}$) instances K'', and by assumption each $Z(K') = Z(K'')$. Hence $Z^{0_F}(K) = Z^{0_G}(K)$.

Third, upon obtaining the quantum isomorphism $\mathcal{U}$ between $\mathcal{F}'$ and $\mathcal{G}'$, we must recover a quantum isomorphism between the original $\mathcal{F}$ and $\mathcal{G}$. Define the matrix $\widehat{\mathcal{U}} = (u_{uv})_{u \in V(\mathcal{G}), v \in V(\mathcal{F})}$ (in other words, we eliminate from $\mathcal{U}$ the row and column corresponding to the new vertices 0_G and 0_F, respectively). $\mathcal{F}'$ and $\mathcal{G}'$ were constructed so that, if γ is chosen to be sufficiently large, then $\widehat{\mathcal{U}}$ is a quantum permutation matrix, and furthermore defines a quantum isomorphism between $\mathcal{F}$ and $\mathcal{G}$.

A Appendix: An alternate approach to connectivity

The proof of Lemma 28 makes use of the 2-dimensional orbits, or *orbitals*, of $\mathrm{Qut}(\mathcal{F} \oplus \mathcal{G})$. This construction, as mentioned earlier, does not extend to dimensions higher than 2. This is why we, via projective connectivity, effectively require that $\mathcal{F}$ and $\mathcal{G}$ contain a *binary* connected constraint function in the hypothesis of Lemma 28. To satisfy this hypothesis, we ensure that the modified constraint functions F' and G' in the proof of Lemma 29 are projectively connected. In this appendix, we present a different construction, due to Roberson [12], which, rather than modify the existing constraint functions, adds new binary connected constraint functions to $\mathcal{F}$ and $\mathcal{G}$, while preserving quantum isomorphism. This removes the need for projective connectivity entirely, simplifies the proof of Lemma 28, and could simplify the proof of Lemma 29, since it is no longer necessary that F' and G' be projectively connected (though we still need $Z^{\mathbf{0}_F}(K) = Z^{\mathbf{0}_G}(K)$ for all planar 1-labeled K). Additionally, the alternate construction makes use of two lemmas which should be of independent interest.

First, we extend Definition 3 to gadgets.

▶ **Definition 30** ($\mathbf{K}_{\mathcal{F}\to\mathcal{G}}$). *For compatible constraint function sets $\mathcal{F}$ and $\mathcal{G}$ and $\mathbf{K} \in \mathcal{P}_{\mathcal{F}}$, let $\mathbf{K}_{\mathcal{F}\to\mathcal{G}} \in \mathcal{P}_{\mathcal{G}}$ be the* corresponding *gadget formed by replacing each constraint signature $F_i \in \mathcal{F}$ with the corresponding $G_i \in \mathcal{G}$. Extend this mapping linearly to $\mathfrak{Q}^{\mathcal{P}}_{\mathcal{F}}$.*

The first lemma shows that, viewing intertwiners themselves as constraint functions, we may add "corresponding" pairs of intertwiners (the signature matrices of corresponding quantum $\mathcal{F}$ and $\mathcal{G}$-gadgets – recall Theorem 24) to $\mathcal{F}$ and $\mathcal{G}$, while preserving equivalence on planar #CSP instances.

▶ **Lemma 31** ([12]). *Let $\mathcal{F}$ and $\mathcal{G}$ be compatible constraint function sets. Let $M_F \in C_{\mathrm{Qut}(\mathcal{F})}(m,d)$ and $M_G \in C_{\mathrm{Qut}(\mathcal{G})}(m,d)$ such that $M_F = M(\mathbf{Q})$ and $M_G = M(\mathbf{Q}_{\mathcal{F}\to\mathcal{G}})$ for some quantum $\mathcal{F}$-gadget $\mathbf{Q} \in \mathfrak{Q}^{\mathcal{P}}_{\mathcal{F}}(m,d)$. Let F and G be the constraint functions satisfying $F^{m,d} = M_F$ and $G^{m,d} = M_G$, and let $\mathcal{F}' = \mathcal{F} \cup \{F\}$ and $\mathcal{G}' = \mathcal{G} \cup \{G\}$. Then $Z(K) = Z(K_{\mathcal{F}\to\mathcal{G}})$ for all planar #CSP($\mathcal{F}$) instances K if and only if $Z(K) = Z(K_{\mathcal{F}'\to\mathcal{G}'})$ for all planar #CSP($\mathcal{F}'$) instances K.*

Proof. The backward direction is immediate. Let K be a planar #CSP($\mathcal{F}'$) instance, and let Ω_K be the corresponding Pl-Holant($\mathcal{F}' \mid \mathcal{EQ}$) instance. Create a "quantum signature grid" $\widehat{\Omega}_K \in \mathfrak{Q}^{\mathcal{P}}_{\mathcal{F}}(0,0)$ by replacing every instance of a vertex v assigned F in Ω_K by the equivalent quantum gadget $\mathbf{Q} \in \mathfrak{Q}^{\mathcal{P}}_{\mathcal{F}}$, matching the cyclically-ordered dangling edges of each gadget to the cyclically-ordered incident edges of v (and contracting the edges between the adjacent equality vertices to preserve bipartiteness). Similarly create $\widehat{\Omega}_{K_{\mathcal{F}'\to\mathcal{G}'}} \in \mathfrak{Q}^{\mathcal{P}}_{\mathcal{G}}(0,0)$ by replacing every instance of a vertex assigned G in $\Omega_{K_{\mathcal{F}'\to\mathcal{G}'}}$ with $\mathbf{Q}_{\mathcal{F}\to\mathcal{G}} \in \mathfrak{Q}^{\mathcal{P}}_{\mathcal{G}}$. Then the index-$\alpha$ summand of $\widehat{\Omega}_K$ or $\widehat{\Omega}_{K_{\mathcal{F}'\to\mathcal{G}'}}$ is a planar #CSP($\mathcal{F}$) instance $K^{\alpha}_{\mathcal{F}}$ or planar #CSP($\mathcal{G}$) instance $K^{\alpha}_{\mathcal{G}}$, respectively, and furthermore $K^{\alpha}_{\mathcal{G}} = (K^{\alpha}_{\mathcal{F}})_{\mathcal{F}\to\mathcal{G}}$. Thus

$$\begin{aligned} Z(K) &= \text{Pl-Holant}_{\Omega_K}(\mathcal{F}' \mid \mathcal{EQ}) \\ &= \text{Pl-Holant}_{\widehat{\Omega}_K}(\mathcal{F} \mid \mathcal{EQ}) \\ &= \text{Pl-Holant}_{\widehat{\Omega}_{K_{\mathcal{F}'\to\mathcal{G}'}}}(\mathcal{G} \mid \mathcal{EQ}) \\ &= \text{Pl-Holant}_{\Omega_{K_{\mathcal{F}'\to\mathcal{G}'}}}(\mathcal{G}' \mid \mathcal{EQ}) \\ &= Z(K_{\mathcal{F}'\to\mathcal{G}'}). \end{aligned}$$

◀

An alternate proof would also need the following lemma, which is equivalent to Lemma 31 once Theorem 9 is proved.

▶ **Lemma 32** ([12]). *Suppose $\mathcal{F}$, $\mathcal{G}$, F, G, $\mathcal{F}'$, and $\mathcal{G}'$ satisfy the hypotheses of Lemma 31. Then $\mathcal{F} \cong_{qc} \mathcal{G} \iff \mathcal{F}' \cong_{qc} \mathcal{G}'$.*

Proof. The backward direction is immediate. Let $\mathcal{U}$ be the quantum permutation matrix defining the quantum isomorphism between $\mathcal{F}$ and $\mathcal{G}$. It suffices to show $\mathcal{U}^{\otimes m+d} f = g$, or equivalently, by (3), $\mathcal{U}^{\otimes m} M_F (\mathcal{U}^{\otimes d})^{\dagger} = M_G$. This identity follows from the proof of the quantum Holant theorem. Indeed, while the statement in Theorem 18 only applies to signature grids (gadgets in $\mathfrak{Q}^{\mathcal{P}}_{\mathcal{F}}(0,0)$), the proof may be easily modified to apply to $\mathbf{Q} \in \mathfrak{Q}^{\mathcal{P}}_{\mathcal{F}}(m,d)$ as follows. After inserting $(\mathcal{U}^{\otimes k})^{\dagger}\mathcal{U}^{\otimes k}$ between each pair of gadgets in the Theorem 17 decomposition of (each summand of) $\mathbf{Q}$ and reassociating to convert every $\mathcal{F}$ signature to the corresponding $\mathcal{G}$ signature and fix the internal equality vertices, we must effectively apply an additional $\mathcal{U}$ or $\mathcal{U}^{\dagger}$ to each original dangling edge of $\mathbf{Q}$ to fully transform each equality vertex with a dangling edge back to itself via $\mathcal{U}^{\otimes a} E^{a,b} (\mathcal{U}^{\otimes b})^{\dagger} = E^{a,b}$. Thus $\mathcal{U}^{\otimes m}\, \mathbf{Q} (\mathcal{U}^{\otimes d})^{\dagger} = \mathbf{Q}_{\mathcal{F}\to\mathcal{G}}$, and applying M to both sides gives the result. ◀

Together, Lemmas 31 and 32 show that, to prove Theorem 9, we may assume that $\mathcal{F}$ and $\mathcal{G}$ contain (the constraint functions created from) any intertwiners M_F and M_G which are the signature matrices of corresponding quantum $\mathcal{F}$ and $\mathcal{G}$-gadgets. In particular, we trivially have $(\mathbf{E}^{1,0} \circ \mathbf{E}^{0,1})_{\mathcal{F}\to\mathcal{G}} = (\mathbf{E}^{1,0} \circ \mathbf{E}^{0,1})$, so we may assume $\mathcal{F}$ and $\mathcal{G}$ both contain $M(\mathbf{E}^{1,0} \circ \mathbf{E}^{0,1}) = J$, the all-1s matrix. J is a connected constraint function, so we may immediately apply Lemma 28. Moreover, since J is already binary, we don't have to worry about reducing arity in the proof of Lemma 28.

On the Fine-Grained Complexity of Small-Size Geometric Set Cover and Discrete k-Center for Small k

Abstract

We study the time complexity of the discrete k-center problem and related (exact) geometric set cover problems when k or the size of the cover is small. We obtain a plethora of new results:

- We give the first subquadratic algorithm for *rectilinear discrete 3-center* in 2D, running in $\widetilde{O}(n^{3/2})$ time.
- We prove a lower bound of $\Omega(n^{4/3-\delta})$ for rectilinear discrete 3-center in 4D, for any constant $\delta > 0$, under a standard hypothesis about triangle detection in sparse graphs.
- Given n points and n *weighted* axis-aligned unit squares in 2D, we give the first subquadratic algorithm for finding a minimum-weight cover of the points by 3 unit squares, running in $\widetilde{O}(n^{8/5})$ time. We also prove a lower bound of $\Omega(n^{3/2-\delta})$ for the same problem in 2D, under the well-known APSP Hypothesis. For arbitrary axis-aligned rectangles in 2D, our upper bound is $\widetilde{O}(n^{7/4})$.
- We prove a lower bound of $\Omega(n^{2-\delta})$ for Euclidean discrete 2-center in 13D, under the Hyperclique Hypothesis. This lower bound nearly matches the straightforward upper bound of $\widetilde{O}(n^{\omega})$, if the matrix multiplication exponent ω is equal to 2.
- We similarly prove an $\Omega(n^{k-\delta})$ lower bound for Euclidean discrete k-center in $O(k)$ dimensions for any constant $k \geq 3$, under the Hyperclique Hypothesis. This lower bound again nearly matches known upper bounds if $\omega = 2$.
- We also prove an $\Omega(n^{2-\delta})$ lower bound for the problem of finding 2 boxes to cover the largest number of points, given n points and n boxes in 12D. This matches the straightforward near-quadratic upper bound.

1 Introduction

1.1 The discrete k-center problem for small k

The *Euclidean k-center* problem is well-known in computational geometry and has a long history: given a set P of n points in $\mathbb{R}^d$ and a number k, we want to find k congruent balls covering S, while minimizing the radius. Euclidean 1-center can be solved in linear time for any constant dimension d by standard techniques for low-dimensional linear programming or LP-type problems [21, 24, 27, 41, 50]. In a celebrated paper from SoCG'96, Sharir [44] gave the first $\widetilde{O}(n)$-time[1] algorithm for Euclidean 2-center in $\mathbb{R}^2$, which represented a significant improvement over previous near-quadratic algorithms (the hidden logarithmic factors have since been reduced in a series of subsequent works [29, 16, 49, 23]). The problem is more difficult in higher dimensions: the best time bound for Euclidean 2-center in $\mathbb{R}^d$ is about n^d (see [3, 2] for some results on the $\mathbb{R}^3$ case), and Cabello et al. [14] proved a conditional lower bound, ruling out $n^{o(d)}$-time algorithms, assuming the Exponential Time Hypothesis (ETH). We are not aware of any work specifically addressing the Euclidean 3-center problem.

The k-center problem has also been studied under different metrics. The most popular version after Euclidean is L_∞ or *rectilinear k-center*: here, we want to find k congruent hypercubes covering P, while minimizing the side length of the hypercubes.[2] As expected, the rectilinear version is a little easier than the Euclidean. Sharir and Welzl in SoCG'96 [45] showed that rectilinear 3-center problem in $\mathbb{R}^2$ can be solved in linear time, and that rectilinear 4-center and 5-center in $\mathbb{R}^2$ can be solved in $\widetilde{O}(n)$ time (the logarithmic factors have been subsequently improved by Nussbaum [42]). Katz and Nielsen's work in SoCG'96 [35] implied near-linear-time algorithms for rectilinear 2-center in any constant dimension d, while Cabello et al. in SODA'08 [14] gave an $O(n \log n)$-time algorithm for rectilinear 3-center in any constant dimension d. Cabello et al. also proved a conditional lower bound for rectilinear 4-center, ruling out $n^{o(\sqrt{d})}$-time algorithms under ETH.

In this paper, we focus on a natural variant of the problem called *discrete k-center*, which has also received considerable attention: here, given a set P of n points in $\mathbb{R}^d$ and a number k, we want to find k congruent balls covering P, while minimizing the radius, with the extra constraint that the centers of the chosen balls are from P.[3] The Euclidean discrete 1-center problem can be solved in $O(n \log n)$ time in $\mathbb{R}^2$ by a straightforward application of farthest-point Voronoi diagrams; it can also be solved in $O(n \log n)$ (randomized) time in $\mathbb{R}^3$ with more effort [15], and in subquadratic $\widetilde{O}(n^{2-2/(\lceil d/2 \rceil+1)})$ time for $d \geq 4$ by standard range searching techniques [4, 40]. Agarwal, Sharir, and Welzl in SoCG'97 [6] gave the first subquadratic algorithm for Euclidean discrete 2-center in $\mathbb{R}^2$, running in $\widetilde{O}(n^{4/3})$ time.

One may wonder whether Euclidean discrete 2-center in higher constant dimensions could also be solved in subquadratic time via range searching techniques. No results have been reported, but an $\widetilde{O}(n^\omega)$-time algorithm is not difficult to obtain, where $\omega < 2.373$ denotes the matrix multiplication exponent: by binary search, the problem reduces to finding two balls of a given radius r with centers in S covering S, which is equivalent to finding a pair $p, q \in S$ such that $c_{pq} = \bigvee_{z \in S}(a_{pz} \wedge a_{zq})$ is false, where a_{pz} is true iff p and z has distance more than r – this computation reduces to a Boolean matrix product. This approach works for arbitrary

[1] The $\widetilde{O}$ notation hides polylogarithmic factors.
[2] All squares, rectangles, hypercubes, and boxes are axis-aligned in this paper.
[3] Some authors define the problem slightly more generally, where the constraint is that the centers are from a second input set; in other words, the input consists of two sets of points ("demand points" and "supply points"). The results of this paper will apply to both versions of the problem.

Table 1 Summary of results on k-center for small k in $\mathbb{R}^2$.

k	Euclidean	rectilinear	Euclidean discrete	rectilinear discrete
1	$O(n)$	$O(n)$	$O(n \log n)$	$O(n)$
2	$\widetilde{O}(n)$ [44]	$O(n)$ [45]	$\widetilde{O}(n^{4/3})$ [6]	$\widetilde{O}(n)$
3		$\widetilde{O}(n)$ [45]		$\widetilde{O}(n^{3/2})$ **(new)**

(not necessarily geometric) distance functions. The main question is whether geometry could help in obtaining faster algorithms in the higher-dimensional Euclidean setting, as Agarwal, Sharir, and Welzl were able to exploit successfully in $\mathbb{R}^2$:

▶ **Question 1.** *Is there an algorithm running in faster than n^ω time for the Euclidean discrete 2-center problem in higher constant dimensions?*

We can similarly investigate the rectilinear version of the discrete k-center problem, which is potentially easier. For example, the rectilinear discrete 2-center problem can be solved in $\widetilde{O}(n)$ time in any constant dimension d, by a straightforward application of orthogonal range searching, as reported in several papers [10, 11, 34]. The approach does not seem to work for the rectilinear discrete 3-center problem. Naively, rectilinear discrete 3-center can be reduced to n instances of (some version of) rectilinear discrete 2-center, and solved in $\widetilde{O}(n^2)$ time. However, no better results have been published, leading to the following questions:

▶ **Question 2.** *Is there a subquadratic-time algorithm for the rectilinear discrete 3-center problem?*

▶ **Question 3.** *Are there lower bounds to show that the rectilinear discrete 3-center problem does not have near-linear-time algorithm (and is thus strictly harder than rectilinear discrete 2-center, or rectilinear continuous 3-center)?*

Similar questions may be asked about rectilinear discrete k-center for $k \geq 4$. Here, the complexity of the problem is upper-bounded by $\widetilde{O}(n^{\omega(\lfloor k/2 \rfloor, 1, \lceil k/2 \rceil)})$, where $\omega(a, b, c)$ denotes the exponent for multiplying an $n^a \times n^b$ and an $n^b \times n^c$ matrix: by binary search, the problem reduces to finding k hypercubes of a given edge length r with centers in S covering S, which is equivalent to finding a dominating set of size k in the graph with vertex set S where an edge pz exists iff the distance of p and z is more than r – the dominating set problem reduces to rectangular matrix multiplication with the time bound stated, as observed by Eisenbrand and Grandoni [28]. Note that the difference $\omega(\lfloor k/2 \rfloor, 1, \lceil k/2 \rceil) - k$ converges to 0 as $k \to \infty$ by known matrix multiplication bounds [25] (and is exactly 0 if $\omega = 2$).

As k gets larger compared to d, a better upper bound of $n^{O(dk^{1-1/d})}$ is known for both the continuous and discrete k-center problem under the Euclidean and rectilinear metric [5, 31, 32]. Recently, in SoCG'22, Chitnis and Saurabh [22] (extending earlier work by Marx [38] in the $\mathbb{R}^2$ case) proved a nearly matching conditional lower bound for discrete k-center in $\mathbb{R}^d$, ruling out $n^{o(k^{1-1/d})}$-time algorithms under ETH. However, these bounds do not answer our questions concerning very small k's. In contrast, the conditional lower bounds by Cabello et al. [14] that we have mentioned earlier are about very small k and so are more relevant, but are only for the continuous version of the k-center problem. (The continuous version behaves differently from the discrete version; see Tables 1–2.)

Table 2 Summary of results on k-center for small k in $\mathbb{R}^d$ for an arbitrary constant d. (CLB stands for "conditional lower bound".)

k	Euclidean	rectilinear	Euclidean discrete	rectilinear discrete

3		$\widetilde{O}(n)$ [14]	$\widetilde{O}(n^{\omega(1,1,2)})$ CLB: $\Omega(n^{3-\delta})$ **(new)**	$\widetilde{O}(n^2)$ CLB: $\Omega(n^{4/3-\delta})$ **(new)**
4		$n^{O(d)}$ CLB: $n^{\Omega(\sqrt{d})}$ [14]	$\widetilde{O}(n^{\omega(2,1,2)})$ CLB: $\Omega(n^{4-\delta})$ **(new)**	$\widetilde{O}(n^3)$

1.2 The geometric set cover problem with small size k

The decision version of the discrete k-center problem (deciding whether the minimum radius is at most a given value) reduces to a *geometric set cover* problem: given a set P of n points and a set R of n objects, find the smallest subset of objects in R that cover all points of P. Geometric set cover has been extensively studied in the literature, particularly from the perspective of approximation algorithms (since for most types of geometric objects, set cover remains NP-hard); for example, see the references in [18]. Here, we are interested in *exact* algorithms for the case when the optimal size k is a small constant.

For the application to Euclidean/rectilinear k-center, the objects are congruent balls/hypercubes, or by rescaling, unit balls/hypercubes, but other types of objects may be considered, such as arbitrary rectangles or boxes.

We can also consider the *weighted* version of the problem: here, given a set P of n points, a set R of n weighted objects, and a small constant k, we want to find a subset of k objects in R that cover all points of P, while minimizing the total weight of the chosen objects.

A "dual" problem is *geometric hitting set*, which in the weighted case is the following: given a set P of n weighted points, a set R of n objects, and a small constant k, find a subset of k points in P that hit all objects of R, while minimizing the total weight of the chosen points. (The continuous unweighted version, where the chosen points may be anywhere, is often called the *piercing* problem.) In the case of unit balls/hypercubes, hitting set is equivalent to set cover due to self-duality.

For rectangles in $\mathbb{R}^2$ or boxes in $\mathbb{R}^d$, size-2 geometric set cover (unweighted or weighted) can be solved in $\widetilde{O}(n)$ time, like discrete rectilinear 2-center [10, 11, 34], by orthogonal range searching. Analogs to Questions 2–3 may be asked for size-3 geometric set cover for rectangles/boxes.

Surprisingly, the complexity of exact geometric set cover of small size k has not received as much attention, but very recently in SODA'23, Chan [17] initiated the study of similar questions for geometric independent set with small size k, for example, providing subquadratic algorithms and conditional lower bounds for size-4 independent set for boxes.

For larger k, hardness results by Marx and Pilipczuk [39] and Bringmann et al. [13] ruled out $n^{o(k)}$-time algorithms for size-k geometric set cover for rectangles in $\mathbb{R}^2$ and unit hypercubes (or orthants) in $\mathbb{R}^4$, and $n^{o(\sqrt{k})}$-time algorithms for unit cubes (or orthants) in $\mathbb{R}^3$ under ETH. But like the other fixed-parameter intractability results mentioned, these proofs do not appear to imply any nontrivial lower bound for very small k such as $k = 3$.

1.3 New results

New algorithms. In this paper, we answer Question 2 in the affirmative for dimension $d = 2$, by presenting the first subquadratic algorithms for rectilinear discrete 3-center in $\mathbb{R}^2$, and more generally, for (unweighted and weighted) geometric size-3 set cover for unit squares, as well as arbitrary rectangles in $\mathbb{R}^2$. More precisely, the time bounds of our algorithms are:

- $\widetilde{O}(n^{3/2})$ for rectilinear discrete 3-center in $\mathbb{R}^2$ and unweighted size-3 set cover for unit squares in $\mathbb{R}^2$;
- $\widetilde{O}(n^{8/5})$ for weighted size-3 set cover for unit squares in $\mathbb{R}^2$;
- $\widetilde{O}(n^{5/3})$ for unweighted size-3 set cover for rectangles in $\mathbb{R}^2$;
- $\widetilde{O}(n^{7/4})$ for weighted size-3 set cover for rectangles in $\mathbb{R}^2$.

New conditional lower bounds. We also prove the first nontrivial conditional lower bounds on the time complexity of rectilinear discrete 3-center and related size-3 geometric set cover problems. More precisely, our lower bounds are:[4]

- $\Omega(n^{3/2-\delta})$ for weighted size-3 set cover (or hitting set) for unit squares in $\mathbb{R}^2$, assuming the APSP Hypothesis;
- $\Omega(n^{4/3-\delta})$ for rectilinear discrete 3-center in $\mathbb{R}^4$ and unweighted size-3 set cover (or hitting set) for unit hypercubes in $\mathbb{R}^4$, assuming the Sparse Triangle Hypothesis;
- $\Omega(n^{4/3-\delta})$ for unweighted size-3 set cover for boxes in $\mathbb{R}^3$, assuming the Sparse Triangle Hypothesis.

The lower bound in the first bullet is particularly attractive, since it implies that conditionally, our $\widetilde{O}(n^{8/5})$-time algorithm for weighted size-3 set cover for unit squares in $\mathbb{R}^2$ is within a small factor (near $n^{0.1}$) from optimal, and that our $\widetilde{O}(n^{7/4})$-time algorithm for weighted size-3 set cover for rectangles in $\mathbb{R}^2$ is within a factor near $n^{0.25}$ from optimal. The second bullet answers Question 3, implying that rectilinear discrete 3-center is strictly harder than rectilinear discrete 2-center and rectilinear (continuous) 3-center, at least when the dimension is 4 or higher. (In contrast, rectilinear (continuous) 4-center is strictly harder than rectilinear discrete 4-center for sufficiently large constant dimensions [14]; see Table 2.)

In addition, we prove the following conditional lower bounds:

- $\Omega(n^{2-\delta})$ for Euclidean discrete 2-center in $\mathbb{R}^{13}$ and unweighted size-3 set cover (or hitting set) for unit balls in $\mathbb{R}^{13}$, assuming the Hyperclique Hypothesis;
- $\Omega(n^{k-\delta})$ for Euclidean discrete k-center in $\mathbb{R}^{7k}$ and unweighted size-k set cover for unit balls in $\mathbb{R}^{7k}$ for any constant $k \geq 3$, assuming the Hyperclique Hypothesis.

In particular, this answers Question 1 in the negative if $\omega = 2$ (as conjectured by some researchers): geometry doesn't help for Euclidean discrete 2-center when the dimension is a sufficiently large constant. Similarly, the second bullet indicates that the upper bound $\widetilde{O}(n^{\omega(\lfloor k/2 \rfloor, 1, \lceil k/2 \rceil)})$ for Euclidean discrete k-center is basically tight for any fixed $k \geq 3$ in a sufficiently large constant dimension, if $\omega = 2$. (See Tables 1–3.)

Lastly, we prove a lower bound for a standard variant of set cover known as *maximum coverage*: given a set P of n points, a set R of n objects, and a small constant k, find k objects in R that cover the largest number (rather than all) of points of P. Geometric versions of the maximum coverage problem have been studied before from the approximation algorithms perspective (e.g., see [9]). It is also related to "outliers" variants of k-center problems (where we allow a certain number of points to be uncovered), which have also been studied for small

[4] Throughout this paper, δ denotes an arbitrarily small positive constant.

k (e.g., see [5]). Recall that the size-2 geometric set cover problem for boxes in $\mathbb{R}^d$ can be solved in $\widetilde{O}(n)$ time (which was why our attention was redirected to the size-3 case). In contrast, we show that maximum coverage for boxes cannot be solved in near-linear time even for size $k = 2$. More precisely, we obtain the following lower bound:

- $\Omega(n^{2-\delta})$ for size-2 maximum coverage for unit hypercubes in $\mathbb{R}^{12}$, assuming the Hyperclique Hypothesis.

What is notable is that this lower bound is tight (up to $n^{o(1)}$ factors), regardless of ω, since there is an obvious $\widetilde{O}(n^2)$-time algorithm for boxes in $\mathbb{R}^d$ by answering n^2 orthogonal range counting queries – our result implies that this obvious algorithm can't be improved!

On hypotheses from fine-grained complexity. Let us briefly state the hypotheses used.

- The *APSP Hypothesis* is among the three most popular hypotheses in fine-grained complexity [46] (the other two being the 3SUM Hypothesis and the Strong Exponential Time Hypothesis): it asserts that there is no $O(n^{3-\delta})$-time algorithm for the all-pairs shortest paths problem for an arbitrary weighted graph with n vertices (and $O(\log n)$-bit integer weights). This hypothesis has been used extensively in the algorithms literature (but less often in computational geometry).
- The *Sparse Triangle Hypothesis* asserts that there is no $O(m^{4/3-\delta})$-time algorithm for detecting a triangle (i.e., a 3-cycle) in a sparse unweighted graph with m edges. The current best upper bound for triangle detection, from a 3-decade-old paper by Alon, Yuster, and Zwick [8], is $\widetilde{O}(m^{2\omega/(\omega+1)})$, which is $\widetilde{O}(m^{4/3})$ if $\omega = 2$. (In fact, a stronger version of the hypothesis asserts that there is no $O(m^{2\omega/(\omega+1)-\delta})$-time algorithm.) As supporting evidence, it is known that certain "listing" or "all-edges" variants of the triangle detection problem have an $O(m^{4/3-\delta})$ lower bound, under the 3SUM Hypothesis or the APSP Hypothesis [43, 48, 20]. See [1, 33] for more discussion on the Sparse Triangle Hypothesis, and [17] for a recent application in computational geometry.
- The *Hyperclique Hypothesis* asserts that there is no $O(n^{k-\delta})$-time algorithm for detecting a size-k hyperclique in an ℓ-uniform hypergraph with n vertices, for any fixed $k > \ell \geq 3$. See [37] for discussion on this hypothesis, and [12, 17, 36] for some recent applications in computational geometry, including Künnemann's breakthrough result on conditional lower bounds for Klee's measure problem [36].

Techniques. Traditionally, in computational geometry, subquadratic algorithms with "intermediate" exponents between 1 and 2 tend to arise from the use of nonorthogonal range searching [4] (Agarwal, Sharir, and Welzl's $\widetilde{O}(n^{4/3})$-time algorithm for Euclidean discrete 2-center in $\mathbb{R}^2$ [6] being one such example). Our subquadratic algorithms for rectilinear discrete 3-center in $\mathbb{R}^2$ and related set-cover problems, which are about "orthogonal" or axis-aligned objects, are different. A natural first step is to use a $g \times g$ grid to divide into

cases, for some carefully chosen parameter g. Indeed, a grid-based approach was used in some recent subquadratic algorithms by Chan [17] for size-4 independent set for boxes in any constant dimension, and size-5 independent set for rectangles in $\mathbb{R}^2$ (with running time $\widetilde{O}(n^{3/2})$ and $\widetilde{O}(n^{4/3})$ respectively). However, discrete 3-center or rectangle set cover is much more challenging than independent set (for one thing, the 3 rectangles in the solution may intersect each other). To make the grid approach work, we need new original ideas (notably, a sophisticated argument to assign grid cells to rectangles, which is tailored to the 2D case). Still, the entire algorithm description fits in under 3 pages.

Our conditional lower bounds for rectilinear discrete 3-center and the corresponding set cover problem for unit hypercubes are proved by reduction from unweighted or weighted triangle finding in graphs. It turns out there is a simple reduction in $\mathbb{R}^2$ by exploiting weights. However, lower bounds in the unweighted case (and thus the original rectilinear discrete 3-center problem) are much trickier. We are able to design a clever, simple reduction in $\mathbb{R}^6$ by hand, but reducing the dimension down to 4 is far from obvious and we end up employing a *computer-assisted search*, interestingly. The final construction is still simple, and so is easy to verify by hand.

Our conditional lower bound proofs for Euclidean discrete 2-center, and more generally discrete k-center, are inspired by a recent conditional hardness proof by Bringmann et al. [12] from SoCG'22 on a different problem. Specifically, they proved that deciding whether the intersection graph of n unit hypercubes in $\mathbb{R}^{12}$ has diameter 2 requires near-quadratic time under the Hyperclique Hypothesis. A priori, this diameter problem doesn't seem related to discrete k-center; moreover, it was a rectilinear problem, not Euclidean (and we know that in contrast, rectilinear discrete 2-center has a near-linear upper bound!). Our contribution is in realizing that Bringmann et al.'s approach is useful for Euclidean discrete 2-center and k-center, surprisingly. To make the proof work though, we need some new technical ideas (in particular, an extra dimension for the $k = 2$ case, and multiple extra dimensions for larger k, with carefully designed coordinate values). Still, the final proof is not complicated to follow.

Our conditional lower bound for size-2 maximum coverage for boxes is also proved using a similar technique, but again the adaptation is nontrivial, and we introduce some interesting counting arguments that proceed a bit differently from Bringmann et al.'s original proof for diameter (a problem that does not involve counting).

2 Subquadratic Algorithms for Size-3 Set Cover for Rectangles in $\mathbb{R}^2$

In this section, we describe the most basic version of our subquadratic algorithm to solve the size-3 geometric set cover problem for weighted rectangles in $\mathbb{R}^2$. The running time is $\widetilde{O}(n^{16/9})$. Refinements of the algorithm will be described in the full version of the paper, where we will improve the time bound further to $\widetilde{O}(n^{7/4})$, or even better for the unweighted case and unit square case. The rectilinear discrete 3-center problem in $\mathbb{R}^2$ reduces to the unweighted unit square case by standard techniques [15, 30].

We begin with a lemma giving a useful geometric data structure:

▶ **Lemma 1.** *For a set P of n points and a set R of n weighted rectangles in $\mathbb{R}^2$, we can build a data structure in $\widetilde{O}(n)$ time and space, to support the following kind of queries: given a pair of rectangles $r_1, r_2 \in R$, we can find a minimum-weight rectangle $r_3 \in R$ (if it exists) such that P is covered by $r_1 \cup r_2 \cup r_3$, in $\widetilde{O}(1)$ time.*

Proof. By orthogonal range searching [4, 26] on P, we can find the minimum/maximum x- and y-values among the points of P in the complement of $r_1 \cup r_2$ in $\widetilde{O}(1)$ time (since the complement can be expressed as a union of $O(1)$ orthogonal ranges). As a result, we obtain

the minimum bounding box b enclosing $P \setminus (r_1 \cup r_2)$. To finish, we find a minimum-weight rectangle in R enclosing b; this is a "rectangle enclosure" query on R and can be solved in $\widetilde{O}(1)$ time, since it also reduces to orthogonal range searching (the rectangle $[x^-, x^+] \times [y^-, y^+]$ encloses the rectangle $[\xi^-, \xi^+] \times [\eta^-, \eta^+]$ in $\mathbb{R}^2$ iff the point (x^-, x^+, y^-, y^+) lies in the box $(-\infty, \xi^-] \times [\xi^+, \infty) \times (-\infty, \eta^-] \times [\eta^+, \infty)$ in $\mathbb{R}^4$). ◀

▶ **Theorem 2.** *Given a set P of n points and a set R of n weighted rectangles in $\mathbb{R}^2$, we can find 3 rectangles $r_1^*, r_2^*, r_3^* \in R$ of minimum total weight (if they exist), such that P is covered by $r_1^* \cup r_2^* \cup r_3^*$, in $\widetilde{O}(n^{16/9})$ time.*

Proof. Let B_0 be the minimum bounding box enclosing P (which touches 4 points). If a rectangle of R has an edge outside of B_0, we can eliminate that edge by extending the rectangle, making it unbounded.

Let g be a parameter to be determined later. Form a $g \times g$ (non-uniform) grid, where each column/row contains $O(n/g)$ rectangle vertices.

Step 1. For each pair of rectangles $r_1, r_2 \in R$ that have vertical edges in a common column or horizontal edges in a common row, we query the data structure in Lemma 1 to find a minimum-weight rectangle $r_3 \in R$ (if exists) such that $P \subset r_1 \cup r_2 \cup r_3$, and add the triple $r_1 r_2 r_3$ to a list L. The number of queried pairs $r_1 r_2$ is $O(g \cdot (n/g)^2) = O(n^2/g)$, and so this step takes $\widetilde{O}(n^2/g)$ total time.

Step 2. For each rectangle $r_1 \in R$ and each of its horizontal (resp. vertical) edges e_1, define $\gamma^-(e_1)$ and $\gamma^+(e_1)$ to be the leftmost and rightmost (resp. bottommost and topmost) grid cell that intersects e_1 and contains a point of P not covered by r_1. We can naively find $\gamma^-(e_1)$ and $\gamma^+(e_1)$ by enumerating the $O(g)$ grid cells intersecting e_1 and performing $O(g)$ orthogonal range queries; this takes $\widetilde{O}(gn)$ total time. For each rectangle $r_2 \in R$ that has an edge intersecting $\gamma^-(e_1)$ or $\gamma^+(e_1)$, we query the data structure in Lemma 1 to find a minimum-weight rectangle $r_3 \in R$ (if exists) such that $P \subset r_1 \cup r_2 \cup r_3$, and add the triple $r_1 r_2 r_3$ to the list L. The total number of queried pairs $r_1 r_2$ is $O(n \cdot n/g) = O(n^2/g)$, and so this step again takes $\widetilde{O}(n^2/g)$ total time. (This entire Step 2, and the definition of $\gamma^-(\cdot)$ and $\gamma^+(\cdot)$, might appear mysterious at first, but their significance will be revealed later in Step 3.)

Step 3. We guess the column containing each of the vertical edges of r_1^*, r_2^*, r_3^* and the row containing each of the horizontal edges of r_1^*, r_2^*, r_3^*; there are at most 12 edges and so $O(g^{12})$ choices. Actually, 4 of the 12 edges are eliminated after extension, and so the number of choices can be lowered to $O(g^8)$.

After guessing, we know which grid cells are completely inside r_1^*, r_2^*, r_3^* and which grid cells intersect which edges of r_1^*, r_2^*, r_3^*. We may assume that the vertical edges from different rectangles in $\{r_1^*, r_2^*, r_3^*\}$ are in different columns, and the horizontal edges from different rectangles in $\{r_1^*, r_2^*, r_3^*\}$ are in different rows: if not, $r_1^* r_2^* r_3^*$ would have already been found in Step 1. In particular, we know combinatorially what the arrangement of r_1^*, r_2^*, r_3^* looks like, even though we do not know the precise coordinates and identities of r_1^*, r_2^*, r_3^*.

We classify each grid cell γ into the following types (see Figure 1):

- Type A: γ is completely contained in some r_j^* ($j \in \{1, 2, 3\}$). Here, we *assign* γ to each such r_j^*.
- Type B: γ is not of type A, and intersects an edge of exactly one rectangle r_j^*. We *assign* γ to this r_j^*. Observe that points in $P \cap \gamma$ can only be covered by r_j^*.

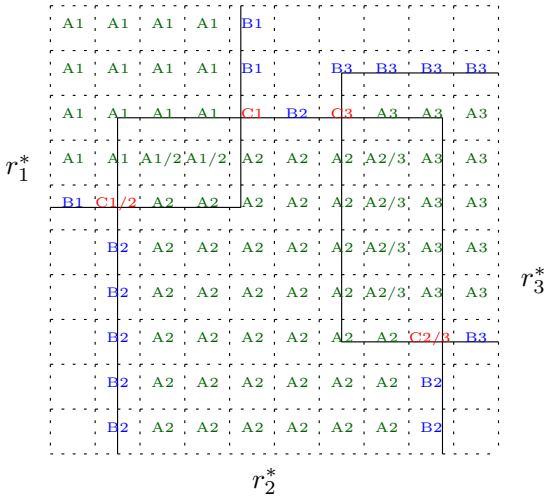

Figure 1 Proof of Theorem 2: grid cells in Step 3. The letter in a cell indicates its type (A, B, or C), and the number (or numbers) in a cell indicates the index (or indices) $j \in \{1, 2, 3\}$ of the rectangle r_j^* that the cell is assigned to.

- Type C: γ is not of type A, and intersects edges from two different rectangles in $\{r_1^*, r_2^*, r_3^*\}$. W.l.o.g., suppose that γ intersects a horizontal edge e_1^* of r_1^* and a vertical edge e_2^* of r_2^*; note that the intersection point $v^* = e_1^* \cap e_2^*$ lies on the boundary of the union $r_1^* \cup r_2^* \cup r_3^*$. By examining the arrangement of $\{r_1^*, r_2^*, r_3^*\}$, we know that at least one of the following is true: (i) we can walk horizontally from v^* to an endpoint of e_1^* (or a point at infinity) while staying on the boundary of $r_1^* \cup r_2^* \cup r_3^*$, or (ii) we can walk vertically from v^* to an endpoint of e_2^* (or a point at infinity) while staying on the boundary of $r_1^* \cup r_2^* \cup r_3^*$.

  If (i) is true, we *assign* γ to r_1^*. Observe that if there is a point in $P \cap \gamma$ not covered by r_1^* (and if the guesses are correct), then γ must be equal to $\gamma^-(e_1^*)$ or $\gamma^+(e_1^*)$ (as defined in Step 2), and so $r_1^* r_2^* r_3^*$ would have already been found in Step 2. This is because except for γ, the grid cells encountered while walking from v^* to that endpoint of e_1^* can intersect only r_1^* and so points in those cells can only be covered by r_1^*.

  If (ii) is true, we *assign* γ to r_2^* for a similar reason.

Note that there are at most $O(1)$ grid cells γ of type C; and the grid cells γ of type B form $O(1)$ contiguous blocks. Let ρ_j be the union of all grid cells assigned to r_j^*. Then ρ_j is a rectilinear polygon of $O(1)$ complexity. We compute the minimum/maximum x- and y-values of the points in $P \cap \rho_j$, by orthogonal range searching in $\widetilde{O}(1)$ time. As a result, we obtain the minimum bounding box b_j enclosing $P \cap \rho_j$. We find a minimum-weight rectangle $r_j \in R$ enclosing b_j, by a rectangle enclosure query (reducible to orthogonal range searching, as before). If $P \setminus (r_1 \cup r_2 \cup r_3) = \emptyset$ (testable by orthogonal range searching), we add the triple $r_1 r_2 r_3$ (which should coincide with $r_1^* r_2^* r_3^*$, if it has not been found earlier and if the guesses are correct) to L. The total time over all guesses is $\widetilde{O}(g^8)$.

At the end, we return a minimum-weight triple in L. The overall running time is $\widetilde{O}(g^8 + n^2/g + gn)$. Setting $g = n^{2/9}$ yields the theorem. ◀

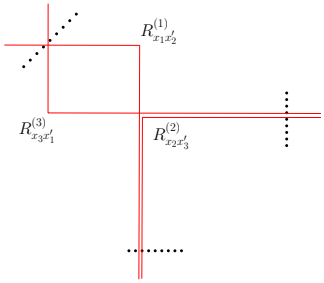

Figure 2 Reduction from the minimum-weight triangle problem to weighted size-3 set cover for orthants in $\mathbb{R}^2$.

3 Conditional Lower Bounds for Size-3 Set Cover for Boxes

In this section, we prove conditional lower bounds for size-3 set cover for boxes in certain dimensions (rectilinear discrete 3-center is related to size-3 set cover for unit hypercubes). We begin with the weighted version, which is more straightforward and has a simple proof, and serves as a good warm-up to the more challenging, unweighted version later.

3.1 Weighted size-3 set cover for unit squares in $\mathbb{R}^2$

An *orthant* (also called a dominance range) refers to a d-sided box in $\mathbb{R}^d$ which is unbounded along each of the d dimensions. (Note that orthants may be oriented in 2^d ways.) To obtain a lower bound for the unit square or unit hypercube case, it suffices to obtain a lower bound for the orthant case, since we can just replace each orthant with a hypercube with a sufficiently large side length M, and then rescale by a $1/M$ factor.

▶ **Theorem 3.** *Given a set P of n points and a set R of n weighted orthants in $\mathbb{R}^2$, finding 3 orthants in R of minimum total weight that cover P requires $\Omega(n^{3/2-\delta})$ time for any constant $\delta > 0$, assuming the APSP Hypothesis.*

Proof. The APSP Hypothesis is known to be equivalent [47] to the hypothesis that finding a minimum-weight triangle in a weighted graph with n vertices requires $\Omega(n^{3-\delta})$ time for any constant $\delta > 0$. We will reduce the minimum-weight triangle problem on a graph with n vertices and m edges ($m \in [n, n^2]$) to the weighted size-3 set cover problem for $O(m)$ points and orthants in $\mathbb{R}^2$. Thus, if there is an $O(m^{3/2-\delta})$-time algorithm for the latter problem, there would be an algorithm for the former problem with running time $O(m^{3/2-\delta}) \leq O(n^{3-2\delta})$, refuting the hypothesis.

Let $G = (V, E)$ be the given weighted graph with n vertices and m edges. Without loss of generality, assume that all edge weights are in $[0, 0.1]$, and that $V \subset [0, 0.1]$, i.e., vertices are labelled by numbers that are rescaled to lie in $[0, 0.1]$. Assume that $0 \in V$ and $0.1 \in V$.

The reduction. For each vertex $t \in V$, we create three points $(t, 1+t)$, $(2, t)$, and $(1+t, -1)$ (call them of type 1, 2, and 3, respectively).

Create the following orthants in $\mathbb{R}^2$:

$$\begin{aligned}
\forall x_1x'_2 \in E:\ R^{(1)}_{x_1x'_2} &= (-\infty, 1+x'_2) \times (-\infty, 1+x_1] && \text{(type 1)}\\
\forall x_2x'_3 \in E:\ R^{(2)}_{x_2x'_3} &= [1+x_2, \infty) \times (-\infty, x'_3) && \text{(type 2)}\\
\forall x_3x'_1 \in E:\ R^{(3)}_{x_3x'_1} &= (x'_1, \infty) \times [x_3, \infty) && \text{(type 3)}
\end{aligned}$$

The weight of each orthant is set to be the number of points it covers plus the weight of the edge it represents. The total number of points and orthants is $O(n)$ and $O(m)$ respectively. The reduction is illustrated in Figure 2.

Correctness. We prove that the minimum-weight triangle in G has weight w (where $w \in [0, 0.3]$) iff the optimal weighted size-3 set cover has weight $3n + w$.

Any feasible solution (if exists) must use an orthant of each type, since the point $(0, 1)$ of type 1 (resp. the point $(2, 0.1)$ of type 2, and the point $(1.1, -1)$ of type 3) can only be covered by an orthant of type 1 (resp. 3 and 2). So, the three orthants in the optimal solution must be of the form $R^{(1)}_{x_1x_2'}$, $R^{(2)}_{x_2x_3'}$ and $R^{(3)}_{x_3x_1'}$ for some $x_1x_2', x_2x_3', x_3x_1' \in E$.

If $x_1 < x_1'$, some point (of type 1) would be uncovered; on the other hand, if $x_1 > x_1'$, some point (of type 1) would be covered twice, and the total weight would then be at least $3n + 1$. Thus, $x_1 = x_1'$. Similarly, $x_2 = x_2'$ and $x_3 = x_3'$. So, $x_1x_2x_3$ forms a triangle in G. We conclude that the minimum-weight solution $R^{(1)}_{x_1x_2}$, $R^{(2)}_{x_2x_3}$ and $R^{(3)}_{x_3x_1}$ correspond to the minimum-weight triangle $x_1x_2x_3$ in G. ◀

3.2 Unweighted size-3 set cover for boxes in $\mathbb{R}^3$

Our preceding reduction uses weights to ensure equalities of two variables representing vertices. For the unweighted case, this does not work. We propose a different way to force equalities, by using an extra dimension and extra sides (i.e., using boxes instead of orthants), with some carefully chosen coordinate values.

▶ **Theorem 4.** *Given a set P of n points and a set R of n unweighted axis-aligned boxes in $\mathbb{R}^3$, deciding whether there exist 3 boxes in R that cover P requires $\Omega(n^{4/3-\delta})$ time for any constant $\delta > 0$, assuming the Sparse Triangle Hypothesis.*

Proof. We will reduce the triangle detection problem on a graph with m edges to the unweighted size-3 set cover problem for $O(m)$ points and boxes in $\mathbb{R}^3$. Thus, if there is an $O(m^{4/3-\delta})$-time algorithm for the latter problem, there would be an algorithm for the former problem with running time $O(m^{4/3-\delta})$, refuting the hypothesis.

Let $G = (V, E)$ be the given unweighted sparse graph with n vertices and m edges ($n \le m$). Without loss of generality, assume that $V \subset [0, 0.1]$, and $0 \in V$ and $0.1 \in V$.

The reduction. For each vertex $t \in V$, create six points

$$\begin{array}{rrrl}
(-1+t, & 0, & 2+t) & \text{(type 1)}\\
(1+t, & 0, & -2+t) & \text{(type 2)}\\
(2+t, & -1+t, & 0) & \text{(type 3)}\\
(-2+t, & 1+t, & 0) & \text{(type 4)}\\
(0, & 2+t, & -1+t) & \text{(type 5)}\\
(0, & -2+t, & 1+t) & \text{(type 6)}
\end{array}$$

Create the following boxes in $\mathbb{R}^3$:

$$\begin{array}{lrcccccc}
\forall x_1x_2' \in E: & R^{(1)}_{x_1x_2'} & = & (-1+x_1, 1+x_1) & \times & [-2+x_2', 2+x_2'] & \times & \mathbb{R}\\
\forall x_2x_3' \in E: & R^{(2)}_{x_2x_3'} & = & [-2+x_3', 2+x_3'] & \times & \mathbb{R} & \times & (-1+x_2, 1+x_2)\\
\forall x_3x_1' \in E: & R^{(3)}_{x_3x_1'} & = & \mathbb{R} & \times & (-1+x_3, 1+x_3) & \times & [-2+x_1', 2+x_1']
\end{array}$$

(call them of type 1, 2, and 3, respectively).

Correctness. We prove that a size-3 set cover exists iff a triangle exists in G.

Any feasible solution (if exists) must use a box of each type, since the point $(-1, 0, 2)$ of type 1 (resp. the point $(2, -1, 0)$ of type 3, and the point $(0, 2, -1)$ of type 5) can only be covered by a box of type 3 (resp. 2 and 1). So, the three boxes in a feasible solution must be of the form $R^{(1)}_{x_1x'_2}$, $R^{(2)}_{x_2x'_3}$ and $R^{(3)}_{x_3x'_1}$ for some $x_1x'_2, x_2x'_3, x_3x'_1 \in E$.

Consider points of type 1 with the form $(-1+t, 0, 2+t)$. The box $R^{(2)}_{x_2x'_3}$ cannot cover any of them due to the third dimension. The box $R^{(1)}_{x_1x'_2}$ covers all such points corresponding to $t > x_1$, and the box $R^{(3)}_{x_3x'_1}$ covers all such points corresponding to $t \le x'_1$. So, all points of type 1 are covered iff $x_1 \le x'_1$. Similarly, all points of type 2 are covered iff $x'_1 \le x_1$. Thus, all points of type 1–2 are covered iff $x_1 = x'_1$. By a symmetric argument, all points of type 3–4 are covered iff $x_3 = x'_3$; and all points of type 5–6 are covered iff $x_2 = x'_2$. We conclude that a feasible solution exists iff a triangle $x_1x_2x_3$ exists in G. ◀

We remark that the boxes above can be made fat, with side lengths between 1 and a constant (by replacing $\mathbb{R}$ with an interval of a sufficiently large constant length).

3.3 Unweighted size-3 set cover for unit hypercubes in $\mathbb{R}^4$

Our preceding lower bound for unweighted size-3 set cover for boxes in $\mathbb{R}^3$ immediately implies a lower bound for orthants (and thus unit hypercubes) in $\mathbb{R}^6$, since the point (x, y, z) is covered by the box $[a^-, a^+] \times [b^-, b^+] \times [c^-, c^+]$ in $\mathbb{R}^3$ iff the point (x, x, y, y, z, z) is covered by the orthant $[a^-, \infty) \times (-\infty, a^+] \times [b^-, \infty) \times (-\infty, b^+] \times [c^-, \infty) \times (-\infty, c^+]$ in $\mathbb{R}^6$.

A question remains: can the dimension 6 be lowered? Intuitively, there seems to be some wastage in the above construction: there are several 0's in the coordinates of the points, and several $\mathbb{R}$'s in the definition of the boxes, and these get doubled after the transformation to 6 dimensions. However, it isn't clear how to rearrange coordinates to eliminate this wastage: we would have to give up this nice symmetry of our construction, and there are too many combinations to try. We ended up writing a computer program to exhaustively try all these different combinations, and eventually find a construction that lowers the dimension to 4! Once it is found, correctness is straightforward to check, as one can see in the proof below.

▶ **Theorem 5.** *Given a set P of n points and a set R of n unweighted orthants in $\mathbb{R}^4$, deciding whether there exists a size-3 set cover requires $\Omega(n^{4/3-\delta})$ time for any constant $\delta > 0$, assuming the Sparse Triangle Hypothesis.*

Proof. We will reduce the triangle detection problem on a graph with m edges to the unweighted size-3 set cover problem for $O(m)$ points and orthants in $\mathbb{R}^4$.

Let $G = (V, E)$ be the given unweighted graph with n vertices and m edges ($n \le m$). Without loss of generality, assume that $V \subset [0, 0.1]$, and $0 \in V$ and $0.1 \in V$.

The reduction. For each vertex $t \in V$, create six points

$(0+t,$	$2+t,$	$-0.5,$	$-0.5)$	(type 1)
$(2-t,$	$0-t,$	$-0.5,$	$-0.5)$	(type 2)
$(1-t,$	$0.5,$	$1+t,$	$1.5)$	(type 3)
$(0.5,$	$1+t,$	$0.5,$	$2-t)$	(type 4)
$(-0.5,$	$-0.5,$	$2-t,$	$0-t)$	(type 5)
$(-0.5,$	$-0.5,$	$0+t,$	$1+t)$	(type 6)

Create the following orthants in $\mathbb{R}^4$:

$$\begin{aligned}
\forall x_1x_2' \in E:\ R^{(1)}_{x_1x_2'} &= [0+x_1,+\infty) \times [0-x_1,+\infty) \times (-\infty,1+x_2') \times (-\infty,2-x_2')\\
\forall x_2x_3' \in E:\ R^{(2)}_{x_2x_3'} &= (-\infty,1-x_2] \times (-\infty,1+x_2] \times (0+x_3',+\infty) \times (0-x_3',+\infty)\\
\forall x_3x_1' \in E:\ R^{(3)}_{x_3x_1'} &= (-\infty,2-x_1') \times (-\infty,2+x_1') \times (-\infty,2-x_3] \times (-\infty,1+x_3]
\end{aligned}$$

(call them of type 1, 2, and 3, respectively).

Correctness. We prove that a size-3 set cover exists iff a triangle exists in G.

Any feasible solution (if exists) must use an orthant of each type, as one can easily check (like before). So, the three orthants in a feasible solution must be of the form $R^{(1)}_{x_1x_2'}$, $R^{(2)}_{x_2x_3'}$ and $R^{(3)}_{x_3x_1'}$ for some $x_1x_2', x_2x_3', x_3x_1' \in E$.

Consider points of type 1 with the form $(0+t, 2+t, -0.5, -0.5)$. The orthant $R^{(2)}_{x_2x_3'}$ cannot cover any of them due to the third dimension. The orthant $R^{(1)}_{x_1x_2'}$ covers all such points corresponding to $t \geq x_1$, and the orthant $R^{(3)}_{x_3x_1'}$ covers all such points corresponding to $t < x_1'$. So, all points of type 1 are covered iff $x_1 \leq x_1'$. By similar arguments, it can be checked that all points of type 2 are covered iff $x_1 \geq x_1'$; all points of type 3 are covered iff $x_2 \leq x_2'$; all points of type 4 are covered iff $x_2 \geq x_2'$; all points of type 5 are covered iff $x_3 \leq x_3'$; all points of type 6 are covered iff $x_3 \geq x_3'$. We conclude that a feasible solution exists iff a triangle $x_1x_2x_3$ exists in G. ◀

In the computer search, we basically tried different choices of points with coordinate values of the form $c \pm t$ or c for some constant c, and orthants defined by intervals of the form $[c \pm x_j, +\infty)$ or $(-\infty, c \pm x_j]$ (closed or open) for some variable x_j (or x_j'). The constraints are not exactly easy to write down, but are self-evident as we simulate the correctness proof above. Naively, the number of cases is in the order of 10^{14}, but can be drastically reduced to about 10^7 with some optimization and careful pruning of the search space. The C++ code is not long (under 150 lines) and, after incorporating pruning, runs in under a second.

It is now straightforward to modify the above lower bound proof for unweighted orthants (or unit hypercubes) in $\mathbb{R}^4$ to the rectilinear discrete 3-center problem in $\mathbb{R}^4$. In the full version of the paper, we also prove a higher conditional lower bound for weighted size-6 set cover for rectangles in $\mathbb{R}^2$.

4 Conditional Lower Bound for Euclidean Discrete 2-Center

In this section, we prove our conditional lower bound for the Euclidean discrete 2-center problem in a sufficiently large constant dimension. The general structure of our proof is inspired by Bringmann et al.'s recent conditional hardness proof [12] for the problem of computing diameter of box intersection graphs in $\mathbb{R}^{12}$, specifically, testing whether the diameter is more than 2. (Despite the apparent dissimilarities of the two problems, what led us to initially suspect that the ideas there might be useful is that both problems are concerned with paths of length 2 in certain geometrically defined graphs, and both problems have a similar "quantifier structure", after unpacking the problem definitions.) Extra ideas are needed, as we are dealing with the Euclidean metric instead of boxes; we end up needing an extra dimension, with carefully tuned coordinate values, to make the proof work.

▶ **Theorem 6.** *For any constant $\delta > 0$, there is no $O(n^{2-\delta})$-time algorithm for Euclidean discrete 2-center in $\mathbb{R}^{13}$, assuming the Hyperclique Hypothesis.*

Proof. We will reduce the problem of detecting a 6-hyperclique in a 3-uniform hypergraph with n vertices, to the Euclidean discrete 2-center problem on $N = O(n^3)$ points in $\mathbb{R}^{13}$. Thus, if there is an $O(N^{2-\delta})$-time algorithm for the latter problem, there would be $O(n^{6-3\delta})$-time algorithm for the former problem, refuting the Hyperclique Hypothesis.

Let $G = (V, E)$ be the given 3-uniform hypergraph. By a standard color-coding technique [7], we may assume that G is 6-partite, i.e., V is partitioned into 6 parts $V_1, \ldots, V_6$, and each edge in E consists of 3 vertices from 3 different parts. The goal is to decide the existence of a 6-hyperclique, i.e., $(x_1, \ldots, x_6) \in V_1 \times \cdots \times V_6$ such that $\{x_i, x_j, x_k\} \in E$ for all distinct $i, j, k \in \{1, \ldots, 6\}$.

Without loss of generality, assume that $V \subset [0, 1]$, i.e., vertices are labelled by numbers that are rescaled to lie in $[0, 1]$. Let $f, g : [0, 1] \to [0, 1]$ be some injective functions satisfying $f(x)^2 + g(x)^2 = 1$. For example, we can take $f(x) = \cos x$ and $g(x) = \sin x$; or alternatively, avoiding trigonometric functions, $f(x) = x$ and $g(x) = \sqrt{1 - x^2}$; or avoiding irrational functions altogether, $f(x) = 2x/(x^2 + 1)$ and $g(x) = (x^2 - 1)/(x^2 + 1)$. (With the last two options, by rounding to $O(\log n)$ bits of precision, it is straightforward to make our reduction work in the standard integer word RAM model.)

The reduction. We construct the following set S of $O(n^3)$ points in $\mathbb{R}^{13}$:

1. For each $(x_1, x_2, x_3) \in V_1 \times V_2 \times V_3$ with $\{x_1, x_2, x_3\} \in E$, create the point
$$p_{x_1x_2x_3} = (f(x_1), g(x_1), f(x_2), g(x_2), f(x_3), g(x_3), 0, 0, 0, 0, 0, 0, 1).$$
2. Similarly, for each $(x_4, x_5, x_6) \in V_4 \times V_5 \times V_6$ such that $\{x_4, x_5, x_6\} \in E$, create the point
$$q_{x_4x_5x_6} = (0, 0, 0, 0, 0, 0, f(x_4), g(x_4), f(x_5), g(x_5), f(x_6), g(x_6), -1).$$
3. For each $(v_i, v_j, v_k) \in V_i \times V_j \times V_k$ with distinct i, j, k such that $\{v_i, v_j, v_k\} \notin E$, $\{i, j, k\} \neq \{1, 2, 3\}$, and $\{i, j, k\} \neq \{4, 5, 6\}$, create a point $z_{v_iv_jv_k}$: the coordinates in dimensions $2i-1, 2i$ are $-f(v_i), -g(v_i)$, and similarly the coordinates in dimensions $2j-1, 2j, 2k-1, 2k$ are $-f(v_j), -g(v_j), -f(v_k), -g(v_k)$, respectively; the 13-th coordinate is
$$\phi_{ijk} = |\{1, 2, 3\} \cap \{i, j, k\}| - 1.5 \in \{-0.5, 0.5\};$$
and all other coordinates are 0. For example, if $i = 1, j = 2, k = 4$,
$$z_{v_1v_2v_4} = (-f(v_1), -g(v_1), -f(v_2), -g(v_2), 0, 0, -f(v_4), -g(v_4), 0, 0, 0, 0, 0.5).$$
4. Finally, add two auxiliary points $s_\pm = (0, \ldots, 0, \pm 3.5)$.

We solve the discrete 2-center problem on the above point set S, and return true iff the minimum radius is strictly less than $\sqrt{10.25}$.

Correctness. Suppose there exists a 6-hyperclique $(x_1, \ldots, x_6) \in V_1 \times \cdots \times V_6$ in G. We claim that every point of S has distance strictly less than $\sqrt{10.25}$ from $p_{x_1x_2x_3}$ or $q_{x_4x_5x_6}$. Thus, S can be covered by 2 balls centered at $p_{x_1x_2x_3}$ and $q_{x_4x_5x_6}$ with radius less than $\sqrt{10.25}$. To verify the claim, consider a point $z_{v_1v_2v_4} \in S$ for a triple $(v_1, v_2, v_4) \in V_1 \times V_2 \times V_4$ with $\{v_1, v_2, v_4\} \notin E$. Observe that the distance between the points $(f(v_\ell), g(v_\ell))$ and $(-f(x_\ell), -g(x_\ell))$ in $\mathbb{R}^2$ is at most 2, with equality iff $v_\ell = x_\ell$. On the other hand, the distance between $(f(v_\ell), g(v_\ell))$ and $(0, 0)$ is 1, and the distance between $(0, 0)$ and $(-f(x_\ell), -g(x_\ell))$ is 1. Thus,
$$\|z_{v_1v_2v_4} - p_{x_1x_2x_3}\|^2 \leq 2^2 + 2^2 + 1 + 1 + 0 + 0 + (0.5 - 1)^2 \leq 10.25,$$

with equality iff $v_1 = x_1$ and $v_2 = x_2$. Furthermore,

$$\|z_{v_1v_2v_4} - q_{x_4x_5x_6}\|^2 \;\le\; 1+1+0+2^2+1+1+(0.5+1)^2 \;\le\; 10.25,$$

with equality iff $v_4 = x_4$. Since $\{x_1, x_2, x_4\} \in E$, we cannot have simultaneously $v_1 = x_1$, $v_2 = x_2$, and $v_4 = x_4$. So, $z_{v_1v_2v_4}$ has distance strictly less than $\sqrt{10.25}$ from $p_{x_1x_2x_3}$ or $q_{x_4x_5x_6}$. Similarly, the same holds for $z_{v_iv_jv_k} \in S$ for all other choices of i, j, k. Points $p_{x'_1x'_2x'_3} \in S$ have distance at most $\sqrt{2+2+2+0+0+0+0} < \sqrt{10.25}$ from $p_{x_1x_2x_3}$, and similarly, points $q_{x'_4x'_5x'_6} \in S$ have distance less than $\sqrt{10.25}$ from $q_{x_4x_5x_6}$. Finally, the auxiliary point s_+ has distance at most $\sqrt{1+1+1+0+0+0+2.5^2} < \sqrt{10.25}$ from $p_{x_1x_2x_3}$, and similarly the point s_- has distance less than $\sqrt{10.25}$ from $q_{x_4x_5x_6}$.

On the reverse direction, suppose that the minimum radius for the discrete 2-center problem on S is strictly less than $\sqrt{10.25}$. Note that the distance between s_+ and $z_{v_iv_jv_k}$ is at least $\sqrt{1+1+1+0+0+0+3^2} > \sqrt{10.25}$, and the distance between s_+ and $q_{x_4x_5x_6}$ is at least $\sqrt{0+0+0+1+1+1+4.5^2} > \sqrt{10.25}$. Thus, in order to cover s_+, one of the two centers must be equal to $p_{x_1x_2x_3}$ for some $\{x_1, x_2, x_3\} \in E$. Similarly, in order to cover s_-, the other center must be equal to $q_{x_4x_5x_6}$ for some $\{x_4, x_5, x_6\} \in E$. Then for every $(v_1, v_2, v_4) \in V_1 \times V_2 \times V_4$ with $\{v_1, v_2, v_4\} \notin E$, the point $z_{v_1v_2v_4}$ has distance strictly less than $\sqrt{10.25}$ from $p_{x_1x_2x_3}$ or $q_{x_4x_5x_6}$. By the above argument, we cannot have $v_1 = x_1$ and $v_2 = x_2$ and $v_4 = x_4$. It follows that $\{x_1, x_2, x_4\} \in E$. Similarly, $\{x_i, x_j, x_k\} \in E$ for all other choices of i, j, k. We conclude that $\{x_1, \ldots, x_6\}$ is a 6-hyperclique. ◀

From the same proof (after rescaling), we immediately get a near-quadratic conditional lower bound for unweighted size-2 geometric set cover for unit balls in $\mathbb{R}^{13}$. In the full version of the paper, we extend the proof to Euclidean discrete k-center for larger constant k, with more technical effort and more delicate handling of the extra dimensions. This is interesting: discrete k-center seems even farther away from graph diameter, but in a way, our proof shows that discrete k-center is a better problem to illustrate the full power of Bringmann et al.'s technique [12].

In the full version of the paper, we also adapt the approach to prove a conditional lower bound for size-2 maximum coverage for boxes. The proof uses a different way to enforce conditions like $\{x_1, x_2, x_4\} \in E$, via an interesting counting argument – we encourage the readers to take a look at the full version.

5 Conclusions

In this paper, we have obtained a plethora of nontrivial new results on a fundamental class of problems in computational geometry related to discrete k-center and size-k geometric set cover for small values of k. (See Tables 1–3.) In particular, we have a few results where the upper bounds and conditional lower bounds are close:

- For weighted size-3 set cover for rectangles in $\mathbb{R}^2$, we have given the first subquadratic $\widetilde{O}(n^{7/4})$-time algorithm, and an $\Omega(n^{3/2-\delta})$ lower bound under the APSP Hypothesis.
- For Euclidean discrete k-center (or unweighted size-k set cover for unit balls) in $\mathbb{R}^{O(k)}$, we have proved an $\Omega(n^{k-\delta})$ lower bound under the Hyperclique Hypothesis, which is near optimal if $\omega = 2$.
- For size-2 maximum coverage for boxes in a sufficiently large constant dimension, we have proved an $\Omega(n^{2-\delta})$ lower bound under the Hyperclique Hypothesis, which is near optimal.

For all of our results, we have managed to find simple proofs (each with 1–3 pages). We view the simplicity and accessibility of our proofs as an asset – they would make good examples illustrating fine-grained complexity techniques in computational geometry. Generally speaking, there has been considerable development on fine-grained complexity in the broader algorithms community over the last decade [46], but to a lesser extent in computational geometry. A broader goal of this paper is to encourage more work at the intersection of these two areas. We should emphasize that while our conditional lower bound proofs may appear simple in hindsight, they are not necessarily easy to come up with; for example, see one of our proofs that require computer-assisted search (Theorem 5).

As many versions of the problems studied here still do not have matching upper and lower bounds, our work raises many interesting open questions. For example:

- Is it possible to make our subquadratic algorithm for rectilinear discrete 3-center in $\mathbb{R}^2$ work in dimension 3 or higher?
- Is it possible to make our conditional lower bound proof for rectilinear discrete 3-center in $\mathbb{R}^4$ work in dimension 2 or 3?
- Is it possible to make our conditional lower bound for Euclidean discrete 2-center in $\mathbb{R}^{13}$ work in dimension 3?
- Is it possible to make our conditional lower bound for size-2 maximum coverage for boxes in $\mathbb{R}^{12}$ work in dimension 2 or 3?
- Although we have ruled out subquadratic algorithms for Euclidean discrete 2-center in $\mathbb{R}^{13}$, could geometry still help in beating n^ω time if $\omega > 2$?

We should remark that some of these questions could be quite difficult. In fine-grained complexity, there are many examples of basic problems that still do not have tight conditional lower bounds (to mention one well-known geometric example, Künnemann's recent FOCS'22 paper [36] has finally obtained a near-optimal conditional lower bound for Klee's measure problem in $\mathbb{R}^3$, but tight lower bounds in dimension 4 and higher are still not known for non-combinatorial algorithms). Still, we hope that our work would inspire more progress in both upper and lower bounds for this rich class of problems.
