Abstract

One hundred and sixty European sea-bass $(78.5 \pm 8.9$ g) were randomly assigned to 8 fibreglass tanks (160 l) according to a 2×2 experimental design [2 processing techniques: extruded diet (E) *vs* pelleted diet (P); 2 feeding levels: 0.86 (1) *vs* 1.06% b.w. (2)], with 2 replicates for each treatment. After 195 days, E2 fed fish reached the highest live weight (329 *vs* 281 g), daily weight gain (1.29 *vs* 1.04 g) and specific growth rate (SGR: 0.74 *vs* 0.65). No difference was noted among diets in feed efficiency (FE) and protein efficiency ratio (PER), although a trend to better FE (0.73 *vs* 0.65) and PER (1.48 *vs* 1.28) was noted for E1 fed fish. Hepatosomatic index was significantly higher in E2 and E1 fed fish (2.56 and 2.53% b.w., respectively), while the lowest mesenteric fat index occurred in P1 fed fish (4.37 *vs* > 5% b.w.). P1 and E1 fed fish showed the highest protein retention ($\approx 25\%$), but the highest energy retention was observed with extruded diets fed at 0.86% b.w. (40.2%). Total NH_3 (395 and 387 mg kg^{-1} b.w. day^{-1}) and reactive phosphorus excretion (136 and 110 mg kg^{-1} b.w. day^{-1}) were not affected by the processing method of the diet. © 1998 Elsevier Science B.V.

1. Introduction

During the last decade, there has been a marked increase in the use of extruded diets for feeding fish. These diets have superior water stability, better floating properties and a higher energy content than pelleted diets (Hilton et al., 1981; Cho et al., 1991; Johnsen and Wandsvik, 1991). The main effects on fish are: an increase in fish growth, an improvement in feed conversion (Robert et al., 1993; Silver et al., 1993; Lanari et al., 1995), a delay in gastric emptying time, an increase in HSI and liver glycogen content, with no effect on carcass composition (Hilton et al., 1981). A significant decrease in nitrogen and phosphorus discharge in waste waters by fish farms has also been observed (Alsted, 1991; Kiaerskou, 1991; Cho, 1993; Johnsen et al., 1993).

The majority of the studies, where extrusion was compared to pelleting, have been performed on single extruded ingredients instead of considering the whole diet, to demonstrate an improvement in carbohydrate digestibility (Luquet and Bergot, 1976; Pieper and Pfeffer, 1980; Kaushik et al., 1989; Takeuchi et al., 1990; Pfeffer et al., 1991; Arnesen and Krogdahl, 1993). In the past, some authors have studied the effects of the processing method (pelleting *vs* extrusion) of the same basal mix on physical properties of the product, nutrient losses and fish performance (Slinger et al., 1979; Hilton et al., 1981), but nowadays different extruders with different processing conditions are available. Besides, some of the positive response of fish to extruded diets seems to depend not on the processing method 'per se' but on the higher fat content of the extruded diets.

From a practical point of view, the improvement in nutrient retention and performance observed with extruded diets (Johnsen et al., 1993; Robert et al., 1993; Lanari et al., 1995) has not resulted in an adjustment in the old feeding charts for fish, according to Cho (1992), and feed efficiency has improved little, mainly due to fish overfeeding. The use of extruded diets has grown enormously in the past few years in marine farms and intensive 'valli' of the Mediterranean sea, but little data are available for sea bass and other marine species (sea bream, dentex, *Sciaenidae*, etc.). There is a need to have a better understanding of the optimal feeding levels of extruded diets for these species, due to their different feeding behaviour and voluntary feed intake compared to salmonids, and to the wide annual range of the temperatures in these farming areas.

The aims of this study were to determine: (1) the physiological response of European sea bass (rate of gain, feed efficiency and body composition) fed the same diet, processed either by extrusion or steam pelleting, at different feeding levels; and (2) the effects of these processing methods on NH_3 and reactive phosphate excretion in European sea bass.

2. Materials and methods

2.1. Growth trial

One hundred and sixty European sea bass (*Dicentrarchus labrax*, L., 78.5 ± 8.9 g) were randomly allotted to 8 fibreglass tanks (160 l) according to a 2×2 experimental design [2 processing techniques: extruded diet (E) *vs* steam pelleted diet (P); 2 feeding rates: 0.86 (1) *vs* 1.06% b.w. (2)]. Consequently, four experimental treatments arose: E1,

E2, P1 and P2; with 2 replicates per treatment. Each tank was supplied by a constant flow of brackishwater (temperature = 23.1 ± 2.1°C; dissolved oxygen = 8.5 ± 2.5 mg l^{-1}; salinity = 21.2 ± 3.6‰ NaCl).

The growth trial lasted 195 days and was performed at the *valle da pesca* 'Villa Bruna', in the Marano lagoon. Portions of the same practical sea bass diet were processed through a pellet mill (Tenchini: mod. FT180) and through a monoscrew extruder (Wenger: mod. X185) (Table 1).

Feed was distributed 5–7 times a day, by automatic dispensers, at the feeding rate previously reported (Table 2). Diets were periodically sampled and analyzed according to AOAC methods (1995), whereas crude fat was determined after acid hydrolysis (Sanderson, 1986). Gross energy content was determined by adiabatic bomb calorimetry (IKA 400), and phosphorus by a photometric method (AOAC, 1995; Ref. 4.8.14).

Mortality and water variables were checked daily and fish were weighed fortnightly. Eighteen fish were sacrificed at the beginning of the experiment and 7 fish per tank at

the end. The gastrointestinal contents were removed and then each fish was minced and freeze-dried. The chemical composition and the energy content of individual fish were determined with the same methods used for feeds.

All data were submitted to two-way analysis of variance. LSD test was used for comparison between means (Snedecor and Cochran, 1982).

2.2. Excretion trial

Six groups of five fish were pre-adapted for 4 weeks to the experimental diets and to six fibreglass tanks supplied with a constant flow (1 1 min^{-1}) of brackish water (see growth trial). Fish were fed 1.06% b.w., in a single meal (at 8:00 AM) according to a 2×2 latin square design (2 diets: E *vs* P, 2 periods), and 3 replicates, with 6 days adaptation phase to the feeding level, followed by a 24-h water sampling period. Every 90 min, water was sampled through a central drain pipe, without disturbing the fish. Temperature (portable thermometer HI 8053), salinity (Atago SC28 salinometer), dissolved oxygen (YSI oxymeter mod. 57) and pH (Orion 250A) were immediately determined. Samples were then acidified (H_2SO_4 2N) and frozen. Total ammonia and reactive phosphorus were measured within 24 h according to Strickland and Parson (1972), after thawing and neutralizing the pH. The amount of metabolites excreted were calculated according to Kaushik (1980). Data were subjected to statistical analysis according to the 2×2 latin square design (Snedecor and Cochran, 1982).

3. Results

The moisture content of the extruded diet was lower than the pelleted diet, while the crude fat, crude fiber and gross energy were slightly higher (Table 1).

The final weight of fish fed the P1 diet was significantly lower than that of P2 and E2 fed fish. Specific growth rate (SGR) and daily weight gains of fish fed E1 and P2 diets were higher than those observed in fish fed pelleted diets at low feeding level and lower than those obtained for the E2 groups (Table 2). The highest daily protein gain (225.5 mg day^{-1}) and daily energy gain (12.58 kJ fish^{-1}) occurred in fish fed the extruded diet at the medium level, while the lowest values were for the P1 fed fish (163.4 mg day^{-1} and 7.98 kJ fish^{-1}, respectively, $P < 0.01$). Feed efficiency and PER values did not

differ among treatments, although a trend was shown towards better values at low feeding level and with the extruded diet (Table 2).

Dressing percentage and mesenteric fat indices were higher and lower, respectively, in sea bass fed the pelleted diet at the low feeding level, in comparison with fish fed the pelleted or extruded diet at medium feeding level (Table 3). Fish receiving the extruded diet at low feed intake gave intermediate results. HSI values increased with the extruded diet and according to increasing feeding level.

Final body composition of sea bass changed markedly in comparison with initial composition. Moisture and protein content were higher in fish fed the P1 diet and significantly decreased when feed intake was increased either with pelleted or extruded diet. Fish fed the E1 diet had intermediate results. Fat and energy content of fish showed trends opposite to those observed for moisture and protein levels. Body ash level was not affected by dietary treatments. P content was higher in fish fed the pelleted diets (Table 3).

Fig. 2. Reactive phosphorus production by European sea bass fed pelleted (black color) or extruded diet (white color).

Fish fed the E1 diet had the highest energy retention (40.2%), while P2 the lowest (31.4%; $P < 0.05$). Due to the low number of replicates for the experimental treatments, the decreasing trend of the protein retention according to increasing feeding level was not statistically confirmed. Gross phosphorus retention was close to 20%, irrespective of the diet type of processing or feeding level (Table 4).

The daily NH_3 excretion of sea bass (385–395 mg total NH_3 kg^{-1} b.w. day^{-1}) was unaffected by the type of diet processing (Table 4). The total ammonia excretion by fish in a 24-h period is reported in Fig. 1. Peak values occurred 6 h after feed distribution for the extruded diet and after 7.5 h for the pelleted diets. The daily amount of reactive phosphorus leached in the water was slightly lower for the extruded diets than the pelleted diets (109.7 vs. 136.4 mg P kg^{-1} b.w. day^{-1}; $P < 0.07$; Table 4). The concentration of soluble P in the tanks increased 1.5–3 h after feeding, returned to basal levels thereafter, showing a common trend to increase again after 15 h, both for E and P diet fed groups (Fig. 2).

4. Discussion

In this trial, both the extruded diet and the increased feeding level significantly affected final weight, SGR, and daily weight gain. Similar effects of feeding level have previously been observed in rainbow trout fed at low (0.9% b.w.) or moderate (1.1% b.w.) feeding levels by Lanari et al. (1995), whereas Hilton et al. (1981) noted that rainbow trout fry reared on an extruded diet had lower weight gains but higher feed efficiency than those reared on a pelleted diet. Nevertheless, it is worth noting that fish size may have an effect on these observations.

The growth rate and feed efficiency that we observed were higher than those previously reported for sea bass with similar levels of pelleted diets (Metailler et al., 1980, 1981; Hidalgo and Alliot, 1988; Ballestrazzi et al., 1994; Ballestrazzi and Lanari, 1996). Also the protein efficiency ratio (1.28–1.48) was better than PER values reported for fry or ongrowing sea bass by the previously cited researchers.

Enlarged livers and increased liver glycogen were observed in rainbow trout fed extruded diets by Hilton et al. (1981), while Mosconi-Bac (1990) reported a hepatic disturbance (large deposits of lipid droplets) in sea bass fry fed to satiation on crumbled diets. Also in this study, enlarged livers occurred, nevertheless the high weight gains observed during the experiment (6.5 months), confirmed that the sea bass readily adapted to the extruded diets, if nutritionally balanced and distributed at 1% b.w. daily.

The lack of effect of the extruded diet on rainbow trout body composition reported by Hilton et al. (1981) can be explained by the small final size of fish, too low (~ 40 g) to be clearly affected by the diets. An increase in feeding level, irrespective of the diet type, causes a marked decrease of moisture and protein body content and a corresponding increase of fat level in fish (Reinitz, 1983; Storebakken and Austreng, 1987) and this also happened in this trial. Nevertheless, higher fat levels in sea bass body does not necessarily mean fatter fillets since the liver and mesentery are fat storage sites in this species.

There are two components of total NH_3 excretion in fish: the endogenous (for maintenance) and exogenous fractions (Iwata, 1970; Brett and Groves, 1979). While the first fraction is affected by fish size and water temperature (Ogino et al., 1973; Savitz, 1969), the second is mainly influenced by nitrogen intake, i.e., dietary protein quality and quantity (Brett and Zala, 1975; Kaushik, 1980; Kaushik and Cowey, 1991). Several researchers have reported on both NH_3 production of starved sea bass and their post-prandial NH_3 excretion (Guérin-Ancey, 1976; Spiridakis, 1989; Vitale-Lelong, 1989; Ballestrazzi et al., 1994). A general trend of a decrease in the first fraction, due to sea bass size (from 450 mg N total kg^{-1} day^{-1}: 2–6 g fry to 160 mg $N–NH_4$ kg^{-1} day^{-1}: 120 g fish) can be deducted from their data. The post-prandial patterns of ammonia excretion are more complex due to the different conditions these authors adopted (different plants, different water flow rate, different temperature), with different fish size, stocking density and different nitrogen intakes. Sea bass fed diets containing plant protein sources or high protein levels showed higher post-prandial NH_3 excretion than those fed diets containing animal proteins or low protein levels (Ballestrazzi et al., 1994). In this trial the total NH_3 excretion, unaffected by the type of diet processing, was higher than post-prandial excretion in the experiment previously cited, although nitrogen intakes were very similar (600 *vs* 630–790 mg N kg^{-1} b.w.), and was probably due to the different ingredient composition of the diets.

The soluble forms of phosphorus affect water quality directly, whereas the particulate form settles to the bottom of the tank or accumulates in the sediment (Lall, 1991). In this trial the leached phosphorus produced by sea bass fed either the extruded or pelleted diet was similar to the values previously obtained by feeding sea bass only with animal protein sources (Ballestrazzi et al., 1994). An estimation of the phosphorus balance in P2 and E2 fed fish, considering dietary P content ($\sim$ 2.0% both), the phosphorus retention (19.1 vs. 17.9%) and the soluble phosphorus (136.4 vs. 109.7 mg kg^{-1} b.w. day^{-1}), indicates that the settling fraction would be higher with the extruded diets than with the pelleted form. This would have environmental positive effects since this fraction is only partly or slowly released from the sludge in soluble forms (Enell, 1987; Persson, 1988).

The extruded diet, increasing the energy retention efficiency, with no effect on protein retention, would be less convenient, at least at the operating temperature adopted (23.1°C), when no problems for the feed intake of this species are encountered. Considering fish growth, their body composition and gross nutrient retention efficiencies, the best results, in this study, were certainly given by feeding the extruded diet at low feeding level (E1), because the rate of growth was adequate (> 1 g day^{-1}), body composition was similar to that of the P2 fed group, but the amount of diet distributed to fish was 17.9% less. Fish feeding the extruded diet at higher feeding level (E2) grew more but showed negative effects on their fat and protein body contents.
