Automatic Camera Control meets Emergency Simulations: an Application to Aviation Safety

Abstract

Computer-based simulations of emergencies increasingly adopt 3D graphics to visualize results and thus generate complex dynamic 3D scenes with many potentially parallel events that affect large groups of virtual characters. To understand the portrayed scenario, a viewer could interactively control a flying camera or switch among a set of virtual cameras that have been previously placed at modeling time. The first solution imposes a cognitive load on the viewer that can distract him/her from the analysis task, and (s)he might miss events while moving the camera. The second solution requires additional work in the modeling phase, and even a very large number of cameras could fail to correctly frame events because of dynamic occlusions. More sophisticated automatic camera control methods could help, but the methods in the literature are designed for sequential dialogue-like events that involve at most two or three characters and therefore would not work. In this paper, we present a fully automated, real-time system that is able to monitor events in emergency simulations, select relevant events based on user-provided filtering rules, and control a virtual camera such that the events of interest are properly presented to the viewer. To illustrate how the system works in practice, we also describe the first application of automatic camera control to the domain of aviation safety.

Keywords: automatic camera control, emergency simulations, aviation safety

1. Introduction

Computer-based simulations of emergencies are increasingly used for a variety of purposes, including planning, prediction of outcomes, accident investigation, and training. Systems have begun to adopt realistic 3D graphics to visualize simulations results (e.g., [1, 2, 3]), thereby generating complex, dynamic 3D scenes with many potentially parallel events affecting large groups of virtual characters. Presenting the resulting animations to a viewer in an effective manner is thus challenging.

The traditional approach to the visualization of 3D simula-11 tions is to place multiple virtual cameras in the scene at mod-12 eling time and switch among them at run time to observe the 13 different events that occur. However, as the spatial complex-14 ity of the scenario and the number of events increase, even 15 a very large number of cameras could fail to correctly frame 16 many events, e.g., because of dynamic occluders that prevent 17 any of the pre-defined cameras from adequately capturing some 18 of the action. Moreover, manually placing the virtual cameras 19 can require a considerable modeling effort that in general must 20 be repeated for each simulation. Even for the same simulation, 21 multiple camera setups may be necessary based on what fea-22 tures a viewer finds the most interesting. For example, a safety 23 expert could be interested in how the entire emergency egress 24 of a crowd from a building evolves, while a firefighter who uses 25 the same simulation for training would need to focus on details 26 that are relevant to first response duties in the field such as the 27 location and evolution of fires.

An alternative solution is to let the viewer interactively control a flying camera during the simulation. However, this approach imposes a cognitive load on the viewer that can distract 31 him/her from the analysis task and that has the additional disad-32 vantage that (s)he might miss events while moving the camera.

Automatic camera control methods could provide solutions to such problems, thus relieving the user from the burden of manual camera placement, selection, and control. However, most methods that have been proposed in the literature are designed for sequential dialogue-like events involving at most two or three characters and are thus not suited to situations that insulations clude several parallel events involving many characters. Indeed, none of these solutions have been adopted for emergency simulations.

In this paper, we present a novel and fully automated, realtime camera control system for emergency simulations that is
table to monitor interesting events and present them to a viewer.
We propose to organize such a system into two conceptual modtable ules: a *Camera Operator* and a *Director*. The *Camera Operator*to is based on extending a recent virtual camera computation aptable proach [4] to calculate, whenever needed, a virtual camera that
tap aims at visualizing the maximum number of currently occurring
to events of interest. The *Director* then analyzes the virtual camera that are computed by the *Camera Operator* and chooses
the which camera to use and when to use it to visualize simulation
to events to the viewer. To illustrate how the system operates in
the practice, this paper applies it to a complex case in the domain of
the aviation safety. However, the system is not limited to aviation
to and could be utilized in other emergency domains.

The paper is organized as follows. In Section 2, we briefly review past work on computer-based emergency simulations and automatic camera control and motivate the need for the proposed approach. In Section 3, we describe the proposed camera control system, and in Section 4, we apply the system to a full

65 a well-known recent accident. Finally, in Section 5, we con- 116 camera at run time. However, depending on the spatial com-64 clude the paper and outline future research directions.

65 2. Related Work & Motivations

66 2.1. Computer-based Emergency Simulations

68 for a variety of purposes, including planning, prediction of out-69 comes, accident investigations, and training. In particular, emer-70 gency evacuations have received considerable attention in the 71 literature. Gwynne et al [5] reviewed 22 evacuation models and 72 classified them into three main categories: optimization, simu-73 lation and risk assessment. EXODUS is a well-known evacua-74 tion model that was successfully applied to analyze both build-75 ing [6] and mass-transport [7] evacuations. The system includes 76 specialized modules to model very specific aspects such as (i) 77 the characteristics of occupants (e.g., age, gender, and physi-78 cal disabilities), (ii) their movements and behaviors, and (iii) 79 the physiological impact of toxicity due to smoke. A variant 80 of EXODUS, called air EXODUS [8], is specifically tailored to 81 aircraft evacuation.

In general, EXODUS and the other evacuation models at-83 tempt to precisely compute the values of several variables to 84 predict an evacuation outcome or analyze a real case, but they 85 do not focus on real-time interaction (e.g., interactions that dy-86 namically affect an evolving simulation) and have limited vi-87 sualization features (e.g., 2D maps or simplified 3D models). 88 In particular, the EXODUS system can be used with vrEXO-89 DUS, which is a 3D visualizer of the simulations that operates 90 as a graphics post-processor of previously generated simula-91 tions. The Glasgow Evacuation Simulator [9] introduced the 92 possibility of opening or closing routes in real time to test dif-93 ferent evacuation paths. Moreover, the simulator supports the 94 visualization of an evacuation using CAD-CAM 3D models of 95 buildings, but occupants are represented only by colored cylin-96 ders.

In addition to advancing the simulation domain, improv-98 ing the realism of graphics and real-time interaction with the 99 simulator would extend the application of evacuation models to 100 training, thus allowing trainees to learn by directly interacting 101 with virtual objects and characters. Moreover, with the help of 102 3D animations, trainees could virtually experience emergency 103 scenarios that are difficult, expensive and dangerous to repro-104 duce in the real world, thereby getting a better understanding of 105 complex scenarios and cause-effect relationships [10, 11]. Sys-106 tems that employ realistic 3D graphics consider various emer-107 gency scenarios such as car accidents with fire and toxic gas 108 propagation in road tunnels [1], smoke hazards in subway sta-109 tions and schools [12], fire drills in buildings [13], and evacua-110 tions of airports [3] and nuclear facilities [2].

111 2.2. Automatic Camera Control

Current approaches to the visualization of the 3D simula-113 tions discussed in the previous section are based on either plac-114 ing virtual cameras in the scene at modeling time, and switching

62 aircraft evacuation scenario that reproduces the main aspects of 115 between them at run time, or manually controlling a moving 117 plexity of the scenario, even a very large number of cameras or 118 a very skilled manual control will fail to correctly frame certain 119 events, e.g., because of dynamic occluders. Moreover, manu-120 ally placing the cameras can involve a considerable modeling 121 effort, which in general has to be repeated for each simulation, Computer-based emergency simulations are increasingly used ¹²² and manual camera control in real time imposes a cognitive load on the viewer that can distract him/her from the analysis task. 124 Many emergency simulations involve hundreds (or even thousands, as in simulations of the 9/11 attack [14]) of independent 126 characters and many different types of events that are occurring 127 in parallel over an area that could be very large. As a result, it 128 is very hard to select and visualize all of the relevant details of 129 such emergencies with the camera control approaches of cur-130 rent simulators.

> Automatic camera control methods could offer a method of 132 addressing these issues. In the following, we analyze the main 133 aspects that an automatic camera control system must consider 134 to present a simulation. For each aspect, we briefly discuss the 135 state of the art and illustrate why current approaches are not 136 adequate for emergency simulations.

> The first fundamental aspect is how to find virtual cameras 138 that ensure the visibility of events of interest. Current auto-139 matic control approaches can be organized into two main cate-140 gories: approaches that search for virtual cameras anywhere in 141 the scene and that can consider an arbitrary number of targets 142 [4, 15, 16], hereinafter called *global solvers*, and approaches 143 that focus on ensuring the continuous visibility of one [17, 18] 144 or a few [19, 20] dynamic targets and that search only in a re-145 gion around a current camera. In both approaches, visibility 146 is typically defined in terms of a combination of various visual properties such as target screen size, occlusion, and angle 148 from which the target is observed. In emergency simulations, 149 events might occur anywhere in the scene; therefore, the abil-150 ity to find virtual cameras anywhere in the scene is substan-151 tially more important than ensuring continuity in visualizing 152 the simulation. Unfortunately, most global solvers typically 153 suffer from performance issues because they rely on stochas-154 tic optimization strategies (e.g., population-based algorithms) 155 to sample the search space. An exception is a recent proposal 156 by Ranon and Urli [4], who introduced more effective candi-157 date camera initialization and evaluation strategies whereby a 158 single virtual camera can be computed in tenths of milliseconds 159 (instead of hundreds) in quite complex scenes.

> The ability to find cameras that can frame various current 161 events of interest is only the first step toward the broader goal of 162 conveying meaning (or at least making it inferable) to a viewer. 163 This topic has been the subject of several research papers, e.g., 164 [21, 22, 23, 24], that focus on narrative events and mimic the 165 language of films by encoding cinematographic rules such as 166 typical shots and continuity editing. However, such approaches 167 are limited to film dialogue-based interactions among two or 168 three characters and to consider one event at each time. For ex-169 ample, the Virtual Cinematographer [23] and the FILM system 170 [24] are able to film events in real time by selecting among a 171 set of idioms. An idiom contains information about the number

172 of targets, shot types and, in the Virtual Cinematographer, the 173 timing of transitions between shots to best communicate events, 174 such as three virtual actors conversing, as they unfold. Camera 175 placement is selected among a few pre-encoded, idiom-specific 176 alternatives, e.g., depending on the targets' visibility. However, 177 there is no guarantee that, in a spatially complex environment, 178 any of the alternatives will provide a suitable framing of tar-179 gets. Lino et al [21] improved upon the two above-mentioned 180 systems by considering a narrative event and computing a set 181 of director volumes, i.e., volumes in the scene that encode both 182 shot type and visibility information for the considered event. 183 Then, they searched the director volumes for optimal virtual 184 cameras that guarantee continuity when cutting between cam-185 eras and selected the best virtual camera based on style ele-186 ments. In this approach, the visibility computations are per-187 formed in 2D (therefore, they are not applicable to multi-level 188 scenes or small objects) and do not consider dynamic occlud-189 ers such as other characters in the scene. In summary, current 190 systems based on cinematographic rules work well in situations 191 where spatial complexity is limited, the scene is mostly static, 192 and camera control targets consists of mainly two or three char-193 acters that are engaged in dialogue-like events. Moreover, such 194 systems can typically consider only one event at a time. Due to 195 these limitations, they are poorly suited to emergency simula-

A system that better addresses the needs of emergency sim-198 ulations was proposed by Galvane et al [25], who focused on 199 presenting events that occur in crowd simulations. Their system 200 relies on Reynolds' model of steering behaviors to control and 201 locally coordinate a collection of camera agents in real time in 202 a manner similar to a group of reporters. Camera agents can be 203 either in a scouting mode, thereby searching for relevant events 235 3. The proposed system 204 to present, or in a tracking mode, thereby following one or more 205 unfolding events. The system was tested using a crowd simu- 236 206 lation with 100 virtual characters in an exterior environment, 237 from a simulation, select interesting ones based on user prefer-207 where it provided a good coverage of events (mainly measured 238 ences, and present the events to a viewer. Events refer to objects 208 as the ratio between observed versus missed events). Com- 239 in the 3D scene, which are considered as targets that should be 209 pared to our method, their camera control approach has vari- 240 visualized. Our system can operate in real time (i.e., while the 210 ous advantages and disadvantages. The main advantage of their 241 simulation updates the 3D scene) without any assumption or 211 method is that it directly provides smooth camera motions in 242 pre-processing of the spatial environment or the behavior and 212 contrast to the static cameras that we use, which is a feature that 243 shape of 3D objects. The system does not attempt to present 213 might be preferable when the result should exhibit cinematic- 244 events using a cinematic language (e.g., preserving continuity 214 like qualities. Moreover, the approach of using a population of 245 between cuts); the system uses only static virtual cameras be-215 cameras naturally enables the simultaneous coverage of events 246 cause they are sufficient for monitoring a simulation. 216 that occur at different locations in the simulation or the cover- 247 217 age of the same event from different perspectives. The disad- 248 ply it to the domain of aviation safety. However, the system is 218 vantage of moving cameras through smooth motion (no "tele-249 not limited to aviation and can be reused in other emergency 219 port") is that it might take some time before a camera is able to 250 domains. 220 reach the position where an event occurs. Because this duration 251 depends on where the cameras are at the moment of event oc- 252 simulation sends a stream of all events that occur to the camera 222 currence, camera movement time is not predictable. Increasing 253 control system. The events are then filtered in real time (on the 223 the number of cameras might help, but this would also increase 254 basis of user-provided filtering rules) to select the ones that are 224 the computational complexity (their paper reports 15 fps for 255 relevant to the current viewer. For each event that passes the 225 30 cameras). Moreover, their approach provides a better per- 256 filtering phase, the system extracts targets, i.e., objects in the 226 formance and was demonstrated using exterior scenes, where 257 simulation that are involved in the event. Every few seconds, 227 cameras can observe and easily detect events that occur without 258 the Director module takes the list of targets that have been ex-228 occlusions. For interior or mixed interior/exterior scenes that 259 tracted so far and asks the Camera Operator module to com-

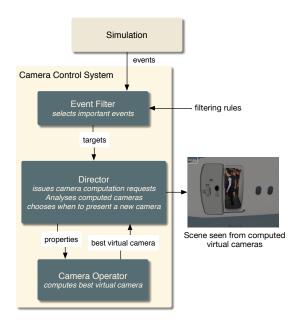

Figure 1: Overview of our system.

229 are typical of emergency evacuations, their camera computa-230 tion methods would likely take more time than in purely exte-231 rior scenes to discover events because they would not be able to 232 detect an event unless it is visible. Finally, their approach does 233 not consider how to select the camera to present events to the

In this section, we present a system that can monitor events

To illustrate how the system works in practice, we will ap-

261 list of properties that the desired virtual camera should satisfy. 312 mation about the bounding volumes of objects and to perform 262 The Camera Operator then tries to determine the virtual cam- 313 ray casting queries to measure visibility. A solution can be re-263 era that best satisfies the request and returns the result to the 314 turned in any amount of time, although in complex scenes, ad-264 Director, which evaluates the result and decides if and when to 315 ditional computation time will generally translate into a better 265 present it to the viewer by activating a transition from the cur- 316 solution (i.e., greater satisfaction of visual properties). We refer 266 rent camera to the new camera. In the following, we describe 317 the reader to [4] for a detailed explanation of the optimization ²⁶⁷ in detail the major activities performed by our system.

268 3.1. The Event Filter Module

273

274

275

276

277

For each event that occurs, the running simulation sends 270 an event description to the camera control system. An event 322 from the camera and ultimately allowing a viewer to understand 271 description is a (subject, action, object) triplet where

- subject is the acting object in the simulation event (e.g., "Flight Assistant 1");
- action is a textual description of the action performed by the subject (e.g., "starts opening door"); and
- object is the object in the simulation that is affected by the action (e.g., "door 1L");

As explained in Section 1, viewers are typically interested 279 in a subset of events, and the subset varies according to the pur-280 poses for which a simulation is run. To select the subset of 281 events, the viewer provides a list of strings, each of which can 334 282 be the name of an object in the simulation or (part of) an ac- 335 283 tion. Filtering rules then perform substring matching between 336 284 the list of strings and the stream of events output from the sim-285 ulator. For example, the list of strings ("Flight Assistant 1", 286 "door") will match all events where Flight Assistant 1 or any 287 door are involved. Matching events are then parsed, and simu-288 lation objects contained in them are inserted in the targets list, ²⁸⁹ which is accessed by the *Director* module.

Because a simulation might, at times, not generate events 291 that match, the camera control system allows the viewer to spec-292 ify a set of targets that should be framed in the absence of inter-293 esting events. For example, one could specify the entire scene 294 if (s)he wants the camera control system to search for global 345 295 overview shots when no events match his/her interests.

296 3.2. The Camera Operator Module

The Camera Operator module is based on a recent open-298 source declarative virtual camera computation library devel-299 oped by Ranon and Urli [4], which is able to compute in a 351 300 given amount of time the virtual camera that best satisfies a list 352 requests are implemented by a Size, Occlusion, Framing, 301 of visual properties. The visual properties can express desired 302 values of the size (area, width or height), visibility, camera an-303 gle and on-screen position for any choice of objects in the 3D 304 scene. From an input list of visual properties, the library first 356 means full satisfaction) expressed as a linear spline. Table 1 305 builds a function that returns a numeric value indicating to what 357 presents the visual properties that we have associated to each 306 extent a given virtual camera satisfies the properties. Then, a 358 target and their corresponding satisfaction functions. For exam-307 solver based on Particle Swarm Optimization [26] iteratively 359 ple, for the Size property, we have defined the spline in terms 308 searches the 3D scene for the virtual camera that maximizes the 309 satisfaction function. The library works with any type of scene 310 or object and does not require any preprocessing of the scene;

260 pute a virtual camera that visualizes the targets by creating a 311 the library relies on the 3D rendering engine to obtain infor-318 approach¹.

> In this paper, we need to define a set of properties that char-320 acterize any virtual camera that can frame a specific list of tar-321 gets, thereby making them prominent in the images rendered 323 the events that involve them. Our proposal is to use the follow-324 ing properties for each target:

- the screen area of the target should preferably be at least 10% of the screen size when we only have one target; in this way, it will be the main or one of the main subjects in the displayed image so that the viewer can easily recognize it, and the viewer will also see objects around it, to understand its position in the scene. When there are more targets, the value is divided by their number;
- the target should be fully visible (no other objects occluding it);
- the target should be framed as close as possible to the center of the screen (so that the viewer's attention is drawn to it);
- the target should be viewed from the front. The front is defined based on the category of the object. For example, in the case of a character, this means being able to see the character's face.
- the target should be viewed from a medium to high angle (we want to avoid viewing the target from too high or too low because in such cases, it could be difficult to understand what the target is doing).

Note that certain properties are more important than others. 346 For example, the visibility of a target is clearly more important 347 than framing it in the center of the screen because it is certainly 348 preferable to be able to see a target, even close to the screen 349 edge, than to not be able to see it because of occlusions caused 350 by other objects.

In the adopted virtual camera computation library, the above 353 and two Angle properties with the target as first argument. The 354 second argument of each property is a satisfaction function that 355 returns values in [0,1] (where 0 means no satisfaction and 1 $_{360}$ of the points (0,0), (0.05, 0.01), (0.08, 0.8), (0.1,1) and (1,1),

Property Type	Semantics	Weight	Satisfaction Function
Size	the target object should cover at least 10% of the screen area, or less if there are multiple target objects	2.5	0 occupied ratio of screen area
Occlusion	the target should not be occluded by other objects	4.0	0 occlusion ratio
Framing	the target object should be framed inside a screen rectangle with minimum and maximum corners equal to (0.2,0.2) and (0.8, 0.8), respectively, in viewport coordinates	1.0	o ratio of target in defined screen rectangle
Angle	camera in front of the object	1.0	1 angle of camera with 2π target front vector
Angle	camera parallel or slightly above object	1.5	angle of camera with target up vector

Table 1: Properties defined for each target object to compute a virtual camera. Weights reflect relative importance of properties and have been determined empirically. Slight variations of weights would not alter substantially the result.

where the x value in the function is the ratio of the screen area $\frac{381}{2}$ each target, a minimum screen area that is much lower than $\frac{10\%}{2}$ 373 variations do not alter substantially the result.

₃₇₆ in visualizing an overview of passengers exiting from the doors ₃₉₆ any angle from 0 to 45 degrees. 377 on a plane. In this case, the goal is not to obtain virtual cameras 397

362 that is occupied by the rendered target and the y value is the 382 and to soften requirements concerning angle (so that, for exam-363 corresponding satisfaction value. The weight of each property 383 ple, top-down virtual cameras also satisfy the requirements). In 364 (shown in the table) is a number that reflects the relative im- 384 our system, viewers can choose (and even modify their choice 365 portance of the property compared to the other properties. For 385 while the simulation is running) whether to promote target rec-366 example, the weight of the Occlusion property is four-times 386 ognizability (i.e., the Camera Operator will try to frame targets 367 larger than the weight of the Framing property. Because the 387 at a close distance using all of the above properties) or event 368 satisfaction of a virtual camera is defined as a weighted sum of 388 coverage (i.e., the Camera Operator will try to frame targets 369 all the property satisfaction functions, this means that in cases 389 at a greater distance if this is necessary to capture more targets ₃₇₀ when both framing and visibility cannot be guaranteed, the op-₃₉₀ using the more relaxed properties described above). In the last 371 timization process will prefer visibility. Weights have been em- 391 case, the properties are modified as follows: for each target, the 372 pirically determined by running a few simulations, and slight 392 minimum screen area becomes 0.5%, the Angle property that 393 considers the target front vector is removed (so that it is equally In certain situations, it might be preferable to use other sets 394 satisfying to frame the target from behind) and the Angle prop-975 of properties. For example, the viewer might be more interested 995 erty that considers the target up vector considers as satisfying

As with all virtual camera computation approaches based 378 that are sufficiently close to recognize a character but to derive 399 on optimization, there is no guarantee that the best returned vir-379 virtual cameras that visualize groups of characters in different 399 tual camera will satisfy all of the given properties. First, such 380 positions in the scene. This can be expressed by requiring, for 400 a camera might not exist; e.g., consider a case in which we are

401 simultaneously interested in two targets that are located in two 457 also accept virtual cameras that do not frame certain targets 402 opposite zones of an aircraft: the pilot's cockpit and the rear 458 in the screen center or with the required angle because these 403 galley. These situations are not unlikely because, in principle, 459 requirements could likely be difficult or impossible to satisfy 404 the simulation might compute events that occur simultaneously 400 for multiple targets simultaneously. Therefore, for each virtual 405 in completely different locations. In general, our system will try 461 camera, we compute two lists of targets: targets that are effec-406 to find the virtual camera that frames more targets because this 462 tively framed (framed targets) and frames that are not effec-407 corresponds to greater satisfaction. In the example of the two 463 tively framed (missed targets). The evaluation has a negligible 408 targets in opposite zones of an aircraft, the system will have 464 computational cost because it was previously performed dur-409 to choose one of the targets and miss the other (which could 465 ing the search process. A virtual camera is deemed to be good 410 be framed later). A more subtle issue is the case where only 466 for the viewer when its framed target list contains at least one 411 certain properties of a target can be satisfied. For example, it 467 target. If a virtual camera is not good, it is discarded. When 412 might be impossible to find a camera that guarantees both the 468 the Camera Operator fails to find a good camera in the allowed 413 required size and (at least partial) visibility. In this case, while 469 time frame, the Director immediately issues a new virtual cam-414 the returned camera satisfies certain target properties, it may 470 era computation request with one target removed from the tar-415 not allow the viewer to understand the events that involve the 471 get list (preferably one of the targets that are already framed by 416 target. More generally, due to the limited time available for 472 the current camera or a random target). The result of the virtual 417 virtual camera computation and the stochastic nature of search, 473 camera computation request will be available for evaluation in 418 the Camera Operator might at times be unable to find a virtual 474 the next execution of the Director module. Targets in the vir-419 camera that satisfies all properties or even all of the properties 475 tual camera missed target list, if present, will be considered as 420 for some targets even if such a virtual camera exists. In general, 476 targets for the next virtual camera computation if no interesting 421 as the geometrical complexity of the scene and/or the number 477 events are detected in the next camera update cycle. 422 of targets increase, this type of issues are more likely to occur. 478 423 An increase in geometrical complexity typically translates into 479 the current camera. It is not always necessary to transition to a 424 more time required to explore the scene in search of a camera 480 new camera; there are times in which new interesting events in-425 that satisfies the visibility properties. A larger number of prop- 481 volve targets that the current virtual camera is already framing, 426 erties increases the time required to evaluate the satisfaction 482 or a newly computed virtual camera does not provide signifi-427 of virtual cameras during the search process. We address all 483 cantly more information than does the current one. For this rea-428 these issues by evaluating the virtual camera that is computed 484 son, before changing the current virtual camera, we compare 429 by the Camera Operator before using it to visualize events to 485 it with the new candidate camera. If the new virtual camera 430 the viewer.

431 3.3. The Director Module

433 process. This module decides which camera is shown to the 434 viewer, how and when to transition to a new camera, issues vir-435 tual camera computation requests to the Camera Operator and 496 evaluates the returned virtual camera. The *Director* module is 493 izes new events is a critical choice. To maximize the coverage 437 executed at regular time intervals (0.2 seconds), and its opera-438 tion is schematized in Figure 2.

440 viewer, the *Director* takes the current targets list from the Event 497 can occur in a short amount of time, this could result in mul-441 Filter module, computes the list of properties, issues a virtual 498 tiple virtual camera changes per second, which would make it 442 camera computation request to the Camera Operator, and stops 499 impossible for the viewer to understand what is occurring. 443 its current execution. If instead this operation was performed 500 447 In such a scenario, the *targets* list is emptied.

The evaluation of the virtual camera returned by the Camera 505 mise between event coverage and comprehension. 449 Operator considers which of the targets are effectively framed, 506 450 i.e., the involved events are recognizable. We define a tar- 507 this solution has the disadvantage that it takes a bit of time for 451 get as effectively framed by a virtual camera if its Size and 508 viewers to understand the camera changes, allocating time for 452 Occlusion properties have a minimum satisfaction value of 509 the camera to transition from the old location to the new loca-450 0.5 and 0.3, respectively, out of 1. This corresponds to the tar- 510 tion could make viewers miss events. However, when the new 454 get being half of the preferred minimum screen area and half 511 camera is close to the current camera in terms of position and 455 visible. For the other properties, we rely on the virtual cam- 512 orientation, a smooth transition may be better for the viewer. 456 era computation process to maximize the satisfaction, but we

A good virtual camera, before being used, is compared to 486 frames more or different targets compared to the current cam-487 era, we transition to it. If they frame the same targets, then 488 we transition to the new camera only if its satisfaction value is The Director module manages the entire camera control 489 greater than the current value by at least 5%. If the newly found 490 camera frames only a subset of the targets that the current cam-⁴⁹¹ era is framing, we maintain the current camera.

The frequency of transitions to a virtual camera that visual-494 of events, we should compute a new virtual camera and possi-495 bly transition to it as soon as the event passes the filtering stage. When it is time to change the camera to be shown to the 496 However, in simulations of emergencies wherein many events

General rules of cinematography dictate that static shots 444 during the previous execution, the Director would take the vir- 501 should last between 2 and 10 seconds. In our system, the viewer 445 tual camera that meanwhile has been computed by the Camera 502 can set the minimum time between virtual camera transitions. 446 Operator, evaluates it and decides if the camera should be used. 503 In testing our system on aircraft accident scenarios, we have 504 empirically noted that a time of 3-4 seconds is a good compro-

Transitions are currently implemented as straight cuts. While

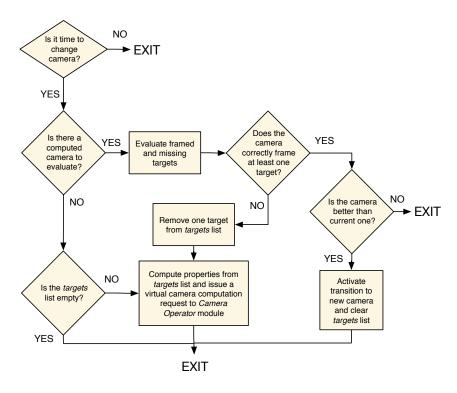

Figure 2: Functioning of the Director module.

513 4. Results

We have extensively tested our system using simulations of different types of aircraft emergencies. In particular, the ex516 amples presented in this section concern a full aircraft water
517 landing (ditching, in aviation terminology) and evacuation sce518 nario. More precisely, we employ an accurate 3D reconstruc519 tion of an Airbus 320 [27], one of the most common aircraft
520 types in service. The reproduced accident is very similar to the
521 accident involving US Airways flight 1549 [28]: a few minutes
522 after take-off, the aircraft suddenly loses thrust in both engines
523 due to a severe strike with a flock of large birds and is forced
524 to ditch because the lack of thrust makes it impossible to reach
525 nearby airports.

The 146 virtual passengers in the simulation can perform several autonomous tasks, which include the following: (i) fasses tening seat belts as soon as the airborne plane shows signs of instability, (ii) maintaining the brace position during ditching until the plane comes to a stop, (iii) reaching for the nearest exit, (iv) locating an alternative exit in the presence of exits that cannot be used (e.g., in the following examples, the rear exits are not usable because they are below the water level), (v) opening overwing doors, (vi) exiting the aircraft using a level exit or an overwing exit, and (vii) going toward the bottom of a slide raft and sitting on it. Moreover, the simulation includes three virtual flight assistants that can perform three additional tasks: (i) open floor level doors, (ii) order passengers to stand back until a raft is fully inflated, and (iii) block unusable exits and redirect passengers. In the examples presented in this section,

two flight assistants help passengers at the front exits, while the other attendant blocks the two unusable rear doors and redirects passengers to the front and overwing exits until all passengers are away from the flooded rear galley.

Each passenger and flight assistant has a unique name (e.g., "Passenger 113" or "Flight Assistant 1") in the simulation, and all aircraft-relevant parts are labeled (e.g., "door 1L" or "door 2L"). These names and labels are used as subjects and/or objects in the event triplets. The event actions concern all of the tasks described above as well as changes in states of the aircraft doors (e.g., closing and opening) and slides (e.g., inflating).

The total number of events in each of the following exam553 ples is 1829. The first 590 events (e.g., fastening seat belts
554 and assuming a brace position) occur in the 4 minutes and 20
555 seconds during which the aircraft is airborne. The other 1239
556 events occur during the evacuation, which lasts approximately 2
557 minutes and 30 seconds. In the following examples, we will fo558 cus on the evacuation because this phase contains a large num559 ber of events in a limited amount of time; thus, it presents a
560 greater challenge to the camera control system. Note that, due
561 to the stochastic nature of particle swarm search, the system can
562 generate different cameras in different runs even if the simula563 tion and its events are identical.

We describe three examples of system use. For each exam-565 ple, we describe the scenario and provide sample screenshots. 566 In addition, to enable the reader to see first-hand the actual out-567 put of the system, we have included a video as additional paper 568 materials². Both the examples presented in this Section and the 622 understanding the egress as a whole. Therefore, in our second 569 video use a frequency of camera transition of 4 seconds. In 623 example (at minutes from 02:05 to 03:29 in the accompanying 570 Section 4.1, we analyse the performance of the system in these 624 video), we set the system to prefer target recognizability, while

The first example (at minutes from 00:18 to 02:03 in the 626 companying video), we set the system to prefer event coverage. 573 accompanying video) considers the perspective of flight assis-574 tant training, in which trainers and trainees are highly interested 628 first passengers begin to exit on the left wing, the camera cor-575 in observing the behavior of the crew. Therefore, we spec- 629 rectly focuses on them (Figure 4a). A few seconds later, passen-576 ify "flight assistant" as a matching string in the filtering rules. 630 gers start to use the right overwing exits. In this case, there is 577 The Event Filter module will then discard all events that do 631 no camera that can simultaneously frame all of the overwing ex-578 not match this string while selecting all evacuation events con- 632 its and the exiting passengers while preserving recognizability; 579 cerning flight assistants (30 in our example). As a result, the 633 therefore, the Director module can choose to continue showing 580 Camera Operator module will receive requests to frame one, 634 passengers exiting on the left wing or switch to the right wing. 581 two, or three flight assistants simultaneously (depending on the 685 Figure 4b shows the second choice. When the front right raft 582 timing of events) as well as the object that they could interact- 688 is fully inflated and passengers start using the front right exit, 583 ing with (e.g., doors). Because it is important to frame the flight 697 our system can find cameras that frame both front and overwing 584 assistants at close distances in this example, we set the system 638 right exits (Figure 4c). When all front and overwing exits are 585 to prefer target recognizability over event coverage. Figure 3 699 available, at each camera update, the system computes the po-586 shows six of the 30 cameras that were computed and used by 640 sition and angle that maximize the properties shown in Table 1 587 our system using these settings during the entire simulation.

589 attendants simultaneously stand up. Because two of them are 643 camera to frame only it (Figure 4f). 590 at the front exits and one is at the rear exits, it is impossible to 644 591 simultaneously frame all of them, and the system finds a camera 645 more distant cameras that can frame more targets. More pre-592 showing the two at the front, as shown in Figure 3a. One of 646 cisely, at the beginning of the simulation, when there are pas-593 the flight assistants at the front exits is the first to reach and 647 sengers only exiting from the left overwing exits, the camera 594 open a door, as shown by the camera in Figure 3b. When the 648 will specifically focus on them, as in Figure 5a, but when pas-595 second flight assistant at the front exits reaches and opens the 649 sengers begin to use the right overwing exits, the system will 596 other front door, both flight assistants order passengers to stand 650 try to find a camera that can simultaneously frame passengers 597 back until the slides are fully inflated. In this case, our system 651 at all of the overwing exits, as in Figure 5b. When the right raft 598 finds a camera that frames both subjects (Figure 3c). When a 652 is inflated and passengers start to use it, the system computes 599 front slide is fully inflated, the system shows the nearby flight 653 a camera that focuses on exits at the right side but continues to 600 attendant stepping aside and indicating the way to passengers, 654 frame passengers exiting from the left overwing exits (Figure as shown in Figure 3d. In contrast, the flight assistant at the rear 602 exits is sending passengers away because water is entering the 603 rear galley (Figure 3e). Only when all passengers have left the 604 rear galley can the flight attendant move forward (Figure 3f) and 658 particular moment in the simulation, the system will compute a 605 exit the aircraft (Figure 3g). When all passengers have exited 606 the aircraft, the other flight assistants can exit (Figure 3h).

The second and third examples consider the perspective of 608 an aircraft designer or an accident investigator, who are inter-662 5f), despite partially reducing recognizability. 609 ested in observing how, where and when passengers and crew 610 exit an aircraft in an accident. In this case, we specify "exit" as 664 perts has not yet been performed, we have informally tested the a matching string in the filtering rules. The Event Filter mod-612 ule then selects all exit events (149 in our case, one for each 666 tion with aviation professionals (researchers and pilots) as well 613 of the 146 passengers plus three for the flight assistants). Exit 667 as individuals who are unfamiliar with aviation (students and 614 events begin at the exact instant a passenger exits the plane and 668 researchers in other domains). In each case, we first informed 615 last about two seconds. As a result, the Camera Operator mod-669 the viewer about the general goals of the videos (i.e., the kind of 616 ule will often receive requests to simultaneously frame many 670 events that the camera control system was instructed to frame). 617 passengers (depending on the timing of exit events) and mainly 671 Then, we showed the video without any comment or verbal 618 focus on doors. In this case, different viewers can be interested 672 explanation. Finally, we discussed about the aircraft accident 619 in observing the exit behaviour with different priorities: some 673 and evacuation depicted by the video to check if there were 620 viewers may be interested in watching passengers and exits at 674 any comprehension issues or doubts concerning the important

625 in the third example (at minutes from 03:30 to the end in the ac-

If the system is set to prefer target recognizability, when the 641 for the highest number of targets (Figure 4d and 4e). In partic-More precisely, immediately after the impact, all three flight 642 ular, when only one exit is used, the system can compute a new

> If event coverage is preferred instead, the system will find 655 5c). Finally, when the left raft is also available, the cameras will 656 try to simultaneously frame all used exits, as in Figure 5d. As 657 in the previous example, when only a subset of exits is used at a 659 more focused camera, as in Figure 5e, but the different settings 660 will also include cameras that simultaneously cover events that 661 are occurring at the two opposite sides of the aircraft (Figure

While an extensive and formal evaluation with domain ex-665 system by using the videos it creates as a means of communica-621 a close distance, while other viewers may be more interested in 675 events. From this purely informal experience, the output pro-676 duced by the system appears to be effective: the videos were 677 clearly understood without ambiguities and the events are ef-678 fectively presented. A possible issue that emerged is that some-

680 few instants for the user to reorient herself, although this issue 736 the front part of the plane. In the other scenarios, passengers 681 concerns mainly viewers who are not familiar with the detailed 737 exit at the same time from doors that are located at both sides 682 internal and external structure of an aircraft. The system proved 738 of the plane, and, especially when target recognizability is set, 683 also very useful while working on the simulation visualization, 739 only one door can be framed at each time. When event cov-684 because it provided a way for developers to focus on specific 740 erage is selected, instead, the system manages to find cameras 685 parts of the simulation and check for graphical glitches.

686 4.1. Implementation and Performance

692 ing the simulation is already demanding on the CPU, the com-693 putational cost of the camera control system should be as low 699 Operator, we increase the probability of finding more satisfying 756 missed. 700 solutions (i.e., cameras that better frame events or frame more 757

722 more complex in terms of average number of targets to frame. 779 rendering preparation. 723 Note also that, in the exit scenario, by preferring event cover-₇₂₄ age over target recognizability, we greatly increase the median 725 number of framed events (by around 65% in the condition with

₇₂₈ in four frames, but it did not result in any significant increase in ₇₈₃ strated the system on a detailed aviation case study. 729 performance. As explained in the previous Section, the reason 784 730 is that in all scenarios events happen very often in parallel and 785 proach to extract interesting events from a simulation, solve vir-781 in different parts of the plane. Therefore, no camera, regardless 786 tual camera computation problems, analyze the results, and de-792 of how much time we spend in computing it, can frame them 787 termine the virtual camera used to present events of interest to 733 together. In the flight assistants scenario, for example, this hap- 788 a viewer. As shown in Section 4, our method allows us to visu-

679 times the change in camera position and orientation required a 735 plane for most of the simulation, while the other stay located in 741 that frame passengers at longer distances, exiting from different 742 doors (e.g. all doors on the same side of the plane).

From this and other experimental activity we performed, we The scenarios presented above are implemented in C# using 744 can draw some indications on how to set the time available to 688 the Unity 4 game engine [29]. The camera control system, as 745 the Camera Operator module. First, one should choose a time 689 well as the simulation, are implemented in C# as a Unity scripts, 746 that is compatible with a target frame rate. Then, one can mul-690 and due to Unity limitations, run on the same thread on the CPU 747 tiply the chosen time by a number of frames, so that the total 691 (i.e., they cannot run in parallel). Since computing and render- 748 computation time will guarantee good results in the scenario at 749 hand. More specifically, the total time is mostly a function of 750 the maximum number of targets that needs to be framed at the 694 as possible. By far, its most expensive activity is the computa- 751 same time (in our examples, a time budget of 21 milliseconds 695 tion of cameras in the Camera Operator module, whose allotted 752 was enough for 10-12 targets). Finally, the number of consec-696 time, as explained in Section 3.2, is a parameter that can be set. 753 utive frames over which a camera computation is carried out 697 However, in deciding its value, one faces two contradicting ob- 754 should be limited since delaying too much the presentation of 698 jectives. On the one hand, by allowing more time to the Camera 755 the newly found camera might cause some brief events to be

All data were obtained on a 2.3 GHz Intel Core i7 proces-701 of them); on the other hand, more time means, in CPU-bound 758 sor with 16 GB RAM and an NVidia GeForce FT 750 M. With 702 applications like our simulation, decreasing the frame rate. For 759 this machine, the simulation, including the camera control sys-₇₀₃ example, in our simulation, if we set the time available to the ₇₆₀ tem, runs at between 30 and 60 fps, depending on the number 704 Camera Operator to 30 milliseconds, this means that each time 761 of animated characters displayed, with an average of 40 fps. 705 a camera needs to be computed, the frame rate will drop dras- 762 As explained above, the frame rate is largely dictated by the 706 tically as the CPU cost for each simulation frame (without the 763 simulation, as the cost of the camera control system is at most 707 camera control) is already, on average, around 25 milliseconds. 764 7 milliseconds per frame for a few consecutive frames for the To help with this issue, we can split the computation of a 765 Camera Operator module, plus the operations of the Director 709 camera among a few consecutive frames to limit its impact on 766 module, which cost about 1 millisecond and is executed every 710 frame rate, with the only drawback of delaying the presentation 767 0.2 seconds. Figure 7 shows the milliseconds spent by simula-711 of the result by a few frames. Figure 6 illustrates the perfor- 768 tion, rendering and camera control code executed on the CPU ₇₁₂ mance, in the scenarios described in the previous Section, of ₇₆₉ over a period of 300 frames in one of the exit scenarios pre-₇₁₃ three different choices about the time for computing a new cam- ₇₇₀ sented above. Green bars refer to rendering preparation calls, 714 era: 7 milliseconds in one frame, 14 milliseconds equally split 771 which take the majority of time because of the large number 715 among two frames, and 21 milliseconds equally split among 772 of animated characters. The bright orange and bright cyan bars 716 three frames. To measure the performance, we use the num- 773 refer to the Camera Operator module, which is executed every 717 ber of framed events, as the average frame rate is similar in all 774 few seconds, with a maximum cost of around 7 milliseconds per 718 cases. By looking at the box plots, it is clear that there is a gen- 775 frame (the two bars respectively refer to the cost of the called 719 eral increase in the number of framed events, for all quartiles, 776 method, and the cost of the subcalls). The zoomed image in the 720 both by going from 7 milliseconds to 14, and from 14 to 21. 777 top right part of the Figure shows instead, in red, the cost of the 721 The increase is more notable in the exit scenarios, which are 778 Director module, which is practically negligible compared to

780 5. Conclusions and Future Work

In this paper, we have presented a novel application of au-We tried also a fourth condition with 28 milliseconds split 782 tomatic camera control to emergency simulations and demon-

Our system extends a recent virtual camera computation ap-794 pens because one of the flight assistants stays in the back of the 789 alize different aspects of aircraft evacuation scenarios without

790 any camera modeling, programming, or control effort by the 791 user. The system is not aviation specific, and could be applied 792 to other safety domains. In particular, one of our next research 793 directions is to apply the system to fire emergencies in build-794 ings. Another interesting potential field of application is video 795 games testing, particularly multi-player games, and perhaps in 796 addition to automatically collected metrics [30]. To this end, it 797 would be interesting to improve event filtering such that more 798 sophisticated rules can be expressed, for example, based on the 799 temporal relations between events.

We plan to conduct a formal evaluation of the system with aviation professionals. However, carrying out a formal expersiment in which the system is contrasted to a control condition (simulator without automatic camera control) would probably create an unfair comparison. It would indeed require the user to take charge of camera control in the non-automated condition and, from our own experience, the workload that manual camera control generates makes it difficult to follow the events with the same ease as automatic camera control. Moreover, when several events happen very closely in time, it can be even impossible for the user to manually follow them.

We also plan to improve the camera control method. A straightforward extension would be the possibility of simultanestraightforward extension would be to cameras when one camstraightforward extension grows the camera operator module
straightforward extension grows the compute additional virtual cameras when the
straightforward extension grows the camera operator module
straightforward extension grows the camera operator module
straightforward extension would be imstraightforward extension when the camera operator module
straightforward extension when the camera operator module
straightforward extension when the camera computation algorithm
straightforward ext

A final interesting issue is the addition of high-level knowledge edge in the virtual camera computation and selection process. Currently, the system reacts to events that are occurring at the moment of changing the current camera without attempting to establish a correlation between past and present events based on their meaning. An ideal visualization of an emergency simulation should instead be able to derive causal relationships between events and perform virtual cameras computation and editing such that these relationships are effectively conveyed to the viewer.
