# 9 Abstract

The quantification of glucocorticoid metabolites in hair is a non-invasive tool that provides important information regarding the endocrine status and represents a valuable method for studying potential stressors that may affect carnivores under both natural and non-natural conditions. Cortisol is the main glucocorticoid hormone of the hypothalamic-pituitary-adrenal gland axis and is considered a standard stress indicator for animal welfare. The current study aimed to compare cortisol levels extracted from hair of both dead, frozen European wildcats (Felis silvestris silvestris) and living feral individuals (Felis silvestris catus) living in different environmental conditions. The results obtained revealed that wild individuals exhibited a significantly (p < 0.001) higher cortisol concentration (n = 15, mean  $\pm$  sd = 8.91  $\pm$  4.48 pg/mg) than feral ones (n = 10, mean  $\pm$  sd = 3.57  $\pm$  1.25 pg/mg), probably as a result of both the physiological and/or environmental factors to which each subspecies was subject. This is the first study in which cortisol concentrations have been compared within the Felis silvestris subspecies, thus enriching the scarce information available for the Felidae. Nevertheless, further research is needed to better understand the various physiological and ecological factors affecting the adrenocortical activity of species or populations living in different environmental contexts.

Keywords: wildcat, feral cat, Felis silvestris, hair cortisol, adrenocortical activity.

# 41 Acknowledgments

- 42 We wish to thank both the staff working for the Province of Gorizia and the Natural History Museums of Pordenone,
- 43 Udine, and Trieste for the hair samples provided. Furthermore, the authors are indebted to all the wildlife technicians,
- 44 interns, and volunteers involved in the collection of field data.

# 81 **1. Introduction**

82 The ability of an organism to adapt to changes in environmental conditions has been receiving increased attention in 83 recent years (Koolhaas et al. 1999; Janczak et al. 2003; Natoli et al. 2005; David et al. 2011; Ruiz-Gomez et al. 2011; 84 Montiglio et al. 2012; Dingemanse and Reale 2018). Abiotic and biotic changes are common within the environment, and animals may respond through temporal variation in their vital rate and/or an alteration in their physiological 85 86 response (Darlington et al. 1990). The activity of the hypothalamic-pituitary-adrenal (HPA) gland axis leads to the 87 release of glucocorticoids (GCs), which are commonly used as indicators of physiological stress (Wingfield and Romero 2001; Wikelski and Cooke 2006). When animals are subjected to a stressor, the hypothalamus releases 88 89 corticotropin-releasing hormones (CRHs) which signal to the adrenal cortex to release steroid hormones (such as GCs) 90 to overcome stressful situations (Sapolsky et al. 2000) and restore homeostasis (Möstl and Palme 2002). This said, prolonged exposure to stressors may lead to chronic GC accumulation leading to chronic stress (Romero 2004) which is 91 92 detrimental. Chronic stress negatively affects individuals' fitness in terms of the depression of immune responses, reduced reproductive success and growth suppression (Romero 2004). The quantification of glucocorticoid metabolites 93 94 is a non-invasive tool that provides important information regarding endocrine status, and is a valuable method to study the potential stressors that may affect carnivores under natural conditions (Barja et al. 2007; Sheriff et al. 2011; Piñeiro 95 96 et al. 2012; Schell et al. 2017). Cortisol is the main glucocorticoid hormone of the HPA gland axis and is considered the 97 standard stress indicator for animal welfare (Mormède et al. 2007). Indeed, despite the various autonomic and endocrine 98 responses that occur when an organism faces a stressful situation, cortisol has become commonly known as the stress 99 hormone. As part of the stress response, cortisol acts on various metabolic pathways providing energy during a stressful 100 situation. Cortisol's role in the endocrine system is metabolic however, and it is also released in response to arousal situations such as during sexual activity (Hamilton et al. 2008). Cortisol levels can be measured using both invasive 101 102 (e.g. blood) and non-invasive methods in faecal samples (Dehnhard et al. 2001; Millspaugh et al. 2002; Huber et al. 103 2003; Ashley et al. 2011), urine (Rehbinder and Hau 2006), milk (Gygax et al. 2006) and saliva (Negrão et al. 2004). 104 However, all these methods provide information in relation to short-term cortisol variations (within 12-24 h) (Sheriff et al. 2011; Russell et al. 2012). Hair and fur have been recognized as a relatively stable matrix that does not decompose 105 as rapidly as other body fluids or tissues (Balíková 2005), and in which the incorporation of blood-borne hormones 106 107 occurs through their passive diffusion from blood capillaries present on the basement membrane during its active growth phase (Pragst and Balikova 2006). These hormones accumulate over a period of weeks or months (Davenport et 108 109 al. 2006; Macbeth et al. 2010) and may remain detectable for long periods (Kintz et al. 2006; Webb et al. 2010) as the 110 cortisol in hair is unaffected by variations in circadian hormone or by factors that induce short-term variations (Caslini 111 et al. 2016). In this sense, measuring cortisol accumulating in hair or fur represents a valuable method to trace rates of 112 long-term stress in both domestic (Comin et al. 2011, 2013, 2014; Peric et al. 2016, 2017, 2018; Stradaioli et al. 2017) 113 and wildlife species (Bechshøft et al. 2011, 2012, 2015; Caslini et al. 2016; Weisser et al. 2016; Prandi et al. 2018). However, the technique's main limit is related to hair's slow growth rate which does not permit fine monitoring over 114 115 short periods as it does not reflect daily or hourly fluctuations in circulating hormones (Koren et al. 2002). Although the dynamics of stress physiology have been studied in a range of taxa, to date, limited information is available concerning 116 117 adrenal activity variations in response to environmental conditions, life-history stages or among individuals (Boonstra 118 2004; Romero 2004; Palme 2005; Wielebnowski and Watters 2007). GC concentration has been shown to change in relation to sex, age class, day time, season and reproductive status (Ziegler and Snowdon 1995; Gardiner and Hall 1997; 119 120 Cavigelli 1999; Romero 2002; Weingrill et al. 2004; Dantzer et al. 2010; Fanson et al. 2012). Furthermore, an existing

- difference in terms of circulating GC concentrations among species has been demonstrated (Roth *et al.* 2001). Cortisol
- 122 level comparisons among species or subspecies have received little attention in recent years, especially as far as the
- 123 Felidae (Fanson et al. 2012; Narayan et al. 2013; Naidenko et al. 2011, 2019) are concerned, and information relating
- 124 to adrenocortical activity expression in the European wildcat (*Felis silvestris silvestris*) is still limited and mostly
- focused on faecal cortisol analyses (Piñeiro et al. 2012, 2015). Indeed, to the best of our knowledge, there are no
- 126 previous studies aimed at assessing the potential differences in GC concentrations between wild and feral cats (*Felis* 127 *silvestris catus*).
- 128 The European wildcat is a medium-sized carnivore widely but patchily distributed throughout Europe (Driscoll and 129 Nowell 2010; Lozano and Malo 2012). It is a protected species listed within the Annex IV of the European Union 130 Council Directive 92/43/EEC, which states that a strict protection regime must be applied across its entire natural range within the EU, both within and outside Natura 2000 sites. The conservation of this carnivore requires considerable 131 132 effort due to its elusive behaviour, low population density and sensitivity toward habitat loss and human persecution (Yamaguchi et al. 2015; Apostolico et al. 2016). Three fragmented populations are present along the Italian peninsula 133 134 (thus, excluding those on Sardinia and Sicily): one in each of central and southern Italy, respectively, and another in the 135 Eastern Alps, which is perhaps conjunctive with the Slovenian and Croatian populations (Mattucci et al. 2013). In Friuli Venezia Giulia the species is well distributed, particularly in the Julian Pre-Alps, but has also exhibited a positive 136 dispersal trend even into lowland areas (Lapini 2006). The tendency to expand both north and southwards seems to have 137 begun in the middle of  $20^{\text{th}}$  century, presumably favoured by two factors: (i) the recent spread of woodland in both the 138 139 Alps and the Karst, and (ii) the legal protection of the species in 1977 (N. L. 968/1977), subsequently confirmed and 140 enhanced in 1992 (N. L. 157/1992). To date, it is estimated that within the Region the species numbers about 220 141 individuals (range: 148-296) (Lapini 2006).
- Understanding the mechanisms of adrenal activity is essential to provide important insights into comparative 142 143 physiology. Comparing HPA gland axis activity between species or subspecies living in different environmental settings may help to cast light on the complex normative patterns of GC expression in various situations, for instance, 144 145 establishing basic information regarding adrenal activity in endangered species living in both wild and captive conditions, providing a foundation for future studies on stress physiology and may help to enhance ex-situ and in-situ 146 147 management plans (Fanson et al. 2012). Moreover, the comparison of physiological activities between subspecies or populations living in different environmental contexts (i.e. wild and feral populations) may be useful in understanding 148 the complexity of ecological factors (e.g. active movements, hunting, competition) involved in the higher metabolic 149 150 levels recorded in wild animals (Naidenko et al. 2011).
- The present pilot study sought to compare hair cortisol concentrations (HCCs) between wild and feral cats. Our hypothesis was that the two subspecies had different physiological responses and were subject to different environmental pressures. Thus, we predicted that the HCCs recorded in wild individuals would be different compared to
- 154 those measured in feral ones.

# 155 **2. Materials and Methods**

#### 156 **2.1 Study area**

Friuli Venezia Giulia is the north-easternmost Italian Region, which borders Austria to the north and Slovenia to the east. It is bordered to the south by the Adriatic Sea, while to the west it adjoins the Veneto Region (**Fig1**). Its climate is characterized by an average annual temperature of about 14.5°C with abundant precipitation (as much as 3,000 160 mm/year in the Pre-alps), especially during autumn (~ 1,200-1,400 mm/year). Habitat varies with location, with forests 161 and open habitats common in Alpine and pre-Alpine territories, while agricultural lands are most abundant in lowland 162 areas (the official website of Friuli Venezia Giulia region, n.d.).

#### 163 **2.2 Data collection**

Hair samples from 15 road-kill wildcats (11 males and four females) and ten living feral individuals (eight males and 164 165 two females) were included in the present study. The wildcat carcasses were opportunistically collected between 2006 and 2014 and deep-frozen to prevent decay. Five individuals (four males and a female) were collected during the mating 166 season (from January to March) while ten (seven males and three females) were found outside the mating season, of 167 which three (a male and two females) were found during the period (from April to May) (Killshaw 2011) when the 168 kittens are born. Hair samples belonging to the Felis silvestris catus subspecies were collected from individuals living 169 170 in colonies near urban settlements (small villages), in which contacts with humans were solely related to feeding behaviour. Nevertheless, no information concerning either the season or year of data collection was available. 171 172 Furthermore, no information regarding their health status or whether the animals were pregnant or not were obtained for 173 either subspecies, though no evident signs of reproduction were noted. Hair samples were removed from the scruff of 174 the neck of both wild and feral cats for two reasons: (i) it represents an area with less contamination by external agents 175 such as saliva and/or soil and (ii) has a uniform hair growth rate. Finally, the samples collected were stored in paper 176 envelopes.

#### 177 **2.3 Data analysis**

178 The attribution to the subspecies silvestris was carried out using the system proposed by Ragni and Possenti (1996), 179 modified by Ballesteros-Duperón et al. (2015). Potential hybrids and feral cats were considered as a single group because hair samples were collected from individuals living within the same colonies. Using QGIS Software (version 180 181 2.18) we applied a buffer with a radius of 1,820 m for each point representing the recovery coordinates of each road-182 killed wildcat. The choice to apply such a buffer was made to reproduce the average home-range size of a wildcat 183 according to Anile et al. (2017). Within the buffer area, we calculated a habitat suitability (HS) value, ranging from 0 (unsuitable habitat) to 100 (optimal habitat), by multiplying the percentage of landscape (PLAND) calculated for each 184 185 habitat with a habitat suitability index (HSI) varying from 0 to 1 (0 = unsuitable habitat; 0.33 = little suitable habitat; 0.66 = suitable habitat; 1 = optimal habitat), randomly defined. Based on the habitat legend obtained from the attribute 186 table of the shapefile named the "Carta della Natura del Friuli Venezia Giulia (2007)" and freely downloadable from 187 188 the Regional IRDAT website, we determined the suitability or unsuitability of each habitat following Lozano et al. 189 (2003), Lozano (2010), Sarmento et al. (2006), and Klar et al. (2008). Finally, we extracted an index of anthropic 190 pressure (IAP) within each buffer, obtained from the attribute table of the "Carta Natura" shapefile and calculated it following the method proposed by Angelini et al. (2009). 191

#### 192 2.3.1 Cortisol radioimmunoassay

Cortisol extraction was carried out using a radioimmunoassay protocol. Strands of hair were washed in 3 mL isopropanol and dried. Unminced hair (5 mg) was extracted in a glass vial using 3 mL of methanol. The vials were then incubated at 37°C for 18 h. After this the methanol was decanted into a separate vial from which it was evaporated to dryness. Next, the liquid in the vial was evaporated to dryness at 37°C under an airstream suction hood. The remaining residue was dissolved in 0.35 mL of phosphate-buffered saline (PBS), 0.05 M, pH 7.5 (RIA buffer). The cortisol in the

hair was measured using a solid-phase microtitre RIA procedure. In brief, a 96-well microtitre plate (OptiPlate, Perkin-198 Elmer Life Science, Boston, MA, USA) was coated with goat anti-rabbit y-globulin serum, diluted 1:1000 in 0.15 mM 199 sodium acetate buffer, pH 9, and incubated overnight at 4°C. The plate was washed twice with RIA buffer, pH 7.4, and 200 incubated overnight at 4°C with 200 µL of the anti-cortisol serum diluted 1:20000. The rabbit anti-cortisol antibody 201 202 used was obtained from Biogenesis (Poole, UK) as described by Leboulenger et al. (1982). The cross-reactivities of this 203 antibody with other steroids are as follows: cortisol 100%, corticosterone 1.8% and aldosterone < 0.02%. After washing 204 the plate with RIA buffer, standards (5 - 200 pg/well), a quality control extract, the test extracts and tracer 205 (Hydrocortisone (Cortisol, [1,2,6,7-3H (N)]-), Perkin-Elmer Life Sciences, Boston, MA, USA) were added, and the 206 plate was incubated overnight at 4°C. The bound hormone was separated from the free hormone by decanting the 207 extract and washing the wells in RIA buffer. After the addition of 200 µL scintillation cocktail, the plate was counted on a beta-counter (Top-Count, Perkin-Elmer Life Sciences, Boston, MA, USA). The intra-assay and inter-assay 208 209 coefficients of variation were 3.6% and 9.8%, respectively. The assay sensitivity (defined as the hormone concentration resulting in a displacement of the labeled hormone at least 2 standard deviations from maximal binding) was 1.23 210 pg/well. To determine the comparability between cortisol standards and endogenous cortisol in cats, hair samples 211 212 containing high concentrations of endogenous cortisol were serially diluted in 0.05 M PBS, pH 7.5. The relationship between hair cortisol concentrations and the standard cortisol curve, determined through linear regression, was linear: 213 the correlation coefficient (r) was 0.99 and the model was provided by the equation y = 0.9796x + 1.68. 214

#### 215 2.3.2 Statistical analysis

Statistical analysis was performed through R Software (version 3.5) and the alpha value was set at 0.05. Data were analyzed in terms of HCC in which subspecies and sex were considered as independent variables and cortisol concentration as a dependent variable.

To determine the effect of subspecies and sex on HCC, Generalized Linear Models (GLMs) following Zuur *et al.* (2009) were used in which the family distribution of the dependent variable was assessed using the R package "fitdistrplus". Models ranking was done based on the Akaike's Information Criterion corrected (AICc) to best fit with reduced sample sizes.

#### 223 **3. Results**

- The average PLAND value calculated within each buffer area (radius = 1,820 m) revealed that habitat was mainly composed of forests and semi-natural areas (47.03 %) followed by agricultural areas (34.95 %), artificial surfaces (16.67 %), water bodies (0.76 %) and wetlands (0.59 %). The average calculated HS index was equal to 51.53 revealing a habitat less suitable for the wild subspecies, while the IAP was equal to 0.66 indicating a notable anthropic pressure in each area.
- From the model ranking using the AICc value as reference parameter, we discerned that the best model was the one in which only the effect of the "subspecies" variable was considered (**Tab1**). Results obtained showed a significant difference (p < 0.001) between subspecies. Cortisol concentrations measured in the hair of frozen wildcats (n = 15) ranged from 3.90 to 19.30 pg cortisol/mg hair (mean ± sd = 8.91 ± 4.48 pg/mg), while those in live feral individuals (n = 10) varied from 2.20 to 6.50 pg cortisol/mg hair (mean ± sd = 3.57 ± 1.25 pg/mg) (**Tab2**; **Fig2**). Cortisol levels encountered in wild males (n = 11) ranged from 4.30 to 19.30 pg cortisol/mg hair (mean ± sd = 9.69 ± 4.81 pg/mg)
- while those in wild females (n = 4) varied from 3.90 to 10.50 pg cortisol/mg hair (mean  $\pm$  sd = 6.78  $\pm$  2.87 pg/mg)

- (Tab3; Fig3). Cortisol concentrations measured in feral males (n = 8) ranged from 2.20 to 6.50 pg cortisol/mg hair (mean  $\pm$  sd = 3.76  $\pm$  1.33 pg/mg) while those in feral females (n = 2) varied from 2.50 to 3.20 pg cortisol/mg hair (mean  $\pm$  sd = 2.81  $\pm$  0.50 pg/mg) (Tab3; Fig3). Nevertheless, no significant difference was found between sexes in either wild
- 239 or feral individuals.

# **4. Discussion**

#### **4.1 Differences in cortisol levels between wild and feral cats**

Using a radioimmunoassay protocol, we were able to detect good levels of hair cortisol in both subspecies. In wild 242 individuals, we obtained an average ( $\pm$  sd) value of 8.91  $\pm$  4.48 pg cortisol/mg hair, while in feral ones we recorded an 243 244 average ( $\pm$  sd) level corresponding to 3.57  $\pm$  1.25 pg cortisol/mg hair. It is important to specify that road-kill events do 245 not affect hair cortisol accumulation for two reasons: (i) cortisol enters the hair shaft through passive diffusion from 246 blood vessels and thus requires a certain amount of time, (ii) the freezing process blocks cortisol accumulation in hair 247 when the blood freezes. Therefore, the potential negative effect of the freezing process can be excluded as the 248 cholesterol substrate inside the hair prevents cortisol degradation (Prandi unpub. data). Average HCC measured in feral cats was similar to that one obtained by Accorsi *et al.* (2008) in domestic cats ( $3.32 \pm 0.27$  pg cortisol/mg HCC). This 249 250 said, the levels measured when compared with those recorded in wild individuals was remarkable, a significant 251 difference being found between HCCs in wild and those in feral cats. Because of the existence of species-specific 252 differences in the secretion of metabolic hormones, the radio-immunological protocols used during the extraction of 253 certain groups of steroid hormones should be performed separately, even in the case of phylogenetically-related species 254 (Palme et al. 1996; Schwarzenberger et al. 1996; Schwarzenberger and Palme 1997; Graham et al. 2001; Möstl and Palme 2002; Young et al. 2004; Palme 2005; Berger et al. 2006; Heistermann et al. 2006). An example of how different 255 256 reproductive and endocrine physiology may be, even among phylogenetically close species, was demonstrated by 257 endocrine studies performed on four rhino species: the white rhino (Ceratotherium simum), black rhino (Diceros 258 bicornis), Indian or greater one-horned rhino (Rhinoceros unicornis) and the Sumatran rhino (Dicerorhinus 259 sumatrensis). Throughout the use of faecal, urine and saliva steroid analysis, authors showed that not one of the four 260 species exhibited reproductive cycles of similar length. What was more, faecal steroid metabolites excreted varied 261 considerably underling the necessity to carry out species-specific endocrine tests (Roth et al. 2001; Schwarzenberger 262 2007).

263 Hair cortisol levels comparison between subspecies has received little attention in recent years, especially as far as the Felidae are concerned (Narayan et al. 2013, Naidenko et al. 2019). For instance, Narayan et al. (2013) compared Faecal 264 265 Cortisol Metabolites (FCMs) in captive Bengal (Panthera tigris tigris) and Sumatran (Panthera tigris sumatrae) but no significant difference in terms of cortisol levels between subspecies was found. However, the main differences with our 266 study were firstly related to the matrix used for cortisol extraction and, secondly, to the captive condition of the two 267 268 tiger populations considered which may have affected faecal cortisol concentrations differently. Despite faecal-based immunoassay being considered one of the most valuable methods for mammals stress assessment, especially for 269 endangered and managed populations, due to its non-invasiveness (Schatz and Palme 2001; Young et al. 2004; Palme 270 271 2005; Keay et al. 2006; Bayazit 2009) it presents some limitations given that FCMs analysis provides a pooled value of 272 GC activity over the short term while HCCs provide a measure of past long-term HPA gland axis activity which cannot 273 be obtained using other analyses (Lafferty et al. 2015). The effect of captivity on GC concentration comparing wild and 274 captive animals has been examined but the results obtained are controversial. For instance, Naidenko et al. (2011)

obtained a significant difference in terms of HPA gland axis activity between wild and captive Amur tigers (Panthera 275 tigris altaica) where wild specimens, probably due to unfavourable environmental conditions in which they lived, 276 277 showed significantly higher cortisol levels compared to captive ones. Contrariwise, Fanson et al. (2012) showed that captive Canada lynx (Lynx canadensis) had higher FGM concentrations than wild lynx. In our case, we could not 278 279 perform a comparison with such studies as a feral existence is not the same as captivity. Nevertheless, differences 280 recorded in terms of HCCs between wild and feral cats may be related to various factors. The first explanation could be 281 related to underlying differences in metabolism, diet, and/or energy regulation which may have affected steroid 282 production. The impact of these factors on steroid production and excretion has also been recorded in other species (von 283 der Ohe and Servheen 2002; Hajamor et al. 2003; Goymann 2005). Moreover, GCs are linked to energy regulation 284 (Romero et al. 2009), so that the major energetic differences between wild and feral individuals could explain the 285 difference recorded in HCCs. Essentially, there is a complex network of interactions between GCs, steroids, and 286 metabolic hormones which means that disturbances in this web may produce a cascade effect on other physiological 287 systems (Fanson et al. 2012).

288 A second explanation might be related to differing degrees of tolerance of each subspecies toward anthropic disturbance 289 or towards other con(sub)specifics. Feral cats are known to live in close contact with humans (and each other), although 290 only in relation to foraging behaviour (Natoli 1994). In this sense, they may be more tolerant toward humans and intraspecific presence than wild individuals. Anecdotal evidence suggests some "feral" cats behave as wildcats. An 291 animal closely resembling a wildcat or a hybrid currently (August 2019, and since at least 2011) lives in a "wild" 292 293 setting, amongst rocks in woodland beneath a road close to a village in the Italian Karst (in an area where true wildcats 294 are present). Only 50 metres from the nearest houses, it does not frequent the feral cat colony less than 75 metres from 295 its earth and has never been observed feeding on food put out for these animals, even in cold weather (Paul Tout, pers. 296 comm.). The Friuli Venezia Giulia Region is characterized by a marked anthropic influence due to the presence of 297 infrastructure across much of its surface area, leading to a reduction in the ecological value of each area affected (Angelini et al. 2009). Consequently, wildcats are forced to live in areas with less suitable or unsuitable habitats. Our 298 299 results showed that, based on the average PLAND value calculated within each buffer, the habitat was composed of a notable percentage of both agricultural (34.95 %) and built-up areas (16.67 %) which, as reported by Lozano et al. 300 301 (2003, 2010), Sarmento et al. (2006), and Klar et al. (2008) are considered as less suitable or unsuitable habitat for the wildcat. What is more, the average IAP calculated within each buffer showed that the area was influenced by a marked 302 anthropic pressure, which may have affected individual wildcat welfare. The effect of anthropic disturbance on cortisol 303 304 accumulation has received considerable attention in recent years and has been studied in various species (Rangel-Negrín 305 et al. 2009; Zwijacz-Kozica et al. 2012; Burbonnais et al. 2013; Creel et al. 2013; Deng et al. 2014; Fourie et al. 2015) 306 including tigers (Naidenko et al. 2019) and wildcats (Piñeiro et al. 2012). For instance, Naidenko et al. (2019) 307 compared faecal glucocorticoid levels between two tiger subspecies, the Amur tiger and Bengal tiger living in two 308 extreme habitats. From the analysis, they recorded that FCMs were significantly higher in Bengal tigers living in India 309 than in Amur tigers living in the Russian Far East and, as explained by the authors, these reasons might be related to 310 tiger density or anthropogenic disturbance. A further study performed by Rangel-Negrín et al. (2009) showed that forest fragmentation may create long-term stressors for spider monkeys (Ateles geoffroyi yucatanensis) affecting population 311 312 viabilities. Deng et al. (2014) revealed a significant positive correlation between FCM levels recorded in giant pandas 313 (Ailuropoda melanoleuca) and the degree of human disturbance within their habitat. Fourie et al. (2015) showed that 314 human impacts on vervet monkeys' (Chlorocebus aethiops) behavioural ecology appeared to be a significant source of 315 stress, especially for males. Furthermore, it was demonstrated that even tourism may exert a negative effect on animal

welfare. Zwijacz-Kozica *et al.* (2012), studying the concentration of FCMs in chamois (*Rupicapra rupicapra*) in relation to tourist pressure in Tatra National Park (South Poland), showed that stress levels increased in relation to increasing numbers of visitors, exhibiting a peak during the summer months in areas where tourists were common. The same result was obtained by Piñeiro *et al.* (2012) measuring cortisol metabolites in fresh wildcat faecal samples within the Natural Park Montes do Invernadeiro (north-western Spain). From their study, they showed that cortisol metabolite concentrations were higher in certain park areas where tourism intensity was higher.

322 A third explanation may be related to differences in terms of environmental pressures to which each subspecies was subjected. For instance, Naidenko et al. (2011) compared cortisol levels between wild and captive Amur tigers, showing 323 324 that wild tigers had significantly higher cortisol concentrations compared to captive ones and that the reason might be 325 related to the unfavourable influences of low temperatures and deep snow cover. As the feral cats lived in colonies in 326 close contact with human beings who regularly supplied them with food, they were not subjected to stressors (i.e. 327 hunting for food) which might have led to increased HPA gland axis activity. Moreover, factors such as interspecific and intraspecific competition might have affected individual wildcats' welfare resulting in higher hair cortisol 328 329 accumulations. In Friuli Venezia Giulia, the main medium-sized carnivores which may compete with the wildcat for 330 territory and/or food resources are the beech marten (Martes foina), the pine marten (Martes martes), the red fox 331 (Vulpes vulpes), and the golden jackal (Canis aureus). However, research focused on assessing the impact of interspecific competition on wildcat welfare is still rather sparse. To the best of our knowledge, the only study carried 332 was that by Piñeiro et al. (2015) in which FCM levels in a free-living population of wildcats in northwest Spain were 333 334 analyzed and showed that the presence of competitors such as pine martens and red foxes did not significantly affect 335 cortisol concentration. As reported by the authors, the absence of a significant effect in relation to red fox presence may 336 be attributable to the generalist behaviour of that species, both in terms of diet (Jędrzejewski and Jędrzejewska 1992) 337 and habitat selection (Lucherini et al. 1995), with subsequently reduced competition. As far as the presence of pine 338 martens is concerned, despite no significant effects being detected, the authors showed that there was a trend for raised 339 cortisol levels measured in wildcats living in habitat selected by the pine marten (i.e. pine forests and shrublands).

Here we encounter a potential explanation for the difference in terms of cortisol levels recorded between wild and feral cats, thus corroborating our hypothesis. Nevertheless, there might be further ecological and physiological factors (e.g. individuals' health status or pregnancy condition) not considered in the current study which could affect HPA gland axis activity in both subspecies.

#### **4.2 Hair cortisol levels comparison between sexes in wild and feral individuals**

No significant difference between sexes was found in either wild or feral individuals. In general, males showed higher 345 cortisol levels than females and this difference was more evident in wild individuals (mean  $\pm$  sd = 9.69  $\pm$  4.81 pg 346 347 cortisol/mg hair for males; mean  $\pm$  sd = 6.78  $\pm$  2.87 pg cortisol/mg hair for females) than in feral ones (mean  $\pm$  sd =  $3.76 \pm 1.33$  pg cortisol/mg hair for males; mean  $\pm$  sd =  $2.81 \pm 0.50$  pg cortisol/mg hair for females). Sex differences in 348 349 cortisol accumulation have been documented in felids (Brown and Wildt 1997; Narayan et al. 2013; Cattet et al. 2014) 350 highlighting the underlying differences in steroid metabolism, excretion routes, and HPA gland axis responses 351 (Goymann 2012). For instance, Narayan et al. (2013) observed a significant difference in terms of FCMs in two captive 352 populations of Bengal and Sumatran tigers. Following the authors, this difference might be due to the females' 353 reproductive hormone cycle (i.e. oestrogen and progesterone) which could have affected the expression of FCMs 354 (Palme et al. 2005). Hair cortisol comparison between sexes has also been identified in other mammal taxa (Dantzer et 355 al. 2010; Creel et al. 2013; Bryan et al. 2014; Lafferty et al. 2015) but the results obtained were sometimes

controversial. For example, Bryan et al. (2014) found no significant differences in HCCs between sexes in American 356 black bears (Ursus americanus) and/or grizzly bears (Ursus arctos horribilis), Creel et al. (2013) found that male lions 357 358 had higher faecal cortisol metabolite levels than females. On the contrary, Dantzer et al. (2010), comparing faecal 359 glucocorticoids levels between sexes in North American red squirrels (Tamiasciurus hudsonicus), showed that females 360 exhibited higher cortisol levels than males. Conflicting results among studies suggest that multiple factors may thus 361 contribute to the observed sex-based difference in stress hormone levels. For example, intraspecific dominance and 362 competition among males may induce a stress situation, but reproduction also seems to play a key role. Adrenal activity 363 has been shown to vary with female reproductive status in different species. In fact, pregnant females have significantly 364 higher levels of GCs than non-pregnant ones (Ziegler and Snowdon 1995; Gardiner and Hall 1997; Cavigelli 1999; 365 Weingrill et al. 2004; Dantzer et al. 2010; Fanson et al. 2012). Gardiner and Hall (1997) obtained a significant difference in plasma cortisol concentrations between males and females in harbour seal (Phoca vitulina) within the 366 367 reproductive period. Weingrill et al. (2004) observed that faecal cortisol levels in free-ranging female chacma baboons (Papio hamadryas ursinus) were significantly higher in females than in males. Dantzer et al. (2010) showed that a 368 369 reproduction-related condition (i.e. pregnancy, lactation, post-lactation) significantly affected FCM levels in free-370 ranging female North American red squirrels. Fanson et al. (2012) observed that males and females in Canada lynx showed differing seasonal pattern in FGM concentrations. In males, FCMs peaked during the breeding season and then 371 decreased during summer. Conversely, FCMs in females were lower in winter/early spring and increased toward the 372 373 end of the breeding season. Thus, in general, the increased metabolic demands associated with reproduction could be 374 driving GC concentrations during reproductive phases (Cavigelli 1999; Goymann et al. 1999; Palme et al. 2003) 375 leading to higher cortisol concentrations in females. In our case, we did not know the reproductive status of each female 376 monitored as no hormonal analysis was performed. However, no evident signs of reproduction were detected. To sum 377 up, therefore, we could say that the difference in cortisol secretion between males and females might be related to both 378 physiological and individual behavioural characteristics.

#### **5.** Conclusions

380 The results presented in this study revealed that wildcats showed significantly higher HCCs than feral individuals, and no significant difference in terms of cortisol levels were obtained between sexes in either population. We are aware that 381 this research presents some limitations in terms of reduced sample size, lack of information regarding the individuals' 382 383 health and reproductive status and the higher number of males sampled compared to females in both groups, which may 384 have biased the lack of significance of some results achieved. Nevertheless, despite such limitations, this is the first time 385 in which hair cortisol levels have been compared between wild and feral cats, thus increasing the limited information available regarding the physiological response of felids exposed to different environmental pressures. The findings 386 387 presented may thus contribute to laying the foundation for future works focused in assessing the various physiological 388 and ecological factors affecting the HPA gland axis activity of those populations living under a range of environmental 389 conditions, thus leading to the establishment of adequate conservation plans toward those species (or subspecies) which 390 are classified as endangered or critically endangered.

Fig2. Box-plot showing the difference in terms of hair cortisol concentration (pg cortisol/mg hair) between subspecies.

**Fig3.** Box-plot showing the difference in terms of hair cortisol levels (pg cortisol/mg hair) between sexes in wild (*Felis silvestris silvestris silvestris catus*) cats.

ID model	lel Independent variables		-2 logLik	AICc	ΔAICc	ωi
1	subspecies	3	119.02	126.16	0	0.70
2	subspecies, sex	5	114.67	127.83	1.67	0.30
3	subspecies, sex, subspecies:sex	9	108.65	138.65	12.49	0.00
4	sex	3	138.04	145.18	19.02	0.00

**Tab1.** Generalized Linear Models (GLMs) ranking with the best model marked in bold. Abbreviations: K = number of parameters; logLik =log-likelihood; AICc = Akaike's Information Criterion corrected;  $\omega i$  = Akaike's weight.

**Tab2.** Hair cortisol concentration (pg cortisol/mg hair) comparison between subspecies. n = number of individuals.

Subspecies	n	n (%)	Mean	SD	Median
Wildcat	15	60	8.91	4.48	7.40
Feral cat	10	40	3.57	1.25	3.39

**Tab3.** Hair cortisol levels (pg cortisol/mg hair) comparison between sexes in wild (*Felis silvestris silvestris*) and feral (*Felis silvestris catus*) cats. n = number of individuals.

Subspecies	Sex	n	n (%)	Mean	SD	Median
Felis silvestris silvestris	Male	11	73.33	9.69	4.81	10.70
	Female	4	26.67	6.78	2.87	6.35
Felis silvestris catus	Male	8	80	3.76	1.33	3.82
	Female	2	20	2.81	0.50	2.81
