Abstract: Combinations of ultrasound (US) and high-pressure homogenization (HPH) at low-medium energy densities were studied as alternative processes to individual US and HPH to produce Tween 80 and whey protein stabilized nanoemulsions, while reducing the energy input. To this aim, preliminary trials were performed to compare emulsification efficacy of single and combined HPH and US treatments delivering lowmedium energy densities. Results highlighted the efficacy of US-HPH combined process in reducing the energy required to produce nanoemulsions stabilized with both Tween 80 and whey protein isolate. Subsequently, the effect of emulsifier content (1-3% $w/w)\,\text{,}$ oil amount (10-20% w/w) and energy density(47-175 MJ/m3) on emulsion mean particle diameter was evaluated by means of a central composite design. Particles of 140-190 nm were obtained by delivering 175 MJ/m3 energy density at emulsions containing 3% (w/w) Tween 80 and 10% (w/w) oil. In the case of whey protein isolate stabilized emulsions, a reduced emulsifier amount (1%, w/w) and intermediate energy density (120 MJ/m3) allowed a minimum droplet size around 220-250 nm to be achieved. Results showed that, in both cases, at least 50% of the energy density should be delivered by HPH to obtain the minimum particle diameter.

Dear Editor,

I would like to submit to your attention the manuscript entitled "Combined high-power ultrasound and high-pressure homogenization nanoemulsification: the effect of energy density, oil content and emulsifier type and content" (Authors: Sonia Calligaris, Stella Plazzotta, Fabio Valoppi, Monica Anese) for consideration for publication on Food Research International.

Recently, we has been demonstrated that combined US-HPH processes can be effective in reducing the energy demand for nanoemulsion preparation by using a combination of synthetic surfactants (Tween 80 and Span 80) with well-known excellent performances under high-energy emulsification (Calligaris et al., 2016 Food Research International 83, 25-30). In particular, US and HPH provided in combination at low and medium energy density values led to nanoemulsions with particle size and stability comparable to those prepared by using individual US or HPH at high energy densities. The aim of this work was to investigate further US-HPH nanoemulsification in obtaining nanoemulsions in the presence of food grade emulsifiers. To this purpose, preliminary trials were carried out to evaluate the effectiveness of US-HPH combined processes to obtain nanoemulsions containing Tween 80 or whey proteins as emulsifiers. Then, a three-variable face centred central composite design was used to study the effect of emulsifier content (1-3% w/w), oil amount (10-20% w/w) and energy density (48-175 MJ/m3) on emulsion mean particle diameter. Finally, the effect of different US and HPH combinations developing the same energy density was studied to identify the optimal energy share between US and HPH allowing minimum droplet diameter to be obtained during a combined process.

Results confirmed the efficacy of US-HPH combined process in reducing the energy required to produce nanoemulsions stabilized with both Tween 80 and whey protein isolate. However, different performances should be expected depending on the emulsifier used. Particles of 140-190 nm were obtained by delivering 175 MJ/m³ energy density at emulsions containing 3% (w/w) Tween 80 and 10% (w/w) oil. In the case of whey protein isolate stabilized emulsions, a reduced emulsifier amount (1%, w/w) and intermediate energy density (120 MJ/m³) allowed a minimum droplet size around 220-250 nm to be achieved. Results showed that, in both cases, at least 50% of the energy density should be delivered by HPH to obtain the minimum particle diameter.

Best regards, Sonia Calligaris Dear Editor,

We send to your attention the research article entitled "Combined high-power ultrasound and high-pressure homogenization nanoemulsification: the effect of energy density, oil content and emulsifier type and content". We have endeavoured to take into account or to respond to the Associate editor's and Reviewer's comments as indicated below.

We hope that this response is satisfactory and that the manuscript will be suitable for publication in Food Research International.

Best regards

Sonia Calligaris

Associated Editor Comments

Although the paper is really interesting, R&D, especially discussion section should be improved to explain the impact of energy density, oil content and emulsifier type and content.

Answer: The R&D part of the manuscript has been deeply revised including more discussion to explain the effects of different variables on nanoemulsion properties (section 3.2 and 3.3).

Reviewer #3:

The present paper involves a comprehensive research about the use of combined high pressure homogenization and ultrasounds to obtain stable nanoemulsions with a lower energy density process.

Several previous works have carried out related experiments, and have already dealt with the use of high pressure homogenization and ultrasounds for nanoemulsion obtaining, already cited in the text. Consequently, results presented in this work expand previous knowledge with new conditions and a more inclusive selection of variables (emulsifier content and type, oil content...). These data seem to be useful for optimization of a putative industrial process, thus its novelty is justified.

The paper is well written, results are interesting, data appear well presented and properly related, but I miss more discussion of the results. E.g.: sections 3.2 and 3.3 are only "results", not "results and discussion". Accordingly, some changes and considerations should be taken into account previously to its publication in the current form.

Answer: We thank the reviewer for the appreciation of the manuscript. As suggested, the R&D part of the manuscript (section 3.2 and 3.3) has been deeply revised including more discussion to explain the effects of different variables on nanoemulsion properties.

MINOR REVISIONS

In general, please, be careful with text presentation. In many cases, some words are written together or there is no space after a dot. Some examples: line 195: 150MPafor, at120MPa line 196: from20 to... line 206: bythe

Answer: We carefully check the text to delete errors.

RESULTS AND DISCUSSION: Please, provide some discussion for the results in sections 3.2 and 3.3.

 reduction, nanoemulsion, food emulsifiers.

33 1. Introduction

The interest in food grade nanoemulsions has rapidly increased in the last decades, due to their 34 unique physico-chemical properties and possible application as delivery systems of bioactive 35 molecules (Karthik, Ezhilarasi, & Anandharamakrishnan, 2017; Sanguansri & Augustin, 2006). 36 Nanoemulsions are heterogeneous systems consisting of two immiscible liquids, with one phase 37 being dispersed as nanometric droplets with diameter lower than 200 nm (Salvia-Trujillo, Soliva-38 Fortuny, Rojas-Grau, McClements, & Martin-Belloso, 2017). Formation and stabilization of 39 nanoemulsions depend on the physical-chemical properties of constituents, including oil and 40 aqueous phases and emulsifiers, as well as on the energy density, i.e. the energy input per unit 41 volume transferred to the sample. Energy density, in turn, depends on treatment intensity and 42 duration (Mohd-Setapar, Nian-Yian, Nuraisha, Kamarudin, & Idham, 2013; Schubert & Engel, 43 44 2004; Schubert, Ax, & Behrend, 2003; Stang, Schuchmann, & Schubert, 2001; Wooster, Golding, & Sanguansri, 2008). Smaller droplets are usually obtained by increasing the emulsifier content and 45 the supplied energy density. Also, at comparable energy densities, the modality of energy delivering 46 can affect the nanoemulsion particle size and stability (Calligaris et al., 2016; Jafari, Assadpoor, He, 47 & Bhandari, 2008). Different mechanical devices capable of generating intense disruptive forces 48 can be used to obtain nanoemulsions. High-power ultrasound (US) and high-pressure 49 homogenization (HPH) are high-energy nanoemulsification processes, which are able to reduce the 50 emulsion particle diameter at nano-level (Abbas, Hayat, Karangwa, Bashari, & Zhang, 2013; 51 52 Canselier, Delmas, Wilhelm, & Abismaïl, 2002; Dumay et al., 2013; McClements, 2005; Silva, Cerqueira, & Vicente, 2012). High-power ultrasonic devices form emulsions with nano-sized 53 54 droplets through the propagation of low frequency sound waves (20-24 kHz), which cause the formation and violent collapse of cavitation bubbles (Abbas et al., 2013; Leong, Wooster, Kentish, 55 & Ashokkumar, 2009). High-pressure homogenizers break large droplets into smaller ones by a 56 57 combination of intensive disruptive forces, such as shear stress, cavitation and turbulent flow conditions, suffered by the product during the passage in the homogenization valve (Stang et al., 58 2001). Both technologies require extremely intense treatments (long times in US and high pressures 59 and/or multiple passes in HPH) to produce emulsions with nano-size droplets (Kentish et al., 2008; 60 McClements & Rao, 2011; Qian & McClements, 2011). This implies the use of specifically 61 designed equipment and relatively high running and maintenance costs, due to elevated energy 62 consumption and frequent replacement of wearing parts. Therefore, the industrial application of US 63 and HPH as high-energy emulsification processes is limited because of their low sustainability. 64

5 Based on these considerations, the possibility to reduce the energy requirements for 6 nanoemulsification might stir up new interest in large-scale production of nanoemulsions. Recently,

3

it has been demonstrated that combined US-HPH processes can be effective in reducing the energy demand for nanoemulsion preparation by using a combination of food-grade synthetic surfactants (Tween 80 and Span 80) with well-known excellent performances under high-energy emulsification (Calligaris et al., 2016). In particular, US and HPH provided in combination at low and medium energy density values led to nanoemulsions with particle size and stability comparable to those prepared by using individual US or HPH at high energy densities.

73 The aim of this work was to investigate further US-HPH nanoemulsification in obtaining nanoemulsions in the presence of food grade emulsifiers. To this purpose, preliminary trials were 74 carried out to evaluate the effectiveness of US-HPH combined processes to obtain nanoemulsions 75 containing Tween 80 or whey proteins as emulsifiers. Then, a three-variable face centred central 76 composite design was used to study the effect of emulsifier content (1-3% w/w), oil amount (10-77 20% w/w) and energy density (48-175 MJ/m³) on emulsion mean particle diameter. Finally, the 78 effect of different US and HPH combinations developing the same energy density was studied to 79 identify the optimal energy share between US and HPH allowing minimum droplet diameter to be 80 obtained during a combined process. 81

82

83 2. Materials and methods

84 2.1. Coarse emulsion preparation

The aqueous phase was prepared by mixing an amount allowing to obtain in the final emulsion 1 to 85 3% (w/w) of Tween 80 (Tween 80®, Sigma Aldrich, Milano, Italy) or whey protein isolate (94.7% 86 protein content; 74.6% β -lactoglobulin, 23.8% α -lactoglobulin, 1.6% bovine serum albumin; 87 Davisco Food International Inc., Le Seur, Germany) with deionized water. The aqueous phase was 88 stirred at 20 °C for 2 h, until the surfactant was completely dissolved. The coarse emulsion was 89 prepared by mixing the aqueous phase with sunflower oil_(10-20% w/w) with a high-speed blender 90 91 (Polytron, PT 3000, Cinematica, Littau, Swiss)_at 8000 rpm for 1 min. The coarse emulsion was immediately subjected to the nanoemulsification processes. 92

93

94 2.2. Nanoemulsification processes

95 2.2.1. High-power ultrasound (US)

An ultrasonic processor (Hieschler Ultrasonics GmbH, mod. UP400S, Teltow, Germany) with a titanium horn tip diameter of 22 mm was used. The instrument operated at constant ultrasound amplitude and frequency of 100 μ m and 24 kHz, respectively. Aliquots of 150 mL of coarse emulsion were introduced into 250 mL capacity (110 mm height, 60 mm internal diameter) glass vessel. The tip of the sonicator horn was placed in the centre of the solution, with an immersion

4

63

101 depth in the fluid of 50 mm. The ultrasound treatments were performed up to 240 s and the 102 temperature was controlled using a cryostatic cooling system set at 4 °C to dissipate the heat 103 generated during the treatment.

104

105 2.2.2. High-pressure homogenization (HPH)

A continuous lab-scale high-pressure homogenizer (Panda Plus 2000, GEA Niro Soavi, Parma, Italy) supplied with two PS type homogenization valves with a flow rate of 10 L/h was used to treat to mL of coarse emulsion. The first valve was the actual homogenization stage and was set at increasing pressure up to 150 MPa. The second valve was set at the constant value of 5 MPa. Additional samples were prepared by subjecting the coarse emulsion to HPH for up to 3 successive passes at 120 MPa. At the exit of the homogenizer, the emulsions were forced into a heat exchanger (GEA Niro Soavi, Parma, Italy) and cooled to room temperature.

113

114 2.2.3. Combined US-HPH

The coarse emulsion (150 mL) was subjected to US followed by HPH. The time between the two treatments did not exceed 30s. US treatments were applied for 20 or 60 s, while homogenization pressure was set at 20, 50, 80 and 100 MPa. Further US-HPH treatments consisting of 20 s + 20 MPa, 22 s + 80 MPa and 60 s + 100 MPa were carried out to provide energy densities of 47, 111 and175 MJ/m³according to a central composite design. Finally, to deliver to the sample energy densities of 145 and 120 MJ/m³, the percentage ratio between the energy delivered by US and HPH was progressively changed.

122

123 2.3. *Temperature measurement*

The sample temperature was measured just before and immediately after (i.e. before the cooling step) HPH process and during US by a copper-constantan thermocouple probe (Ellab, Hillerød, Denmark) connected to a portable data logger (mod. 502A1, Tersid, Milan, Italy).

127

128 2.4. Energy density computation

The energy density, i.e. the energy input per unit volume (E_{ν} , MJ/m³), was computed as described by Bot et al. (2017). In particular, the E_{ν} transferred from the probe to the sample during ultrasound treatments was calculated by using equation (1) (Raso, Mañas, Pagán, & Sala, 1999):

$$E_{\nu} = \frac{mc_{p}(\partial T / \partial t)}{V} \times t \tag{1}$$

- where *m* is the sample mass (kg), c_p is the sample heat capacity (4186 J/(kg K)), *V* is the sample volume (cm³), and *t* (s) is the duration of the ultrasonication time.
- The energy density transferred from the valve to the sample during the HPH treatment was determined as described by Stang et al. (2001), according to equation (2):

137
$$E_v = \Delta P$$
 (2)

138 where ΔP is the pressure difference operating at the nozzles.

139 The energy density of multiple passes HPH and combined treatments was calculated as the sum of 140 the energy density values of the corresponding single pass HPH or US plus HPH treatments.

141

142 2.5. Droplet size

The mean diameter of emulsion droplets was measured by using the dynamic light scattering instrument Zetasizer Nano ZS (Malvern, Milan, Italy). Samples were diluted 1:10 (v/v) with deionised water prior to the analysis to avoid multiple scattering effects. The angle of observation was 173°. Solution refractive index and viscosity were set at 1.333 and 1.0 cP, respectively, corresponding to the values of pure water at 20 °C.

148

54 55

149 2.6. Polynomial equations and statistical analysis

150 Modelling was aimed at describing the variation of mean particle diameter as a function of the variables of the central composite design. In particular, a 3-factors face central composite 151 design (CCF) was used. The three considered factors were oil content, emulsifier concentration and 152 energy density. The ranges of variables were chosen on the basis of information from the 153 preliminary trials, showing that the application of values outside the considered intervals led to non-154 155 emulsified samples. For each factor, extreme, lower and upper values were identified and combined to form the factorial part of the design (8 factorial points). In particular, oil content, emulsifier 156 concentration and energy density were set at 10, 15 and 20% (w/w), 1, 2 and 3% (w/w) and 48, 111 157 and 175 MJ/m³, respectively. The energy density values were obtained by US-HPH combined 158 treatments of 20 s+20 MPa, 22 s+80 MPa and 60 s+100 MPa. To complete the CCF, 6 axial points 159 (combinations of the extreme value of one factor and the intermediate level for the others) and 1 160 161 central point (combination of the intermediate values of the three factors) were defined. All the factorial and axial points were replicated once, while the central point was replicated 6 times. The 162 full set of sampling points is reported in Table 1. A software package (Statistica for Windows v. 10, 163 StatSoft, Inc.) was used to fit the second order response surface to the observed data according to 164 52 165 53 the following equation:

166 $y = B_0 + \sum_{i=1}^{k} B_i x_i + \sum_{i=1}^{k} B_{ii} x_i^2 + \sum_{j>i\geq 1}^{k} B_{ij} x_i x_j$ (3)

where B_0 is a constant, and B_i , B_{ij} , B_{ij} are regression coefficients of the model, x_i and x_j are the independent variables in coded values, and k is the number of factors.

Shapiro-Wilk test was used to evaluate normality of the data, while the possible presence of outliers and the homogeneity of variance were evaluated by residual analysis. Goodness of fit was measured with the adjusted determination coefficient (R^2_{adj}). *p*-Values for the coefficients of the response surface were defined using standard *t*-test. Three-dimensional counter plots were drawn to illustrate the effects of the considered factors on the responses. To this purpose, the values of the response were plotted on the *z*-axis against the two most relevant factors, keeping the third one fixed to a constant value (the central one).

Results relevant to preliminary trials are the average of at least three measurements carried out on two replicated experiments. Data are reported as mean value \pm standard deviation. Statistical analysis was performed by using R v. 2.15.0 (The R Foundation for Statistical Computing). Bartlett's test was used to check the homogeneity of variance, one way ANOVA was carried out and Tukey test was used to determine statistically significant differences among means (*p*<0.05).

7

181

182 **3. Results and discussion**

183 3.1. Individual vs combined US-HPH nanoemulsification preliminary trials

Preliminary trials were performed to assess the capability of US-HPH combined processes to 184 produce nanoemulsions containing 2% (w/w) Tween 80 or whey protein isolate, as emulsifiers, in 185 comparison to US and HPH individual treatments. In particular, the combined US-HPH processes 186 consisted of 20 s or 60 s US followed by HPH process at 20, 50, 80 and 100 MPa. The reverse 187 process (HPH-US) was not considered based on previous results highlighting that only US before 188 HPH allowed the efficacy of combined process to be improved (Calligaris et al., 2016). The 189 individual US treatments were conducted for 20 to 240 s, whereas HPH homogenization was 190 performed by increasing pressure from 20 to 150MPafor 1 pass, and at120 MPa for 3 passes. The 191 energy densities provided by the combined treatments to the samples ranged from 20 to 360 MJ/m^3 192 193 (Table 2). Figure 1 shows the particle size distributions of emulsions stabilized by Tween 80 or whey protein isolate obtained by means of the combined US-HPH as well as single US and HPH 194 processes. 195

US-HPH processes allowed obtaining monomodal distributions using both emulsifiers at US times 196 and pressure levels as low as 20 s and 50 MPa, respectively (Figures 1a and 1b). It must be noted 197 that monomodal distributions were also obtained in both Tween 80 and whey protein isolate 198 stabilized emulsions by means of 240 s US (278 MJ/m³) and HPH at pressure higher than 80 MPa 199 (80 MJ/m³) (Figures 1c, 1d, 1e and 1f). The particle distribution amplitude and the mean particle 200 201 diameter decreased with the increase in the energy density provided to samples, as well evidenced by the distribution width, the mean particle diameter value and the corresponding polydispersity 202 index (PDI) (Figure 1, Table 2). In the energy density range of 78-125 MJ/m³, particles with 203 diameter of about 220 nm and 300 nm were obtained using Tween 80 and whey protein isolate, 204 respectively (Table 2). Combined treatments at energies of 155-175 MJ/m³ further reduced the 205 distribution width and particle dimensions below 220 nm (Figure 1, Table 2). It is noteworthy that 206 diameters in the same order of magnitude were obtained only by applying 3 passes HPH at 120 207 MPa, corresponding 360 MJ/m³ of energy density (Table 2). Such high_energy levels pose different 208 issues, including rapid wear and tear of plants and high energy consumption, which, in turn, 209 increase process costs and reduce process sustainability and industrial feasibility (Yang, Marshall-210 Breton, Leser, Sher, & McClements, 2012). By contrast, results of the study showed that the 211 combination of US and HPH actually led to produce Tween 80 and whey protein isolate stabilized 212 nanoemulsions at energy densities lower than those required by the individual treatments. 213 Synergistic homogenization effects of US and HPH have been previously attributed to the effect of **₽**₽4 5¥5 the sequential application of different emulsification processes (Calligaris et al., 2016). It particular, 54

8

63 64 65

55

the first homogenization by US would reduce particle dimension and distribution width of the 216 coarse emulsion favouring the further droplet break-up in the second HPH step (Abbas et al., 2013; 217 Calligaris et al., 2016; Pandolfe, 1995). Results of this study also shows that within each 218 emulsifying process, the distribution width and the mean particle diameter of Tween 80 containing 219 220 emulsions was lower than that of whey protein isolate containing ones (Figure 1, Table 2). This can 221 be attributed to the chemical features of the considered emulsifiers and their ability to absorb on oil-222 water interfaces. Being Tween 80 a small non-ionic surfactant, it can rapidly adsorb to the oil-water interface during high-energy emulsification leading to the formation of small particles (Amani, 223 York, Chrystyn, & Clark, 2009; Ghosh, Mukherjee, & Chandrasekaran, 2013). On the contrary, due 224 to their high molecular weight, globular whey proteins are expected to slowly cover oil droplet 225 surface generated during the high-energy emulsification process (Adjonu, Doran, Torley, & 226 Agboola, 2014; Dissanayake & Vasiljevic, 2009; O'Regan & Mulvihill, 2010; Pearce & Kinsella, 227 1978). 228

229

230 3.2. Identification of the best US-HPH emulsifying conditions

To define the best performing process conditions to obtain nanoemulsions at the lowest energy 231 level, a three factors face centred central composite design (CCF) was used. To this aim, the oil 232 content, emulsifier concentration and emulsification energy density were considered as independent 233 variables and their effect on emulsion mean particle diameter was studied (Table 1). According to 234 the results of the preliminary trials, US-HPH treatments were applied to provide samples with low-235 medium energy densities. Table 1 also shows the mean particle diameter of emulsions obtained 236 under the different CCF conditions. The regression coefficients and the relative analysis of variance 237 of the polynomial models for the dependent variables are presented in Table 3. R²_{adj} values for the 238 responses were higher than 0.894. 239

The results showed that linear and quadratic terms of energy density (E_v and E_v^2 , respectively), and linear terms of oil (*Oil*) and emulsifier (*Emuls*) contents had significant effects on mean particle diameter of Tween 80 stabilized emulsions, showing *p*-values lower than 0.001. Similarly, energy density (both linear and quadratic term) and oil content (linear term) significantly affected droplet dimensions of whey protein stabilized emulsions (p<0.001, 0.01 and 0.05, respectively).

To evaluate the effects of the independent variables on the dependent one and to predict the optimum values of each variable for minimum mean droplet diameter to be achieved, contour-plots were generated. Figure 2 shows the contour-plots relevant to the effect of energy density and oil **content** (Figure 2a) or surfactant content (Figure 2b) on particle dimensions of Tween 80 stabilized emulsions. Nanoemulsions with the lowest diameter were obtained at <u>the highest</u> energy <u>-densities</u>

9

64

and were associated to the lowest oil content (Figure 2a). In particular, the mean particle diameter 250 251 decreased from about 400 nm to less than 160 nm as the energy density of the treatment increased. This indicated that the progressive enhancement of disruptive forces at the homogenization valve 252 led to the generation of particles getting smaller due to the rapid absorption of Tween 80 at the 253 oil/water interface. As the oil content increased at constant emulsifier level, the mean particle 254 diameter also increased. It is likely that the passage at the homogenization valve of a higher 255 256 quantity of oil reduced the efficacy of the treatment being the energy delivered to be shared between an increased oil quantity at a constant emulsifier concentration. Moreover, the surfactant content (2 257 % w/w) could be not enough to surround all the newly formed oil droplets. This observation is 258 supported by results reported in Figure 2b, showing the mean particle diameter of Tween 80 259 stabilised emulsions as a function of energy density and emulsifier content, while maintaining oil 260 content constant at 15 % (w/w). In fact, increasing the Tween 80 level produced a significant 261 decrease in oil droplet dimensions. 262

Different behaviour was observed for whey protein stabilized emulsions (Figure 3). The minimum 263 oil droplet diameter was achieved by transferring to the 10% (w/w) oil emulsion intermediate 264 energies of about 110-140 MJ/m³ (Figure 3a). Beyond these energy values, a further decrease of 265 droplet size was not observed. Similar considerations can be also drawn by observing the plot of 266 mean droplet diameter as a function of whey protein content and energy density (Figure 3b), by 267 imposing 15% (w/w) value to the oil content variable. Also in this case, the best performing 268 conditions in terms of emulsion droplet size were achieved at intermediate energy densities. It is 269 possible that higher energy density values produced a progressive unfolding of whey proteins, 270 leading to a reduction of their emulsifying properties. -To this regard, different studies highlighted 271 272 the capability of HPH to modify the protein structure. In particular, Oboroceanu et al. (2011) showed that high pressure microfluidization treatments (>50 MPa) of β -lactoglobulin induced 30% 273 protein denaturation, accompanied by changes in secondary structure. Similarly, Bouaouina, 274 Desrumaux, Loisel and Legrand (2006) reported that high pressure homogenization could modify 275 the structure of whey protein, exposing the buried hydrophobic residues. Moreover, a recent study 276 of Ali et al. (2018) reported HPH treatments to induced secondary structure transformation and 277 protein aggregation via intermolecular disulfide bridges. Additionally, observing Figure 3b, it can 278 be noted that whey protein isolate concentration did not to significantly affect the particle 279 dimensions. An amount of 1% (w/w) whey proteins resulted to be sufficient to stabilize oil-water 280 interface developed by the applied US-HPH combined treatments. Exceeding 1% (w/w) content, 281 proteins were likely to locate in the continuous aqueous phase rather than at the oil-water interface

(Yan, Park, & Balasubramaniam, 2017). Based on these considerations, whey protein content can
be minimized while maintaining good emulsification efficacy.

In the light of these results, the energy density developed by US-HPH process and the formulation conditions allowing the minimum dimension of emulsion oil droplets to be obtained, were estimated. For Tween 80 stabilized emulsions, 3% (w/w) emulsifier concentration, 10% (w/w) oil content and at least 145 MJ/m³ energy density would guarantee emulsions with droplet diameter_of 140-190 nm. In the case of whey protein stabilized emulsions, a minimum droplet size around 200-250 nm can be achieved by supplying energy density values lower than 120 MJ/m³_to an emulsion containing 10% (w/w) oil and 1% (w/w) emulsifier.

292

3.3. Effect of energy density share between US and HPH during combined emulsification processes

Different combinations of US time and HPH pressure can be employed to deliver the same energy 295 density during a US-HPH process. For instance, 120 MJ/m³ can be transferred to the system by 296 applying 22 s+90 MPa, 44 s+60 MPa or 75 s+30 MPa. Therefore, the last part of the research aimed 297 to study the effect of the ratio between US and HPH in delivering the energy density during US-298 HPH nanoemulsification. The total energy densities, oil and emulsifier contents were selected based 299 on CCF results as those allowing the lowest nanoemulsion droplet diameter to be generated. Energy 300 density, oil content and emulsifier concentrations were 145 MJ/m³, 10% (w/w) and 3% (w/w) for 301 the Tween 80 containing system; 120 MJ/m³, 10% (w/w) and 1% (w/w) for whey protein isolate 302 containing one. The selected energy densities were, then, provided by using different combinations 303 304 of US time and HPH pressure, progressively increasing the energy share generated by US and concomitantly reducing the one delivered by HPH, as shown in Table 4. 305

All combined processes resulted in lower particle dimensions than the corresponding individual 306 homogenization treatments delivering the same energy density, in agreement with the CCF data and 307 previously reported results (Calligaris et al., 2016). In particular, in the case of Tween 80 containing 308 309 emulsions, the combinations in which 50-75% of the total energy density was delivered by HPH and the remaining energy by US, resulted in particle diameters in the range of 150-170 nm. It is 310 noteworthy that an increase in energy share delivered by US (75%), with a concomitant reduction of 311 HPH-delivered one (25%), produced larger diameters, confirming the higher emulsification efficacy 312 of HPH as compared to US. Similarly, in the case of whey protein isolate stabilized emulsions, 313 314 lower diameters were observed when at least 50% of total energy share was delivered by HPH. 315 52 These treatments, in fact, allowed particles with mean diameters of about 230 nm to be obtained, again validating the CCF model. It can be concluded that the high pressure homogenization step of **5**}6

the combined process has to be considered the critical phase to obtain fine emulsions. The US
 treatment before HPH would prevalently serve to reduce particle size and distribution width of the
 coarse emulsion before entering in the homogenization valve. In other words, the US step would
 improve the efficiency of the second HPH homogenization in obtaining particles even lower.

321

322 Conclusions

323 In this work, the efficacy of combined US-HPH emulsification processes at low energy density to obtain nanoemulsions was demonstrated. Moreover, the proposed combined nanoemulsification 324 appears to be versatile, since it can be exploited by using different levels of both Tween 80 and 325 whey protein isolate as emulsifiers as well as oil at different contents. Depending on the emulsifier 326 327 used in the formulation, the best performing processing parameters (total energy density and energy density share between US and HPH) and formulation conditions (oil and emulsifier contents) has to 328 be tested and defined. In fact, the emulsifier characteristics greatly affected -the performances of 329 combined US-HPH process. In all cases, the combined process led to nanoemulsions at energy 330 density levels which were approximately half of those required by single US or HPH to obtain the 331 same emulsification performances in terms of mean particle diameter. 332

From an industrial perspective, these results open interesting possible opportunities in the attempt to design more sustainable emulsification processes and devices. It should be stressed that homogenization pressure lower than 60 MPa and ultrasonication duration of a few seconds appear compatible with the actual industrial needs, leading to a possible reduction of the total ownership cost. Finally, the proposed approach could definitively contribute to increasing the exploitability of nanoemulsions in food at large-scale production facilities.
